Dedicated to my colleagues, the instrument and process control engineers. It is hoped that by applying the knowledge found on these pages, we will make our industries more efficient, safer, and cleaner, and thereby will not only contribute to a happier future for all mankind, but will also advance the recognition and prestige of our profession.

CONTRIBUTORS

The names of all the authors of all four editions of this handbook are listed at the beginning of each section of each chapter. Here, their academic degrees, titles, and positions that they held at the time of making their last contributions are also listed. Those authors who have participated in the preparation of this fourth edition are distinguished by an asterisk.

***JÁNOS ABONYI**	PhD, Assistant Professor, University of Veszprém, Hungary
ROBERT H. APPLEBY	BSMath, MSStat, Facilities Manager, Immaculate Conception Church
***JAMES B. ARANT**	BSChE, PE, Principal of J. B. Arant & Assoc. Consulting, U.S.A.
***TIBOR BAAN**	BME, CEO, Aalborg Instruments and Controls Inc.
MIGUEL J. BAGAJEWICZ	PhD, AIChe, Professor, University of Oklahoma, Norman, Oklahoma, U.S.A.
***STEVEN BAIN**	BscEE, PE, I&C Engineer, CH2M Hill
ROBERT J. BAKER	BS, Technical Director, Wallace & Tiernan Div. of Pennwalt Corp.
ROGER M. BAKKE	BS, MS, Senior Engineer, IBM Corp.
***ANDRÁS BÁLINT**	PhD, Assistant Professor, University of Veszprém, Hungary
***RUTH BARS**	PhD, Associate Professor, Budapest University of Technology and Economics, Hungary
CHET S. BARTON	PE, PSEE, Senior Process Automation Engineer, Jacobs Engineering, Baton Rouge, Louisiana, U.S.A.
***HANS D. BAUMANN**	PhDME, PE, President, H.B. Services Partners, LLC
CHESTER S. BEARD	BSEE, Author, Retired from Bechtel Corp.
***KEN BEATTY**	BSME, MEMME, Director of Advanced Product Development, Flowserve
***JONAS BERGE**	Engineer, SMAR, Singapore
JOHN W. BERNARD	BSChE, MSIE, PE, Manager, Systems Technology, The Foxboro Co.

***MICHAEL L. BERNS**	MSEE, PE, Electrical Engineer, Alcan Plastic Packaging
***PETER GRAHAM BERRIE**	PhD, Marketing Communications Manager, Endress + Hauser Process Solutions AG, Switzerland
***VIPUL BHSANAR**	BE, I&C Specialist, Consultant, Canada
PAUL B. BINDER	BSME, Program Manager, Leeds & Northrup
***TERRENCE BLEVINS**	MSEE, Principal Technologist, Emerson Process Management, U.S.A.
RICHARD W. BORUT	Senior Manager, M. W. Kellogg Co.
STUART A. BOYER	PE, BSc, EE, President, Iliad Engineering, Inc., Canada
***WALTER BOYES**	Editor in Chief, Control Magazine
AUGUST BRODGESELL	BSEE, President, CRB Systems Inc.
ROBERT D. BUCHANAN	BSCE, MS, Environmental Consultant
GEORGE C. BUCKBEE	PE, BSChE, MSChE, Control Engineer, Top Control, Clarks Summit, Pennsylvania, U.S.A.
ERIC J. BYRES	PE, Research Facility, British Columbia Institute of Technology, Canada
***FRED M. CAIN**	BSME, PE, Director of Engineering, Flowserve Corp.
ANTHONY M. CALABRESE	BSChE, BSEE, MSChE, PE, Senior Engineering Manager, M. W. Kellogg Co.
***OSCAR CAMACHO**	PhD, Professor, Universidad de Los Andes, Venezuela
BRYAN DELL CAMPBELL	BSEE, MEE, Electrical Engineer, Stanley Tools
DANIEL E. CAPANO	President, Diversified Technical Services, Inc., Stamford, Connecticut, U.S.A.
RICHARD H. CARO	BChE, MS, MBA, CMC Associates, Acton, Massachusetts, U.S.A.
***MICHAEL D. CHAPMAN**	AAS, Startup and Control System Eng. Supervisor, Bechtel Corp.
HARRY L. CHEDDIE	PE, BSc, Principal Engineer, Exida.com, Sarnia, Ontario, Canada.
***GEORGE S. CHENG**	PhD, Chairman, CTO, CyboSoft, General Cybernation Group, Inc.
***XU CHENG**	PhD, Emerson Process Management, Power and Water Solutions
WILLIAM N. CLARE	BSChE, MSChE, Engineering Manager, Automated Dynamics Corp.
SCOTT C. CLARK	BS, ChE, Project Engineer, Merck & Co., Inc., Elkton, Virginia, U.S.A.
JOHN R. COPELAND	BSEE, MSEE, PhDEE, Partner, Jackson Associates
ARMANDO B. CORRIPIO	BSChE, MSChE, PhDChE, PE, Professor of Chemical Engineering, Louisiana State University

NICHOLAS O. CROMWELL	BSChE, Principal Systems Architect, The Foxboro Co.
LOUIS D. DINAPOLI	BSEE, MSEE, Manager, Flowmeter Marketing and Technology, BIF Products of Leeds & Northrup Co.
ROBERT G. DITTMER	BSEE, Corporate Process Control Engineer, PPG Industries
ASEGEIR DRØIVOLDSMO	MS, Research Scientist, OECD Halden Reactor Project, Halden, Norway
SAMUEL G. DUKELOW	BSME, National Sales Manager, Bailey Meter Co.
***WATSON PARNELL DURDEN**	ASInstrTech, Systems Engineer, Westin Engineering
***RANDY A. DWIGGINS**	BCChE, MSSysE, PE, Performance Improvement Consultant, Invensys Systems
LAWRENCE S. DYSART	BSEE, Engineer, Robertshaw Controls Co.
SHIBI EMMANUEL	MTech, BTech, Head of I & C, Dar Al Riyablh Consultants, Al Khobar, Saudi Arabia
***HALIT EREN**	PhD, Curtin University of Technology, Australia
GEORG F. ERK	BSME, MSChE, PE, Consulting Engineer in Instrumentation and Control Systems, Retired from Sun Refining
EDWARD J. FARMER	BSEE, PE, President, Ed Farmer & Associates, Inc.
***BRIDGET ANN FITZPATRICK**	BSChE, MBA, Senior Consultant, Mustang Engineering
PAUL G. FRIEDMANN	BSChE, MSE, Control Consultant, CRB Systems
JEHUDA FRYDMAN	Manager, Electrical Engineering Section, Mobil Chemical Co., Plastics Div.
LUDGER FÜCHTLER	Dipl. Eng., Marketing Manager, Endress + Hauser Process Solutions AG, Reinach, Switzerland
***STEPHAN E. GAERTNER**	BSChE, PE, Sales Engineer, Clipper Controls
***WINSTON GARCIA-GABIN**	PhD, MSc, Professor, Universidad de Los Andes,Venezuela
***DAVID J. GARDELLIN**	BSME, PE, President and CEO of Onyx Valve Co.
CHARLES E. GAYLOR	BSChE, PE, Manager of Engineering Services, Hooker Chemical Corp.
***BRUCE J. GEDDES**	I&C Design Consultant, Calvert Cliffs Nuclear Power Plant
***JOHN PETER GERRY**	MSChE, PE, President, ExperTune Inc.
***ASISH GHOSH**	CE, MIEE, Vice President, ARC Advisory Group
***PEDRO M. B. SILVA GIRÃO**	Professor, Laboratótio de Medidas Eléctricas, Portugal
***ALAN CHARLES GIBSON**	BAS, ADE, Contract Instrument Engineer, Australia
***IAN H. GIBSON**	BSc, DipChE, Process, Controls & Safety Consultant, Australia

*RICHARD A. GILBERT	PhD, Professor of Chemical Engineering, University of South Florida
DAVID M. GRAY	BSChE, Specialist Engineer, Leeds & Northrup Instruments
JOSEPH A. GUMP	BSChE, Process Panel Manager, Control Products Corp.
BHISHAM P. GUPTA	BS, MSME, DSc, PE, Instrument Engineer, Aramco,Saudi Arabia
BERNHARD GUT	Dipl. Eng. Informatik, Head of Department for Communications, Endress + Hauser GmbH + Co., Germany
*GÖRGY GYÖRÖK	PhD, Vice Director, Budapest Polytechnic, Hungary
DIANE M. HANLON	BSEE, BSME, Engineer, E.I. DuPont de Nemours & Co.
HASHEM MEHRDAD HASHEMIAN	MSNE, ISA Fellow, President, Analysis and Measurement Services Corp., Knoxville, Tennessee, U.S.A.
HAROLD I. HERTANU	MSEE, PE, Senior Project Engineer, Malcolm Pirnie Inc.
*JENÖ HETHÉSSY	PhD, Associate Professor, Budapest University of Technology and Economics, Hungary
CONRAD H. HOEPPNER	BSEE, MSEE, PhD, PE, President, Industrial Electronics Corp.
HAROLD L. HOFFMAN	BSChE, PE, Refining Director, Hydrocarbon Processing
PER A. HOLST	MSEE, Director of Computing Technology, The Foxboro Co.
*KARLENE A. HOO	PhD, Associate Professor of Chemical Engineering,Texas Tech University
MICHAEL F. HORDESKI	BSEE, MSEE, PE, Control System Consultant, Siltran Digital
FRANKLIN B. HOROWITZ	BSChE, MSChE, PE, Process Engineer, Crawford & Russell Inc.
DAVID L. HOYLE	BSChE, Principal Field Application Engineer, The Foxboro Co.
DAVID W. HOYTE	MACantab, Consultant, IBM Corp.
JOHN C. HUBER	PhDEE, Laboratory Manager, 3M Co.
STUART P. JACKSON	BSEE, MSEE, PhD, PE, President, Engineering and Marketing Corp. of Virginia
RAJSHREE RANKA JAIN	BSChE, Applications Engineer, Capital Controls Co.
*JAMES EDWARD JAMISON	BScChE, PE, Lead Engineer, Instrumentation, Electrical & Control Systems, OPTI Canada Inc.
*BRUCE ALAN JENSEN	BS, MSChE, Technical Solutions Manager, Yokagawa Corp. of America
KENNETH J. JENTZEN	BSEE, MSEE, Manager, Project Engineering and Maintenance, Mobil Chemical Co.
DONALD R. JONES	BSME, PE, Consultant, Powell-Process Systems, Inc.

BABU JOSEPH	PhDChE, Professor of Chemical Engineering, Washington University
VAUGHN A. KAISER	BSME, MSE, PE, Member of Technical Staff, Profimatics Inc.
***BABAK KAMALI**	BSEE, Control and Automation Designer, PSJ Co., Iran
LES A. KANE	BSEE, Mechanical/Electrical Editor, Hydrocarbon Processing
GENE T. KAPLAN	BSME, Project Design Engineer, Automated Dynamics Corp.
DONALD C. KENDALL	BSChE, MSChE, Senior Systems Analyst, The Foxboro Co.
***PRABHAKAR Y. KESKAR**	PhDEE, PE, Principal Technologist, CH2M Hill
CHANG H. KIM	BSChE, Senior Group Leader, UniRoyal Inc.
PAUL M. KINTNER	BSEE, MSEE, PhDEE, Manager, Digital Products,Cutler-Hammer Inc.
KLAUS H. KORSTEN	Dipl. Eng., Marketing Manager, Endress + Hauser Process Solutions AG, Reinach, Switzerland
***BÉLA LAKATOS**	MSc, PhD, Professor, University of Veszprém, Hungary
JAMES W. LANE	BSChE, MSChE, PE, Executive Director, Tenneco Inc.
***CULLEN G. LANGFORD**	BSME, PE. President, Cullen G. Langford Inc.
AVERLES G. LASPE	BS, PE, Senior Control Application Consultant, Honeywell Inc.
DONALD W. LEPORE	BSME, Design Engineer, The Foxboro Co.
CHENG S. LIN	DrEng, PE, Consultant, Tenneco Inc.
***KLAUS-PETER LINDNER**	Dipl. Inform., Specialist for New Technologies, Endress + Hauser GmBH + Co., Switzerland
***BÉLA LIPTÁK**	ME, MME, PE, Process Control Consultant
DAVID H. F. LIU	PhDChE, Principal Scientist, J. T. Baker Inc.
MICHAEL H. LOUKA	BS, Section Head, IFE Halden Virtual Reality Centre, Halden, Norway
ORVAL P. LOVETT JR.	BSChE, Consulting Engineer, E.I. DuPont de Nemours & Co.
DALE E. LUPFER	BSME, PE, Process Automation Consultant, Engel Engineering Co.
***MATTHEW H. MACCONNELL**	BSChE, MBA, PE, Technology Manager, Air Products and Chemicals, Inc.
***JÁNOS MADÁR**	MSCSChE, Research Assistant, University of Veszprém, Hungary
VICTOR J. MAGGIOLI	BSEE, Principal Consultant, E.I. DuPont de Nemours & Co.
CHARLES L. MAMZIC	BSME, CA. Director, Marketing and Application Engineering, Moore Products Inc.

***M. SAM MANNAN**	PhD, PE, Associate Professor of Chemical Engineering, Texas A&M University
ALAN F. MARKS	BSChE, PE, Engineering Specialist, Control Systems, Bechtel Petroleum Inc.
***EDWARD M. MARSZAL**	BSChE, CFSE, PE, Principal Engineer, Exida
FRED D. MARTON	Dipl. Eng., Managing Editor, Instruments and Control Systems
***GREGORY K. MCMILLAN**	MSEE, Professor, Washington University of Saint Louis
***RICK MEEKER**	Process Control Solutions, Inc.
DANIEL T. MIKLOVIC	ASNT, BSEE, MSSM, CMfgE, MIMC, Senior Consultant, H.A. Simons Ltd.
***HERBERT L. MILLER**	MSME, PE, Vice President, Control Components
FERENC MOLNÁR	MSEE, Department Manager, Chinoin Pharmaceutical and Chemical Works Ltd., Hungary
CHARLES F. MOORE	BSChE, MSChE, PhDChE, Professor of Chemistry, University of Tennessee
JOHN A. MOORE	BSChE, PE, Senior Application Specialist, Leeds & Northrup Instruments
RALPH L. MOORE	BSME, MSME, MSInstE, PE, Instrument Engineer, E.I. DuPont de Nemours & Co.
***DOUG MORGAN**	BSChE, Project Engineer, Control Systems International, U.S.A.
PAUL W. MURRILL	BSChE, MSChE, PhDChE, PE, Vice-Chancellor, Louisiana State University
THOMAS J. MYRON, JR.	BSChE, Senior Systems Design Engineer, The Foxboro Co.
MIKLÓS (NICHOLAS) NAGY	ME, Chief Engineer, Flygt Submersible Pump Co.
***MARK NIXON**	BSEE, Chief Architect, Delta V Control System, Emerson Process Management
***DAVID S. NYCE**	BSEE, MBA, Owner, Revolution Sensor Company
***SHINYA OCHIAI**	BSME, MSME, PhD, PE, Adjunct Professor, Texas A&M University
RICHARD H. OSMAN	PE, Engineering Manager, Robicon Corp.
GLENN A. PETTIT	Manager, Plastic Instrumentation, Rosemount Engineering Co.
***MICHAEL J. PIOVOSO**	PhD, PE, Associate Professor, Pennsylvania State University
WALLACE A PRATT, JR.	BSEE, Chief Engineer, HART Communication Foundation, Austin, Texas, U.S.A.
***SUBRAMANIUM RENGANATHAN**	PhD, Vice Chancellor, Bharath Institute of Higher Education and Research, Chennai, India
***R. RUSSELL RHINEHART**	PhDChE, Professor and Head, School of Chemical Engineering, Oklahoma State University
JAMES B. RISHEL	BSME, President, Corporate Equipment

HOWARD C. ROBERTS	BAEE, PE, Consultant, Lecturer at University of Colorado, Denver
***ALBERTO ROHR**	EE, Dr.Eng., Consultant, Italy
***RUBÉN DARIO ROJAS**	PhD, Universidad de Los Andes, Venezuela
DERRICK KEITH ROLLINS, SR.	BS, MS, PhD, AIChE, Associate Professor, Iowa State University, Ames, Iowa, U.S.A.
***MICHEL RUEL**	PE, President, Top Control
DOUGLAS D. RUSSELL	BSEE, MSEE, Group Leader, The Foxboro Co.
DONALD R. SADLON	BSEE, General Manager, Automated Dynamics Corp.
CHAKRA J. SANTHANAM	BSChE, MSChE, PE, Management Staff, Arthur D. Little Inc.
PÉTER SZILÁRD SCHERMANN	Senior Consultant at Comprimo BV and Professor of Process Dynamics, University of Groningen, the Netherlands
WALTER F. SCHLEGEL	BE, Assistant Chief Process Engineer, Crawford & Russell Inc.
PHILLIP D. SCHNELLE, JR.	BSEE, MSEE, PE, Technical Service Engineer, E.I. DuPont de Nemours & Co.
MICHAEL R. SHAFFER	PhD, PE, Adjunct Professor, Florida Institute of Technology
***FRANCIS GREGWAY SHINSKEY**	BSChE, Process Control Consultant
JOSEPH P. SHUNTA	PhDChE, PE, Principal Consultant, E.I. DuPont de Nemours & Co.
BURBINDER B. SINGH	BE, MBA, MCSE, Consultant Control Systems Engineer, Chicago, Illinois, U.S.A.
***ROBERT J. SMITH II**	EET, Plant Engineer, Rock-Tenn Co.
DAVID A STROBHAR	PE, SBHFE, President, Beville Engineering, Inc., Dayton, Ohio, U.S.A.
***ANGELA ELAINE SUMMERS**	PhD, PE, President, Sis-Tech Solutions, LLC
***GUSZTÁV SZECSÖ**	BSEE, MSEE, PhD. Professor of Control Engineering University of Miskolc, Hungary
JAMES E. TALBOT	BSEP, Senior Account Executive, Lewis, Gilman & Kynett
***JAMES F. TATERA**	BS, MBA, Senior Process Analysis Consultant, Tatera and Associates Inc., U.S.A.
MAURO C. TOGNERI	BSEE, President, Powell-Process Systems
***G. KEVIN TOTHEROW**	BSEE, President, Sylution Consulting
THOMAS H. TSAI	BSE, PE, Director, Tenneco Inc.
***ANN TUCK**	BSME, Senior Control Systems Engineer, Bechtel Corp.
***ISTVÁN VAJK**	PhD, Professor, Budapest University of Technology and Economics, Hungary
JÁNOS (JOHN) VENCZEL	BSEE, MSEE, Senior RF Engineer, Automation Industries

IAN VERHAPPEN	PE, BSCE, Engineering Associate, Syncrude Canada Lts., Fort McMurray, Alberta, Canada
***STEFANO VITTURI**	Dr. Eng., Italian National Council of Research, Italy
***HAROLD L. WADE**	PhD, President, Wade Associates, Inc.
MICHAEL H. WALLER	BME, SM, ME, PE, Associate Professor, Miami University
CHARLES G. WALTERS, JR.	BSEE, Electrical/Instrument Engineer, Geraghty and Miller Inc.
MARVIN D. WEISS	BSE, MSChE, Assistant Professor of Mechanical Engineering, Valpariso University
PETER ERIC WELLSTEAD	BSc, MSc, DSc, FIEE, CE, Reader in Control Engineering, University of Manchester, England
***CURT W. WENDT**	BSET, PE, I&C Group Leader, CDM
***HARRY H. WEST**	PhD, Research Associate, Texas A&M University
ANDREW C. WIKTOROWICZ	BS, PE, President, Automated Dynamics Corp.
THEODORE J. WILLIAMS	BSChE, MSChE, MSEE, PhDChE, PE, Professor of Engineering, Director of Purdue Laboratory for Applied Industrial Control, Purdue University
ROBERT A. WILLIAMSON	BSME, BA, PE, Supervisor, The Foxboro Co.
***JOHN WILSON**	BSChE, Business Manager, Fisher Controls International, LLC
***WILLY WOJSZNIS**	PhD, Technologist, DeltaV Advanced Control, Emerson Process Management, U.S.A.

INTRODUCTION

This is the fourth edition of the *Instrument Engineers' Handbook* (*IEH*). This handbook serves the automation and control engineering (ACE) profession and has been published once every decade since 1969. The subject of the first volume is measurement; the second volume deals with control; and the third volume is devoted to the topics of software and digital networks.

In the introduction to each new edition, I give a summary of the key developments of the previous decade and point to the challenges we face in the coming decade. Before discussing the previous and the next decades, however, I will say a few words about the growing pains of the ACE profession. I will conclude this introduction with a brief summary of the history of this handbook.

AUTOMATION AND CONTROL ENGINEERING (ACE)

Ours is a very young profession. When the first edition of the *Instrument Engineers' Handbook* (*IEH*) was published, Marks' *Mechanical Engineers' Handbook* was in its fifth and Perry's *Chemical Engineers' Handbook* was in its sixth edition. It is partly for this reason that while people know what kind of engineer an ME or a ChE is, they have no idea what I do when I say that my field is process control or instrumentation. I just get a blank stare.

It is time for us to change that. The first step should be to use a name for our profession that people understand. It is time for our profession to develop a distinct identity.

When I was teaching at Yale, my course was offered under the Chemical Engineering Department. This was not because Yale had anything against our profession; it was simply because they did not know where to put my course. Even this handbook of mine proves the confusion about our identity, because Taylor & Francis publishes this handbook among its Electrical Engineering books. Once again, the reason is not that Taylor & Francis has something against our profession. No, the reason is that we have not yet developed our distinct identity.

"Automation" is a term that the wider public understands. Therefore, I would suggest that we consistently refer to our profession as Automation and Control Engineering (ACE). Together with that, the name of our professional society should also be changed to International Society of Automation (ISA). Another clarifying step could be to change the title of our society magazine from *InTech* to *AutomationTech* because "In" does not say much.

The potentials of the ACE profession are great. While as a profession we have been anonymous, we have already designed fully automated Mars explorers and fully optimized industrial plants. Now it is time to let the world know that we exist. It is time to add to the list of ME, EE, or ChE professional engineering licenses one for ACE engineers; it is time for universities to offer degrees in ACE engineering and for publishers to set up ACE departments.

We should not be shy about this. After all, no engineering profession can claim what we can. No engineering profession can offer to increase the global gross domestic product by trillions of dollars simply through optimization, without building a single new plant, while also *increasing* safety and *reducing* pollution. We can do that. We can increase productivity without using a single pound of additional raw material and without requiring a single additional BTU of energy. Yes, our profession does deserve a distinct identity.

DEVELOPMENTS OF THE LAST DECADE

These days, the computer is our main tool of control. The chapters of this volume describe how the computer is being used in optimizing our processes, providing self-diagnostics, and displaying status information in operator-friendly formats. Today, the World Wide Web provides access to great quantities of data; in the future it will also provide problem-solving capability, so that through the grid, every ACE engineer will have a supercomputer at his or her disposal.

During the last decade, the artificial separation between the roles of DCS, PLC, and PC packages has started to disappear because their separate roles of control (DCS), logic sequencing (PLC), or simulation, and business-related tasks (PC) are beginning to be integrated. I believe that in the near future DCS will simply mean digital control system. Once the digital bus protocols are integrated into a single global standard, the presently required interfacing cards (and the associated risk of mixup) will disappear, and therefore our control systems will become safer, simpler, and more effective.

In the paragraphs below I review some of the developments of the last decade.

Is the Age of the PID Over?

Designating a valve on a flow sheet as a temperature control valve (TCV) will not suspend the laws of nature, and this arbitrary designation will not, for example, prevent the valve from affecting the process pressure. Similarly, the number of available control valves in a process will not necessarily coincide with the number of process properties that need to be controlled. Multivariable herding or envelope control overcomes this limitation of uncoordinated single loop controllers and lets us control all variables that need to be controlled, while minimizing interactions.

The majority of our control loops are still keeping single process variables on set point, but the age of multivariable control has already arrived. In the majority of cases, we still tend to control levels, flows, and temperatures as if these single loops operated in a vacuum, but others are already recognizing that loops do interact and that the opening or closing of a control valve affects not only the one variable we are controlling. For these reasons, the decoupling of interactions based on relative gain calculations have become important tools in the tool boxes of ACE engineers.

Many of us have concluded that the single-loop mentality is wrong because our plants do not produce flows, levels, and temperatures; hence, the control of these variables should not be our ultimate goal. Our ultimate goal should be to optimize the productivity and safety of the whole plant. As a consequence, we are now thinking in terms of unit operation controllers. In these multivariable control systems, the total unit operation (be it a boiler, a distillation column, or a compressor) is being controlled.

The Set Point

Advances have also been made in rethinking the role of the set point. In one aspect, the single set point is often replaced by a set point gap, so that as long as the controlled variable is within that gap, the output is unaltered. This tends to stabilize sensitive loops, such as flow.

Another aspect in which the set point is treated differently today is its effect on the controller output. In many algorithms a change in set point does not change the proportional or derivative contributions to the output because the P and D modes act only on the measurement.

In other algorithms, while the set point change does affect the integral contribution to the output, the set point change is “feedforwarded” directly to the output to minimize reset windup. Reset windup is also minimized by external feedback, taken from the slave measurement in case of cascade loops, from the valve signal in case of selective loops, and from the inverse model in feedforward loops.

Dynamics and Dead Time

The dynamics of control are also better understood today. It is clear that for quarter amplitude damping the gain product of the loop should be about 0.5. This means that in order to keep this product constant, if the process gain doubles, the controller gain must be cut in half. This understanding is critical to the control of all nonlinear processes (heat transfer, chemical reaction, pH, etc.). Clearly understanding this goal also allows for gain adaptation based on either measurements or modeling.

Similarly, the role of dead time is also better understood today. Most ACE engineers know that the integral and derivative control modes must be tuned to match the dead time. Therefore, the control goal is to reduce the loop dead time to a minimum and keep it constant. If that is not possible because the process dead time must vary (transportation lag caused by displacing a fixed volume), it is necessary to match that variable dead time with adapted I and D settings. When the dead time is large, the regular PID algorithm is replaced with sample-and-hold or predictor algorithms.

Unit Operations Controllers

An already existing multipurpose reactor package (described in this volume) can be reconfigured through software modifications to become a stripper, distillation, or crystallizer unit controller. Other multivariable, envelope, and matrix control systems described in this volume are aimed at increasing the efficiency or the productivity of the process, while treating the individual variables — the temperatures, pressures, and levels — only as constraints.

There are hundreds of expert systems, all serving some form of optimization. From the perspective of their methods of operation, one can group them into model-based and model-free methods. They both control multivariable unit operations and because they both evaluate the total process, they also eliminate the interactions between the various controlled and manipulated variables.

Expert systems, which are used in unit operations controllers, are also useful in decoupling the interactions through relative gain and other techniques. Probably the greatest progress has occurred in the area of model-based control, which utilizes both steady-state and dynamic models and allows both for the prediction of process responses before they occur and for continual refinement of the model by empirical updating. In this regard neural networks, artificial intelligence, statistical process control, fuzzy logic, and empirical optimization strategies have all made some contribution.

Model-Based and Model-Free Control

Model-Based Control (MBC), Model Predictive Control (MPC), and Internal Model Control (IMC) are suited for the optimization of well-understood unit processes, such as heat transfer or distillation. Their performance is superior to that of model free systems because they are capable of anticipation and thereby can predict the process response to new situations. In this sense their performance is similar to that of feedforward control systems, while model-free systems behave in a feedback manner only.

The performance of a model-free expert system can be compared to the behavior of a tennis player. The tennis player does not necessarily understand Newton's laws of motion or the aerodynamic principles that determine the behavior of a tennis ball. The tennis player has simply memorized the results of a large number of past "process" responses. This is also the basis of most human learning. All the neural network–based software packages mimic this method of learning.

Neural networks, fuzzy logic, and statistical process control are all such model-free methods, which can be used without the need for knowing the mathematical model of the process. The major difference between fuzzy logic and neural networks is that the latter can only be trained by data, but not with reasoning. Fuzzy logic is superior from this perspective because it can be modified both in terms of the gain (importance) of its inputs and in terms of the functions of its inputs.

The main limitations of all model-free expert systems are their long learning period (which can be compared to the maturing of a child) and the fact that their knowledge is based solely on past events. Consequently, they are not prepared to handle new situations. Therefore, if the process changes, they require retraining because they can only anticipate repetitive events.

Artificial Neural Networks (ANN)

One of the tools used in building models is the Artificial Neural Network (ANN), which can usually be applied under human supervision or can be integrated with expert and/or fuzzy logic systems. Figure 1 shows a three-layer ANN network, which serves to predict the boiling point of a distillate and the Reid vapor pressure of the bottoms product of a

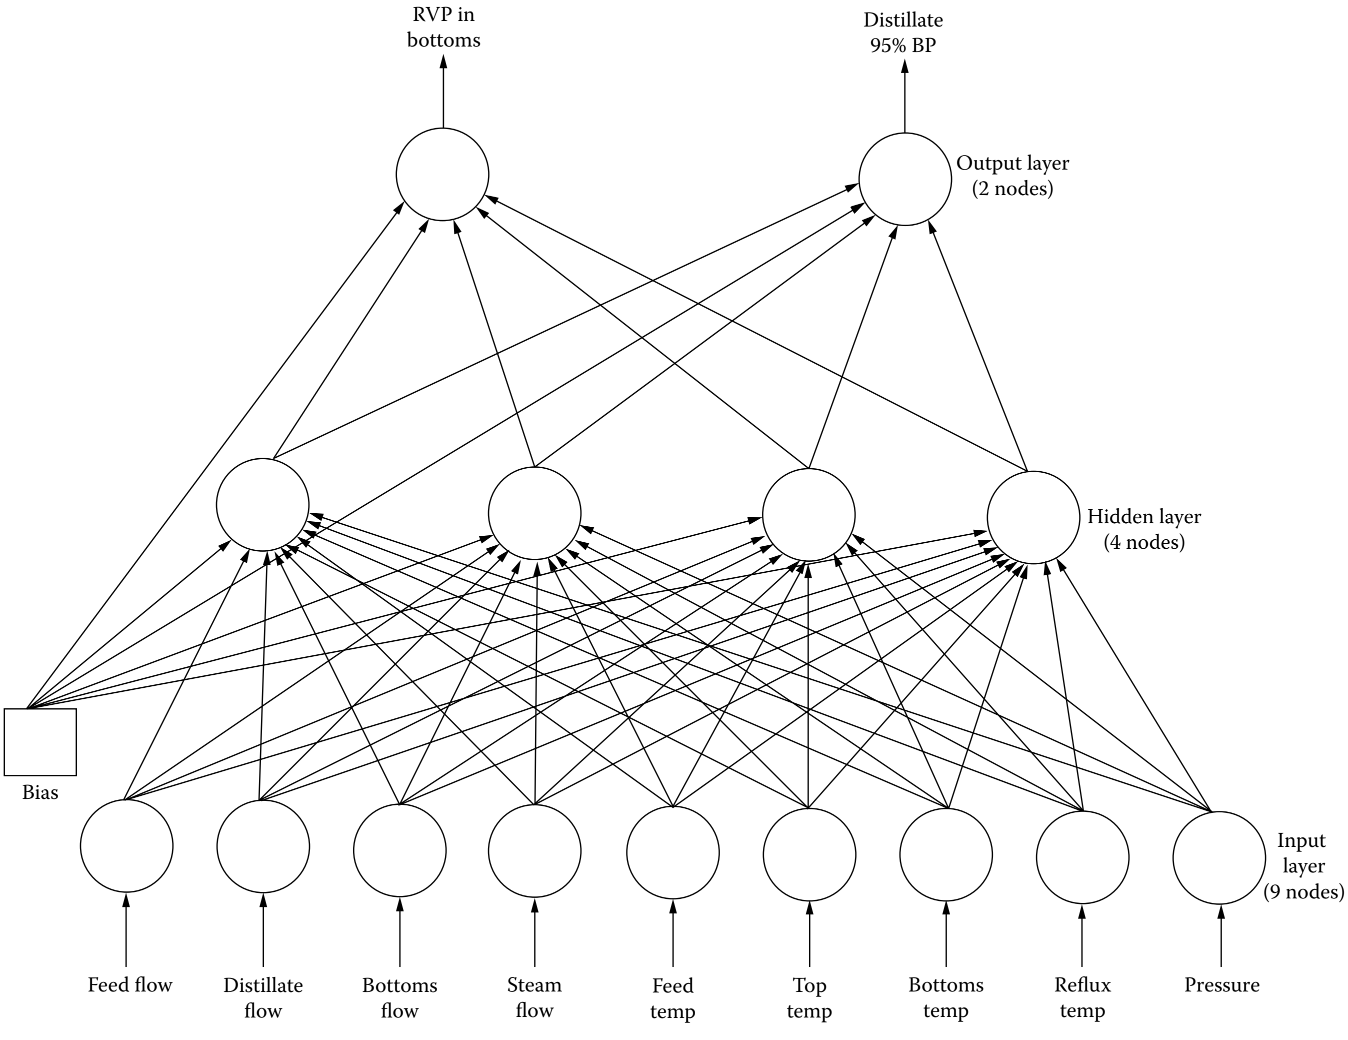

FIG. 1
A three-layer artificial neural network (ANN) can be used to predict the quality of overhead and bottoms products in a distillation column.

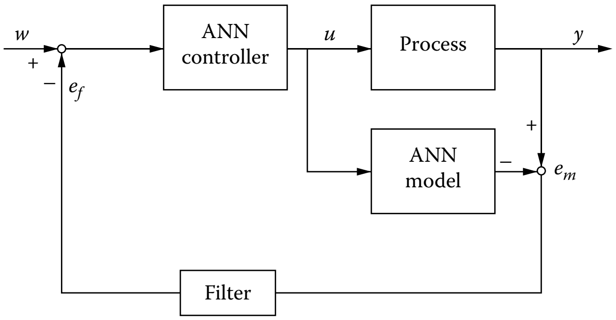

FIG. 2
The use of an artificial neural network in an IMC (Internal Model Control) application.

column. Such predictive ANN models can be valuable because they are not limited by either the unreliability or the dead time of analyzers.

The "personality" of the process is stored in the ANN network by the way the processing elements (nodes) are connected and by the importance assigned to each node (weight). The ANN is "trained" by example and therefore it contains the adaptive mechanism for learning from examples and to adjust its parameters based on the knowledge that is gained through this process of adaptation. During the "training" of these networks, the weights are adjusted until the output of the ANN matches that of the real process.

Naturally, these networks do need "maintenance" because process conditions change; when that occurs, the network requires retraining. The hidden layers help the network to generalize and even to memorize.

The ANN network is also capable of learning input/output and inverse relationships. Hence it is useful in building Internal Model Control (IMC) systems based on ANN-constructed plant models and their inverses. In a neural controller (Figure 2), the ANN can be used in calculating the control signal.

Herding Control

When a large number of variables is involved, model free herding control can be considered. This approach to control can be compared to the herding of sheep, where the shepherd's dog goes after one animal at a time and changes the direction or speed of the whole herd by always influencing the behavior of the least cooperative sheep.

I have successfully applied such herding algorithms in designing the controls of the IBM headquarters building in New York City. By herding the warm air to the perimeter (offices with windows) from the offices that are heat generators even in the winter (interior offices), the building became self-heating. This was done by changing the destination of the return air from one "hot" office at a time (the one that was the warmest in the building) and simultaneously opening the supply damper of the "coldest office" to that same header.

I have also applied the herding algorithm to optimize the process of computer chip manufacturing by eliminating the minute pressure differences that can cause dust-transporting drafts, which in turn can ruin the chips.

In general, herding control is effective if thousands of manipulated variables exist and they all serve some common goal.

Common-Sense Recommendations

While evaluating and executing such sophisticated concepts as optimized multivariable control, the ACE engineer's best friend is common sense and our most trusted teacher is still Murphy, who says that anything that can go wrong, will. In order to emphasize the importance of common sense, I will list here some practical recommendations:

- Before one can control a process, one must fully understand it.
- Being progressive is good, but being a guinea pig is not. Therefore, if the wrong control strategy is implemented, the performance of even the latest digital hardware will be unacceptable.
- An ACE engineer is doing a good job by telling plant management what they need to know and not what they like to hear.
- Increased safety is gained through backup. In case of measurement, reliability is increased by the use of multiple sensors, which are configured through median selectors or voting systems.
- If an instrument is worth installing, it should also be worth calibrating and maintaining. No device can outperform the reference against which it was calibrated.
- All man-made sensors detect relative values, and therefore the error contribution of references and compensators must always be included in the total error.
- Sensors with errors expressed as percent of the actual reading are preferred over those with percent of full-scale errors. If the actual percent of reading error increases as the reading moves down-scale, the loop performance will also deteriorate.
- It is easier to drive within the limits of a lane than to follow a single line. Similarly, control is easier and more stable if the single set point is replaced by a control gap.
- Process variables should be allowed to float within their safe limits as they follow the load. Constancy is the enemy of efficiency. Optimization requires efficient adaptation to changing conditions.
- Trust your common sense, not the sales literature. Independent performance evaluation based on the recommendations of international and national users' associations (SIREP-WIB) should be done *before* installation, not after it. The right time for "business lunches" is *after* start-up, not before the issue of the purchase order.
- Annunciators do not correct emergencies; they just throw those problems that the designers did not know how to handle into the laps of the operators. The smaller the annunciator, the better the design.

FUTURE NEEDS

I have already mentioned such needs as the establishment of our professional identity as automation and control engineers (ACE) or the need to integrate DCS, PLC, and PC hardware into a new digital control system (DCS+) that incorporates the features of all three. I have also briefly mentioned the need for bringing order into our "digital Babel" and to stop the trend toward software outsourcing (selling DCS systems without some software packages), which is like selling violins without the strings.

I would not be surprised if, by the end of the 21st century, we would be using self-teaching computers. These devices would mimic the processes taking place in our children's brains, the processes that allow babies to grow into Einsteins by learning about their environment. These devices would be watching the operation of a refinery or the landing and takeoff of airplanes and eventually would obtain as much knowledge as an experienced operator or pilot would have.

If this comes to pass, some might argue that this would be a step forward because machines do not forget; do not get tired, angry, or sleepy; and do not neglect their job to watch a baseball game or to argue with their spouse on the phone. This might be so, yet I would still prefer to land in a human-piloted airplane. I feel that way because I respect Murphy more than most scientists and I know that he is right in stating that "anything that can happen, will." For this reason, the knowledge of the past, which is the knowledge of the computer, might still not be enough.

In addition to new control tools, we will also have new processes to control. Probably the most important among these will be the fuel cell. The fuel cell is like a battery, except that it does not need recharging because its energy is the chemical energy of hydrogen, and hydrogen can come from an inexhaustible source, namely water. In order to gain the benefits of tripling the tank-to-wheel efficiency of our transportation systems while stopping global warming, we will have to learn to control this new process. The challenge involves not only the control of the electrolytic process that splits the water by the use of solar energy, but also the generation, storage, and transportation of liquid or slurry hydrogen.

As I was editing this reference set for the fourth time, I could not help but note the new needs of the process control industry, which are the consequences of the evolution of new hardware, new software, and new process technologies. Here, in the paragraphs that follow, I will describe in more detail what I hope our profession will accomplish in the next decade.

Bringing Order to the "Digital Babel"

In earlier decades, it took time and effort to reach agreement on the 3- to 15-PSIG (0.2- to 1.0-bar) pneumatic and later on the 4- to 20-mA DC standard current signal range. Yet when these signal ranges were finally agreed upon, the benefit was universal because the same percentage of full scale measurement was represented by the same reading on every device in the world.

Similarly, the time is ripe for a single worldwide standard for all digital I/O ranges and *digital communication protocols.* The time is ripe for such an internationally accepted digital protocol to link all the digital "black boxes" and to eliminate the need for all interfacing.

By so doing, we could save the time and effort that are being spent on figuring out ways to interconnect black boxes and could invest them in more valuable tasks, such as enhancing the productivity and safety of our processing industries.

Networks and Buses

Protocol is the language spoken by our digital systems. Unfortunately, there is no standard that allows all field devices to communicate in a common language. Therefore the creation and universal acceptance of a standard field bus is long overdue.

There is nothing wrong with, say, the Canadians having two official languages, but there is something wrong if a pilot does not speak the language of the control tower or if two black boxes in a refinery do not speak the same language. Yet the commercial goal of manufacturers to create captive markets resulted in some eight protocols. These control-oriented communication systems are supported by user groups, which maintain Internet sites as listed below:

AS-Interface	www.as-interface.com
DeviceNet	www.odva.org
HART	www.hartcomm.org
PROFIBUS	www.profibus.org
Found. Fieldbus	www.fieldbus.org
OPC Foundation	www.opcfoundation.com
WorldFIP	www.worldfip.org
ControlNet	www.controlnet.com
MODBUS	www.modbus.org
Ethernet TCP/IP*	www.industrialethernet.com

*TCP - Transmission control protocol
IP - Internet protocol

During the last decade, HART has become the standard for interfacing with analog systems, while Ethernet was handling most office solutions. SCADA served to combine field and control data to provide the operator with an overall view of the plant. While there was no common DCS fieldbus protocol, all protocols used Ethernet at the physical and TCP/IP at the Internet layer. MODBUS TCP was used to interface the different DCS protocols.

The layers of the communication pyramid were defined several ways. OSI defined it in seven (7) layers, #1 being the physical and #7 the application layer (with #8 being used for the "unintegrated," external components). The IEC-61512 standard also lists seven levels, but it bases its levels on physical size: (1) control module, (2) equipment, (3) unit, (4) process cell, (5) area, (6) site, and (7) enterprise.

As I noted earlier, in the everyday language of process control, the automation pyramid consists of four layers: #1 is the level of the field devices, the sensors and actuators; #2 is control; #3 is plant operations; and #4 is the level of business administration.

Naturally, it is hoped that in the next decade, uniform international standards will replace our digital Babel, so that we once again can concentrate on controlling our processes instead of protecting our plants from blowing up because somebody used the wrong interface card.

Software Outsourcing

Another problem in the last decade was the practice of some DCS vendors to sell their "violins without strings," to bid their packages without including all the software that is needed to operate them.

To treat software as an extra and not to include the preparation of the unique control algorithms, faceplates, and graphic displays in the basic bid can lead to serious problems. If the plant does not hire an engineering firm or system integrator to put these strings onto the DCS violin, the plant personnel usually cannot properly do it and the "control music" produced will reflect that. In such cases the cost of plugging the software holes can exceed the total hardware cost of the system.

The cause of another recurring problem is that the instructions are often written in "computerese."

In some bids, one might also read that the stated cost is for "hardware with software license." This to some will suggest that the operating software for the DCS package is included. Well, in many cases it is not; only its license is.

Similarly, when one reads that an analyzer or an optimization or simulation package needs "layering" or is in the "8th layer," one might think that the bid contains eight layers of fully integrated devices. Well, what this language often means is that the cost of integrating these packages into the overall control system is an extra.

So, on the one hand, this age of plantwide digital networks and their associated advanced controls has opened the door for the great opportunities provided by optimization. On the other hand much more is needed before the pieces of the digital puzzle will conveniently fit together, before these "stringless violinists" can be integrated into a good orchestra of automation.

Connectivity and Integration

Utilizing our digital buses, one can plug in a PC laptop or use a wireless hand tool and instantly access all the data, displays, and intelligence that reside anywhere in a DCS network. This capability, in combination with the ability for self-tuning, self-diagnosing, and optimizing, makes the startup, operation, and maintenance of our plants much more efficient.

The modern control systems of most newly built plants consist of four levels of automation. In the field are the intelligent and self-diagnosing local instruments (sensors, valves, motors, safety devices). This first level is connected by a number of data highways or network buses to the next level in this automation pyramid, the level of control. The third level is plant operations, and the fourth is the enterprise-wide business level.

The functions of the DCS workstations include control/operation, engineering/historian, and maintenance functions, while the enterprise-wide network serves the business functions. In addition, wireless hand tools are used by the roving operators, and external PCs are available to engineers for their process modeling and simulation purposes.

HARDWARE-RELATED IMPROVEMENTS NEEDED

I will discuss below some of the areas in which the next decade should bring improvements in the quality and intelligence of the components that make up our control systems. I will discuss the need for better testing and performance standards and the improvements needed in the sensors, analyzers, transmitters, and control valves. I will place particular emphasis on the potentials of "smart" devices.

Meaningful Performance Standards

The professional organizations of automation and control engineers (ACE) should do more to rein in the commercial interests of manufacturers and to impose uniform performance testing criteria throughout the industry. In the sales literature today, the meanings of performance-related terms such as inaccuracy, repeatability, or rangeability are rarely based on testing, and test references are rarely defined. Even such terms as "inaccuracy" are frequently misstated as "accuracy," or in other cases the error percentages are given without stating whether they are based on full scale or on actual readings. It is also time for professional societies and testing laboratories to widely distribute their findings so that these reliable third-party test results can be used by our profession to compare the performance of the various manufacturers' products.

We the users should also require that the manufacturers always state not only the inaccuracy of their products but also the rangeability over which that inaccuracy statement is valid. In other words, the rangeability of all sensors should be defined as the ratio between those maximum and minimum readings for which the inaccuracy statement is still valid.

It would also be desirable to base the inaccuracy statements on the performance of at least 95% of the sensors tested and to include in the inaccuracy statement not only linearity, hysteresis, and repeatability but also the effects of drift, ambient temperature, over-range, supply voltage variation, humidity, radio frequency interface (RFI), and vibration.

Better Valves

In the next decade, much improvement is expected in the area of final control elements, including smart control valves.

This is because the performance of the control loop is much affected not only by trim wear in control valves but also by stem sticking caused by packing friction, valve hysteresis, and air leakage in the actuator. The stability of the control loop also depends on the gain of the valve during the tuning of the loop.

In order for a control loop to be stable, the loop is tuned (the gain of the controller is adjusted) to make the gain product of the loop components to equal about 0.5. If the control valve is nonlinear (its gain varies with the valve's opening), the loop will become unstable when the valve moves away from the opening where it was when the loop was tuned. For this reason, the loop must be compensated for the gain characteristics of the valve; such compensation is possible only if the valve characteristics are accurately known.

For the above reasons, it is desirable that the users and the professional societies of ACE engineers put pressure on the manufacturers to accurately determine the characteristics of their valves. The other performance capabilities of the final control elements also need to be more uniformly defined. This is particularly true for the rangeability of control valves. For example, a valve should be called linear only if its gain (Gv) equals the maximum flow through the valve (Fmax) divided by the valve stroke in percentage (100%) throughout its stroke.

The valve manufacturers should also be required to publish the stroking range (minimum and maximum percentages of valve openings) within which the valve gain is what it is claimed to be (for a linear valve it is Fmax/100%). Similarly, valve rangeability should be defined as the ratio of the minimum and maximum valve Cvs, at which the valve characteristic is still what it is specified to be.

Smarter Valves

A traditional valve positioner serves only the purpose of maintaining a valve at its intended opening. Digital valve controllers, on the other hand, provide the ability to collect and analyze data about valve position, valve operating characteristics, and valve performance trending. They also provide two-way digital communication to enable diagnostics of the entire valve assembly and instrument. Section 6.12 in this handbook and the following Web pages provide more information: Metso Automation (http://www.metsoautomation.com/), (http://www.emersonprocess.com/fisher/products/fieldvue/dvc/index.html)

The potentials of smart valves are likely to be further increased and better appreciated in the next decade. The main features of a smart valve include its ability to measure its own:

- Upstream pressure
- Downstream pressure
- Temperature
- Valve opening position
- Actuator air pressure

Smart valves will also eliminate the errors introduced by digital-to-analog and analog-to-digital conversions and will guarantee the updating of their inputs about 10 times per second. In addition, they will be provided with the filters required to remove the errors caused by turbulence in these readings. As a consequence, smart valves will also be able to measure the flow, by solving equations, such as the one below for liquid flow:

$$Q = \frac{C_v}{\sqrt{\frac{SPGRAV}{\Delta P_A}}}$$

where

Q = Flow rate (GPM)
F_L = Recovery coefficient
C_v = Flow capacity factor
P_1 = Upstream pressure (PSIA)
P_v = Liquid vapor press (PSIA)
P_c = Critical pressure (PSIA)
ΔP_A = Valve pressure drop (PSI) or

If Choked:

$$\Delta P_A = F_L^2 \left[P_1 - \left(0.96 - 0.28 \sqrt{\frac{P_V}{P_C}} \right) \right] P_V$$

The smart valves of the coming decade will hopefully not only measure their own flows but will also measure them over a rangeability that exceeds most flowmeters (from 25:1 to over 100:1) because they in effect are variable-opening orifices.

If the sensors of the intelligent control valve are connected to a PID chip mounted on the valve, the smart valve becomes a local control loop. In that case, only the operator's displays need to be provided remotely, in a location that is convenient for the operator. In such a configuration, it will be possible to remotely reconfigure/recalibrate the valve as well as to provide it with any limits on its travel or to diagnose stem sticking, trim wear, or any other changes that might warrant maintenance.

"Smarter" Transmitters, Sensors, and Analyzers

In the case of transmitters, the overall performance is largely defined by the internal reference used in the sensor. In many cases there is a need for multiple-range and multiple-reference units. For example, pressure transmitters should have both atmospheric and vacuum references and should have sufficient intelligence to automatically switch from one to the other on the basis of the pressure being measured.

Similarly, d/p flow transmitters should have multiple spans and should be provided with the intelligence to automatically switch their spans to match the actual flow as their measurement changes.

The addition of "intelligence" could also increase the amount of information that can be gained from such simple detectors as pitot tubes. If, for example, in addition to detecting the difference between static and velocity pressures, the pitot tube was able to also measure the Reynolds number, it would be able to approximate the shape of the velocity profile. An "intelligent pitot tube" of such capability could increase the accuracy of volumetric flow measurements.

Improved On-Line Analyzers

In the area of continuous on-line analysis, further development is needed to extend the capabilities of probe-type analyzers. The needs include the changing of probe shapes to obtain self-cleaning or to improve the ease of cleaning by using "flat tips." The availability of automatic probe cleaners should also be increased and the probe that is automatically being cleaned should be made visible by the use of sight flow indicators, so that the operators can check the cleaner's effectiveness.

More and more analyzers should become self-calibrating, self-diagnosing, and modular in their design. In order to lower maintenance costs, analyzers should also be made more modular for ease of replacement and should be provided with the intelligence to identify their defective modules. The industry should also explore the use of multiple-probe fiber-optic analyzers with multiplexed shared electronics.

Improving Operators' Displays

The control rooms of the coming decades will be more operator-friendly and more enterprise-wide optimization oriented. The human-machine interfaces (HMIs) in the control rooms are only as good as the ability of the operators to use them.

The hand, the psychological characteristics, the hearing, and color discrimination capability of the human operator must all be part of the design. Even more importantly, the design should also consider the personality and education of the average operator. Therefore, a well-designed HMI is the operator's window on the process.

In past decades, the operator's window on the process was little more than the faceplate of an analog controller and an annunciator. Today, when a single operator is expected to oversee the operation of processes having hundreds if not thousands of variables, the operator must be provided with diagnostic, trend, and historical data in an easily understandable and familiar format.

For that purpose, it is advisable to provide in the control room a large display panel, on which (as one of the options) the operation of the whole plant can be displayed. Using that graphic flowsheet, the operator should have the ability to focus in on any unit operation of interest. As the operator focuses in on smaller and smaller sections of the plant, the information content of the display should increase. In the process of "focusing," the operator must be able to select subsystems, individual loops, or loop components, such as a single control valve. At each level of scale, the display should identify all abnormal conditions (by color and flashing), while providing all the trend and status data for all related variables.

Another essential feature of modern control systems is their suitability for smooth growth of the plant. This capability is very important in process control because plants are ever expanding and therefore their control systems must also grow with the expansions. A modular approach to operator stations makes the expansion of the plant easier.

Optimization and Advanced Controls

In some ways we have already passed the age of the single-loop PID control. Yet in the coming decade much more improvement is expected both in multivariable unit operations control and in model-based optimization.

We all know that it is time to stop controlling flows, pressures, and temperatures and to start controlling and optimizing pumping stations, boilers, and chemical reactors. In the next decade, hopefully we will see the development of the universal software package for the various unit operations that can be adapted to specific plants just by the entering of design data for the particular process.

Plant-Wide Modeling and Optimization

In addition to its role in providing better control, process modeling and simulation can also improve the training of operators. If the simulation model is accurate and if it integrates the dynamics of the process with that of its control system, it can be used to train operators for plant startup without risking the consequences of their inexperience. Needless to say, the building of good models is expensive, but once prepared, they are very valuable.

Business- or enterprise-wide optimization includes the model of not only the manufacturing process, but also the optimization of the raw material supply chain and of the packaging and product distribution chain. This is a higher and more important level of optimization because it requires the simultaneous consideration of all areas of optimization and the finding of enterprise-wide operation strategies, which will keep all areas within their optimum areas of operation.

Plant-wide optimization also involves more than the optimization of the unit processes because it must also consider documentation, maintenance, production scheduling, and quality management considerations. Plant-wide optimization requires the resolution of the conflicting objectives of the operations and strategies.

Naturally, it should be kept in mind that modeling and optimization can only be achieved when the control loops are correctly tuned, the measurements are sampled fast enough, and interactions between loops have been eliminated.

Efficiency and Productivity Controllers

This handbook already describes a large number of methods to increase the efficiency of unit operations. For example, in the section describing the methods of pumping station optimization, it is pointed out that the lifetime operating cost of a pumping station is about a *hundred times higher than its initial cost.* The returns on the optimization of other unit operations are similar, although not that high. It is for this reason that in the coming decade, optimization is expected to increase.

When using multivariable envelopes for unit operation optimization, the individual variables of levels, pressures, and temperatures become only constraints, while the overall goal is to maximize the efficiency or productivity of the controlled process. New software packages are needed to "educate" and give "personality" to today's multivariable controllers to transform these general-purpose units into chemical reactor, distillation tower, compressor, or any other type of unit operation controllers.

Unit Operation Controllers of the Future

The next decade could bring a building-block approach to control systems. In this approach all "empty boxes" could be very similar, so that a unit operations controller that was, say, to optimize a dryer, could be converted to control an evaporator or a pumping station just by loading into it a different software package and connecting a different set of I/Os. Once the particular software package was loaded, the unit controller would be customized by a menu-driven adapter package, organized in a question-and-answer format.

During the customization phase, the user would answer questions on piping configuration, equipment sizes, material or heat balances, and the like. Such customization software packages could not only automatically configure and tune the individual loops but could also make the required relative gain calculations to minimize the interaction among them.

HISTORY OF THE HANDBOOK

The birth of this handbook was connected to my own work: In 1962 — at the age of 26 — I became the Chief Instrument Engineer at Crawford & Russell, an engineering design firm specializing in the building of plastics plants. C&R was growing and with it the size of my department also increased. Yet, at the age of 26 I did not dare to hire experienced people because I did not feel secure enough to lead and supervise older engineers.

So I hired fresh graduates from the best engineering schools in the country. I picked the smartest graduates and I obtained permission from C&R's president, Sam Russell, to spend every Friday afternoon teaching them. In a few years C&R not only had some outstanding process control engineers but had them at relatively low salaries.

By the time I reached 30, I felt secure enough to stop disguising my youth. So I shaved off my beard and threw away my phony, thick-rimmed eyeglasses, but my Friday's notes remained. They still stood in a 2-foot-tall pile on the corner of my desk.

"Does Your Profession Have a Handbook?"

In the mid-1960s an old-fashioned Dutch gentleman named Nick Groonevelt visited my office and asked: "What is that pile of notes?" When I told him, he asked: "Does your profession have a handbook?" "If it did, would I bother to prepare all these notes?" I answered with my own question. (Actually, I was wrong in giving that answer, because Behar's *Handbook of Measurement and Control* was already available, but I did not know about it.) "So," Nick proposed, "let me publish your notes and then the instrument engineers will have a handbook!" In 1968 the first edition of the *Instrument Engineers' Handbook* (*IEH*) was published.

In 1968, the Soviet tanks — which I fought in 1956 in Budapest — were besieging Prague, so I decided to dedicate the three volumes of the *IEH* to the Hungarian and Czech freedom-fighters. A fellow Hungarian-American, Edward Teller, wrote the preface to the first edition; Frank Ryan — the editor of *ISA Journal* — wrote the introduction. Because of the publication of the first edition of the *IEH*, in 1973 I was elected the youngest ISA fellow ever.

Later Editions

By the end of the 1970s the world of process control had changed. Pneumatics were on the way out, and new solutions like DCS control and on-line analyzers proliferated. It was time to revise the handbook. The second edition was published in 1985. It was well received.

By the mid-1990s the handbook was ready for another updated edition. By that time the process control market was becoming globalized, "smart" instruments had evolved, and such hardware inventions as fiber-optic probes and throttling solenoid valves proliferated. So I stopped teaching at Yale, cut back on consulting, and prepared the third edition. In this edition I also added a third volume to the two-volume set to cover all the evolving digital software packages, communication networks, buses, and optimization packages.

Work on the fourth edition of the *IEH* started in the new millenium, and the first volume on measurement and analysis was published in 2003. The second volume is in your hands now.

During the nearly four decades of its existence, the *Instrument Engineers' Handbook* (*IEH*) has become the most widely used reference source for the automation and control (ACE) engineering profession. During this period, our experience and our knowledge of control principles have penetrated all the fields of modern science and technology. I hope that the three volumes of the *IEH* will continue to play a major role in spreading this knowledge and understanding.

The Contents of the *IEH* Volumes

In 1968, this handbook started out as a two-volume reference set and, in that respect, it has not changed. The first volume still deals with measurement, the second with control. What is new is that the third volume deals with digital networks and software systems.

This fourth edition updates the information content of the previously published sections, incorporates the new developments of the last decade, and broadens the horizons of the work from an American to a global perspective. In the first volume, one chapter was devoted to each major measured variable including the detection of flow, level, temperature, pressure, density, viscosity, weight, composition, and safety sensors. Each subchapter (section) was devoted to the discussion of a different method of making that measurement.

This second volume of the *IEH* deals with process control and covers both control hardware and control strategies. The hardware discussed includes transmitters, controllers, control valves, and displays, including the design of control rooms. The chapters on control systems provide in-depth coverage both of the theory of control and of the unit processes of pumping, distillation, chemical reaction, heat transfer, and many others. The individual sections (subchapters) begin with a flowsheet symbol and if the subject matter is a hardware item, start with a feature summary.

This summary provides quick access to specific information on the available sizes, suppliers, ranges, and inaccuracies of the devices covered in that section. The reader is advised to turn to the section of interest and, based on the information in the feature summaries, decide whether the costs, inaccuracies, and other characteristics meet the requirements of the particular application.

We know that there is no greater resource than the combined knowledge and professional dedication of a well-educated new generation. We live in an age when technology can make the difference in overcoming the social and environmental ills on this planet. We live in an age when an inexhaustible and nonpolluting energy technology must be developed. It is hoped that this handbook will make a contribution toward these goals and in addition will also improve the professional standing of automation and control engineers around the world.

(*liptakbelaieh4@aol.com*)

DEFINITIONS

Absolute (Dynamic) Viscosity (μ)	Constant of proportionality between applied stress and resulting shear velocity (Newton's hypothesis).
Absorbance (*A*)	Ratio of radiant energy absorbed by a body to the corresponding absorption of a blackbody at the same temperature. Absorbance equals emittance on bodies whose temperature is not changing. ($A = 1 - R - T$, where R is the reflectance and T is the transmittance.)
Absorption	The taking in of a fluid to fill the cavities in a solid.
Accumulation	In safety and relief valve terminology, accumulation is the pressure increase over the maximum allowable working pressure of a tank or vessel during discharge through the pressure relief valve. It is given either in percentage of the maximum allowable working pressure or in pressure units such as pounds per square inch or in bars.
Accuracy	See **Inaccuracy**, which is the term used in this handbook.
Adaptive Control	See **Control, Adaptive**
Admittance (*A*)	The reciprocal of the impedance of a circuit. The admittance of an AC circuit is analogous to the conductance of a DC circuit. (Units: siemens.)
Adsorption	The adhesion of a fluid in extremely thin layers to the surfaces of a solid.
Alarm	A signal designed to alert, inform, guide, or confirm deviations from acceptable system status.
Alpha Curve	In resistance bulb terminology, it is the relationship of the resistance change of an RTD vs. temperature. In European alpha curves, the alpha value is 0.00385 ohms per degree C, while in American curves it is 0.00392.
Ampacity	The current (amperes) a conducting system can support without exceeding the temperature rating assigned to its configuration and application.
Amperometric Titration	Titration in which the end point is determined by measuring the current (amperage) that passes through
Amperometry	The process of performing an amperometric titration. The current flow is monitored as a function of time between working and auxiliary electrodes while the voltage difference between them is held constant; in other designs, the current is monitored as a function of the amount of reagent added to bring about titration of an analyte to the stoichiometrically defined end point. Also called constant potential voltametry.
Amplifier	A device that enables an input signal to control a signal source independent of the signal and is thus capable of delivering an output that is related to and is greater than the input signal.
Apparent Viscosity	Viscosity of a non-Newtonian fluid under given conditions. Same as consistency.
Approach	The different between the wet-bulb temperature of the ambient air and the water temperature leaving a cooling tower. The approach is a function of cooling tower capacity; a large cooling tower will produce a closer approach (colder leaving water) for a given heat load, flow rate, and entering air condition. (Units: °F or °C.)
Artificial Neural Networks (ANNs)	An ANN can learn complex functional relations by generalizing from a limited amount of training data; hence, it can thus serve as black-box model of nonlinear, multivariable static and dynamic systems and can be trained by the input–output data of these systems. ANNs attempt to mimic the structures and processes of biological neural systems.

	They provide powerful analysis properties such as complex processing of large input/output information arrays, representing complicated nonlinear associations among data, and the ability to generalize or form concepts–theory.
Attenuation	Loss of communication signal strength.
Auto-Manual Station	A device that enables an operator to select either the output of a controller or a manually generated signal.
Backlash	In mechanical devices, it is the relative movement between interacting parts that results from the looseness of these parts when motion is reversed.
Backplane	Physical connection between individual components and the data and power distribution buses inside a chassis.
Backpressure	In relief and safety valve terminology, it is the pressure on the discharge side of a pressure relief valve. This pressure is the sum of the superimposed and the built-up backpressures. The superimposed backpressure is the pressure that exists in the discharge piping of the relief valve when the valve is closed.
Balanced Safety Relief Valve	A safety relief valve with the bonnet vented to atmosphere. The effect of backpressure on the performance characteristics of the valve (set pressure, blow-down, and capacity) is much less than on a conventional valve. The balanced safety relief valve is made in three designs: (1) with a balancing piston, (2) with a balancing bellows, and (3) with a balancing bellows and an auxiliary balancing piston.
Balling Degrees	Unit of specific gravity used in the brewing and sugar industries.
Balun (Balanced/ Unbalanced)	A device used for matching characteristics between a balanced and an unbalanced medium.
Band Pass Filter	An optical or detector filter that permits the passage of a narrow band of the total spectrum. It excludes or is opaque to all other wavelengths.
Bandwidth	Data carrying capacity, the range of frequencies available for signals. The term is also used to describe the rated throughput capacity of a given network medium or protocol.
Barkometer Degrees	Unit of specific gravity used in the tanning industry.
Baseband	A communication technique where only one carrier frequency is used to send one signal at a time. Ethernet is an example of a baseband network. Also called narrow-band. Contrast with **Broadband**.
Basic Control	Continuously executed algorithms that drive the process or equipment to a specified state and keep it there, such as indicators, regulatory and device controls, and interlocks.
Batch	A quantity of material produced by the single execution of a batch process. A batch also refers to the intermediate materials during the manufacturing process.
Baumé Degree	A unit of specific gravity used in the acid and syrup industry.
Bay	The area between two bents of lines of framing members; usually longitudinal.
Bent	A line of structural framework composed of columns or ties; a bent may incorporate diagonal bracing members; usually transverse.
Blackbody	The perfect absorber of all radiant energy that strikes it. A blackbody is also a perfect emitter. Therefore, both its absorbance and emissivity (E) are unity. A blackbody radiates energy in predictable spectral distributions and intensities, which are a function of the blackbody's absolute temperature.
Black Box Model	See **Empirical Model**.
Blowdown	In case of cooling towers, it is the water discharged to control the concentration of impurities in circulated water. (Units: percentage of circulation rate.)
Blowdown (Blowback)	In relief valves, it is the difference between the set pressure and the reseating (closing) pressure of a pressure relief valve, expressed in percent of the set pressure, in bars, or in pounds per square inch.
Bode Diagram	A plot of the logarithm of gain or magnitude ratio and a plot of the logarithm of phase angles against the logarithm of frequency for a transfer function.
Boiling Point Rise	This term expresses the difference (usually in °F) between the boiling point of a constant composition solution and the boiling point of pure water at the same pressure. For example, pure water boils at 212°F (100°C) at 1 atmosphere, and a 35% sodium hydroxide solution boils at about 250°F (121°C) at 1 atmosphere. The boiling point rise is therefore 38°F (21°C). In a Dühring plot, the boiling point of a given composition solution is plotted as a function of the boiling point of pure water.

Bolometer	Thermal detector that changes its electrical resistance as a function of the radiant energy striking it.
Bonding	The practice of creating safe, high capacity, reliable electrical connectivity between associated metallic parts, machines, and other conductive equipment.
Brightness Pyrometer	A device that uses the radiant energy on each side of a fixed wavelength of the spectrum. This band is quite narrow and usually centered at 0.65 microns in the orange-red area of the visible spectrum.
British Thermal Unit (BTU)	The amount of heat required to raise the temperature of one pound of water by one degree Fahrenheit at or near 60° Fahrenheit.
Brix Degree	A specific gravity unit used in the sugar industry.
Broadband	A communication technique that multiplexes multiple independent signals simultaneously, using several distinct carriers. A common term in the telecommunication industry to describe any channel having a bandwidth greater than that of a voice-grade channel (4 kHz). Also called wideband. Contrast with **Baseband**.
BTU "Dry"	The heating value of a gas expressed on a "dry basis." The common assumption is that pipeline gas contains 7 pounds (or less) of water vapor per million standard cubic feet.
BTU "Saturated"	The heating value of a gas expressed on the basis that the gas is saturated with water vapor. This state is defined as the condition when the gas contains the maximum amount of water vapor without condensation, when it is at base pressure and 60°F.
Bubble Point	The temperature at which a mixture of liquids first starts to boil.
Built-Up Backpressure	In connection with safety relief valves, the variable backpressure that develops as a result of flow through the pressure relief valve after it opens. This is an increase in pressure in the relief valve's outlet line caused by the pressure drop through the discharge headers.
Burning	In combustion-related terminology, burning is when the flame does not spread or diffuse but remains at an interface where fuel and oxidant are supplied in proper proportions.
Calibrate	To ascertain the outputs of a device corresponding to a series of input values that the device is to receive, measure, or transmit.
Calibration Cycle	The application of known values as inputs to a device and the registering of the corresponding output readings over the range of that device, in both ascending and descending directions.
Calibration Traceability	The relationship of the calibration of an instrument to that of one or more instruments calibrated and certified by a national standardizing laboratory.
Campaign	The total production run of one product, for example, for a single order or season, consisting of one or more lots.
Capacitance (*C*)	The amount of charge, in coulombs, stored in a system necessary to raise the potential difference across it 1 volt; represented by the SI unit farad.
Capacitor	Device consisting of two conductors electrically isolated by an insulator. The conductors are called plates, and the insulator is referred to as the dielectric. The larger the capacitor, the smaller its impedance, and the more AC current will flow through it.
Cascade Control	See **Control, Cascade**.
Characteristic Impedance	The impedance that, when connected to the output terminals of a transmission line appear to be infinitely long, for there are no standing waves on the line, and the ratio of voltage to current is the same for each point of the line [nominal impedance of wave-guide].
Chatter	Rapid, abnormal reciprocating variations in lift during which the disc contacts the seat.
Chronopotentiometry	When the potential difference between a metallic measuring electrode and a reference electrode is monitored as a function of time. At the measuring electrode an oxidation or reduction of a solution species is taking place.
Closing Pressure (Reseat Pressure)	In relief and safety valve terminology, the pressure, measured at the valve inlet, at which the valve closes, flow is substantially shut off, and there is no measurable lift.
Coax	Jargon meaning "coaxial cable," consisting of a center wire surrounded by low K insulation, surrounded by a second shield conductor. It has low capacitance and inductance for transmission of high-frequency current.
Co-Current Operation	The process feed and steam (or other utility fluid) follow parallel paths through such processes as an evaporator train.

Countercurrent Operation	The feed and steam enter the evaporator train at opposite ends.
Cold Differential Test Pressure (CDTP)	The pressure at which the PRV is adjusted to open during testing. The CDTP setting includes the corrections required to consider the expected service temperature and backpressure.
Cold Junction	See **Reference Junction**.
Combustion Air Requirement Index (CARI)	This dimensionless number indicates the amount of air required (stoichiometrically) to support the combustion of a fuel gas. Mathematically the Combustion Air Requirement Index is defined by the equation below: $\text{CARI} = \dfrac{\text{Air/Fuel Ratio}}{\sqrt{\text{SG}}}$
Common Mode Interference	See **Interference, Common Mode**.
Common Mode Rejection	The ability of a circuit to discriminate against a common mode voltage.
Common Mode Voltage	A voltage of the same polarity relative to ground on both sides of a differential input.
Common Resource	An equipment entity that services more than one unit, either simultaneously (shared-use resource) or one at a time (exclusive-use resource).
Compliance	The reciprocal of stiffness.
Conductance (*G*)	The reciprocal of resistance. (Units: Siemens [formerly "mhos"].)
Conductivity (*g*)	The reciprocal of resistivity. All solids and liquids have some degree of conductivity. For the purpose of this section, any material above 1 micro Siemen/cm will be considered to be conductive (this includes most metals and water with any ions).
Conformity	The degree or closeness to which one curve approximates another curve. Conformity can be expressed as independent, terminal based, or zero based. Independent conformity is obtained when the calibration curve is so positioned as to minimize the maximum deviation between it and the specified curve. Terminal-based conformity is obtained when the two curves are so positioned that their readings coincide at zero and full span. Zero-based conformity is when they coincide only at zero.
Consistency	In terms of viscosity, the resistance of a substance to deformation. It is the same as viscosity for a Newtonian fluid and the same as apparent viscosity for a non-Newtonian fluid.
Constant Backpressure	In connection with safety relief valves, the backpressure that does not change under any condition of operation, whether the pressure relief valve is closed or open.
Control Action	For a controller, the nature of the change in the output of the controller, which is affected by the controller's input.
Control Action, Derivative (Rate) (*D*)	A control action in which the controller output is proportional to the rate of change of the input.
Control Action, Integral (Reset) (*I*)	A control action in which the controller output is proportional to the time integral of the input. In this case the rate of change of the controller output is proportional to the input.
Control Action, Proportional (*P*)	A control action in which there is a continuous linear relationship between the controller's output and its input.
Control, Cascade	Control configuration in which the output of one controller (the "master") is the set point of another controller (the "slave").
Control, Differential Gap	Control in which the output of the controller remains at a minimum or maximum value until the controlled variable reaches the top limit of a band or gap, at which point the output reverses and stays in that state until the controlled variable crosses the bottom limit of the gap. At that point, the controller output returns to its original condition.
Control, Feedback	Control in which a measurement is compared to a set point to produce an error signal. This error is acted upon in such a way as to reduce the magnitude of the error.
Control, Feedforward	Control in which one or more conditions that are outside the feedback loop and have an influence on the controlled variable are converted into some corrective action in order to minimize the deviations from the set point of the controlled variable.
Control Horizon	The number of future manipulated variable moves that are taken into account in developing the optimal MPC solution.
Controlled Variable	The variable that is detected to originate the feedback signal for the controller.
Controller, Direct Acting	A controller that increases its output signal when its measured variable (input signal) increases.

Controller, On-Off	A two-position controller, of which one of the two discrete output signal values is zero.
Controller, Program	A controller that automatically adjusts its set point to follow a prescribed program.
Controller, Ratio	A controller that maintains a predetermined ratio between two variables.
Controller, Reverse Acting	A controller that decreases its output signal as the value of its measured variable (input signal) increases.
Controller, Sampling	A controller using intermittent readings of the controlled variable (error or set point) to affect control action.
Controller, Self-Operated (Regulator)	A controller that derives the required energy for its operation from the system that it controls.
Controller, Time Schedule	A controller in which the set point (or the reference-input signal) automatically follows some predetermined time schedule.
Control Module	A set of equipment and functions that can carry out basic control. For example, a control loop consisting of one or more sensors, actuators, and control functions is a control module. It is also the lowest-level equipment grouping that acts as a single entity from a control standpoint, but cannot execute procedural elements. May be an individual measurement (with suitable signal conditioning or state names) or a grouping of directly coupled actuators with their associated measurements, alarms, and control actions, including subordinate Control Modules as appropriate. Examples are an uncontrolled temperature, a flow control loop, an automatic block valve with limit switches, or a header containing interlocked (mutually exclusive) block valves.
Control, Optimizing	Control that does not hold the controlled variable constant but seeks and maintains a value of the controlled variable that will result in the most advantageous operation of the process.
Control Recipe	An equipment-specific recipe that defines the production of a single batch. It is usually derived from a master recipe.
Control, Supervisory	Control in which a supervisory controlled periodically applies some corrective action, such as set point changes, to a number of controllers.
Control System, Multi-Variable	A control system that uses two or more process variable measurement signals to affect control.
Control, Time Proportioning	Control in which the outputs are periodic pulses whose duration is varied in relation to the actuating error signal.
Control, Velocity Limiting	Control in which the rate of change of some variable is prevented from exceeding a predetermined limit.
Conventional Safety Relief Valve	A safety relief valve with the bonnet vented either to atmosphere or internally to the discharge side of the valve. The performance characteristics (set pressure, blow-down, and capacity) are directly affected by changes of the backpressure on the valve.
Coordination Control	Control functions existing at multiple levels to schedule batches and manage recipes, procedural control execution, equipment entity allocation, and batch data.
Corner Frequency	In the asymptotic form of the Bode diagram, that frequency that is indicated by a break point. It is the junction of two confluent straight lines asymptotic to the log gain curve.
Coulometry	A process of monitoring analyte concentration by detecting the total amount of electrical charge passed between two electrodes that are held at constant potential or when constant current flow passes between them.
Countercurrent Operation	The process feed and steam (or other utility fluid) enter at opposite ends as they flow through such processes as an evaporator train.
Counterflow Cooling Tower	A cooling tower in which the airflow is in the opposite direction from the fall of water through the water cooling tower.
CPVC (Chlorinated Polyvinyl Chloride)	A low cost, reasonably inert polymer used for some noninsertion sensors. It is easily solvent-welded. The max temperature range is about 225°F.
Cross-Flow Cooling Tower	A cooling tower in which airflow through the fill is perpendicular to the plane of the falling water.
Crystallography	How the atoms are arranged in the object; a direct relation exists between these arrangements and materials properties (conductivity, electrical properties, strength, etc.).
Curie (Ci)	A unit of radiation source size, corresponding to 37 billion disintegrations per second.
Damping	The progressive reduction or suppression of oscillation in a device or system.
Damping Factor	In the case of the free oscillation of a second-order linear system, it is the

	ratio of the greater by the lesser of a pair of consecutive swings of the output in opposite directions (without sign) about an ultimate steady-state value.
Data Servers	A standard interface to provide data exchange between field devices and data clients.
Deadband	The range through which an input can be varied without causing an observable change in the output. Deadband is the range through which the measurand may be varied by reversing direction without producing an observable response in the output signal.
Dead Time	See **Time, Dead**.
Dead Zone	See **Zone, Dead**.
Deflagration or Explosion	A process where the flame front advances through a gaseous mixture at subsonic speeds.
Deionized Water	Water of extremely high purity, with few ions to carry current. If exposed to air for any significant period, it will have a conductivity of about 5 micro Siemens/cm due to dissolved CO_2.
Demultiplexing	Separating of multiple input streams that were multiplexed into a common physical signal back into multiple output streams.
Derivative Gain	See **Gain, Derivative**.
Derivative Time	See **Time, Derivative**.
Design Pressure	This pressure is equal to or less than the maximum allowable working pressure. It is used to define the upper limit of the normal operating pressure range.
Detonation	A process where the advancement of the flame front occurs at supersonic speeds.
Device Description (DD)	In digital systems, a clear and unambiguous, structured text description that allows full utilization/operation of a field device by a host/master without any prior knowledge of the field device.
Device Description Language (DDL)	In the Foundation fieldbus technology concept, it is the definition and description of function blocks and their parameters.
Dew Point	Saturation temperature of a gas–water vapor mixture.
Dew Point Temperature (DPT)	The temperature at which condensation begins if air is cooled under constant pressure.
Dielectric	A material that is an electrical insulator or in which an electric field can be sustained with a minimum of dissipation of power. Dielectric materials include metal-oxides, plastics, and hydrocarbons.
Dielectric Compensation	A scheme by which changes in insulating liquid composition or temperature can be prevented from causing any output error. It requires a second sensor and homogeneous liquid.
Dielectric Constant	A unit expressing the relative charge storage capability of various insulators. Full vacuum is defined as 1.0, and all gases are indistinguishable from each other for practical purposes. TFE has a dielectric constant of 2.0, cold water about 80. It has no units because it is the ratio of the dielectric constant of a substance to that of vacuum. For the dielectric values of selected materials refer to Table 3.3p of the first volume of this handbook.
Diode	A two-terminal electronic (usually semiconductor) device that permits current flow predominantly in only one direction.
Direct Acting Controller	See **Controller, Direct Acting**.
Discontinuity	An abrupt change in the shape [or impedance] of a wave-guide [creating a reflection of energy].
Distance/Velocity Lag	A delay attributable to the transport of material or to the finite rate of propagation of a signal.
Dither	A useful oscillation of a small magnitude, which is introduced to overcome the effect of friction, hysteresis, or recorder pen clogging.
Drift	An undesired change in the output of a device, which occurs over time and is unrelated to the input, the environment, or the load. In the case of cooling towers it is the water loss due to liquid droplets entrained in exhaust air. Usually under 0.2% of circulated water flow rate.
Drift Eliminator	An assembly constructed of wood or honeycomb materials that serves to remove entrained moisture from the discharged air.
Droop	See **Offset**.
Dry-Bulb Temperature (TDB)	The temperature of air measured by a normal thermometer.
Dust-Ignition-Proof	Enclosed in a manner to exclude ignitable amounts of dust or amounts that might affect performance. Enclosed so that arcs, sparks, or heat otherwise generated or liberated inside of the enclosure will not cause ignition of exterior accumulations or atmospheric suspensions of dust.
Dynamic Gain	See **Gain, Dynamic**.

Dynamic Matrix	A matrix built from step responses to predict the changes in the process output that result from the moves of the manipulated variable over the control horizon.
Economy	In case of the evaporation process, this term is a measure of steam use and is expressed in pounds of vapor produced per pound of steam supplied to the evaporator train. For a well-designed evaporator system the economy will be about 10% less than the number of effects; thus, for a triple-effect evaporator the economy will be roughly 2.7.
Effective Coefficient of Discharge	This is a coefficient used to calculate the minimum required discharge area of the PRV.
Electrochemical Process	The changes in voltage or current flow that occur between two electrodes in a solution (electrolyte) over time. The oxidation or reduction of the analyte provides data that are related to concentration.
Electrolytic Probe	Probe that is similar to a galvanic probe, except that a potential is applied across the electrodes and the electrodes are not consumed. Dissolved oxygen detection is a primary application of this type of probe.
Electromagnetic Wave (Energy)	A disturbance that propagates outward from any electric charge that oscillates or is accelerated; far from the charge it consists of vibrating electric and magnetic fields that move at the speed of light and are at right angles to each other and to the direction of motion.
Electron Microscope	A scientific instrument that uses a beam of highly energetic electrons to examine objects on a very fine scale.
Element, Final Control	The controlling element that directly changes the value of the manipulated variable. It can be a control valve, a damper, an electric power modulator, or a variable-speed pump.
Element, Primary	The element that converts the measured variable into a form which can be measured.
Elevated Range, Elevation	See **Range, Suppressed Zero**.
Elevation, Zero	See **Zero Elevation**.
Emissivity or Emittance (*E*)	The emissivity of an object is the ratio of radiant energy emitted by that object divided by the radiant energy that a blackbody would emit at that same temperature. If the emittance is the same at all wavelengths, the object is called a gray body. Some industrial materials change their emissivity with temperature and sometimes with other variables also. Emissivity always equals absorption and it also equals 1 minus the sum of reflectance and transmittance: $(E = A = 1 - T - R)$
Empirical Model	This type of model can be used for processes for which no physical insight is available or used. This model structure belongs to families that are known to have good flexibility and have been "successful in the past." The parameters of the models are identified based on measurement data. A complete mechanistic model is constructed from *a priori* knowledge.
Equipment Control	The procedural, basic, and coordination control capability that enables an equipment entity to perform its function. It is not part of a recipe but may be directed by a recipe.
Equipment Entity	A set of process and control equipment and associated control capability that has been grouped together to provide some specified process or equipment functionality.
Equipment Module	A group of equipment that can carry out a finite number of specific minor processing activities. An equipment module may include one or more control modules. It is typically centered around a piece of process equipment, such as a weigh tank, heat exchanger, filter, or weighing scale. It is an equipment entity incorporating necessary devices, control modules, and application-specific states and modes to execute some basic process-oriented task or group of tasks. It may include equipment procedural elements (typically phase logic) and/or subordinate equipment modules but may not overlap other equipment modules. Examples are a common (exclusive-use) weigh tank, a recirculation/transfer pump within a unit, and a shared-use ingredient dosing system.
Equivalent Time Sampling (ETS)	The process that captures high-speed electromagnetic events in real time (nanoseconds) and reconstructs them into an equivalent time (milliseconds), which allows easier measurement with present electronic circuitry.
Ergonomics	An empirical approach to the study of human–machine interactions, with the

	objective of improving efficiency and reducing strain and discomfort of the operator.
Error	The difference between the measurement signal and its ideal value. A positive error denotes that the indication of the instrument is greater than the ideal value.
Error, Systematic	An error which, when a number of measurements are made under the same conditions, measuring the same value of a given quantity, either remains constant or varies according to some definite law when conditions change.
Error, Zero	The error of a device when it is operating at the lower range-value, which is commonly referred to as its zero.
Ethernet	A baseband local area network specification developed by Xerox Corporation, Intel, and Digital Equipment Corporation to interconnect computer equipment using coaxial cable and transceivers.
Evaporation Loss	Water evaporated from the circulating water into the atmosphere in the cooling process. (Unit: percentage of total GMP.)
Excitation, Maximum	The maximum excitation that can be applied to a device at rated operating conditions without causing damage or performance degradation beyond specified tolerances.
Exception Handling	Procedures and functions that deal with conditions outside the normal or desired behavior of a process.
Explosion Proof	All equipment that is contained within enclosures that are strong enough to withstand internal explosions without damage and tight enough to confine the resulting hot gases so that they will not ignite the external atmosphere. This is the traditional method of protection and is applicable to all sizes and types of equipment.
Fan Pitch	The angle a fan blade makes with the plane of rotation. (Unit: degrees from horizontal.)
Fan Stack (Cylinder)	Cylindrical or modified cylindrical structure in which the fan operates. Fan cylinders are used on both induced draft and forced draft axial-flow propeller-type fans.
Farad (*F*)	A unit of capacitance. Because this is a very large unit, a unit equal to one trillionth of a farad (called a pico Farad, symbol: “pF”) is commonly used in RF circuits.
Feedback Control	See **Control, Feedback**.
Feedforward Control	See **Control, Feedforward**.
FEP (Fluorinated Ethylene Propylene)	A fluorocarbon that is extremely chemically inert, melts at a reasonable temperature, and can be plastic-welded fairly easily. Hard to bond with adhesives. Max. temperature range limited to the 300°F (150°C) area.
Fieldbus	An all-digital, two-way, multi-drop communications system for instruments and other plant automation equipment.
Firewall	A router or access server, designated as a buffer between any public networks and a private network.
Flash Point	The lowest temperature at which a flammable liquid gives off enough vapors to form a flammable or ignitable mixture with air near the surface of the liquid or within the container used. Many hazardous liquids have flash points at or below room temperature. They are normally covered by a layer of flammable vapors that will ignite in the presence of a source of ignition.
Fluidity	Reciprocal of absolute viscosity; unit in the cgs system is the rhe, which equals 1/poise.
Floutter	Rapid, abnormal reciprocating variations in lift, during which the disc does not contact the seat.
Forced Draft Cooling Tower	A type of mechanical draft water cooling tower in which one or more fans are located at the air inlet to force air into the tower.
Forman	Vocal-tract resonance.
Formula	A part of recipe that include process inputs, process parameters, and process outputs. The list of process inputs, outputs, and data (operating set points, reported values, timing, etc.) required to execute the batch procedure.
Frequency, Damped	The frequency of a damped oscillatory response of a system resulting from a nonoscillatory stimulus.
Frequency Response Characteristics	The frequency-dependent relation, both in terms of gain and phase, between steady-state sinusoidal inputs and the resulting steady-state sinusoidal outputs.
Fuel Cells	Cells that convert the chemical energy of fuels such as hydrogen into electrical energy, while the electrode and the electrolyte remain unaltered. Fuel is converted at the anode into hydrogen ions, which travel through the electrolyte to

	the cathode, and electrons, which travel through an external circuit to the cathode. If oxygen is present at the cathode, it is reduced by these electrons, and the hydrogen and oxygen ions eventually react to form water.
Function Block	A logical processing unit of software that has one or more input and output parameters.
Fuzzy Logic Modeling	This type of model is used for processes that are not fully understood. It is a linguistically interpretable rule-based model, which is based on the available expert knowledge and measured data.
Gain, Closed Loop	The ratio of a change in output to a change in input of a closed loop system at a specified frequency.
Gain, Derivative (Rate Gain)	The ratio of the maximum gain that results from the proportional plus derivative actions in a controller to the gain due to the proportional mode alone.
Gain, Dynamic	For a sinusoidal signal, it is the magnitude ratio of the steady-state amplitude of the output signal from a device to the amplitude of the input signal to that device.
Gain, Loop	At a specified frequency, it is the ratio of the magnitude of the change in the feedback signal to the change in its corresponding error signal.
Gain (Magnitude Ratio)	For a linear system, it is the ratio of the amplitude of a steady-state sinusoidal output and the amplitude of the input that caused it.
Gain, Proportional	The ratio of the change in the output of a controller with proportional action to the change in the input of the controller.
Galvanic Probe	A probe in which no external voltage is applied across its electrodes and the current flows as the cell is depolarized when diffusion of the analyte occurs. Electrodes are consumed during this operation and require periodic replacement.
General Recipe	A type of recipe that expresses equipment- and site-independent processing requirements. It is the highest level of recipe.
Gray Body	An object with a constant emittance of less than unity. This emittance is constant at all wavelengths (over that part of the spectrum where the measurement takes place). This means that gray-body radiation curves are identical to those of a blackbody, except that they are dropped down on the radiated power density scale.
Gross Calorific Value	The heat value of energy per unit volume at standard conditions, expressed in terms of British thermal unit per standard cubic feet (BTU/SCF) or as kilocalorie per cubic Newton meters ($\text{Kcal/N} \cdot \text{m}^3$) or other equivalent units.
Ground	A conducting connection, whether intentional or accidental, between an electrical circuit or equipment and the earth, or to some conducting body that serves in place of earth. (See NFPA 70-100.)
Ground Fault Protector	Device used to open ungrounded conductors when high currents, especially those due to line-to-ground fault currents, are encountered.
Guard	The "electronic guard" (called a "shield" in some RF level literature) consists of a concentric metallic element with an applied voltage that is identical to the voltage on the conductor that it is "guarding." This negates the capacitance between the guarded conductor and the outside world.
Guided Wave Radar (GWR)	A contact radar technology where Time Domain Reflectometry (TDR) has been developed into an industrial-level measurement system where a probe immersed in the medium acts as the waveguide.
Hagen–Poiseuille Law	Defines the behavior of viscous liquid flow through a capillary.
HART	Is an open, smart field instrumentation protocol that is a de facto fieldbus. It imposes a 1200-bit-per-second digital signal on a twisted pair of wires carrying a 4- to 20-mA input.
Home Run Wiring	Wire between the cabinet where the Fieldbus host or centralized control system resides and the first field junction box or device.
Hub (Shared)	Multi-port repeater joining segments into a network.
Hunting	An undesirable oscillation of some appreciable magnitude, prolonged even after the external stimuli that caused it disappear.
Hygrometer	An apparatus that measures humidity.
Hygroscopic Material	A material with great affinity for moisture.
Hysteresis	That property of an element or system that shows the dependence of its output for a given excursion of the input on the history of prior excursions and on the direction of the current traverse. Hysteresis in a damper or valve is caused mostly by friction. Hysteresis in

	a process transmitter is the maximum difference between readings taken at the same measurand with upscale and downscale approaches to the readings. It is due to inelastic qualities of the sensing element, friction, and backlash.
Impedance	Maximum voltage divided by maximum current in an alternating current circuit. Impedance is composed of resistive, inductive, and capacitive components. Like direct current circuits, the quantity of voltage divided by current is expressed in ohms.
Inaccuracy	The degree of conformity of a measured or indicated value to a recognized standard value. It is usually expressed in terms of measured variable, percent of span, percent of upper-range value, or percent of actual reading.
Inaccuracy Rating	The quantity that defines the limit that errors will not exceed while the device is operating under specified conditions. Can be expressed in terms of the measured variable (for example ±0.5°F), in terms of percent span, in percent upper-range value, in percent of scale length, or in percent of actual output reading.
Infrared	That portion of the spectrum whose wavelength is longer than that of red light. Only the portion between 0.7 and 20 microns gives usable energy for radiation detectors.
Insulation Resistance	The resistance measured across the insulation at reference operating conditions when a specified direct current voltage is applied. The goal of the measurement is to determine whether the expected leakage current will or will not be excessive.
Integral Action Rate (Reset Rate)	For PI or PID controllers, it is the ratio of the initial rate of output change caused by the integral action to the change in steady-state output caused by the proportional action. Reset rate is often expressed as the number of repeats per minute because it equals the number of times the proportional correction is repeated by the integral action every minute.
Integral Controller	See **Controller, Integral**.
Interface	(1) Shared boundary. For example, the physical connection between two systems or two devices. (2) Generally, the point of interconnection of two components and the means by which they must exchange signals according to some hardware or software protocol.
Interoperability	A marketing term with a blurred meaning. One possible definition is the ability for like devices from different manufacturers to work together in a system and be substituted one for another without loss of functionality at the host level (HART).
Intrinsic Safety	When under all conditions, the available energy is limited to levels that are too low to ignite the hazardous atmosphere. This method is useful only for low-power equipment such as instrumentation, communication, and remote-control circuits.
Kinematic Viscosity (υ)	Dynamic viscosity/density = $\upsilon = \mu/\rho$.
Lambda	The desired closed loop time constant, often set to equal the loop lag time.
Latency	Latency measures the worst-case maximum time between the start of a transaction and the completion of that transaction.
Lift	The rise of the disc in a pressure relief valve.
Line Driver	Inexpensive amplifier and signal converter that conditions digital signals to ensure reliable transmissions over extended distances without the use of modems.
Linearity, Independent	The maximum deviation of a calibration curve from a straight line that is so positioned as to minimize that maximum deviation.
Linearity, Terminal-Based	The maximum deviation of a calibration curve from a straight line, if the line is so positioned that they coincide at the upper and lower range values.
Linearity, Zero-Based	The maximum deviation of a calibration curve from a straight line, if the line is so positioned that they coincide at the lower range value and to minimize the maximum deviation.
Linear Programming	A mathematical technique for solving a set of linear equations and inequalities in order to maximize or minimize an additional function called an objective function.
Loop Gain Characteristics	For a closed loop, it is the characteristic curve of the ratio of the change in the return signal to the change in the corresponding error signal.
Loop Transfer Function	This value of a closed control loop is obtained by taking the ratio of the Laplace transform of the return signal

	to the Laplace transform of the corresponding error signal.
Lot	Products produced by a set of similar batches, usually using the same master recipe. A collection of batches prepared using the same recipe. Typically, all batches of a lot are prepared from the same homogeneous source of raw material.
Louvers	Assemblies installed on the air inlet faces of a tower to eliminate water splash-out.
Lower Explosive Limit (LEL)	The lowest concentration of gas or vapor in air where, once ignition occurs, the gas or vapor will continue to burn after the source of ignition has been removed.
Lower Range-Limit	See **Range-Limit, Lower**.
Low-Pass Filters	Filters that are used to remove high-frequency interference or noise from low-frequency signals.
Makeup	In cooling towers it is water added to replace loss by evaporation, drift, blowdown, and leakage. (Unit: percentage of circulation rate.)
Manchaster	A digital signaling technique that contains a signal transition at the center of every bit cell.
Manipulated Variable	The variable that is manipulated in order to reduce the controller's error and thereby to bring the controlled variable closer to set point.
Manufacturing Range	A range around the specified burst pressure within which the marked or rated burst pressure must fall. Manufacturing range is not used in ISO standards.
Master Recipe	A recipe for producing a batch of products using a particular set of process equipment.
Maximum Allowable Operating Pressure (MAOP)	The maximum pressure expected during normal operation.
Maximum Allowable Working Pressure (MAWP)	This is the maximum pressure allowed for continuous operation. As defined in the construction codes (ASME B31.3) for unfired pressure vessels, it equals the design pressure for the same design temperature. The maximum allowable working pressure depends on the type of material, its thickness, and the service conditions set as the basis for design. The vessel may not be operated above this pressure or its equivalent at any metal temperature other than that used in its design; consequently for that metal temperature, it is the highest pressure at which the primary pressure relief valve can be set to open.
Measurand	The physical parameter to be measured.
Mechanical Draft Cooling Tower	A tower through which air movement is effected by one or more fans. There are two general types of such towers: those that use forced draft with fans located at the air inlet and those that use induced draft with fans located at the air exhaust.
Mechanical Emissivity Enhancement	Mechanically increasing the emissivity of a surface to near-blackbody conditions (using multiple reflection).
Micron	Equivalent to 0.001 millimeters or 10,000 Ångstrom units. A unit used to measure wavelengths of radiant energy.
Model-Based Control (MBC)	In model-based control (MBC), a process model is used to make control decisions. The controller uses this model of the process to calculate a value for the manipulated variable, which should make the controlled variable behave in the desired way. The "inverse" nomenclature arises from how the model is used. In a normal modeling approach, one specifies the process input, and the model predicts the process output response. In contrast, MBC determines the process input (manipulated variable) that will cause a desired process output response (controlled variable value) to occur. This is the model inverse.
Model Predictive Control (MPC)	A model-based control technique that uses process output prediction and calculates consecutive controller moves in order to satisfy control objectives.
Modem	Modulator–demodulator. Device that converts digital and analog signals. At the source, a modem converts digital signals to a form suitable for transmission over analog communication facilities. At the destination, the analog signals are returned to their digital form. Modems allow data to be transmitted over voice-grade telephone lines.
Modulation	The result of a process whereby a characteristic of one wave is varied in accordance with some characteristics of another wave.
Morphology	The shape and size of the particles making up the object; a direct relation exists between these structures and materials properties (ductility, strength, reactivity, etc.)

Multiple-Effect Evaporation	Multiple-effect evaporations use the vapor generated in one effect as the energy source to an adjacent effect. Double- and triple-effect evaporators are the most common; however, six-effect evaporation can be found in the paper industry, where kraft liquor is concentrated, and as many as 20 effects can be found in desalinization plants.
Multiplexing	A method that allows multiple logical signals to be transmitted simultaneously across a single physical channel. Compare with **Demultiplexing**.
Narrow-Band Pyrometer	A radiation pyrometer that is sensitive to only a narrow segment of wavelengths within the total radiation spectrum. Optical pyrometers are one of the devices in this category.
Natural Draft Cooling Tower	A cooling tower in which air movement is essentially dependent upon the difference in density between the entering air and internal air. As the heat of the water is transferred to the air passing through the tower, the warmed air tends to rise and draw in fresh air at the base of the tower.
Net Calorific Value	The measurement of the actual available energy per unit volume at standard conditions, which is always less than the gross calorific value by an amount equal to the latent heat of vaporization of the water formed during combustion.
Network	All of the media, connectors, and associated communication elements by which a communication system operates.
Neurons	A brain cell that passes information by receiving and transmitting electrical impulses. Nodes in neural networks serve similar functions.
Neutral Zone	See **Zone, Neutral**.
Newton	The internationally accepted unit of force, defined as the force required to accelerate one kilogram by one m/sec^2. It equals 0.2248 pound-force or about 4 ounces.
Nodes	Processing elements in neural networks.
Nominal Tonnage (Cooling)	In cooling towers, one nominal ton corresponds to the transfer of 15,000 BTU/hr (4.4 kW) when water is cooled from 95 to 85°F (35 to 29.4°C) by ambient air having a wet-bulb temperature of 78°F (25.6°C) and when the water circulation rate is 3 GPM (11.3 lpm) per ton.
Nonfragmenting Disc	A rupture disc design that, when burst, does not eject fragments that could interfere with the operation of downstream equipment (i.e., relief valves).
Nonincendive Equipment	Equipment that in normal operations does not constitute a source of ignition. Therefore, its surface temperature shall not exceed ignition temperature of the specified gas to which it may be exposed, and there are no sliding or make-and-break contacts operating at energy levels capable of causing ignition. Used for all types of equipment in Division 2 locations. Relies on the improbability of an ignition-capable fault condition occurring simultaneously with an escape of hazardous gas.
Nonlinearity	Nonlinearity is expressed as a percent of full range output (%FRO) and is determined from the maximum difference between a datum on the output vs. measurand plot and a best straight line (BSL) drawn through the data.
Normal Mode Rejection	The ability of a circuit to discriminate against normal mode voltage. It can be expressed as a dimensionless ratio, as a scalar ratio, or in decibels (20 times the $\log_{10}$ of that ratio).
Normal Mode Voltage	A voltage across the input terminals of a device.
Offset	When in a controller the set point is fixed and in the steady state there is a deviation, it is called offset. The change in offset that results from a no-load to a full-load condition is often called "droop."
Oil Immersion	Equipment is submerged in oil to a depth sufficient to quench any sparks that may be produced. This technique is commonly used for switch-gears, but it is not utilized in connection with instruments.
On-Off Controller	See **Controller, On-Off**.
Open Loop Gain	The steady-state gain of a control loop when the other control loop(s) is(are) in manual. (Their control valve opening is constant.)
Operating Pressure	The operating pressure of a vessel is the pressure, in pounds per square inch gauge, to which the vessel is usually subjected in service. A processing vessel is usually designed for a maximum allowable working pressure, in pounds per square inch gauge, that will provide a suitable margin above the operating pressure in order to prevent any undesirable operation of the relief device. It is suggested that this margin be approximately 10%, or 25 PSI (173 kPa), whichever is greater. Such a margin will

	be adequate to prevent the undesirable opening and operation of the pressure relief valve caused by minor fluctuations in the operating pressure.
Operating Pressure Margin	The margin between the maximum operating pressure and the set pressure of the PRV.
Operating Pressure Ratio	The ratio of the maximum operating pressure to the set pressure of the PRV.
Operating Ratio of a Rupture Disc	The ratio of the maximum operating pressure to the marked burst pressure expressed as a percentage (common U.S. definition). The ratio of the maximum operating pressure to the minimum of the performance tolerance expressed as a percentage (common ISO definition).
Operation	A procedure that controls the execution of a number of phases in a batch. A major programmed processing action or set of related actions, normally consisting of one or more phases.
Optical Pyrometer	Also called brightness pyrometer, it uses a narrow band of radiation within the visible range (0.4 to 0.7 microns) to measure temperature by color matching and other techniques.
Optimizing Control	See **Control, Optimizing**.
Overpressure	The pressure increase over the set pressure of the primary relief device. When the set pressure is the same as the maximum allowable operating pressure (MAOP), the accumulation is the same as the overpressure. Pressure increase over the set pressure of the primary relieving device is overpressure. *Note*: From this definition it will be observed that when the set pressure of the first (primary) safety or relief valve is less than the maximum allowable working pressure of the vessel, the overpressure may be greater than 10% of set pressure.
Overrange Limit	The maximum input that can be applied to a device without causing damage or permanent change in its performance.
Partial Pressure	In a mixture of gases, the partial pressure of one component is the pressure of that component if it alone occupied the entire volume at the temperature of the mixture.
Pascal-Seconds (Pas)	Internationally accepted unit of absolute (dynamic) viscosity. Pas = Newton-sec/m^2 = 10 poise = 1000 centipoise.
PDVF, Polyvinylidene Fluoride	This fluorocarbon has substantially lower temperature limits than the others (250°F or 120°C) and is less inert chemically. It is dissolved by the ketones (acetone, MEK, MIBK) and attacked by benzene and high concentrations of sulfuric acid. The most insidious enemy is caustic, which causes brittleness and cracking. It has much better toughness and abrasion resistance, than the other fluorocarbons, as well as unique electrical properties ($K = 8$).
PE (Polyethylene)	A low temperature insulation that is compatible with a wide range of corrosives but is attacked by most petroleum products. Generally limited to situations where fluoro- and chlorocarbons are not allowed, such as the tobacco and nuclear power industries. Max. allowable temperature is in the 180°F (80°C) area.
PEEK (Polyether Etherketone)	A high-temperature, injection-molded polymer that is chemically quite inert. This material has wide chemical application. Temperature capability is high at 450 to 500°F (225 to 260°C). Avoid any liquids with "phenol" in their name. Adhesive bonding to the molded parts would be difficult.
Perceptron	A transfer function used in some neural networks.
PFA (Per-Fluoro-Alkoxy)	A fluorocarbon that is quite inert chemically, melts at a fairly high temperature, and is easily plastic welded. It can be used up to 550°F (290°C), but as a probe insulation it is generally limited to 350°F (175°C) due to bonding limitations with the metal rod.
Phase	A set of logic steps that completes a major processing function, such as charge, mix, heat, and reaction. A batch is usually in a stable state at the end of a phase. It is the lowest level of procedural control to accomplish a process-oriented task. Phases may be further subdivided into equipment-oriented steps and transitions for executing its defined task, as described in European standard IEC 60848 (1988) for specification of sequential function charts. Normally, the phase boundaries represent points of process transition, hold, or activity. The boundaries define major milestones and possible points of safe intervention. Phases may exist either as part of a recipe procedure (recipe phase) or independently for equipment control (equipment phase); however, any constituent steps are always part of the equipment phase.

Phase Difference Sensor (PDS)	A contact radar technology; unlike TDR-based systems, which measure using sub-nanosecond time intervals, PDS derives level information from the changes in phase angle.
Phase Shift	Of a signal, it is a change of phase angle with transmission. Of a transfer function, it is a change of phase angle with test frequency.
Phoneme	The sound of a human voice.
Photodetector	Measures thermal radiation by producing an output through release of electrical changes within its body. Photodetectors are small flakes of crystalline materials, such as CdS or InSb, which respond to different portions of the spectrum, consequently showing great selectivity in the wavelengths at which they operate.
Pixel (“Picture Element”)	Square dot, used in machine vision and camera technology.
Plenum	Air distribution ducting, chamber, or compartment.
Poise (μ)	Unit of dynamic or absolute viscosity (dyne-sec/cm^2).
Poiseuille (pi)	Suggested name for the new international standard unit of viscosity, the Pascal-second.
Polarography	Process for monitoring the diffusion current flow between working and auxiliary electrodes as a function of applied voltage as it is systematically varied. Concentration of analyte allows for flow of the diffusion current, which is linearly dependent on the analyte concentration. Polarography can be applied using direct current, pulsed direct current, or alternating current voltage excitation wave forms. Dissolved oxygen determination is an example of an application for which polarography is used.
Potentiometry	When no current is passing between electrodes. Examples: ORP, pH, selective-ion electrodes. The potential difference (at zero current) is monitored between the measuring and reference electrodes.
Potting	Potting compound completely surrounding all live parts and thereby excluding the hazardous atmosphere has been proposed as a method of protection. There is no known usage except in combination with other means.
Power Factor	The ratio of total true power (watts) to the apparent power total rms (root-mean-square) volt-amperes.
PP (Polypropylene)	Similar to PE. Used for low cost, and where fluoro- and Chlorocarbons are excluded. Max. temperature is in the area of 200°F.
Pressure, Design	The pressure that is used in the design of a device for the purpose of determining the required minimum wall thickness and other characteristics for a given maximum working pressure (MWP) at a given temperature.
Pressure, Maximum Working (MWP)	The very maximum pressure that is permissible in a device under any circumstances during operation, at a specified temperature.
Pressure Relieving Device	The broadest category in the area of pressure relief devices, includes rupture discs and pressure relief valves of both the simple spring-loaded type and certain pilot-operated types.
Pressure Relief Valve (PRV)	A generic term that might refer to relief valves, safety valves, and pilot-operated valves. The purpose of a PRV is to automatically open and to relieve the excess system pressure by sending the process gases or fluids to a safe location when its pressure setting is reached.
Pressure, Surge	It is the sum of the operating pressure plus a pressure increment that develops for a very short time while pumps are starting or valves are closing.
Primary Standard	A measuring instrument calibrated at a national standard laboratory such as NIST and used to calibrate other sensors.
Procedural Control	Control that sequentially directs subordinate procedural elements or basic controls to execute the steps required by its defined process-oriented task.
Procedure	A user-defined set of instructions that define the strategy for making a single batch of a particular type or grade of product.
Process Cell	A set of equipment required for production of one or more batches. It usually consists of one or more units. It is a grouping of equipment that comprises one or more complete trains and defines the immediate local domain for production scheduling (analogous to a work cell in discrete manufacturing).
Process Inputs	Identity and quantity of raw materials and other resources required to make a batch. Other resources include energy and manpower requirements.
Process Outputs	Identity and quantity of products and/or energy produced at the end of a batch.
Process Parameters	Variables, such as temperature, pressure, and time, that are set points and

	comparison values needed for the production of a batch.
Proof	A specific gravity unit used in the alcohol industry.
Proportional Band	In a proportional-only controller, it is the change required in the input signal to result in a full range change in the controller's output.
Proportional Controller	See **Controller, Proportional**.
Protocol	Formal description of a set of rules and conventions that govern how devices on a network exchange information. In communications it is a set of conventions or rules that must be adhered to by both communicating parties to ensure that information being exchanged between two parties is received and interpreted correctly.
Prosodic Characteristics	The pitch of voice; the duration and intensity of speech.
Prosody	Accent and voice modulation.
Psychrometer	An instrument used primarily to measure the wet-bulb temperature.
(P)TFE (Tetra-Fluoro-Ethylene)	In the abbreviation, the "P" stands for "polymerized." It is the oldest, highest temperature, and most inert fluorocarbon probe insulation. Extremely difficult to adhesive bond, it is usable up to 550°F (290°C), but on probes, its temperature limit is determined by the type of bonding to the probe rod (300, 450, or 550°F). This is the most common probe insulation in the industry. Since it never melts (it disintegrates producing HF at 600 +°F), it is difficult to fabricate, is impossible to plastic-weld, and exhibits a high degree of microporosity. Can be destroyed by butadiene and styrene monomer.
Purging, Pressurization, Ventilation	These processes depend upon the maintenance of a slight positive pressure of air or inert gas within an enclosure so that the hazardous atmosphere cannot enter. Relatively recent in general application, it is applicable to any size or type of equipment.
Quevenne Degrees	A specific gravity unit used in the expressing the fat content of milk.
Raceway	A general term for enclosed channels, conduit, and tubing designed for holding wires and cables.
Radar (Radio Detection and Ranging)	A system using beamed and reflected radio-frequency energy for detecting and locating objects, measuring distance or altitude, navigating, homing, bombing, and other purposes; in detecting and ranging, the time interval between transmission of the energy and reception of the reflected energy establishes the range of an object in the beam's path.
Radio Frequency	A frequency that is higher than sonic but less than infrared. The low end of the RF range is 20 kHz, and its high end is around 100,000 MHz.
Radio Frequency Interference (RFI)	A phenomenon where electromagnetic waves from one source interfere with the performance of another electrical device.
Range	The region in which a quantity is measured, received, or transmitted. The limits of this region are the lower and upper range-values.
Range, Cooling	For a cooling tower, it is the difference between the temperatures of water inlet and outlet. For a system operating in a steady state, the range is the same as the water temperature rise through the load heat exchanger. Accordingly, the range is determined by the heat load and water flow rate, not by the size or capability of the cooling tower.
Range, Elevated Zero	A range in which the zero value of the measured variable is greater than the lower range-value. Sometimes the term "suppressed range" is also used, but "elevated zero" is preferred.
Range, Suppressed-Zero	A range in which the zero value of the measured variable is less than the lower range value. Sometimes the term "elevated range" is also used, but "suppressed zero range" is preferred.
Range-Value, Lower	The lowest value of the measured variable less that the particular device is adjusted to measure.
Range-Value, Upper	The highest value of the measured variable that the device is adjusted to measure.
Rate Control Action	See **Control Action, Derivative**.
Rated Relieving Capacity	It is the maximum relieving capacity of the PRV. These data are normally provided on the nameplate of the PRV. The rated relieving capacity of the PRV exceeds the required relieving capacity and is the basis for sizing the vent header system.
Ratio Controller	See **Controller, Ratio**.
Ratio Pyrometer	See **Two-Color Pyrometer**.
Reactance (*X*)	That part of the impedance of a circuit that is caused by either capacitance or inductance or both. (Units: ohms.)

Rear Mount	A technique for making long inactive sections, by mounting the probe on the end of a pipe, with its coax cable running through the pipe to the top of the tank. The coax must survive the process temperature, so it is often of high-temperature construction.
Recipe	A set of procedures and formula variables that specify the production of a batch. There are four types of recipes: general, site, master, and control. A recipe is the complete set of data and operations that define the control requirements for a particular type or grade of final or intermediate product. Specifically, each recipe comprises a header, formula, procedure, and equipment requirements.
Reference Junction	The thermocouple junction that is at a known or reference temperature. It is that point at which the thermocouple extension wires are connected to the lead wires or to an instrument.
Reference Junction Compensation	The means by which the effect of temperature variations at the reference junction is corrected for.
Reflectance or Reflectivity (*R*)	The percentage of the total radiation falling on a body that is directly reflected without entry. Reflectance is zero for a blackbody, and nearly 100% for a highly polished surface. ($R = 1 - A - T$, where A is the absorbance and T is the transmissivity.)
Regulator	See **Controller, Self-Operated**.
Relative Gain (RG)	The ratio of the steady-state gain of the loop with other loops in manual, divided by the steady-state gain of the loop when the other loops are in automatic.
Relative Gain Array	A matrix of dimensionless gain ratios giving one RG value for each pairing of manipulated and controlled variables.
Relative Humidity	The ratio of the mole fraction of moisture in a gas mixture to the mole fraction of moisture in a saturated mixture at the same temperature and pressure. Or, the ratio of the amount of moisture in a gas mixture to the amount of moisture in a saturated mixture at equal volume, temperature, and pressure.
Relative Viscosity	Ratio of absolute viscosity of a fluid at any temperature to that of water at 20°C (68°F). Since water at this temperature has a μ of 1.002 cp, the relative viscosity of a fluid equals approximately its absolute viscosity in cp. Since density of water is 1, kinematic viscosity of water equals 1.002 cSt at 20°C.
Relief Valve	An automatic pressure relieving device actuated by the static pressure upstream of the valve, which opens in proportion to the increase in pressure over the operating pressure. It is used primarily for liquid service.
Relieving Pressure	The sum of opening pressure plus overpressure. It is the pressure, measured at the valve's inlet, at which the relieving capacity is determined.
Reopening Pressure	The opening pressure when the pressure is raised as soon as practicable after the valve has reseated or closed from a previous discharge.
Repeatability	For full range traverses of a number of consecutive measurements, approaching from the same direction, it is the closeness of agreement among the outputs of the sensor when measuring the same value under the same operating conditions. It is usually expressed in percent of span. A more accurate term for it would be nonrepeatability.
Reproducibility	For a number of consecutive measurements, approaching from both directions, it is the closeness of agreement among the outputs of the sensor when measuring the same value under the same operating conditions over a period of time. It is usually expressed in percent of span. A more accurate term for it would be nonreproducibility.
Reset Control Action	See **Control Action, Integral**.
Resistive Component	AC current can be separated into two components; the portion that is in phase with the excitation voltage is the resistive component.
Resistivity (*ρ*)	It is the property of a conductive material that determines how much resistance a unit cube will produce. (Units: ohm-centimeters.)
Resolution	The least interval between two adjacent discrete details that can be distinguished one from the other.
Resonance	A condition evidenced by large oscillatory amplitude, which results from a small amplitude periodic input, when the frequency of that input is approaching one of the natural frequencies of the system.
Response Time	The time it takes for the output of a device, resulting from the application of a specified input under specified

	operating conditions to move from its initial value to within some specified percentage of its final steady-state value.
Reverse Acting Controller	See **Controller, Reverse Acting**.
Richter Degrees	A specific gravity unit used in the alcohol industry.
Riser	In case of a cooling tower, it is the piping that connects the circulating water supply line from the level of the base of the tower or the supply header to the tower inlet connection.
RMS Value	See **Value, RMS**.
Roentgen	A unit for expressing the strength of a radiation field. In a 1-Roentgen radiation field, 2.08 billion pairs of ions are produced in a cubic centimeter of air.
Roentgen Equivalent Man (rem)	A unit of allowable radiation dosage, corresponding to the amount of radiation received when exposed to 1 roentgen over any period of time.
Root Valve	The first valve off the process.
Rupture Tolerance	For a rupture disc it is the tolerance range on either side of the marked or rated burst pressure within which the rupture disc is expected to burst. Rupture tolerance may also be represented as a minimum–maximum pressure range. Also referred to as performance tolerance in ISO standards.
Safety Relief Valve	An automatic pressure-actuated relieving device suitable for use as either a safety or relief valve.
Safety Valve	An automatic pressure-relieving device actuated by the static pressure upstream of the valve and characterized by rapid and full opening or pop action. It is used for steam, gas, or vapor service.
Sand Filling	All potential sources of ignition are buried in a granular solid, such as sand. The sand acts, in part, to keep the hazardous atmosphere away from the sources of ignition and, in part, as an arc quencher and flame arrester. It is used in Europe for heavy equipment. It is not used in instruments.
Saturated Solution	A solution that has reached the limit of solubility.
Saturation	A condition where RF current from a probe-to-ground is determined solely by the impedance of the probe insulation. Increased conductivity in the saturating medium, even to infinity, will not cause a noticeable change in that current or in the transmitter output.
Saturation Pressure	The pressure of a fluid when condensation (or vaporization) takes place at a given temperature. (The temperature is the saturation temperature.)
Saybolt Furol Seconds (SFS)	Time units referring to the Saybolt viscometer with a Furol capillary, which is larger than a universal capillary.
Saybolt Universal Seconds (SUS)	Time units referring to the Saybolt viscometer.
Scale Factor	The value of the scale divisions on an instrument. To compute the value of the measured variable, the number of scale divisions is multiplied by this scale factor.
Scaling	The conversion from engineering units to fractions or percentages.
Sealing	The atmosphere is excluded from potential sources of ignition by sealing them in airtight containers. This method is used for components such as relays, not for complete instruments.
Seal-Off Pressure	The pressure, measured at the valve inlet after closing, at which no further liquid, steam, or gas is detected at the downstream side of the seat.
Segment	The section of a network that is terminated in its characteristic impedance. Segments are linked by repeaters to form a complete network.
Self-Regulation	The property of a system, which permits attainment of equilibrium after a disturbance without the intervention of a controller.
Sensitivity	The ratio of the change in output to the change of the input that causes it after a steady state been reached.
Sensor	An input device that provides a usable output in response to the input measurand. (A sensor is also commonly called a sensing element, primary sensor, or primary detector. The measurand is the physical parameter to be measured.)
Service	Term used by NFPA-70 (NEC) to demarcate the point at which utility electrical codes published by IEEE (NESC) take over. Includes conductors and equipment that deliver electricity from utilities.
Servomechanism	An automatic feedback control device in which the controlled variable is a mechanical position or some derivative of that position.
Set Point	An input variable of a controller that sets the desired value of the variable that is being controlled.

Set Pressure (Opening Pressure)	The pressure at which the relief valve is set to open. It is the pressure measured at the valve inlet of the PRV, at which there is a measurable lift, or at which discharge becomes continuous as determined by seeing, feeling, or hearing. In the pop-type safety valve, it is the pressure at which the valve moves more in the opening direction compared to corresponding movements at higher or lower pressures. A safety valve or a safety relief valve is not considered to be open when it is simmering at a pressure just below the popping point, even though the simmering may be audible.
Shear Viscometer	Viscometer that measures viscosity of a non-Newtonian fluid at several different shear rates. Viscosity is extrapolated to zero shear rate by connecting the measured points and extending the curve to zero shear rate.
Signal, Analog	A signal representing a continuously observed variable.
Signal, Digital	Information represented by a set of discrete values in accordance with a prescribed law.
Signal-to-Noise Ratio	The ratio of the amplitude of a signal to the amplitude of the noise. The amplitude can be a peak or an rms value, as specified.
Signum	A transfer function used in some back-propagation neural networks.
Sikes Degree	A specific gravity unit used in the alcohol industry.
Simmer (Warn)	The condition just prior to opening at which a spring-loaded relief valve is at the point of having zero or negative forces holding the valve closed. Under these conditions, as soon as the valve disc attempts to rise, the spring constant develops enough force to close the valve again.
Single-Effect Evaporation	Single-effect evaporation occurs when a dilute solution is contacted only once with a heat source to produce a concentrated solution and an essentially pure water vapor discharge.
Site Recipe	A recipe that includes site-specific information, such as local language and locally available raw materials.
Slab	A set of nodes.
Smart Field Device	A microprocessor-based process transmitter or actuator that supports two-way communications with a host; digitizes the transducer signals; and digitally corrects its process variable values to improve system performance. The value of a smart field device lies in the quality of data it provides.
Span	The difference between the upper and lower range-values.
Specific Humidity	The ratio of the mass of water vapor to the mass of dry gas in a given volume.
Specific Viscosity	Ratio of absolute viscosity of a fluid to that of a standard fluid, usually water, both at the same temperature.
Spectral Emissivity	The ratio of emittance at a specific wavelength or very narrow band to that of a blackbody at the same temperature.
Split Ranging	A configuration in which, from a single input signal, two or more signals are generated or two or more final control elements are actuated, each responding consecutively, with or without overlap, to the magnitude of the input signal.
Standard Air	Dry air having a density of 0.075 lb/cu. ft. at 70°F and 29.92 in. Hg.
Start-to-Leak Pressure	For a safety relief valve it is the pressure at the valve inlet at which the relieved fluid is first detected on the downstream side of the seat before normal relieving action takes place.
Steady State	A variable is at steady-state condition when it is exhibiting negligible change over a long period of time.
Stiction (Static Friction)	The resistance to the starting of motion. When stroking a control valve, it is the combination of sticking and slipping.
Stiffness	In the case of a spring element, it is the ratio of the change in force or torque to the resulting change in deflection.
Stoke	Unit of kinematic viscosity υ (cm^2/sec).
Stress	Force/Area (F/A).
Subchannel	In broadband terminology, a frequency-based subdivision creating a separate communications channel.
Subsidence Ratio	The ratio of the peak amplitudes of two successive oscillations of the same sign, measured in reference to an ultimate steady-state value.
Superimposed Backpressure	Backpressure that is present in the discharge header before the pressure relief valve starts to open. It can be constant or variable, depending on the status of the other PRVs in the system.
Suppression	See **Range, Elevated-Zero**.
Suppression, Zero	See **Zero Suppression**.
Surge Pressure	See **Pressure, Surge**.
Switched Hub	Multiport bridge joining networks into a larger network.
Systematic Error	See **Error, Systematic**.

System, Linear	A system is linear if its time response to several simultaneous inputs is the sum of their individual (independent) time responses.
Tapping	See **Dither**.
Teflon, TFE, FEP, and PFA	Most people interchange the name Teflon with TFE. This is completely incorrect, but understandable. TFE was the first fluorocarbon polymer to carry the trade name “Teflon” at E.I. DuPont. DuPont chose to use the “Teflon” trade name for a whole family of fluorocarbon resins, so FEP and PFA made by DuPont are also Teflon. To complicate the matter, other companies now manufacture TFE, FEP, and PFA, which legally cannot be called Teflon, since that name applies only to DuPont-made polymers.
Thermopile	Measures thermal radiation by absorption to become hotter than its surroundings. It is a number of small thermocouples arranged like the spokes of a wheel, with the hot junction at the hub. The thermocouples are connected in series and the output is based on the difference between the hot and cold junctions.
Throughput	The maximum number of transactions per second that can be communicated by the system.
Time Constant (*T*)	If a first-order system is responding to a step or an impulse, T is the time required to complete 63.2% of the total rise or decay. In higher-order systems, there is a time constant for each of the first-order components of the process.
Time, Dead	The time interval between the initiation of an output change or stimulus and the start of the resulting observable response.
Time Domain Reflectometry (TDR)	A TDR instrument measures the electrical characteristics of wideband transmission systems, subassemblies, components, and lines by feeding in a voltage step and displaying the superimposed reflected signals on an oscilloscope equipped with a suitable time-base sweep.
Timeout	Event that occurs when one network device expects to hear from another network device within a specified period of time, but does not. The resulting timeout usually results in a retransmission of information or the dissolving of the session between the two devices.
Time, Ramp Response	The time interval by which an output lags an input, when both are varying at a constant rate.
Time, Settling	After a stimulus to a system, the time required for the output of the system to enter and remain within a specified narrow band centered on its steady-state value. If the stimulus is a step or impulse, the band is often specified as ±2%.
Topology	Physical arrangement of network nodes and media within an enterprise networking structure or the surface features of an object or “how it looks,” its texture; there is a direct relation between these features and materials properties (hardness, reflectivity, etc.).
Total Emissivity	The ratio of the integrated value of all spectral emittances to that of a blackbody.
Train	A grouping within one process cell of units and associated lower-level equipment that is capable of making a batch of material. A train may define a single equipment path for a batch or multiple possibilities, of which one will be selected based on availability during execution of the control recipe. Multiple batches can be processed simultaneously in the same train (but different units).
Tralles Degrees	A specific gravity unit used in the alcohol industry.
Transducer	A device that receives information in the form of one quantity and converts it to information in the form of the same or another quantity. This general definition also applies to primary elements or transmitters. An input transducer produces an electrical output, which is representative of the input measurand. Its output is conditioned and ready for use by the receiving electronics. (The terms “input transducer” and “transducer” can be used interchangeably.)
Transfer Function	A statement of influence of an element or system, in a mathematical, tabular, or graphical form. This influence can be that of an element or system on a signal or action, which is compared at input and output terminals.
Transient	The behavior of a variable during transition between two steady states.
Transient Overshoot	It is the maximum overshoot beyond the final steady-state value of an output, which results from a change in an input.
Transistor	Three-terminal, solid state electronic device made of silicone, gallium-arsenide or germanium and used for

	amplification and switching in integrated circuits.
Transmittance or Transmissivity (*T*)	The percentage of the total radiant energy falling on a body that passes directly through it without being absorbed. Transmittance is zero for a blackbody and nearly 100 percent for a material like glass in the visible spectrum region. ($T = 1 - A - R$, where A is the absorbance and R is the reflectance.)
Transmitter	A transducer that responds to a measured variable generated by a sensor and converts it to a standardized transmission signal. This signal is a function of only the measured variable. The term "transmitter," as commonly used with industrial process control instrumentation, has a narrower definition than those of a sensor or transducer: A transmitter is a transducer that responds to a measured variable by means of a sensing element and converts it to a standardized transmission signal that is a function only of the measured variable.
Twaddell Degree	A specific gravity unit used in the sugar, tanning, and acid industries.
Two-Color Pyrometer	Measures temperature as a function of the radiation ratio emitted around two narrow wavelength bands. Also called ratio pyrometer.
Unit	A major piece of process equipment with its associated equipment modules. Mixers, storage tanks, and reactors are examples of units. The associated equipment modules include pumps, valves, heat exchangers, and agitators that are closely associated with the major process equipment. Units operate relatively independently of one another. They are equipment that contains and performs some major processing activity or activities (e.g., react, crystallize, make solution) on one batch at a time. A unit normally comprises a major piece of equipment and directly associated control modules and/or equipment modules that are not shared with other units.
Unit Procedure	A major programmed processing action or set of related actions, normally consisting of one or more operations. Unit procedures are naturally related to a distinct regime of production: for example, all processing carried out in one batch unit of a multiunit production line.
Unit Recipe	A part of a recipe that defines a part of batch production requirements within a unit. It usually includes a number of operations and phases.
Upper Explosive Limit (UEL)	The highest concentration of gas or vapor in air in which a flame will continue to burn after the source of ignition has been removed.
Upper Range-Limit	The upper limit of the value of the measured variable that a particular instrument is capable of measuring.
Varactor	Voltage-sensitive capacitor.
Variable Backpressure	Backpressure that varies due to changes in operation of one or more pressure relief valves connected into a common discharge header.
Variable, Controlled	See **Controlled Variable**.
Variable, Manipulated	See **Manipulated Variable**.
Velocity Gradient (Shear)	Rate of change of liquid velocity across the stream—V/L for linear velocity profile, dV/dL for nonlinear velocity profile. Units are $V-L$ = ft/sec/ft = sec^{-1}.
Velocity Head	The velocity head is calculated as $v^2/2g$, where v is the flowing velocity and g is the gravitational acceleration (9.819 m/s^2 or 32.215 ft/s^2 at 60 degrees latitude).
Velocity Limit	The limit that the rate of change of a particular variable may not exceed.
Virtual Field Device (VFD)	It is used to remotely view local device data described in an object dictionary. A typical device will have at least two VFDs.
Voltage, Common Mode	See **Common Mode Voltage**.
Voltage, Normal Mode	See **Normal Mode Voltage**.
Water Loading	In case of cooling towers it is the water flow divided by effective horizontal wetted area of the tower. (Unit: GPM/ft^2 or m^3/hr m^2.)
Wave-Guide	A device that constrains or guides the propagation of electromagnetic waves along a path defined by the physical construction of the wave-guide; includes ducts, a pair of parallel wires, and a coaxial cable.
Wet-Bulb Temperature (WBT)	If a thermometer bulb is covered by a wet, water-absorbing substance and is exposed to air, evaporation will cool the bulb to the wet-bulb temperature of the surrounding air. This is the temperature read by a psychrometer. If the air is saturated with water, the wet-bulb, dry-bulb, and dew-point temperatures will all be

	the same. Otherwise, the wet-bulb temperature is higher than the dew-point temperature but lower than the dry-bulb temperature.
White Box Modeling	This type of modeling is feasible if a good understanding of the process exists. In such cases, the dynamic models are derived based on mass, energy, and momentum balances of the process.
Wide Band (Total) Pyrometer	A radiation thermometer that measures the total power density emitted by the material of interest over a wide range of wavelengths.
Wobbe Index	AGA 4A defines the Wobbe Index as a numerical value, which is calculated by dividing the square root of the relative density (a key flow orifice parameter) into the heat content (or BTU per std. cubic foot) of the gas. Mathematically, the Wobbe Index is defined by the equation below: $\text{Wobbe Index} = \dfrac{\text{calorific value}}{\sqrt{\text{specific gravity}}}$
(E)Xtensible Markup Language (XML)	A computer authoring language for publishing documents through the World Wide Web on the Internet. For use in automation, it is better and more flexible than hypertext markup language (HTML).
Zero Elevation	When the zero of a range is elevated, the amount of its elevation is the quantity by which the zero of the measured variable exceeds the lower range-value.
Zero Suppression	When the zero of a range is suppressed, the amount of the suppression is the quantity by which the zero of the measured variable is below the lower range-value.
Zone, Dead	A range of input through which the output remains unchanged. This holds true if the input signal is rising or dropping.
Zone, Neutral	For two-position controllers (switches), the neutral intermediate zone is the range of input values in which the previously existing output value is maintained. If the output is *A* at low inputs and *B* at high ones, on a rising input, *A* is maintained until the input reaches the value corresponding to the set point of switch *A* plus this zone, while, when the input is dropping, the switch will change its output from *B* to *A* when the input has passed through the dead zone and reached the set point of switch *A*.

SOCIETIES AND ORGANIZATIONS

AATCC	American Association of Textile Chemists and Colorists
ACC	American Chemistry Council
ACGIH	American Conference of Governmental Industrial Hygenists
ACS	American Chemical Society
AGA	American Gas Association
AIA	Automatic Imaging Association
AIChE	American Institute of Chemical Engineers
AMTEX	American Textile Partnership
ANSI	American National Standards Institute
AOCS	American Oil Chemists’ Society
APHA	American Public Health Association
API	American Petroleum Institute
ARI	Air Conditioning and Refrigeration Institute
ASA	American Standards Association
ASCE	American Society of Civil Engineers
ASM	Abnormal Situation Management Consortium
ASME	American Society of Mechanical Engineers
ASRE	American Society of Refrigeration Engineers
ASTM	American Society for Testing and Materials or ASTM International
Awwa	American Water Works Association
BSI	British Standards Institution
CARB	California Air Resources Board
CCITT	Consultative Committee for International Telegraphy and Telephony
CCSDS	Consultative Committee for Space Data Systems
CDC	Centers for Disease Control (United States)

WEF	Water Environment Federation
WIB	The International Instrument Users' Association
WIDO	World Intellectual Property Office

ABBREVIATIONS, NOMENCLATURE, ACRONYMS, AND SYMBOLS

NOTES

1. Whenever the abbreviated form of a unit might lead to confusion, it should not be used and the name should be written out in full.
2. The values of SI equivalents were rounded to three decimal places.
3. The words meter and liter are used in their accepted English spelling form instead of those in the standards, namely, metre and litre, respectively.

1oo1	one out of one
1oo2	one out of two
1oo2D	one out of two with diagnostics
2oo2	two out of two
2oo3	two out of three
2oo3d	two out of three with diagnostics
2D	two-dimensional
3D	three-dimensional

A

a	acceleration
A	1) area; 2) ampere, symbol for basic SI unit of electric current; also admittance
Å	Ångstrom (= 10^{-10} m)
AA	atomic absorption
AAS	atomic absorption spectrometer
abs	absolute (e.g., value)
ABS	acrylonitrile-butadiene-styrene
AC, ac, a-c	alternating current
A/C	air to close
ACFM	volumetric flow at actual conditions in cubic feet per minute (= 28.32 alpm)
ACL	asynchronous connection-less
ACM	automatic control mode
ACMH	actual cubic meter per hour
ACMM	actual cubic meter per minute
ACS	analyzer control system
ACSL	advanced continuous simulation language
A/D	analog-to-digital, also analog-to-digital converter
AD	actuation depth
ADC	analog-to-digital converter
ADIS	approved for draft international standard circulation
ADPCM	adaptive differential pulse-code modulation
AE	analyzer element
A&E	alarm and event
AES	atomic emission spectrometer
AF or a-f	audio frequency
AFC	alkaline fuel cell
AFD	adjustable frequency drive
AGA3	American Gas Association Report No. 3
AGC	automatic generation control or automatic gap control
ai	adobe illustrator
AI	analog input or artificial intelligence
AI-AT	analog input–air temperature
AI-RT	analog input–return temperature
a(k)	white noise
ALARA	as low as reasonably achievable
ALARP	as low as reasonably practicable
AliS	alternate lighting of surfaces
ALP	low pressure air
Alpm	actual liters per minute
ALSW	admissible load supply well
alt	altitude
AM	amplitude modulation or actual measurement or alarm management
AMC	annual maintenance contract or adaptive model controller or auto-manual cascade
AMLCD	active matrix LCD
amp	ampere; also A, *q.v.*
AMPS	advanced mobile phone system
AMS	asset management solutions or analyzer maintenance solutions
a/n	alpha numeric
ANN	artificial neural network
ANS	adaptive neural swarming

AO	analog output
A/O	air to open
AOTF	acousto-optical tunable filters
AP	access point
APC	automatic process control or advanced process control
APDU	application (layer) protocol data unit
API	application programming interface or absolute performance index
°API	API degrees of liquid density
APM	application pulse modulation
APSL	air pressure switch, low
AR	auto regressive
ARA	alarm response analysis
ARIMA	auto regressive integrated moving average
ARP	address resolution protocol
ARX	auto regressive with external inputs (model)
ARW	antireset windup
AS	adjustable speed
ASCI	autosequentially commutated current-fed inverter
ASCII	American Standard Code for Information Interchange
AS-I	actuator sensor interface
ASIC	application-specific integrated chips
ASK	amplitude shift keying
ASU	air separation unit
asym	asymmetrical; not symmetrical
AT	air temperature or analyzer transmitter
ATG	automatic tank gauging
atm	atmosphere (= 14.7 psi)
ATP	adenosine triphosphate
ATR	attenuated total reflectance
AUI	attachment unit interface
AUTRAN	automatic utility translator
aux	auxiliary
AV	auxiliary (constraint) variable
AVC	air velocity controller
AVR	automatic voltage regulator
AWG	American wire gauge

B

B	bottom product flow rate
B2B	business-to-business
°Ba	Balling degrees of liquid density
BAC	biologically activated carbon
bar	1) barometer; 2) unit of atmospheric pressure measurement (= 100 kPa)
bara	bar absolute
barg	bar gauge
bbl	barrels (= 0.1589 m^3)
BCD	binary coded decimal
BCM	backup communication module
BCS	batch control system
BD	blow down
°Bé	Baumé degrees of liquid density
BEP	best efficiency point
BFO	beat frequency oscillator
BFW	boiler feed water
Bhp, BHP	brak horsepower (= 746 W)
BIBO	bounded input, bounded output
°Bk	Barkometer degrees of liquid density
blk	black (wiring code color for AC "hot" conductor)
BMS	burner management system or boiler management system
BO	basic operation
BOD	biochemical oxygen demand
bp or b.p.	boiling point
BPCS	basic process control system
BPS or bps	bits per second
BPSK	binary phase shift keying
Bq	becquerel, symbol for derived SI unit of radioactivity, joules per kilogram, J/kg
°Br	Brix degrees of liquid density
BSL	best straight line
BSTR	batch stirred tank reactor
BTR	block transfer read
BTU	British thermal unit (= 1054 J)
BWD	backwash drain
BWG	Birmingham wire gauge
BWR	backwash return
BWS	backwash supply

C

c	1) velocity of light in vacuum (3×10^8 m/s); 2) centi, prefix meaning 0.01
C	coulombs or symbol for discharge coefficient, also capacitance
°C	Celsius degrees of temperature
ca.	*circa*: about, approximately
CAC	channel access code
CAD	computer-aided design
Cal	calorie (gram, = 4.184 J); also g-cal
CAMAC	control advance moving average
CAN	control area network or control and automation network
CAPEX	CAPital EXpenditure
CARI	combustion air requirement index
CAS	cascade
CATV	community antenna television (cable)
CBM	condition-based maintenance
CBT	computer-based timing
cc	cubic centimeter (= 10^{-6} m^3)
CC	cooling coil
CCD	charge-coupled device
CCF	common cause failure or combination capacity factor
ccm	cubic centimeter per minute
CCR	central control room
Ccs	constant current source

CCS	computer control system or constant current source
CCTV	closed circuit television
CCW	counterclockwise
cd	candela, symbol for basic SI unit of luminous intensity
CD	compact disk, collision detector, compel data or dangerous coverage factor, cold deck
CDDP	cellular digital packet data
CDF	cumulative distribution function
CDMA	code division multiple access
CDPD	cellular digital packet data
CDT	color detection tube
CDTP	cold differential test pressure
CE	Conformité Europeéne (European Conformity) applicable to electrical safety
CEHED	chlorination–caustic extraction–hypochlorite bleaching–caustic extraction–chlorine dioxide
CEMS	continuous emissions monitoring system
CENP	combustion engineering nuclear power
CF	cleanliness factor or cubic foot
CFA	continuous flow analyzer
CFE	cartridge filter effluent
CEM	cause and effect matrix
CFM or cfm	cubic foot per minute (28.32 lpm)
CFR	Code of Federal Regulations
CF/Yr	cubic foot per year
CHP	combined heat and power
CHS	chemical sludge
CHWP	chilled water pump
CHWR	chilled water return
CHWS	chilled water supply
Ci	curie (= 3.7 × 10^{10} Bq)
CI	cast iron or corrosion inhibitor
CIM	computer-integrated manufacturing
CIO	channel input–output
CIP	1) computer-aided production; 2) control and information protocol (an application layer protocol supported by DeviceNet, ControlNet, and Ethernet/IP); or 3) clean in place
CJ	cold junction
CL	clamp on
CL1	electrically hazardous, Class 1, Division 1, Groups C or D
CLD	chemiluminescence detector
CLOS	common Lisp object system
CLP	closed-loop potential factor
cm	centimeter (= 0.01 m) or cubic meter
CM	condition monitoring or communication (interface) module or control module
CMF	Coriolis mass flowmeter
CMMS	computerized maintenance management system
CMOS	complementary metal oxide semiconductor
CMPC	constrained multivariable predictive control
cmph	cubic meter per hour
CMR	common mode rejection
CMRR	common mode rejection ratio
CMS	carbon molecular sieve
CMV	common-mode voltage
CNC	computerized numerical control
CNI	ControlNet International
Co	cobalt
CO	controller output or carbon monoxide or contact output
CO_2	carbon dioxide
CO_2D	carbon dioxide demand
COD	chemical oxygen demand
COF	coefficient of haze
COM	component (or compiled) object model
COND	conductivity
COP	coefficient of performance
cos	cosine, trigonometric function
COT	coil outlet temperature
COTS	commercial off-the-shelf
COV	coil outlet velocity
cp or c.p.	1) candle power; 2) circular pitch; 3) center of pressure (cp and ctp may also be used for centipoises)
cpm	cycles per minute; counts per minute
cps	1) cycles per second (= Hz); 2) counts per second; 3) centipoises (= 0.001 Pa.S)
CPS	computerized procedure system
CPU	central processing unit
CPVC	chlorinated polyvinyl chloride
CR	corrosion rate
CRC	cyclical redundancy check or cyclic redundancy code (an error detection coding technique based upon modulo-2 division; sometimes misused to refer to a block check sequence type of error detection coding)
CRDS	cavity ring-down spectroscopy
CRH	cold reheat
CRLF	carriage return-line feed
CRT	cathode ray tube
Cs	cesium
CS	1) carbon steel; 2) constant speed; 3) chlorine solution
CSD	crystal size distribution
CSH	constant speed held
CSL	car seal lock
CSMA/CD	carrier sense, multiple (medium) access with collision detection
CSO	car seal open
CSS	central supervisory station
CSSD	compatible single side band
cSt	centi stoke
CSTR	continuous-stirred tank reactor
CT	cooling tower or the product of *C* for disinfectant concentration and *T* for time of contact in minutes

CTDMA	concurrent time domain multiple access
CTMP	chemi-thermo-mechanical pulp
CTWP	cooling tower water pump
CV	controlled variable or control valve
CVAAS	cold vapor atomic absorption spectroscopy
CVF	circular variable filters
cvs	comma-separated variables
CW	clockwise
CWA	Clean Water Act
CWR	cooling water return
CWS	cooling water supply
CWT	centralized waste treatment

D

d	1) derivative; 2) differential, as in dx/dt; 3) deci, prefix meaning 0.1; 4) depth; 5) day
D	diameter; also dia and ϕ or derivative time of a controller or distillate flow rate
DA	data access or direct action or difference in aeration
D/A	digital-to-analog
DAC	device access code or digital-to-analog converter
DACU	data acquisition and control unit
DAE	differential algebraic equation
DAMPS	digital advanced mobile phone system
DAS	data acquisition system
DB or dB	decibels
dBa	decibels with "*A*" weighing to approximate the human ear
DBB	double-block and bleed
DBPSK	differential binary phase shift keying
DC or dc	direct current
DC	diagnostic coverage
DCAC	direct contact after cooler
DCE	data communications equipment
DCOM	distributed COM
DCS	distributed control system
DD	data definition or device description
D/DBP	disinfectants/disinfection byproducts
DDC	direct digital control
DDE	dynamic data exchange
DDL	device description language (an object-oriented data modeling language currently supported by PROFIBUS, FF, and HART)
DEDED	chlorine dioxide treatment–caustic extraction–chlorine dioxide treatment–caustic extraction–chlorine dioxide treatment
deg	degree; also ° ($\pi/180$ rad)
DEMUX	demultiplexer
Deoxo	deoxidation unit
DES	data encryption standard
DF	direction of flow
DFIR	diffused infrared
DFR	digital fiber-optic refractometer
DFT	digital (or discrete) Fourier transforms
DG	directed graph
DH	data highway
DH+	data highway plus (high-speed peer-to-peer link)
DHCP	dynamic host configuration protocol
DI	discrete (digital) input
dia	diameter; also D and ϕ
DIAC	dedicated inquiry access code
DIR	diffused infrared
DIS	draft international standard
DIX	Digital-Intel-Xerox (DIX is the original specification that created the de facto Ethernet standard; IEEE 802.3 came later, after Ethernet was established)
d(k)	unmeasured disturbance
D(k)	measured disturbance
DLE	data link escape
DLL	dynamic link library
DLPD	digital light processor display
Dm or dm	decimeter
DM	delta modulation
DMA	dynamic mechanical analyzer or direct memory access
DMC	dynamic matrix control(ler)
DMFC	direct methanol conversion fuel cell
DMM	digital multi-meter
DN	diameter nominal, the internal diameter of a pipe in rounded millimeters
DO	dissolved oxygen or discrete (digital) output
DOAS	differential optical absorption spectroscopy
d/p cell	differential pressure transmitter (a Foxboro trademark)
DP	decentralized peripheral
DPC	damper position controller
DPCM	differential pulse code modulation
DPD	*N*,*N*-Diethyl-*p*-phenylenediamine
DPDT	double pole double throw (switch)
dpi	dots per inch
DPS	differential pressure switch
DQPSK	differential quadrature phase shift keying
DR	decay ratio
DSB	double side band
DSL	digital subscriber line
DSN	distributed sensor network
DSP	digital signal processing
DSR	direct screen reference
DSSS	direct sequence spread spectrum
DST	dirty service trim
DSTM	dual-scan twisted nematic
DT or dt	dead time (second or minutes) or delay time
DTB	draft tube baffle
DTC	digital temperature compensation or dead time compensator
DTD	document type definition
DTE	data terminal equipment
DTGS	deuterated tryglycine sulfate

DTL	diode-transistor logic
DTM	device type manager (an active-X component for configuring an industrial network component; a DTM “plugs into” an FDT)
DU	dangerous component failure occurred in leg but is undetected
DV	disturbance variable
DVC	digital valve control or discrete valve coupler
DVM	digital voltmeter
DWS	dewatered sludge

E

e	1) error; 2) base of natural (Naperian) logarithm; 3) exponential function; also exp $(-x)$ as in e^{-x}
E	1) electric potential in volts; 2) scientific notation as in $1.5E-03 = 1.5 \times 10^{-3}$; 3) tray efficiency in distillation
E{.}	expected value operator
E&I	electrical and instrumentation
EA	evolutionary algorithm or exhaust air
EAD	exhaust air damper
EAF	exhaust air fan
EAI	enterprise application integration
EAM	enterprise asset management
EAPROM	erasable alterable programmable read-only memory
EBCDIC	extended binary code for information interchange
EBR	electronic batch records
ECD	electron capture detector
ECG	electrocardiogram
ECKO	eddy-current killed oscillator
ECLiPS	English control language programming software
ECN	effective carbon number
ECTFE	ethylene chloro-tetra-fluoro-ethylene (Halar)
ED	explosive decompression
EDD	electronic device description
EDS	electronic data sheet (DeviceNet)
EDTA	ethylenediaminetetraacetic acid
EDXRF	energy dispersive x-ray fluorescence
E/E/PE	electrical/electronic/programmable electronic
E/E/PES	electrical/electronic/programmable electronic system
EEPROM	electrically erasable programmable read only memory
EFB	external feedback
EFD	engineering flow diagram
EFRVD	expected flow rate value through dryer
e.g.	*exempli gratia*: for example
EHC	electro-hydraulic control or extended horizon adaptive controller
EHM	equipment health management
e(k)	feedback error
E.L.	elastic limit or enthalpy logic
ELD	electroluminescent display
Em	minimum error
EM	equipment module
Emf or EMF	1) electromotive force (volts); 2) electromotive potential (volts)
EMI	electro-magnetic interference
EMI/RFI	electromagnetic and radio frequency interference
em(k)	process/model error
EN	European standard
ENB	Ethernet card
EP	evolutionary programming or equipment phase
EPA	enhanced performance architecture
EPC	engineering-procurement-construction (firm or industry)
EPCM	engineering, procurement, and construction management (companies)
EPDM	ethylene propylene diene terpolymer
EPROM	erasable programmable read only memory
EPS	electronic pressure scanner, encapsulated postscript file, emergency power supply, or expanded polystyrene
EPSAC	extended prediction self-adaptive controller
EQ or eq	equation
ER	external reset
ERM	enterprise resource manufacturing
ERP	enterprise resource planning or effective radiated power
ERW	electric-resistance-welded
ES	evolutionary strategy
ESD	emergency shutdown (system)
ESN	electronic serial number
ESP	environmental simulation program
ETFE	ethylene-tetrafluoroethylene copolymer (Tefzel)
ETM	elapsed time meter
ETMI	expected total mass input
ETMP	expected total mass produced
ETS	equivalent time sampling
EU	engineering unit
EVOP	evolutionary operation or evolutionary optimum
EWMA	exponentially weighed moving average
Exp	exponential function as in exp $(-at) = e^{-at}$; also *e*

F

F	frequency; also freq or filter, also farad, symbol for derived SI unit of capacitance, ampere · second per volt, A · s/V, also feed flow rate
°F	Fahrenheit degrees [$t°C = (t°F - 32)/1.8$]
FAH	flow alarm, high

FAL	flow alarm, low
FAN	fuzzy, analytical intelligence, neural network
FARM	frame acceptance and reporting mechanism
FAT	factory acceptance testing
FB	friction bound
FBAP	function block application process (FF)
FBD	function block diagram
FBG	fiber bragg grating
FBT	fire box temperature
FC	1) flow controller; 2) fail closed; 3) forced circulation; 4) fire command panel
FCC	fluid catalytic cracking unit
FCCU	fluidized catalytic cracking unit
FCOR	filtering and correlation (method)
FCS	frame check sequence or field control system
FCV	flow control valve
FD	forced draft
FDE	fault disconnection electronics
FDL	fieldbus data link
FDM	frequency division multiplexing
FDMA	frequency division multiple access
FDS	flame detection system or fines density sensor
FDT	field device tool (a MS Windows-based framework for engineering and for configuration tools)
FE	1) final element; 2) flow element; 3) filter effluent
FED	field emission display
FEED	front end engineering and design
FEGT	furnace exit gas temperature
FEP	fluorinated ethylene propylene
FES	fixed end system
FF	1) Foundation Fieldbus; 2) feedforward
FF-HSE	Foundation Fieldbus, high-speed Ethernet
FFIC	flow ratio controller
FFT	fast Fourier transform
FGB	fiber bragg grating
FGD	flue gas desulfurization
FGR	flue gas recirculation
FH	frequency hopping
Fhp	fractional horsepower (e.g., $^{1}/_{4}$ HP motor)
FHSS	frequency hopped spread spectrum
FI	1) flow indicator; 2) fail intermediate; 3) filter influent
FIA	flow injection analyzer
FIC	flow indicator controller
FID	flame ionization detector
FIE	flame ionization element
FIFO	first-in, first-out
Fig. or FIG.	figure
FIR	finite impulse response (model)
FISCO	Fieldbus Intrinsic Safety COncept
fl.	fluid
FL	fail last (position)
fl. oz.	fluid ounces (= 29.57 cc)

FM	frequency modulated or Factory Mutual
FMAX	maximum feed availability
FMCW	frequency-modulated carrier wave
FMEA	failure mode and effects analysis
FMEDA	failure modes, effects, and diagnostic analysis
FMS	1) fieldbus message specification; 2) fieldbus messaging services/system
FNC	function byte
FO	1) fiber optic; 2) fail open
FOP	fiber optic probe
FOPDT	first order plus dead time
FOSS	first order system series
FOV	field of view
fp or f.p.	freezing point
FPC	fine particle content
FPD	flame photometric detector
FPGA	field programmable gate arrays
FPM or fpm	feet per minute (= 0.3048 m/m)
fps or ft/s	feet per second (= 0.3048 m/s)
FRC	flow recording controller
FRM	frequency response method
FRO	full range output
FS or fs	full scale or flow switch or full stroke
FSA	fault state active
FSC	fail safe controller
FSH	flow switch, high
FSHL	flow switch, high-low
FSK	frequency shift keying
FSL	flow switch, low
FSNL	full speed no load
FSPF	first stage permeate flow
FST	full stroke testing
FT	Fourier transfer or flow transmitter
FTA	fault tree analysis
FTC	fail to close
FTIR	Fourier transform infrared
FTL	fuzzy technology language
FTNIR	Fourier near infrared
FTO	fail to open
FTP	file transfer protocol
FTS	fault tolerant system
FTU	formazin turbidity unit
FW	finished water

G

g	acceleration due to gravity (= 9.806 m/s^2) or conductivity
G	giga, prefix meaning 10^9 or process gain or conductance
GA	genetic algorithm
gal.	gallon (= 3.785 liters)
GB	gigabyte, 1,000,000,000 bytes
GbE	gigabit Ethernet
Gbps or GBPS	gigabits per second
G_c	feedback controller transfer function
GC	gas chromatograph

g-cal	gramcalorie, *q.v.*; also cal
GD	group of dryers
G_d	unmeasured disturbance transfer function
G_D	measured disturbance transfer function
G_D	approximate feedforward transfer function model
GEOS	geosynchronous Earth orbit satellites
GFC	gas filter correlation
G_ff	feedforward controller transfer function
GHz	giga-Hertz
GI	galvanized iron
GIAC	general inquiry access code
GLR	gas-to-liquid ratio
G-M	Geiger–Mueller tube, for radiation monitoring
G_m	model transfer function
GMC	generic model control
GMR	giant magneto resistive
GMV	generalized minimum variance
GOSUB	go to subroutine
GOX	gaseous oxygen
GP	genetic programming
G_p	process transfer function or process gain
GPa	giga-Pascal (10^9 Pa)
GPC	generalized predictive control
GPCP	general process control programming
GPH or gph	gallons per hour (= 3.785 lph)
GPC	generalized predictive controller
GPM or gpm	gallons per minute (= 3.785 lpm)
GPS	global positioning satellite
gr	gram
grn	green (wiring code color for grounded conductor)
GSC	gas-solid chromatography
GSD	Profibus version of an electronic data sheet
GT	gas turbine
GTG	gas turbine generator
GTO	gate-turn-off thyristor
GUI	graphical user interface
GWR	guided wave radar
Gy	gray, symbol for derived SI unit of absorbed dose, joules per kilogram, J/kg

H

h	1) height; 2) hour; 3) suffix indicating heavy key component; 4) hour
H	1) humidity expressed as pounds of moisture per pound of dry air; 2) henry, symbol of derived SI unit of inductance, volt · second per ampere, V · s/A; 3) high; 4) humidifier
H1	field-level fieldbus, also refers to the 31.25 Kbps instrinsically safe SP-50, IEC61158-2 physical layer
HAD	holographic autostereoscopic display or historical data access
HART	highway addressable remote transducer
HAZOP	HAZard and OPerability studies
HC	horizontal cross-connect or heating coil
HCN	hydrogen cyanide
HD	hot deck
HEC	header error check
HF	hydrogen fluoride or hydrofluoric acid
HFE	human factors engineering
HFT	hardware fault tolerance
HGBP	hot gas bypass
HGC	hydraulic gap control
hh	suffix indicating heavier key component
HH	high-high
hhv	higher heating value
HIC	hand indicating controller
HIPPS	high-integrity pressure protection system
HIPS	high-integrity protection systems
HIS	human interface station
HIST	host interface system test
HK	heavy key
HLL	high-level logic
HLLS	high-low limit switch
HMI	human–machine interface
HMP	hexametaphosphate
HMSD	hexamethyldisiloxane
hor.	horizontal
HP or hp	horsepower (U.S. equivalent is 746 W) or high pressure
HPBF	high performance butterfly valves
HPD	hybrid passive display
HPLC	high pressure (or precision) liquid chromatography
hr	hour
H&RA	hazard & risk analysis
HRH	hot reheat
HRL	hysteresis, repeatability and linearity
HRSG	heat recovery steam generator
HS	hand switch or hot standby
HSE	high-speed Ethernet (host-level fieldbus)
HSF	hydrofluosilic acid
his	human system interface
HTG	hydrostatic tank gauging
HTML	hyper text markup language
HTTP	hyper text transfer protocol
HV	high voltage
HVAC	heating, ventilation, and air conditioning
H/W	hardware
HWD	height, width, depth
HWP	hot water pump
HWS	hot water supply
Hz	Hertz, symbol for derived SI unit of frequency, one per second (l/s)

I

I	integral time of a controller in units of time/repeat
IA	instrument air or impedance amplifier

IAC	inquiry access code
IAE	integral of absolute error
IAQ	indoor air quality
ibid	in the same place
IC	integrated circuitry, intermediate cross-connect, initial condition, or inorganic carbon
I&C	instrumentation and control or information and control
ICA	independent computing architecture
ICCMS	inadequate core cooling monitoring system
ICMP	Internet control message protocol
ICP	inductively coupled plazma
ID	inside diameter or induced draft
IDCOM	identification command
i.e.	*id est*: that is
IE	integral error
I&E	instrument and electrical
IEC	interactive evolutionary computation
IEH	Instrument Engineers' Handbook
IETF	Internet engineering task force
IF	intermediate frequency
IFS	initiate fault state
IGBT	insulated gate bipolar transistor
IGV	inlet guide vane
IIS	Internet information server
IL	instruction list
ILD	instrument loop diagrams
IMC	internal model control or injection cycle
iMEMS	integrated micro-electro-mechanical system
IN	insertion
in.	inch (= 25.4 mm)
IrGaAs	iridium gallium arsenide
in-lb	inch-pound (= 0.113 N × m)
I/O	input/output
IP	Internet protocol or ionization potential or intermediate pressure
I-P	current-to-pressure conversion
IPA	isopropyl alcohol
IPL	independent protection layer
IPS	in-plane switching
IPTS	international practical temperature scale
IR	infrared
IRQ	interrupt request queue
IS	intermediate system or intrinsic safety
ISAB	ionic strength adjustment buffer
ISE	integral of squared error or ion selective electrode
ISFET	ion-selective field effect transistor
ISM	industrial, scientific, medical
ISP	Internet service provider or interoperable system provider
IT	information technology (as in IT manager or IT department) or current transmitter
ITAE	integral of absolute error multiplied by time
ITD	indium tin oxide
ITSE	integral of squared error multiplied by time
ITT	intelligent temperature transmitters
IWF	initial weighing factor
IXC	intereXchange carrier

J

J	joule, symbol for derived SI unit of energy, heat or work, newton-meter, N · m
JB	junction box
JIT	just-in-time manufacturing
JSR	jump to subroutine
JT	Joule Thomson
JTU	Jackson turbidity unit

K

k	kilo, prefix meaning 1000
K	coefficient, also dielectric constant or process gain
°K or K	degrees Kelvin, symbol for SI unit of temperature or process gain (dimensionless)
Kbs, Kbps	kilo bits per second
KBs	kilo bytes per second
k-cal	kilogram-calories (= 4184 J)
kg	kilogram, symbol for basic SI unit of mass
kg-m	kilogram-meter (torque, = 7.233 foot-pounds)
KHP	potassium acid phthalate
kip	thousand pounds (= 453.6 kg)
kJ	kiloJoule
km	kilometer
KOH	potassium hydroxide
K_p	proportional gain of a PID controller
kPa	kilo-Pascals
K_u	ultimate controller gain
kVA	kilovolt-amperes
KVSP	Kalrez valve stem packing
kW	kilowatts
KWD	kilowatt demand
kWh	kilowatt-hours (= 3.6 × 10^6 J)
KWIC	Kilowatt indicating controller

L

l	suffix indicating light key component
L	1) liter (= 0.001 m^3 = 0.2642 gallon), 2) length; 3) inductance, expressed in henrys; 4) low; 5) reflux flow rate
L2F	laser two-focus anemometer
Lab	CIE functions for lightness, red/green, blue/yellow
LACM	local automatic control mode
LAG	liquid argon
LAN	local area network
LAS	link active scheduler (FF)
Lat	latitude

Lb or lb	pound (= 0.4535 kg)
lbf	pound force
lbm	pound mass
LC	level controller or liquid chromatography
LCD	liquid crystal display
Lch	CIE functions for lightness, chroma, hue
LCI	load commutated inverter
LCM	life cycle management
LCSR	loop current step response
LCV	level control valve
LD	ladder diaphragm or load
LDA	laser Doppler anemometer
LDAD	load distribution algorithm (dryers)
LDAW	load distribution algorithm (wells)
LDP	large display panel
LEC	local exchange carrier or lower explosive limit
LED	light emitting diode
LEL	lower explosive limit
LEO	low Earth orbit satellites
LEPD	light emitting polymer display
LF	linear feet
L/F	reflux-to-feed ratio
LFL	lower flammable limit
LGR	liquid-to-gas ratio
LI	level indicator
LIC	level indicator controller
LIDAR	laser induced doppler absorption radar or light detection and ranging
LIFO	last-in first-out
lim. or lim	limit
lin.	linear
LIN	liquid nitrogen
liq.	liquid
LK	light key
ll	suffix indicating lighter key component
L/L	lead-lag
LL	leased lines or low-low
LLC	logical link control
LLK	lighter than light key
LLOI	low-level operator interface
lm	lumen, symbol for derived SI unit of luminous flux, candela.steradian, cd.sr
ln	Naperian (natural) logarithm to base e
LNG	liquified natural gas
LO	lock open or local override
LOC	limiting oxygen concentration
log or $\log_{10}$	logarithm to base 10; common logarithm
LOI	local operation interface
long.	longitude
LOPA	layers of protection analysis
LOR	local-off-remote
LOS	line of sight
LOX	liquid oxygen
LP	1) liquified petroleum; 2) linear programming; 3) low pressure
LPC	1) large particle content; 2) line predictive coding
LPG	1) liquified petroleum gas; 2) liquified propane gas
lph	liters per hour (0.2642 gph)
lpm	liters per minute (0.2642 gpm)
LPR	linear polarization resistance
LPV	linear parameter varying
LQG	linear quadratic Gaussian
LRC	1) longitudinal redundancy check; 2) level recording controller
LRL	lower range limit
LRV	lower range value
LS	1) level switch; 2) lime slurry
LSB	least significant bit
LSI	large-scale integrator
LSL	lower specification limit
LTI	linear time-invariant
LV	low voltage
LVDT	linear variable differential transformer
LVN	limiting viscosity number
lx	lux, symbol for derived SI unit of illumination, lumen per square meter, lm/m^2

M

m	1) meter, symbol for basic SI unit of length; 2) milli, prefix meaning 10^{-3}; 3) minute (temporal); also min
M	1) thousand (in commerce only); Mach number; 2) molecular weight; 3) mole; 4) mega, prefix meaning 10^6
mA or ma	milliamperes (= 0.001 A)
MAC	medium access control or model algorithm control or main air compressor
MACID	medium access control identifier
MAE	minimum absolute error
MAOP	maximum allowable operating pressure
MAP	manufacturing automation (access) protocol
MAU	media access unit
MAWP	maximum allowable working pressure
Max	maximum
MB	megabyte, 1,000,000 bytes or megabits
MBC	model-based control
MBPC	model-based predictive control
MBPS, mbps, Mbps, Mbs, MBs	megabits per second
MC	main cross-connect
MCFC	molten carbonate fuel cell
mCi or mC	millicuries (= 0.001 Ci)
m.c.p.	mean candle power
MCP	main control panel or manual control mode
MCR	master control relay
MCT	mercury cadmium telluride or minimum cycle time

MDBS	mobile data base station
MDIS	mobile data intermediate system
MDPH	maximum pressure difference (header towell)
m/e	mass-to-energy ratio
med.	medium or median
MEDS	medium Earth orbit satellites
MEMS	micro electro mechanical structures
m.e.p.	mean effective pressure
MES	manufacturing execution system, management execution system, or mobile end station
MeV	mega-electron volt
MF	micro filtration
MFAC	model free adaptive control
MFC	model free control or microbiological fuel cell
MFD	mechanical flow diagram
MFE	magnetic flux exclusion
mfg	manufacturer or manufacturing
MFI	melt flow index or melt factor index
MFR	manual flow rate
mg	milligrams (= 0.001 gr)
MGD	million gallons per day
mg/l	milligrams per liter
mho	outdated unit of conductance, replaced by Siemens (*S*), *q.v.*
MHz	megahertz
mi	miles (= 1.609 km)
MI	melt index
MIB	management information base
micro	prefix = 10^{-9}; also μ (mu) or µm and sometimes u, as in ug or µg, both meaning microgram (= 10^{-9} kg)
micron	micrometer (= 10^{-6} m)
MIE	minimum ignition energy
MIMO	multiple-input multiple-output
MIMOSA	machinery information management open system alliance
min	1) minutes (temporal); also m; 2) minimum, 3) mobile identification number
MIR	multiple internal reflection
MIS	management information system
ml	milliliters (= 0.001 l = 1 cc)
MLR	multiple linear regression
mm	millimeters (= 0.001 m) or millimicron (= 10^{-9} m)
MMAC	multiple model adaptive control
mmf	magnetomotive force in amperes
MMI	man–machine interface
mmpy	millimeters per year
MMS	machine monitoring system or manufacturing message specification
MMSCFD	million standard cubic feet per day
MMV	manually manipulated variable
MOC	management of change
MODBUS	a control network
MODEM	modulator/demodulator
MOEA	multiobjective evolutionary algorithm
MOGA	multiobjective genetic algorithm
MOGP	multiobjective genetic programming
mol	mole, symbol for basic SI unit for amount of substance
mol.	molecules
MOON	M out of N voting system
MON	motor octane number
MOS	metal oxide semiconductor
MOSFET	metallic oxide semiconductor field-effect transistor
MOV	metal oxide varistor or motor-operated valve or most open valve
MOVC	most open valve control
mp or m.p.	melting point
MP	medium pressure
MPa	mega Pascal (10^6 Pa)
MPC	model predictive control
MPEC	mathematical problem with equilibrium constraints
MPFM	multiphase flowmeter
mph or MPH	miles per hour (1.609 km/h)
MPHC	model predictive heuristic controller
MPM or mpm	meters per minute
mps or m/s	meters per second
MPS	manufacturing periodic/aperiodic services
Mpy	mills per year
mR or mr	milliroentgens (= 0.001 R)
MRAC	model reference adaptive control
mrd	millirads (= 0.001 rd)
mrem	milliroentgen-equivalent-man
MRP	material requirement planning or manufacturing resource planning or material/product planning
ms	milliseconds (= 0.001 s)
MS	mass spectrometer or Microsoft
MSA	metropolitan statistical areas
MSB	most significant bit
MSC	monitoring and sequential control
MSD	most significant digit
MSDS	material safety data sheet
MT	measurement test
MTBE	methyl tertiary butyl ether
MTBF	mean time between failures
MTSO	mobile telephone switching offices
MTTF	mean time to fail
MTTFD	mean time to fail dangerously
MTTFS	mean time to spurious failure
MTTR	mean time to repair
MTU	master terminal unit
MUX	multiplexer
MV	minimum variance or manipulated variable
MVA	multiple-domain vertical alignment
MVC	minimum variance controller or multivariable control

MW	megawatts (= 10^6 W)
MWC	municipal waste combustors
MWD	molecular weight distribution

N

n	1) nano, prefix meaning 10^6; 2) refractive index; 3) number of trays
N	newton, symbol for derived SI unit of force, kilogram-meter per second squared, $kg \cdot m/s^2$
N_0	Avogadro's number (= 6.023×10^{23} mol^{-1})
N-16	nitrogen-16
NA	numeric aperture
NAAQS	National Ambient Air Quality Standards
NAP	network access port/point
NARMAX	nonlinear autoregressive w/exogenous moving average input nodes
NARX	nonlinear autoregressive w/exogenous input nodes
NAT	network address translation
NB	nominal bore, internal diameter of a pipe in inches
NBJ	nonlinear Box-Jenkins
NC or N/C	normally closed (switch contact)
NC	numeric controller
NCAP	networking capable application processors
NDIR	nondispersive infrared
NDM	normal disconnect mode
NDT	nondestructive testing
NEC	National Electrical Code
NESC	National Electrical Safety Code
NEXT	near end cross-talk
nF	nano filtration
NFI	near field imaging
NFIR	nonlinear finite impulse response
NIC	network interface card
NIP	normal incident pyrheliometer
NIR	near infrared
Nm or nm	nanometer (10^{-9} meter)
NMR	nuclear magnetic resonance
NMV	normal mode voltage
NO or N/O	normally open (switch contact)
NOE	nonlinear output error
NPN	transistor with base of p-type and emitter and collector of n-type material
NPS	nominal pipe size, the internal diameter of a pipe in inches
NPSH	net positive discharge head
NPSHA	net positive discharge head available
NPSHR	net positive discharge head required
NPT	network time protocol
NR	narrow range
NRM	normal response mode
NRZ	nonreturn to zero (NZR refers to a digital signaling technique)
NS	nominal pipe size, the internal diameter of a pipe in inches
NTC	negative temperature coefficient
NTP	network time protocol or normal temperature and pressure, corresponding to 1 atm. absolute (14.7 psia) and 0°C (32°F)
NTSC	national television standards code
NTU	nephalometric turbidity unit
NUT	network update time

O

OA	operational amplifier or outside air
OAC	operator automatic control
OAD	outside air damper
OCD	orifice-capillary detector
OD	outside diameter or oxygen demand
ODBC	open database connectivity or communication
OEM	original equipment manufacturer
OES	optical emission spectrometer
oft or OFT	optical fiber thermometry
ohm	unit of electrical resistance; also Ω (omega)
OI	operator interface
OI-F	operator interface for filtering
OI-P	plant operator interface
OIU	operator interface unit
OJT	on-the-job training
OL	overload
OLE	object linking and embedding
OLED	organic LED
OLE_DB	object linking and embedding data base
OMAC	open modular architecture controls
OMMS	optical micrometer for micro-machine
ON	octane number
OP	output or operating point
OPAM	online plant asset management
OPC	object link embedding (OLE) for process control
OPEX	OPerational EXpenditure
OP-FRIR	open path Fourier-transform infrared
OP-HC	open path hydrocarbon
OP-TDLAS	open path tunable diode-laser absorption spectroscopy
OP-UV	open path ultraviolet
Or	orange (typical wiring code color)
OREDA	Offshore Reliability Data Handbook
ORP	oxidation-reduction potential
OS	operator station or operating system
OSFP	open shortest path first
OSI	open system interconnection (model)
OSI/RM	open system interconnect/reference model
OT	operator terminal or open tubular
OTDR	optical time domain reflectometer
OTSG	once-through steam generator
oz	ounce (= 0.0283 kg)
OZ	ozone

OZA	ozonated air
OZW	ozonated water

P

p	1) pressure; 2) pico, prefix meaning 10^{-12}, also resistivity
P&ID	piping and instrumentation diagram
Pa	pascal, symbol for derived SI unit of stress and pressure, newtons per square meter, N/m^2
PA	plant air, phase angle, or pole assignment
PAC	path average concentration or process automation controllers
PAFC	phosphoric acid fuel cell
PAH	pressure alarm, high
PAL	phase alternating line or pressure alarm, low
PAM	pulse amplitude modulation
PAN	personal area network
Pas	Pascal-second, a viscosity unit
PAS	process automation system (successor to DCS) or project application specification
PB	proportional band of a controller in % (100%/controller gain) or push button
PC	personal computer (MS-Windows based) or pressure controller
PCA	principal component analysis
PCB	printed circuit board
PCC	pressure correction control
PCCH	pressure correction control mode
PCCS	personal computer control system
PCDD	polychlorinated dibenzo-*p*-dioxin
PCDF	polychlorinated dibenzo furans
PCL	peer communication link
PCM	pulse code modulation
PCR	principal component regression
PCS	process control system or personal communication services
pct	percent; also %
PCT	Patent Cooperation Treaty
PCTFE	polychlorotrifluoroethylene
PCV	pressure control valve
PD	positive displacement or proportional and derivative or percentage detected or position detector
PDA	personal digital assistant or photodiode array
PDD	pulsed discharge detector
PDF	probability density function, probability of failure or portable document file
PDIC	pressure differential indicating controller
PDLCP	partial differential linear complementary problem
PdM	predictive maintenance
PDM	pulse duration modulation
PDP	plasma display panel
PDS	phase difference sensor
PDU	protocol data unit
PDVF	polyvinylidene fluoride
PE	polyethylene or penalty on error or pressure element
PED	pressure equipment directive
PEEK	poly ether ether ketone
PEL	permissible exposure level
PEMFC	proton exchange membrane fuel cell or polymer electrolyte membrane fuel cell
PES	programmable electronic system
Pf	picofarad (= 10^{-12} F)
PF or p.f.	power factor
PFA	per-fluoro-alkoxy copolymer (a form of Teflon)
PFC	procedure functional chart or procedure function chart
PFD	process flow diagram or probability of failure on demand
PFDavg	average probability of failure on demand
PFPD	pulsed flame photometric detector
PGC	process gas chromatograph
PGNAA	prompt gamma neutron activation analysis
pH	acidity or alkalinity index (logarithm of hydrogen ion concentration)
PHA	process hazard analysis
pi or pl	Poiseuille, a viscosity unit
PI	proportional and integral or pressure indicator
P/I	pneumatic-to-current (conversion)
P&I	piping and instrument (diagram)
PIC	pressure indicating controller or path integrated concentration
PID	proportional, integral, and derivative (control modes in a classic controller) or photoionization detector
P&ID	piping (process) and instrumentation diagram (drawing)
PI-MDC	path integrated minimum detectable concentration
PIMS	process information management system
PIO	program input–output
PIP	process industry practices
PIR	precision infrared radiometer
PL	preload
PLC	programmable logic controller
PLD	programmable logic devices
PLED	polymeric LED
PLL	phase locked loop
PLS	physical layer signaling or partial least squares
PM	photo multiplier or penalty on moves or phase modulation
PMA	physical medium attachment
PMBC	process model based control
PMD	photomultiplier detector
PMF	probability mass function

PMLCD	passive matrix LCD
PMMC	permanent magnet moving coil
PMS	plant monitoring system
PMT	photo-multiplier tube or photometer tube
PN	pressure, nominal
PNP	transistor with base of n-type and emitter and collector of p-type material
PO	polymer
POF	positive opening feature
POL	problem oriented language
POPRV	pilot operated pressure relief valve
POTW	publicly owned treatment works
PP	polypropylene or pole placement
ppb or PPB	parts per billion
PPC	process procedure chart
PPD	pounds per day
ppm or PPM	parts per million or pulse position modulation
ppmV	volumetric parts per million
PPP	point-to-point protocol
ppt	parts per trillion
PRBS	pseudo random binary sequence
PRC	pressure recording controller or production cycle
PRD	pressure relief device
Precip	precipitate or precipitated
PRV	pressure relief valve or pressure reducing valve
PS	power supply (module) or pressure switch or partial stroke
PSA	pressure swing adsorption
PSAT	pre-startup acceptance test
PSD	power spectral density or photosensitive device
PSE	pressure scale effect
PSG	phosphosilicate glass
PSH	pressure switch, high
PSI	pre-startup inspection
psi or PSI	pounds per square inch (= 6.894 kPa)
PSIA or psia	absolute pressure in pounds per square inch
PSID or psid	differential pressure in pounds per square inch
PSIG or psig	above atmospheric (gauge) pressure in pounds per square inch
PSK	phase shift keying
PSL	pressure switch, low
PSM	process safety management
PSS	programmable safety system
PSSR	pre-startup safety review
PST	partial stroke testing
PSTN	public switched telephone network
PSU	post-startup
PSV	pressure safety valve
pt	point or part or pint (= 0.4732 liter)
PT	pressure transmitter
PTB	Physikalisch-Technische Bundesanstalt
PTC	positive temperature coefficient or programmable telemetry controller
PTFE	polytetrafluoroethylene (conventional Teflon)
PU	per unit
PUVF	pulsed ultraviolet fluorescence
PV	process variable (measurement) or the HART primary variable
PVC	polyvinyl chloride
PVDF	polyvinylidene fluoride
PVHI	process variable high (reading or measurement)
PVLO	process variable low (reading or measurement)
PW	private wire
PWM	pulse width modulation
PWR	pressurized water reactor
PZT	lead-zirconate-titanate ceramic

Q

q	1) rate of flow; 2) electric charge in coulombs, C
q^{-1}	backward shift operator
Q	quantity of heat in joules, J or electric charge
°Q	Quevenne degrees of liquid density
QA	quality assurance
QAM	quadrature amplitude modulation
QBET	quench boiler exit temperature
QCM	quartz crystal microbalance
QEV	quick exhaust valve
QMS	quality management system
QoS	quality of service
QPSK	quadrature phase shift keying
qt	quart (0.9463 liter)
q.v.	*quod vide*: which see
QV	quaternary variable

R

r	radius; also rad
R	1) resistance, electrical, ohms; 2) resistance, thermal, meter-kelvin per watt, $m \cdot K/W$; 3) gas constant ($= 8.317 \times 10^7$ erg $\cdot$ mol^{-1},$°C^{-1}$); 4) roentgen, symbol for accepted unit of exposure to *x* and gamma radiation, ($= 2.58 \times 10^{-4}$ C/kg)
r^2	multiple regression coefficient
Ra	radium
RA	return air or reaction (failure) alarm or reverse action
RACM	remote automatic control mode
Rad	1) radius; also r; 2) radian, symbol for SI unit of plane angle measurement or symbol for accepted SI unit of absorbed radiation dose, (= 0.01 Gy)
RAD	return air damper
RADAR	radio detection and ranging

RAID	redundant array of inexpensive disks
RAM	random access memory
RASCI	responsible for, approves, supports, consults, informed
RAT	return air temperature
RBC	remote base communication module
RCF	rotational centrifugal force
RCU	remote control unit
R&D	research and development
RD	rupture disk
RDP	remote desktop protocol
Re	Reynolds number
REC	roll eccentricity compensation
ReD	Reynolds number corresponding to a particular pipe diameter
redox	oxidation–reduction
rem	measure of absorbed radiation dose by living tissue (*r*oentgen *e*quivalent *m*an)
rev	revolution, cycle
RF or rf	radio frequency or return fan
RFC	request for comment (an Internet protocol specification) or rotational centrifugal force or rising film concentrator
RFF	remote fiber fluorimetry
RFI	radio frequency interference
RFQ	request for quote
RG	relative gain
RGA	residual gas analyzer or relative gain array or relative gain analysis
RGB	red, green, and blue
RGM	reactive gaseous mercury
RH	relative humidity or reheated or reheater
RHA	relative humidity alarm
RHC	receding horizon adaptive controller or reheat coil
RHCV	relative humidity control valve
RHE	relative humidity element
RHPZ	right half plane zero
RI	refractive index
RIO	remote operator interface
RIP	routing information protocol
RJT	ring joint type
r(k)	set point
RLL	relay ladder logic
RMS or rms	root mean square (square root of the mean of the square) or rotary mirror sleeves
RNG	ring number
RO	reverse osmosis
ROI	return on investment
ROM	read-only memory
RON	research octane number
RPC	remote procedure call (RFC1831)
RPG	remote password generator
RPM or rpm	revolutions per minute
rps	revolutions per second

R_r	reaction rate, slope
RRF	risk reduction factor
RRT	relative response time (the time required to remove the disturbance)
RS	recommended standard
RSA	rural service areas
RSS	root sum squared
RSSI	received signal strength indicator
RTD	resistance temperature detector
RTL	resistance-transistor logic
RTO	real time optimization or operation
RTOS	real time operating system
RTR	remote transmission request
RTS	ready (or request) to send
RTS/CTS	request to send/clear to send
RTU	remote terminal unit
RUDS	reflectance units of dirt shade
RV	relief valve
RVDT	rotary variable differential transformer
RVP	Reid vapor pressure
RW	raw water
RWF	raw water flow
RWS	remote work station

S

S or s	1) second, symbol for basic SI unit of time; 2) Laplace variable; 3) Siemens (Siemens/cm), symbol for unit of conductance, amperes per volt, A/V; 4) separation
SA	supply air
SAN	surface acoustic wave
SAP	service access point
SASFC	single automatic stage flow control
sat.	saturated
SAT	site acceptance test or supervisory audio tone or supply air temperature
SAW	surface acoustic wave
S.B.	set-point bandwidth
SC	system codes or speed controller
SCADA	supervisory (system) control and data acquisition
SCCM	standard cubic centimeter per minute
SCD	streaming current detector or sulfur chemilumenesce detector
SCE	saturated calomel electrode
SCFH	standard cubic feet per hour
SCFM	standard cubic feet per minute (air flow at 1.0 atm and 70°F)
SCM	station class mark
SCMM	standard cubic meter per minute
SCO	synchronous connection oriented
SCOT	support coated open tubular (column)
SCR	silicone-controlled rectifier or selective catalytic reduction
SCS	sample control system

SD	component in leg has failed safe and failure has been detected
S/D	shut down (valve)
SDIU	Scanivalve digital interface unit
SDN	send data with no acknowledgement
SDS	smart distributed system
SEA	spokesman election algorithm or slurry density sensor
Sec or sec	seconds; also s
SEI	system efficiency index
SELV	source: extra low voltage
SER	sequence of event recorder
SF	supply fan
S/F	smoke and fire (detector)
SFC	sequential function chart or system function configuration or static frequency converter
SFD	system flow diagram or start of frame delimiter
SFF	safe failure fraction
SFI	sight flow indicator
SFR	spurious failure rate
SG or SpG	specific gravity; also sp. gr.
S/H or S&H	sample and hold
SH	superheated or superheater
SHE	standard hydrogen electrode
SHS	sample handling system
SI	system international
SIC	speed indicating controller
SID	system identification digit (number)
SIF	safety instrumented function
SIG	special interest group
SIL	safety integrity level
sin	sine, trigonometric function
SIS	safety instrumented system
SISO	single-input single output
SKU	stock keeping units
SLAMS	state and local air monitoring stations
SLC	safety life cycle or single loop controller
slph	standard liters per hour
slpm	standard liters per minute
SMC	sliding mode control
SMCr	sliding mode controller
SMR	specialized mobile radio
SMTP	simple mail transfer (management) protocol
S/N	signal-noise (ratio)
SNCR	selective non-catalytic reduction
SNG	synthetic natural gas
SNMP	simple network management protocol
SNR	signal-to-noise ratio
SNTP	simple network time protocol
SOA	safe operation area
SOAP	simple object access protocol (an Internet protocol that provides a reliable stream-oriented connection for data transfer)
SOE	sequence of events
SOER	sequence of events recorder
SOFA	secondary over fire air
SOFC	solid oxide fuel cell
SONAR	sound navigation ranging
SOP	standard operating procedure
SP	set point or Smith predictor
SPC	statistical process control
SPDT	single pole double pole throw (switch)
Sp. G or sp. gr.	specific gravity; also SG
Sph	starts per hour
SPI	serial peripheral interface
SPL	1) sound pressure level or 2) sound power level
SPR	set-point rate
SPRT	standard platinum resistance thermometer
SPST	single pole single throw (switch)
Sq	square
SQC	statistical quality control
SQL	structured (or standard, or sequential) query language
Sr	steradian, symbol for SI unit of solid angle measurement
SRD	send and request data with reply
SRS	safety requirements specification
SRV	safety relief valve
SS	stainless steel or selector switch
SSB	single side band
SSC	solid state contactor
SSE	size scale effect
SSF	Saybolt seconds furol
SSL	secure socket layers
SSR	solid state relay
SSU	Saybolt seconds universal
ST	structured text or steam turbine
STC	self-tuning controller
std.	standard
STEL	short term exposure limit
STEP	standard for the exchange of product model data
STG	steam turbine generator
STIG	steam injection gas turbine
Stm.	steam
STP	shielded twisted pair or standard temperature and pressure, corresponding to 70°F (21.1°C) and 14.7 psia (1 atm. Abs.)
STR	spurious trip rates or self-tuning regulator
SU	security unit or component in leg has failed safe and failure has not been detected
SUS	Seybold universal seconds or stochastic uniform selection
SV	secondary variable or safety valve or solenoid valve
S/W or SW	software
SWIR	short wave infrared
s^2_y	sample variance of output *y*

T

t	1) ton (metric, = 1000 kg); 2) time; 3) thickness
T	1) temperature; 2) tera, prefix meaning 10^{12}; 3) period (= 1/Hz, in seconds); 4) tesla, symbol for derived SI unit of magnetic flux density, webers per square meter, Wb/m2
$T^{1}/_{2}$	half life
TAH	temperature alarm, high
TAL	temperature alarm, low
Tan	tangent, trigonometric function
Tanh	hyperbolic tangent
TAS	thallium-arsenic-selenide
Tau	process time constant (seconds)
TBM	tertiary butyl mercaptan
TBP	true boiling point
t/c	thermal coefficient of linear expansion
TC	thermocouple, temperature controller or total carbon
TCAM	timer/counter access modules
TCD	thermal conductivity detector
TCI	track command in
TCO	track command out
TCP	transmission control protocol
TCP/IP	transmission control protocol/Internet protocol
TCV	temperature control valve
t_d	process dead time (seconds)
T_d	derivative time (in seconds) of a PID controller
TD	time delay
TDLAS	tunable diode laser absorption spectroscopy
TDM	time division multiplexing
TDMA	time division multiple access
TDP	dew point temperature
TDR	time domain reflectometry
TE	temperature element
T/E	thermoelectric
TEM	transmission electron microscope
TFELD	thin film electroluminescent display
TFT	thin film transistor
TG	thermogravimetry
TGQ	total gas supply
TH	upper limit of comfort zone
THC	total hydrocarbon
THR	total heat release
Ti	integral time (in seconds) of a PID controller
TI	test interval (time interval between tests) or temperature indicator
TIC	temperature indicating controller or total inorganic carbon
TIFF	tagged image file format
TISAB	total ionic strength adjustment buffer
TL	lower limit of comfort zone
TLV	threshold limit value
TMP	1) thermo-mechanical pulp; 2) transmembrane pressure
TMR	triple modular redundancy
TMT	tube metal temperature
TN	total nitrogen or twisted nematic
t_o (t_d)	process dead time (seconds)
TOC	total organic carbon
TOD	total oxygen demand
TOF	time of flight
TOP	technical and office protocol
TP	turbine protection
TPD	tons per day
TQM	total quality management
TR	temperature recorder or time delay relay
T/R	transmit/receive
TRC	temperature recording controller
TRI	track reference in
TRO	track reference out
T.S.	tensile strength
TSA	temperature swing adsorption
TSH	temperature switch, high
TSL	temperature switch, low
TSM	thermal stress monitoring
TSR	terminate and stay resident
TT	temperature transmitter or transit time
TTC	tungstram titanium carbide or time to close
TT&C	telemetry, tracking and command
TTFM	transit time flow measurement
TTL	transistor-transistor logic or time to live
TTO	time to open
TTP	through the probe
t_u	ultimate period
TV	tertiary variable
°Tw	Twadell degrees of liquid density
TWA	time weighed average
TWB	wet bulb temperature
TWM	technical working method
TY	temperature relay
τ (Tau)	process time constant (seconds)
τF	PV filter time constant F

U

u	prefix = 10^{-6} when the Greek letter μ is not available
UART	universal asynchronous receiver transmitter
UBET	unbiased estimation
UCMM	unconnected message manager
UDP	user/universal data/datagram protocol
UEL	upper explosive limit
UF	ultra filtration
$u_{fb}(k)$	feedback controller output
UFD	utility flow diagram
$u_{ff}(k)$	feedforward controller output
UFL	upper flammable limit
UGS	underground gas storage
UHF	ultra high frequency
UHSDS	ultra high speed deluge system
u(k)	controller output

UML	universal modeling language
UPS	uninterruptable power supply
UPV	unfired pressure vessel
URL	upper range limit
URV	upper range value
USART	universal synchronous/asynchronous receiver transmitter
USB	universal serial bus
USL	upper specification limit
USV	unloading solenoid valve
UTP	unshielded twisted pair
UTS	ultimate tensile stress
UUP	unshielded untwisted pair
UV	ultraviolet
UVS	uninterruptible voltage supply
UV-VIS-NIR	ultraviolet-visible-near infrared

V

v	velocity
v or V	volt, symbol for derived SI unit of voltage, electric potential difference and electromotive force, watts per ampere, W/A
VA	vertical alignment
Vac	a.c. voltage
VAV	variable air volume
VBA	visual basis for applications
VCO	voltage controlled oscillator
VCR	virtual communication relationship
VDC	volts DC
VDF	vacuum fluorescent display
VDT	video display tube
VDU	video display unit or visual display unit
vert.	vertical
VF	vacuum fluorescent
VFD	variable frequency drive or vacuum fluorescent display or virtual field device
VFIR	very fast infrared
VHF	very high frequency
VIS	visible
V-L	vapor–liquid (ratio)
V/M	voltmeter
VME	Virsa Module Europe (IEEE 1014-1987)
VMS	vibration monitoring system
VOC	volatile organic compounds or volatile organic carbon
VP	valve position
VPA	valve position alarm
VPC	valve position controller
VPN	virtual private network
VPS	valve position switch
VR	virtual reality
VRL	very low frequencies
VRML	virtual reality modeling language
vs.	versus
VSA	vacuum swing absorption
VSD	variable speed drive
V&V	verification & validation
VVVF	variable voltage variable frequency drive

W

w	1) width; 2) mass flow rate
W	1) watt, symbol for derived SI unit of power, joules per second, J/s; 2) weight; also wt water; 3) water
WAN	wide area network
Wb	weber, symbol for derived SI unit of magnetic flux, volt · seconds, V · s
WCOT	wall coated open tubular (column)
WDXRF	wavelength dispersion x-ray fluorescence
WF	weighing factor
WFS	water flow switch
WG	standard (British) wire gauge
Wh	white (wiring code color for AC neutral conductor)
WI	Wobble Index
WLAN	wireless local area network
WPAN	wireless personal area network
WS	work station
wt	weight; also W

X

x	molar fraction of light component in bottom product
X	reactance in ohms
XLS	limit switch
XML	eXtensible markup language
XP	blade pitch position
x-ray	electromagnetic radiation
XRF	x-ray fluorescence
XSCV	superheat control valve
XSET	start-up setting
XYZ	tri-stimulus functions

Y

Y	expansion factor, or molar fraction of light component in distillate
y(k)	process output
yd	yard (= 0.914 m)
yr	year

Z

z	molar fraction of light component in feed
Z	1) atomic number (proton number); 2) electrical impedance (complex) expressed in ohms
ZAFC	zinc air fuel cells
ZC	position controller
ZEB	zero energy band
ZIC	position indicating controller
ZOH	zero order hold
ZSC	limit switch – closed

ZSCO	limit switch – closed/open
ZSO	limit switch – open
ZSRG	zero signal reference grid
ZT	position transmitter or zone temperature
∂	partial derivative

MISCELLANEOUS LETTER SYMBOLS

α (alpha)	1) geometric angle; 2) radiation particle (helium atom); 3) linear expansion coefficient; 4) average relative volatility between the key components across the column
β (beta)	radiation particle (electron)
γ (gamma)	1) electromagnetic radiation; 2) surface tension; also σ (sigma)
Δ (delta)	difference, change or deviation from a steady-state condition
ε (epsilon)	1) emmissivity; 2) linear strain, relative elongation $\varepsilon \times \Delta 1/1^\circ$
η (eta)	1) efficiency; 2) viscosity (absolute); also μ
θ (theta)	thermal resistance
λ (lambda)	1) thermal conductivity; 2) wavelength; 3) relative gain
Λ (lambda)	relative gain array
μ (mu)	1) viscosity (absolute); also η; 2) linear attenuation coefficient; 3) prefix, micro = 10^{-6}; also u; 4) mμ: millimicron (10^{-9} m)
μm	micron (10^{-6} m)
ν (nu)	viscosity, kinematic
π (pi)	1) surface pressure; 2) constant = 3.1416…
ρ (rho)	1) density; 2) resistivity
σ (sigma)	1) surface tension; also γ; 2) conductivity; 3) normal stress; 4) nuclear capture cross section
Σ (sigma)	summation
τ (tau)	1) time delay; 2) shear stress; 3) time constant
ω (omega)	angular velocity expressed in radians per second
Ω (omega)	ohm
ϕ	diameter, also dia and D
~	alternating current
′	minute, angular or temporal
″	second, angular
$\perp$	perpendicular to, normal to
$\|$	parallel
%	percent; also pct

GREEK ALPHABET

Α, α	alpha
Β, β	beta
Γ, γ	gamma
Δ, δ	delta
Ε, ε	epsilon
Ζ, ζ	zeta
Η, η	eta
Θ, θ	theta
Ι, ι	iota
Κ, κ	kappa
Λ, λ	lambda
Μ, μ	mu
Ν, ν	nu
Ξ, ξ	xi
Ο, o	omicron
Π, π	pi
Ρ, ρ	rho
Σ, σ	sigma
Τ, τ	tau
Υ, υ	upsilon
Φ, ϕ	phi
Χ, χ	chi
Ψ, ψ	psi
Ω, ω	omega

W. P. DURDEN (1995) **H. EREN** (2005)

Types: Analog and digital instruments

Costs: A few dollars to thousands of dollars depending on functionality and complexity

Sensors: Common sensors for both types; additionally, IC (integrated circuitry) and intelligent sensors for digital instruments

Components: Purely analog components for analog instruments; analog and digital components and microprocessors for digital instruments

Displays: Needle indicator for analog instruments, numeric light emitting diode (LED) or liquid crystal display (LCD) for digital instruments

Communications: Wired (e.g., 20 mA) for analog instruments; wired, RF, microwave, optical, sonic, etc. for digital instruments

Networking: Limited network capabilities for analog instruments; unlimited capabilities for digital instruments

INTRODUCTION

Instruments are manmade devices that measure the parameters of physical variables. They may be analog, digital, or a combination of the two. Nowadays, most instruments are digital because of their advantages over analog counterparts. However, the front ends of many instruments are still analog; that is, most signals from sensors and transducers and the first stage of signal processing are still analog. Nevertheless, it is important to mention that in recent years digital instruments operating purely on digital principles have been developing fast. Today's smart sensors based on digital principles contain the complete signal condition circuits and the sensors in a single chip. The outputs of smart sensors can directly be interfaced with other digital devices.

Sensors and transducers are the most basic and primary elements of all instruments. They respond to physical variations to produce continuous outputs that convey useful information. The outputs may be in the forms of amplitudes, frequencies, or phase differences of currents, voltages, power, or energy. As in the case of all signal-bearing systems, in both analog and digital instruments, there are useful signals that respond to the physical phenomena and unwanted signals that are imposed as various forms of noise.

In the last 10 to 15 years or so, due to rapid progress in integrated circuit (IC) technology and the availability of low-cost analog and digital components and microprocessors, considerable progress in digital instruments has taken place. Therefore, this section will concentrate primarily on digital instruments. However, signals and signal processing will be introduced first since they are common to both types of instruments. In the following sections, the underlying principles of analog and digital instruments will be discussed separately, some examples will be given, and a comparison between the two will be provided at the end of the chapter.

AN OVERVIEW OF SIGNALS AND SIGNAL PROCESSING

All instruments operate on signals detected by sensors from physical phenomena. One of the main differentiators between analog and digital instruments is the signal processing, which requires different theoretical approaches and hardware. The signals generated by sensors can be processed in three different ways:

1. By analog techniques that directly deal with analog signals
2. By converting analog signals into digital forms and implementing the systems as digital instruments
3. By dealing with the signals purely in digital forms as digital-to-digital inputs and outputs

A *signal* is defined as "any physical quantity that varies with time, space, or any other independent variable." Most signals occurring in real world are analog in nature, i.e., they provide a continuous stream of information about the physical quantity. Common electrical signals include variations in voltages, currents, frequencies, electric and magnetic properties, phase relations, etc. On the other hand, the physical phenomena may be temperature, position, sound, vibration, chemical reactions, biological activity, light intensity, and so on.

Analog signals are processed by *analog signal processing* techniques, which can be described as a body of theoretical and practical methods that can be implemented. These techniques include but not restricted to amplifying, filtering, transmitting, estimating, detecting, modulating, demodulating, analyzing, displaying, and reproduction of signals. On the other hand, due to easy and cost-effective availability of advanced microprocessors and the supporting components, the majority of modern instruments are digital and require *digital signal processing*. Digital systems provide powerful processing and data handling capabilities simply by software and/or firmware implementations. Also, once the signals are converted to digital formats, they can be managed by any computer or digital system. This provides a wide range of possibilities for data processing, communications, storage, and visual displays.

CONTINUOUS AND DIGITAL SIGNALS

Continuous signals, also known as analog signals, are defined for every value of time from $-\infty$ to $+\infty$. Continuous signals can be periodic or nonperiodic. In periodic signals, the signal repeats itself in an oscillatory manner, e.g., the sinusoidal waveform (as in Figure 1.1m), which can be expressed as:

$$x(t) = X_m \sin(\omega t) \quad -\infty < t < \infty \qquad \textbf{1.1(1)}$$

where $x(t)$ is a time-dependent signal, $\omega = 2\pi ft$ is the angular frequency, and X_m is the maximum value.

The signals can be periodic but not necessarily sinusoidal; for example, they may be triangular, sawtooth, or rectangular waveforms. The periodic signals can be expressed as a combination of pure sinusoidal waveforms known as the *Fourier series.* That is:

$$\begin{aligned} x(t) = X_0 + X_1 \sin(\omega_1 t + \phi_1) + X_2 \sin(\omega_2 t + \phi_2) + \cdots \\ + X_n \sin(\omega_n t + \phi_n) \end{aligned} \qquad \textbf{1.1(2)}$$

where $\omega_1, \omega_2, \ldots, \omega_n$ are the frequencies (rad/s); $X_0, X_1, \ldots, X_n$ are the maximum amplitudes of respective frequencies; and $\phi_1, \phi_2, \ldots, \phi_n$ are the phase angles.

In Equation 1.1(2), the number of terms may be infinite, and the higher the number of elements the better the approximation. Nevertheless, high-frequency contents can have significant effect on digital signal processing, as will be explained next.

Digital Signals

Digital signals are arrays of numbers that are used in computational analysis of systems and signals. Digital signals can either be generated or directly be derived from analog signals using A/D (analog to digital) converters.

Analog-to-Digital In the A/D conversion process, analog signals are first sampled at discrete time intervals to obtain a sequence of samples that are spaced uniformly in time. This is achieved by multiplying a continuous signal by a periodic train of Dirac delta functions spaced T seconds apart. T represents the sampling period; its reciprocal is the sampling rate ($f_s = 1/T$). After the analog signals have been sampled, *quantization* is necessary to put the discrete-time signal into discrete numerical values. This is followed by *coding* to convert the quantized values to binary sequences.

For example, a discrete-time sinusoidal signal may be expressed in terms of sequences as:

$$x(nT) = A\sin(\omega nT + \theta), \qquad \textbf{1.1(3)}$$

where n is the integer variable termed the *sample number*, and T is the time interval between samples known as the *sampling period.*

The Fourier series representation of a periodic discrete-time signal $x(n)$ sequence is:

$$x(n) = \sum_{k=0}^{N-1} c_k e^{j2\pi kn/N} \qquad \textbf{1.1(4)}$$

where N is the fundamental period.

The coefficient c_k is given by:

$$c_k = \frac{1}{N}\sum_{n=0}^{N-1} x(n)\exp\left[\frac{-j2\pi kn}{N}\right] \qquad \textbf{1.1(5)}$$

The frequency-domain of discrete-time signals that are not necessarily periodic can be expressed in a discrete Fourier transform (DFT) as:

$$X(\omega T) = \sum_{n=-\infty}^{\infty} x(n)\exp[-j\omega nT] \qquad \textbf{1.1(6)}$$

and

$$x(n) = \frac{1}{2\pi}\int_0^{2\pi} X(\omega T)\exp[-j\omega Tn]d(\omega T) \qquad \textbf{1.1(7)}$$

These equations are essential in signal processing for digital instruments where analog-to-digital signal conversion takes place.

In all digital instruments, the Nyquist sampling theorem must be observed; that is, "the number of samples per second must be at least twice the highest frequency present in the continuous signal," Equation 1.1(2). As a rule of thumb, depending on the significance of the high frequencies, the

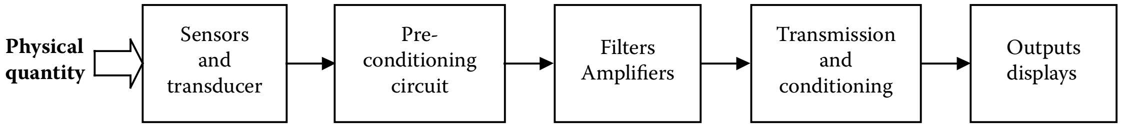

FIG. 1.1a
Functional blocks of an analog instrument.

sampling must be about 5 to 10 times the highest frequency component in the signal.

ANALOG INSTRUMENTS

Analog instruments are characterized by their continuous signals. A purely analog instrument measures, transmits, displays, and stores data in analog form. The signal processing is realized by analog components that are integrating together as functional blocks, as illustrated in Figure 1.1a. Some examples of functional blocks are bridges, amplifiers, filters, oscillators, modulators, offset circuits, level converters, and buffers.

Three basic components are common in all types of analog signal processing: resistors, capacitors, and inductors. The main function of a resistor is to limit the current. The current will flow through a capacitor only if the voltage changes across it. In the case of inductors, voltage is established only as a result of a change in the current across it. Other analog components, including semiconductor devices such as diodes, transistors, operational amplifiers, and rectifiers, are based on these three basic elements.

Two basic types of semiconductor devices exist: bipolar and metal oxide semiconductors (MOS). Many modern analog components and circuits are manufactured in integrated circuit (ICs). ICs contain all basic circuit components such as resistors, transistors, and diodes densely packed on silicon chips. The operational amplifier (op amp) is an example of an IC.

Operational amplifiers are fundamental building blocks of analog signal processing circuits. They are made either as integrated (monolithic) circuits or hybrid circuits (combination of monolithic and discrete parts). An op amp is made from hundreds of transistors, resistors, and capacitors in a single chip. It has two inputs (inverting and noninverting) and a single output. A good operational amplifier has the following properties:

- High input resistance, hundreds of megaohms or few gigaohms
- Low output resistance, less than few ohms or fraction of one ohm
- Low input offset voltage, a few millivolts or micro-ohms
- Low input bias current, a few picoamps
- Very high open loop gain, 10^4 to 10^6
- Low intrinsic noise
- High common mode rejection ratio (CMRR)
- Low sensitivity to changes in power voltage
- A broad operating frequency range
- High environmental stability

Operational amplifiers can be configured as inverting or noninverting amplifiers. In addition, they can perform many other functions, for example as multipliers, adders, limiters, and filters.

Another version of op amps is the instrumentation amplifiers, which are essentially high-performance differential amplifiers that consist of several closed loops within the chip. Instrumentation amplifiers are used extensively in applications where sensor signals are extremely weak and noisy. An instrumentation amplifier has improved CMRR (up to 160 dB), high input impedances (e.g., 500 MΩ), low output impedance, low offset currents and voltages, and better temperature characteristics than common op amps do.

ANALOG SIGNAL PROCESSING

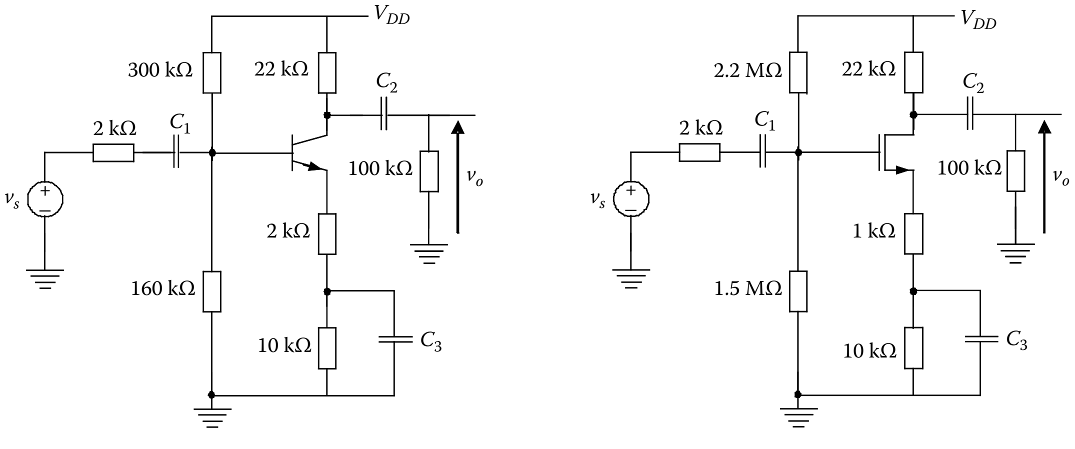
A small number of the most essential functional blocks necessary for analog signal processing, such as amplifiers, adders, integrators, filters, modulators, and demodulators, will be explained next.

Amplifiers An amplifier is a device that provides amplification of the input signal in terms of voltage, current, or power. Many different types of amplifiers exist, including voltage, power, current, transconductance, and transresistance amplifiers, and, in terms of frequency range, audio (15 Hz to 20 kHz), radio frequency (RF = 20 kHz to 0.1 GHz), and video (10 Hz to 6 MHz) amplifiers. As an example, Figure 1.1b illustrates two single-transistor amplifiers, bipolar and MOSFET (metal oxide semiconductor field effect transistor). See Figure 1.1b.

Adders An adder (summer) is a circuit, based on op amps, whose output is the weighted algebraic sum of all its inputs. In the case of the voltage adder, in Figure 1.1c, inputs V_1, V_2, and V_3 are added to give an inverted output, that is:

$$V_0 = -\frac{R_0}{R_1}V_1 - \frac{R_0}{R_1}V_2 - \frac{R_0}{R_1}V_3 \qquad \mathbf{1.1(8)}$$

More inputs can be connected without affecting the response of the existing inputs since the inverting input is held at a virtual ground by the feedback mechanism.



(a) (b)

FIG. 1.1b
Single-transistor amplifiers: (a) bipolar common-emitter, (b) MOSFET common source.

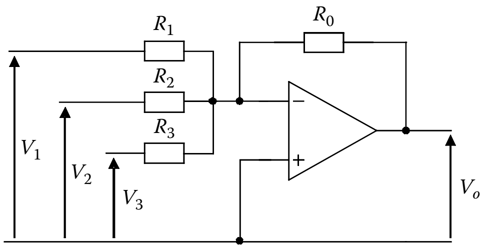


FIG. 1.1c
An adder with three inputs.

Integrators An integrator can be defined as a circuit whose output rate of change is proportional to the applied input. The output of an integrator for an input V_i is:

$$\frac{dV_0}{dt} = kV_i \quad \text{or} \quad V_0 = k\int V_i dt \qquad \mathbf{1.1(9)}$$

This equation shows that the output V_o is obtained by integration of the input V_i. Figure 1.1d illustrates an integrator based on an op amp. The integrator is an important building block in the design and implementation of active filters.

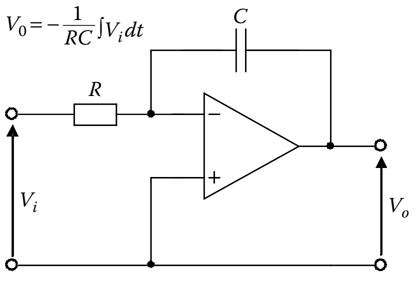

FIG. 1.1d
An integrator.

Differentiators can be obtained by changing the positions of R and C.

Filters Analog filters are essential parts of both analog and digital instruments. They are used to extract the useful information from the sensors, as most sensors generate broadband signals containing various forms of noise. Filters are useful for the elimination of external and internal noise that interferes with operation of an instrument.

There are two basic types of analog filters, passive and active. Passive filters are made from purely passive components, such as resistors, capacitors, and inductors. Active filters contain active elements such as op amps in addition to the passive components. The filters can be configured to be low-pass, high-pass, band-pass and band-stop, or notch filters. The subject of filters is an important but vast topic; therefore, some limited detail is provided below.

Low-Pass Active Filters A typical example of a low-pass filter is given in Figure 1.1e. In the process of an active low-pass filter design, the cutoff frequency of the filter must be determined first. The cutoff frequency is the frequency at which the gain of the filter is about –3 dB.

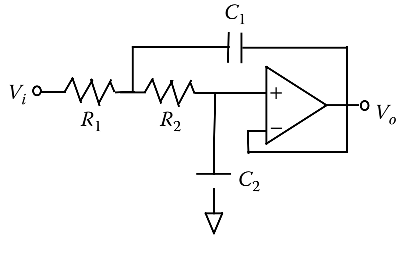

FIG. 1.1e
A low-pass filter.

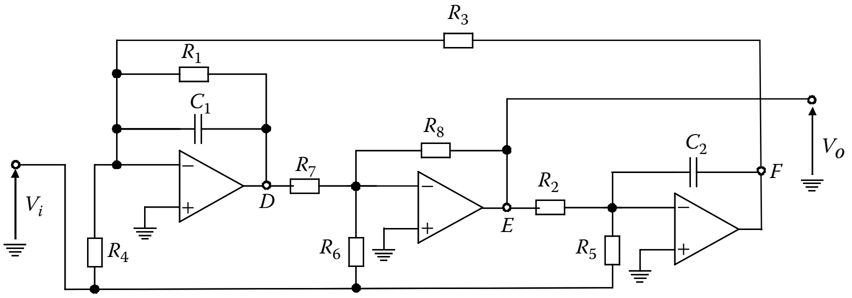

FIG. 1.1f
A three-amplifier biquad filter.

The choice of resistors in filters is critical. As a rule of thumb, resistors R_1 and R_2 are selected as 25 kΩ for a 10 kHz or 250 kΩ for 100 Hz filter. The values of capacitors can be calculated for the selected frequency by substituting the selected resistance values. The calculations are repeated to obtain the nearest available capacitors by changing the resistor values.

High-Pass Active Filters High-pass active filters are analogous to low-pass filters and pass only high frequencies.

Band-Pass or Band-Stop Active Filters A straightforward way of building a band-pass or a band-stop filter is by combining low-pass and high-pass filters in cascaded form.

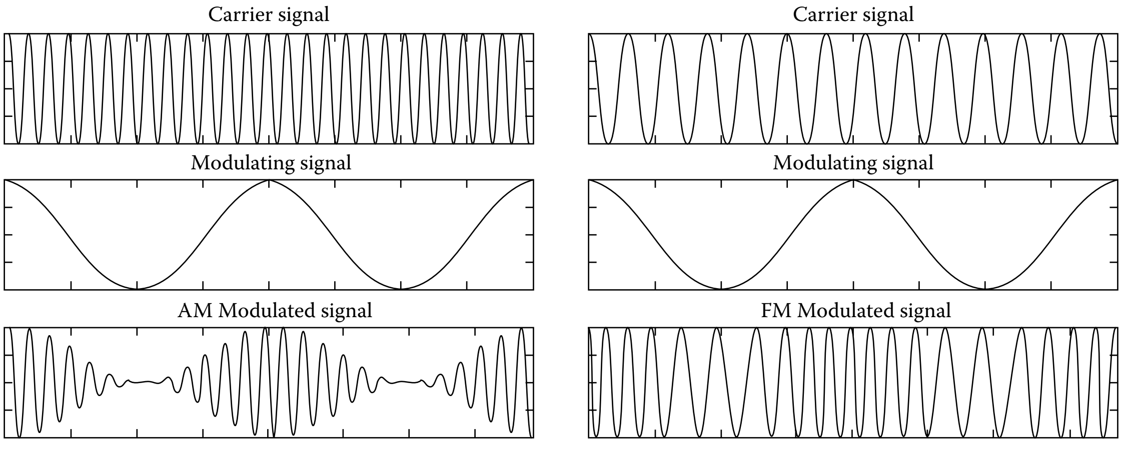
Notch Filters These filters are usually used to suppress single sharp frequencies such as 50 Hz. The best performance is obtained by adjusting component values while monitoring the circuit performance on an oscilloscope.

Various design techniques are used to configure analog filters. Some of these design techniques include Butterworth, Chebyshev, and Bessel–Thomson filters. The complexity of filters increases as the order of the filter (number of poles) increases. A typical complex active filter is illustrated in Figure1.1f.

Modulators and Demodulators In many electronic systems, modulations and demodulations are essential for allowing convenient and efficient transmission and reception of information. Basically, *modulation* is the process of encoding information on a carrier signal such that its amplitude, frequency, or phase varies with the message signal, known as the modulating signal. There are three types of modulation: amplitude modulation (AM), frequency modulation (FM), and phase modulation. Examples of AM and FM are illustrated in Figure 1.1g. *Demodulation* is the process by which information is extracted from the carrier signal.

APPLICATION AND EXAMPLES OF ANALOG INSTRUMENTS

Analog instruments are used in many applications where digital readouts are required. Examples of such applications are control panels, testing systems, manufacturing and production equipment, dashboards in all types of transportation



(a)

(b)

equipment, laboratories, explosion-proof areas, consumer products, and machinery. A typical example of analog instruments is the multimeter, as illustrated in Figure 1.1h.

DIGITAL INSTRUMENTS

In most modern instruments, the original analog information acquired from a physical variable is converted to digital form to obtain a digital instrument. Analog-to-digital (A/D) converters are used for signal conversion together with appropriate multiplexers and sample-and-hold devices. The multiplexers enable the connection of many sensors and transducers to the same signal-processing media. The typical building blocks of a digital instrument are illustrated in Figure 1.1i.

Digital systems are particularly useful in performing mathematical operations, numeric displays, and storing and transmitting information. Digital instruments consist of three essential subsystems: converters, general-purpose processors together with mass storage and communication peripherals, and application-specific software. In this section, some essential features of digital instruments will be discussed, including signal conversion, intelligent and IC sensors, basic hardware, inputs and outputs, communications and networks, virtual instruments, and software.

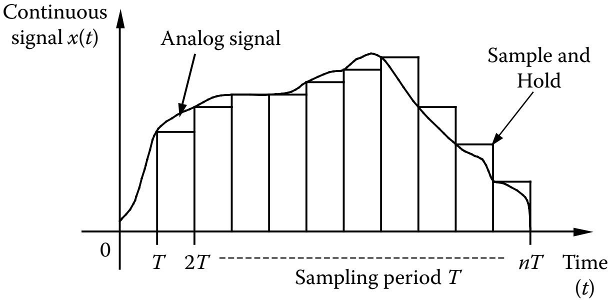

FIG. 1.1j
Analog-to-digital conversion process.

Signal Conversion

Analog-to-Digital Conversion Analog-to-digital (A/D) and digital-to-analog (D/A) converters are used to interface the analog environment (the real world) and the digital environment. Analog signals obtained from a myriad of real-world sources, including temperature, motion, sound, and electrical signals, are converted to digital forms by A/D converters. After the conversion, the signals are processed using many different algorithms such as digital filters and statistical techniques. When necessary, the processed signals then can be converted back to analog forms to drive devices requiring analog inputs such as mechanical loads and sound speakers.

A/D conversion involves three stages: sampling, quantization, and encoding. Once the analog signals are sampled, quantization takes place to determine the resolution of the sampled signals. In coding, the quantized values are converted to binary numbers. Figure 1.1j illustrates a typical A/D conversion process of an analog signal.

All modern A/D converters produce digital output values in the integer format. These can be in binary codes or the twos-complementary form. The length of the output word defines theoretical resolution of the A/D converter and the ranges that an A/D converter can produce. The smallest change in the input voltage (V_{LSB}) that A/D can convert is:

$$V_{LSB} = \frac{V_{\max} - V_{\min}}{2^n} \qquad \textbf{1.1(10)}$$

where n is the number of bits produced by the A/D converter and $V_{\max}$ and $V_{\min}$ are the maximum and minimum input voltages that an A/D converter can handle correctly.

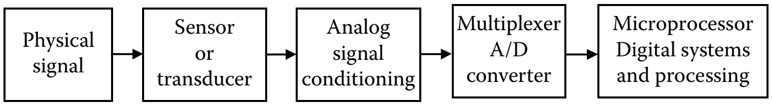

FIG. 1.1i
Basic building blocks of a digital instrument.

Due to a diverse range of application requirements, many different types of A/D converters exist. The most popular are counter ramp, successive approximation (serial), flash (parallel), and delta–sigma (Δ/Σ) converters.

Quantization A number of quantization methods exist, one of which is *amplitude quantization*, defined as the process by which a signal with a continuous range of amplitudes is transformed into a signal with discrete amplitudes. In this method, the process is usually memoryless; that is, the quantizer does not depend on previous sample values to predict the next value. Although this is not an ideal solution, it is commonly used in practice.

The precision of the quantizer is limited by the number of discrete amplitude levels available to approximate the continuous signal amplitudes. These levels are referred to as representation or reconstruction levels, and the spacing between two representation levels is called the *step size.* Quantization, like sampling, introduces some degree of uncertainty in the value of the analog signal. For A/D converters with large number of bits (8 bits or more) this effect can modeled as an additive noise. The amount of quantization noise relative to the signal, or Signal-to-Noise Ratio (SNR), depends on the nature and magnitude of the input signal. Quantization noise can be both nonlinear and signal dependent. However, provided that the step size is sufficiently small, it is reasonable to assume that the quantization error is a uniformly distributed random variable and its effect is similar to that of thermal noise.

In addition to quantization noise, A/D converters have other sources of noise, such as internal voltage reference noise and thermal amplifier noise. In practice, most converters rarely achieve their theoretical noise floor. Therefore, when selecting an A/D converter, one uses the number of bits of converter as a rough estimate of its resolution. Nevertheless, in practical applications, a close examination of the converter specifications should reveal its true performance.

Coding Coding is a process of representing the finite output states of the quantizer by a sequence of *n* bits. The codes formed using bits are normally known as *binary codes* and can be of two types: unipolar and bipolar.

Unipolar codes are used to represent unipolar quantities, that is, quantities with a predefined sign (positive or negative). The most common unipolar codes are *natural binary, BCD* (Binary-Coded Decimal), and the *Gray Code.* In order to illustrate the coding process, the natural binary code is described below.

In the natural binary code, each bit of a number represents a successive power of two according to the position that the bit occupies. Given a number of *n*-digits (represented by D_{n-1}, D_{n-2}, … D_1 and D_0), the value of the number is determined by the following expression:

$$D_{n-1}D_{n-2}\dots D_1D_0 = D_{n-1}\times 2^{n-1} + D_{n-2}\times 2^{n-2} + \cdots + D_1\times 2^1 + D_0\times 2^0 \qquad \mathbf{1.1(11)}$$

D_{n-1} is the Most Significant Bit (MSB), and D_0 is the Least Significant Bit (LSB).

However, the output code of an A/D converter is normally interpreted as a fraction of its Full Scale (FS) value, which is considered as the unit. So the binary codes from an A/D conversion process must be interpreted in fractional numbers, which is equivalent to dividing the value of each bit by 2^n.

Digital-to-Analog Converters Analog signal generation from the digital world may be part of the measurement process or may be required for control or sensor stimulation purposes. Digital signals are converted to analog waveforms by D/A converters and must be filtered and amplified before being applied to the appropriate output transducers. However, some new types of instrumentation now deal exclusively with digital signals. These include logic and computer network analyzers, logic pattern generators, and multimedia and digital audio devices. Such instruments usually include high-speed digital interfaces to move data in and out of the instrument at high speeds.

Digital information requires digital-to-analog converters (D/A) for the conversion of the binary words into appropriately proportional analog voltages. A typical D/A converter consists of three major elements:

1. Resistive or capacitive networks
2. Switching circuitry, operational amplifiers, and latches
3. A reference voltage

Also, an important requirement is the switching of the reference voltage from positive to negative for bipolar signals.

Intelligent and IC Sensors

In recent years, progress in electronic instruments has been making a major turnaround due to the availability of IC sensors in the form of micro- and nanosensors. Most of these sensors are smart sensors that have intelligence due to integration of complex digital processors into the same chip. A general scheme of a smart sensor is illustrated in Figure 1.1k. In this particular example, the sensor is under a microprocessor control. Excitation is produced and modified depending on the required operational range. The processor may contain

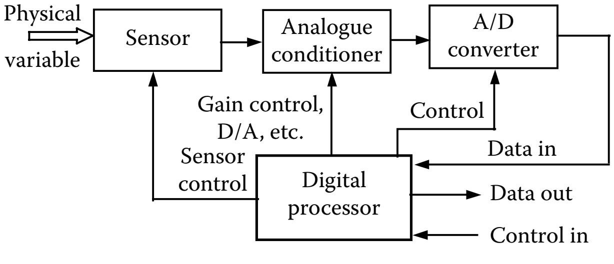

FIG. 1.1k
General form of smart sensors.

full details of the transducer characteristics in ROM (read only memory) enabling the correct excitation, gain, and so on.

Basic Hardware

Microprocessors and micro-controllers constitute the heart of almost all types of modern digital instruments and instrumentation systems. They play an important role in data acquisitions, data processing, and control. The applications of microprocessors and micro-controllers in instruments and instrumentation systems can be categorized according to the following roles:

1. *Data handling* functions that include data acquisition, data processing, information extraction, data compression, interpretation, recording, storage, and communication
2. *Instrumentation control,* which includes sensors, actuators, system resources, and process controls
3. *Human-machine interface,* one of the significant roles of digital systems, to provide a meaningful and flexible user interface to the operators for ergonomic information and control display
4. *Experimentation and procedural development,* consisting of commissioning, testing, and general prototyping of the targeted system under investigation

Micro-controllers and digital signal processors are special microprocessors that have built-in memory and interface circuits within the same IC. Due to smaller sizes, simplicity and low cost, and power efficiency, micro-controllers are commonly used in electronic instruments and the associated instrumentation systems. Therefore, in this section, detailed information on micro-controllers will be provided.

Micro-Controllers Many micro-controllers are single-chip devices that have memory for storing information and are able to control read/write functions and manipulating data. The performance of a micro-controller is classified by its size, that is, the number of bits that the CPU (central processing unit) can handle at a time. Many types or families of micro-controllers are offered by a diverse range of manufacturers. Therefore, in order to select appropriate micro-controllers for a specific task, it is vital to understand the differences in the characteristics of different families.

The software for micro-controllers to perform specific tasks can be written in either assembly codes or high-level languages such as Basic or C. The program written in other digital devices can be downloaded into the system memory through the serial communication port of the micro-controller. All high-level programs are compiled into machine language for execution. Significant numbers of compilers are available on the market for the different families of micro-controllers.

Digital Signal Processors Digital signal processors (DSPs) are specialized microprocessors that involve partial computer architecture and fulfill fast operational needs. A simplified block diagram of a typical DSP processor is given in Figure 1.1l.

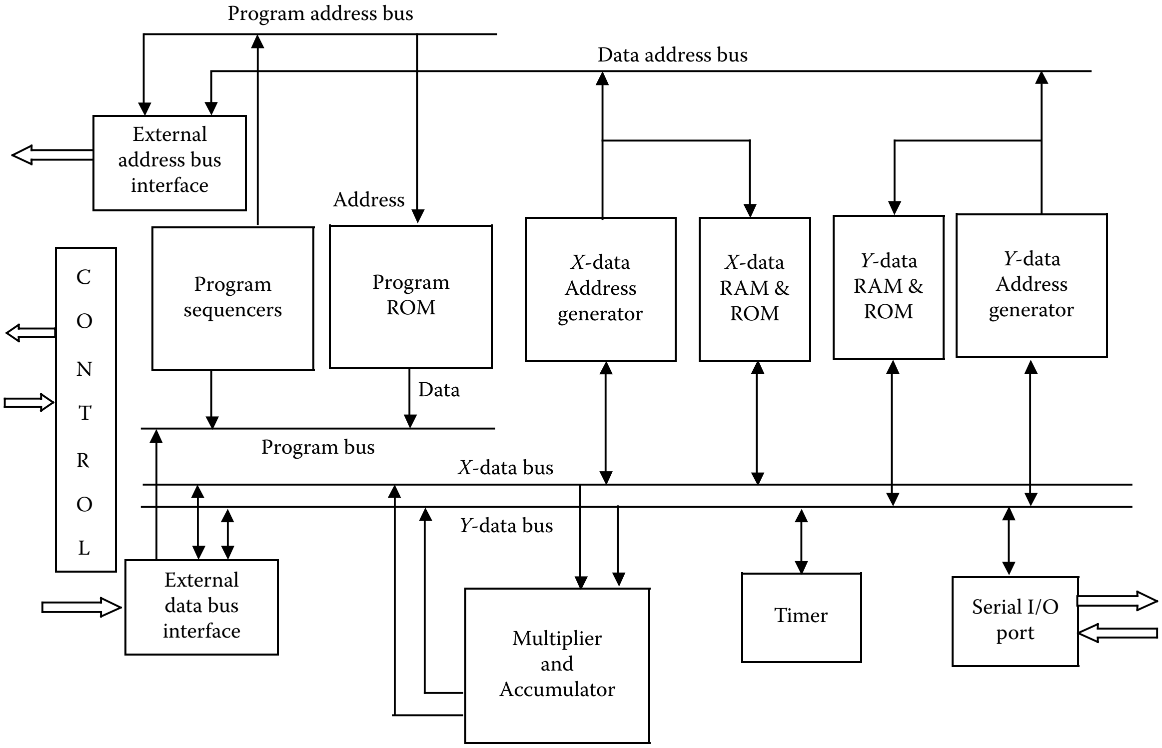

FIG. 1.1l
Block diagram of a typical DSP.

DSPs incorporate special hardware features that are capable of speeding up calculation of digital filters, fast Fourier transforms (FFTs), and other frequency-based algorithms. Modern general-purpose microcomputers can also address the needs of digital signal processing if some of the necessary hardware and special instructions are added. As a result, the distinction between the DSP processor and microprocessors, in general, is in the degree of specialization. This particular DSP has two data memories, denoted as X and Y (Figure 1.11). For the implementation of signal processing, say in a finite impulse response (FIR) filter, X-memory can be used to store the samples of input signals and Y-memory to store the impulse response.

One of the main characteristics of the DSP processors is the capability of handling integers for which they are designed. Most of the existing DSP processors are either 16- or 32-bit devices. For example, the Motorola DSP56300 processors are 24-bit integer processors that offer a compromise between inexpensive 16-bit and powerful 32-bit devices.

Inputs and Outputs

The data communication between micro-controller and outside world is realized through input and output (I/O) pins. The format of data transmission of a micro-controller can be universal asynchronous receiver transmitter (UART) — a port adapter for asynchronous serial communications. A diverse range of I/O hardware and software is available. Some of these I/Os suitable for instruments and instrumentation systems are explained below:

1. *Universal Synchronous/Asynchronous Receiver Transmitter (USART)*—a serial port adapter for either asynchronous or synchronous serial communications. Communications using a USART are typically much faster than those using UARTs.
2. *Synchronous serial port*—Synchronous serial ports are used to communicate with high-speed devices such as memory servers, display drivers, additional A/D ports, etc. In addition, they are suitable to implement simple micro-controller networks.
3. *Serial Peripheral Interface (SPI)* (Motorola) — A synchronous serial port functioning as an enhanced UART.
4. *I^2C bus—Inter-Integrated Circuit bus* (Philips)—is a simple two-wire serial interface that was originally developed for 8-bit applications. The I^2C bus is a two-line, multi-master, multi-slave network interface with collision detection. Up to 128 devices can be connected on the network, and they can be spread out over 10 m. The two lines of the network consist of the serial data line and the serial clock line. Each node on the network has a unique address, which accompanies any message passed between nodes. Since only two wires are needed, it is easy to interconnect a number of devices.
5. *Controller Area Network (CAN)* is a multiplexed wiring scheme that was developed jointly by Bosch and Intel for wiring in automobiles. The CAN specification is being used in industrial control in both North America and Europe.

Data-Acquisition Boards A data-acquisition board is a plug-in I/O board that allows the treatment of a set of analog signals by a computer. Thus, these boards are the key elements to connect a computer to a process in order to measure or control it. Data-acquisition boards normally operate on conditioned signals, that is, signals which have already been filtered and amplified by analog circuits. However, some data-acquisition boards can deal with the signals directly generated by sensors. These boards include all the necessary signal-conditioning circuits.

The number of analog inputs normally managed by a data-acquisition board is eight or 16. This system is made up of an analog multiplexer, an amplifier with programmable gain, a sample-and-hold circuit, and an A/D. All the elements of this system are shared by all the analog input channels. Some data-acquisition boards also offer analog outputs to carry out control operations. When available, the normal number of analog outputs is two.

In addition to analog inputs and outputs, data-acquisition boards also supply digital I/O lines and counters. Digital lines are used for process control and communication with peripheral devices. Counters are used for applications such as counting the number of times an event occurs or generating a time base.

Communications and Networks

In many applications, instruments are networked by computers to measure many variables of a physical process. The resulting arrangement for performing the overall measurement function is called the *measurement system.* In measurement systems, instruments operate autonomously but in a coordinated manner. The information generated by each device is communicated between the instruments themselves or between the instrument and other devices such as recorders, display units, base stations, or a host computer. Currently, the coordination of instruments is largely realized by digital techniques.

In digital instrumentation systems, the transmission of data between devices is realized relatively easily by using serial or parallel transmission techniques. However, as the measurement system becomes large by the inclusion of many instruments, communication can become complex. To avoid this complexity, message interchange standards are used, such as RS-232, USB, EIA-485, and IEEE-488.

For long-range data transmission, modem, microwave, or radio frequency (RF) media are selected. In these cases, various modulation techniques are used to convert digital signals to suitable formats. For example, most modems use frequency-shift keyed (FSK) modulation. The digital interface with modems uses various protocols such as MIL-STD-188C to transmit signals in simplex, half-duplex, or full duplex forms depending on the directions of the data flow. The simplex interface transmits data in one direction, whereas full duplex transmits it in two directions simultaneously.

In industrial applications, several standards for digital data transmission are available. These are commonly known in engineering literature as *fieldbuses*. Among many others, some of these standards, such as the WordFIP, Profibus, and Foundation Fieldbus, are widely accepted and used. The fieldbuses are supported by hardware and software (for example, National Instruments chips and boards) that allow increases in the data rates suitable with high-speed protocols.

Virtual Instruments and Software

Traditional instrumentation systems are made up of multiple stand-alone instruments that are interconnected to carry out a determined measurement or control an operation. Functionality of all these stand-alone instruments can be implemented in a digital environment by using computers, plug-in data-acquisition boards, and supporting software implementing the functions of the system. The plug-in data-acquisition boards enable the interface of analog signals to computers, and the software allows programming of the computer to look and function as an instrument. The systems implemented in this way are referred to as *virtual instrumentation systems.*

The major advantage of virtual instrumentation is its flexibility; changing a function simply requires modification of supporting software. However, the same change in a traditional system may require to adding or substituting a stand-alone instrument, which is more difficult and expensive. For example, a new analysis function, such as a Fourier analysis, can be easily added to a virtual instrumentation system by adding the corresponding software to the analysis program. However, to do this with a traditional instrumentation system, a new stand-alone instrument (for example, spectrum analyzer) would have to be added to the system.

Virtual instruments also offer advantages in displaying and storing information. Computer displays can show more colors and allow users to quickly change the format of displaying the data that is received by the instrument. Virtual displays can be programmed to resemble familiar instrument panel components, including buttons and dials. In Figure 1.1m, an example of a virtual display corresponding to a two-channel oscilloscope is shown. Computers also have more mass storage than stand-alone instruments do; consequently, virtual instruments offer more flexibility in data handling.

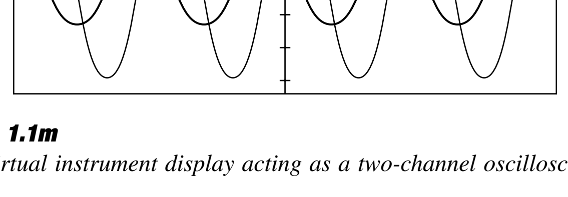

FIG. 1.1m
A virtual instrument display acting as a two-channel oscilloscope.

Software for Virtual Instruments To develop the software of a virtual instrumentation system, a programming language or special software can be used. However, the option of using a traditional programming language (C, for example) can generate several problems, including difficulty in programming the graphical elements and difficulty in learning the language.

Currently, a more utilized option is the Microsoft Visual Basic programming language, which runs under the Windows operating system. Visual Basic has become quite popular in the development of virtual instrumentation systems because it combines the simplicity of the Basic programming language with the graphical capabilities of Windows. Another important reason for its popularity is that it is an open language, meaning that it is easy for third-party vendors to develop products that engineers can use with their Visual Basic programs. Several companies now sell Dynamic Link Libraries (DLLs), which add custom controls, displays, and analysis functions to Visual Basic. The controls and displays mimic similar functions found on stand-alone instruments, such as toggle switches, slide controls, meters, and LEDs. By combining various controls and displays, any virtual instrument can easily be programmed.

A third option for developing virtual instrumentation systems is to use a software package specifically designed for the development of these systems, such as LabView or PC600. The crucial advantage of these packages is that it is not necessary to be a Windows programmer to use them. Several packages of this type exist, but only one, LabView by National Instruments, has reached great diffusion.

LabView is an entirely graphical language based on two concepts: the *front panel* and the *block diagram.* It is extendible, so new functional modules can be added to a program. The modules can also be written using general-purpose languages, such as C or C++. These languages provide great flexibility to program functions that perform complex numerical operations on the data.

The applications of virtual instruments are gaining momentum in instrumentation systems. Nowadays, palm and laptop computers are widely available and they can easily be equipped with commercial data-acquisition boards such as the PCMCIA interface cards. Together with a suitable interface, software, and sensors, these computers function just as any digital instrument would.

Application and Examples of Digital Instruments

Digital instruments have all the functionality of their analog counterparts and are used in all types of instrumentation systems. Modern digital instruments are rapidly replacing analog instruments due to advantages in communications, data handling, and networking capailities, as will be explained in the next section.

An example of digital instrumentation is a blood pressure recorder "Comparison of Analog and Digital Instruments,"

FIG. 1.1n
A digital ambulatory blood pressure recorder. (Courtesy of SunTech Medical, www.suntechmed.com.)

illustrated in Figure 1.1n. This wireless outdoor system operates on solar power. It measures temperature, humidity, pressure, wind speed and direction, and rainfall. A wireless link allows the transmission of data up to 48 km. Several instruments can be networked together.

COMPARISON OF ANALOG AND DIGITAL INSTRUMENTS

Digital hardware allows programmable operation; therefore, it is possible to modify the functions of an instrument through the software, which increases flexibility and reliability. However, it is worth mentioning that some signals with extremely wide bandwidths require intensive real-time processing in the digital environment. In these cases, analog instruments may be the only solution.

Many modern digital instruments have built-in intelligence; hence, they can make self calibrations, self diagnosis, and corrections in acquired data. A new trend is that calibrations of instruments can be conducted over the Internet by using appropriate sites of manufacturers and standards authorities.

Digital instruments are suitable in applications where multiple measurements are necessary, as in the case of process industry, for two main reasons:

1. Ease in communication and networking by means of remote communication methods such as RF, microwave, the Internet, and optical techniques
2. Availability of almost infinite memory for data storage

In digital instruments, however, converting an analog signal allows certain errors (for example, quantization error) to be introduced. The extent of error depends on the sampling rates and number of bits of the A/D converter. By the same token, digital instruments minimize the reading error that can occur in analog displays. Errors such as parallax and shadowing are also eliminated. Digital instruments also reduce the margin for error due to inaccurate interpolation. Analog meters can be very sensitive to movement or rough handling, while digital meters are immune to such dynamic effects.

One of the distinct advantages of analog instruments is the easy interpretation of displays. The operator can get an intuitive feel about the variables being measured at a glance. There is no such spatial reference with digital displays, which require mental interpretation. This requires an additional step in the thought process and also some familiarity with the equipment. This additional step of interpretation may not be tolerable in some applications, such as driving cars, where instantaneous decisions may need to be made. In addition, analog instruments are relatively cheaper for the same functionality due to their simplicity.

INTRODUCTION

The first use of digital computers was for acquiring data from the plant and logging that data without influencing plant operations. These systems were called data acquisition systems (DAS).

Supervisory control evolved, as the information collected by DAS was processed in order to generate optimal set points for the individual control loops. These set points were first sent to existing analog controllers and later to the digital control algorithms within DCS systems. This method of operation is called supervisory control, which these days often also incorporates optimization functions.

The discussion in this section will first cover the design when supervisory computers are operating with controllers, followed by a description of supervisory computers in combination with DCS systems.

HISTORY OF SUPERVISORY CONTROL

In 1957, the Ramo–Woodridge Corporation introduced the RW 300, the first solid-state digital computer designed for process control, at the National Meeting of the American Institute of Chemical Engineers in Los Angeles. The computer was designed based upon a magnetic drum containing 8064 words of 20-bit length. The external input/output supported 540 one-bit digital inputs, 1024 analog inputs, 540 digital outputs, and 36 analog outputs.

The RW 300 was designed to interface directly with the existing analog control system of a process. The role of this system was an enhancement to the existing process control instrumentation, and it functioned as a supervisory control device.

The software program consisted of models of the process in varying degrees of sophistication, which were updated based upon real-time data and then perturbed using optimization or maximization routines. These were usually simple linear programming algorithm perturbation routines. The models provided new sets of operating conditions (set points), which would improve the process performance according to some performance criteria. These new conditions were then outputted to the process. Essentially, the process was moved from one set of steady-state conditions to another in response to changes in such uncontrolled disturbances as feed characteristics, ambient conditions, heat transfer coefficients, and catalyst activity.

In spite of the seemingly small memory capacity of the RW 300 as compared to today's standards, the RW 300 was successfully installed in a number of sophisticated chemical and refinery processes. The very first process control system to be successfully installed was on the Texaco phosphoric acid polymerization unit at Port Arthur, Texas.

Within the next few years, several companies introduced their versions of the process control computer. These companies included IBM, General Electric, Foxboro, Control Data Corporation, and many others. The first process control computer to perform dynamic regulatory control of a process was installed at the Riverside Cement Company's Victorville plant in the United States and controlled two cement kilns and raw feed blending.

The first improvement in the field of the process control computer was an increase in magnetic drum capacity. Memory size first doubled to 16K, then 32K, and then kept rising. The next improvement in the process control computer design was the introduction of high-speed core memory, which increased the computational speed from milliseconds to microseconds. A giant leap in technology came with the replacement of solid-state circuitry (diodes, resistors, and transistors) with silicon integrated circuits. The new technology offered greatly increased speed, capacity, and most of all, reliability.

Another chapter in the evolution of the process control computer came with the development of direct digital control (DDC), wherein the function of the analog instrumentation was incorporated in the computer, and the analog controllers were thereby eliminated. The motivation was to reduce the control system cost and increase design flexibility for new processes. This new design concept initially met with mixed reviews, primarily because the computers—especially the software, which had become complicated—were not sufficiently reliable, and in most cases, when the computer went down, so did the process.

However, as minicomputers began to replace the old process control computers, it became economically feasible to provide redundancy by installing dual computers. This was frequently done. Then a major advancement came in 1976 when Honeywell announced the first distributed digital control system (DCS), named the TDC 2000. The hallmark of the system was reliability based upon redundancy in microprocessor-based controllers, redundancy in communications, and redundancy in operator interface.

Generic Features of DCS

Currently, most large-scale process plants such as oil refineries, petrochemical complexes, and various other processing plants are controlled by microcomputer-based DCS (distributed control systems). As is discussed in detail in Chapter 4, these systems generally include the following features:

1. Cathode ray tube (CRT)-based operator consoles and keyboards, which are used by plant operators or engineers to monitor and control the process
2. Controllers, multifunction control modules, and programmable logic controllers (PLCs), which provide the basic control computation or operation
3. A communication network, which is used to transfer the information between control modules and operator consoles across the node on the network
4. I/O (Input/Output) modules, which are used to convert the field instrumentation signals from analog to digital and digital to analog form for controller modules and console displays
5. Fieldbus communication links, which are used for communication between remote I/O devices and control modules
6. Historical module, which is used for data storage for pertinent process data or control data and for online data retrieval or archiving
7. Computer interface, which is used for communication between the nodes on the DCS network and the supervisory computer
8. Software packages for real-time monitoring, control, reporting, graphics, and trending

The generic arrangement for these components is shown in Figure 1.2a. This arrangement is a natural outcome for

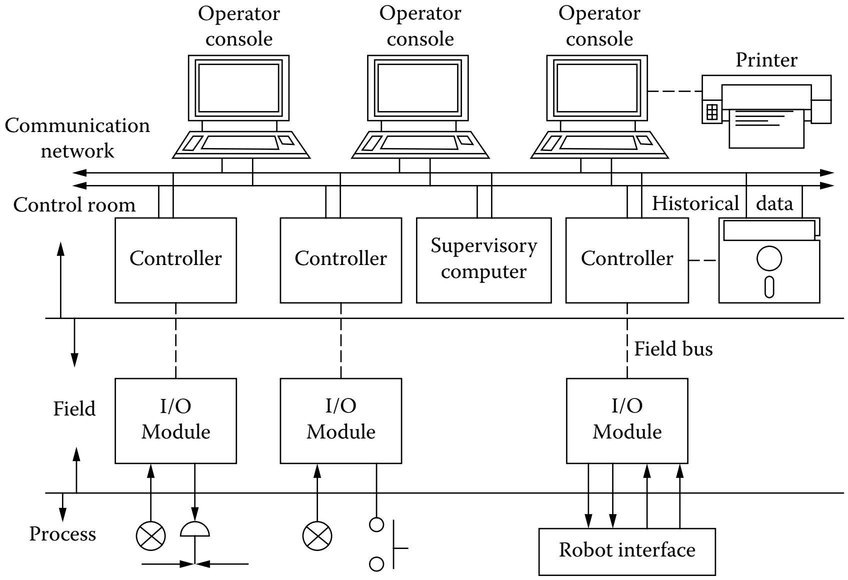

FIG. 1.2a
Generic features of DCS.

large-scale process control because the parallel operations of the control tasks are required for both continuous and batch process control. Therefore, the distributed control is a natural way of satisfying the parallel nature of the process from a geographical point of view.

DCS replaces conventional control systems to perform basic control. The supervisory control functions that in the past were performed by the computer systems described above, plus additional functions such as online information evaluation, are usually still performed by a supervisory computer, which is linked to a DCS.

COMPUTER-SUPERVISED ANALOG CONTROLLERS

The computer's capability to perform complex mathematical calculations and to make logical decisions provide a unique opportunity for improving the performance of any process through the application of supervisory control. All processes are affected by disturbances; some can be measured or calculated, others are not. Examples of disturbances are feed composition and concentration variations, ambient conditions, drifts in catalyst activities, heater and heat exchanger fouling, and economics.

Functions

Supervisory control has three fundamental functions:

1. Calculation of the present state of the process in terms of key process parameters such as yield, severity, and efficiency.
2. Calculation of critical process constraints, such as compressor capacity, column flooding limits, explosion limits, vacuum condenser capacity, and raw material.
3. Calculation of new process conditions, in terms of set points, which will meet the requirements of the objective function. The objective function can be one of a number of goals such as maximizing throughput, yield, and profit or minimizing deviation.

Tasks

The supervisory control computer requires:

1. A process model
2. Cost functions
3. Optimization algorithms
4. Constraints and limits

The supervisory computer typically performs the following types of tasks:

- Determines the process operating constraints, such as a column flooding condition in distillation or a surge condition of a compressor. Basic material balance, energy balance, or heat transfer calculations are utilized in creating the required process models. Because of the complex nature of the process itself, the computation of the model is a difficult task and might require iterative computation to satisfy convergent criteria.
- Determines the present operating state of the process based on the online, real-time information based on temperatures, pressures, and feed characteristics to obtain reactor yields or determines the desired state according to the constraints and optimization criteria.
- Determines the optimum control strategy based on the online, real-time information to achieve the control command by adjusting the manipulated variables or set points at the DCS level. Once such an algorithm is used in the supervisory computer, the response of the process to control strategy commands will gradually move this process from an initial state to a final desired state, avoiding the process constraints and following the optimum path such that one of the following objective functions is obtained: minimum cost, minimum energy, maximum yield, or maximum profit.
- Predicts impending alarms based on rigorous mathematical models using present and past history, process data, and control commands. Anticipating alarm conditions in advance of the process reaching these conditions is a vital function of supervisory control. Proper grouping of the pertinent process variables in a preclassified manner allows the severity of the alarms to be identified and allows actions to be pinpointed that can then be initiated quickly by operators.

Supervisory Computer for Analog Loops

The functions of a supervisory computer control system are shown in Figure 1.2b. It controls four process loops, but can be extended to as many loops as needed. Typically, 50 loops are assigned to one computer.

In this configuration, if analog controllers are being supervised, the proportional, integral and derivative (PID) settings of the analog controllers are kept intact. They are not changed. The process variables are measured, and their transmitted measurements are sent not only to the analog controller but also to the analog to digital (A/D) converter of the multiplexer.

These signals are processed by the computer, which takes into consideration the optimal control algorithm, the external constraints, and the management decisions, while generating the set points for the corresponding analog controllers. These set points are sent back to their corresponding controllers through the D/A converter of the demultiplexer. This operation is carried out for all the loops in a sequential, cyclic fashion on time-sharing basis.

Process Models

The model of a process can be a simple first-order linear one or a more complicated multivariable nonlinear model. It is essential to obtain a fairly accurate process model, and for

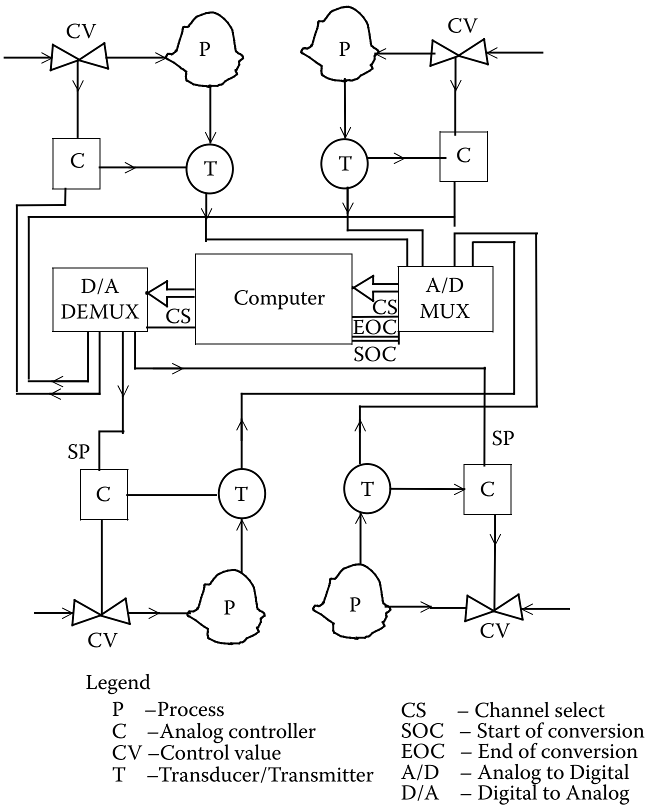

FIG. 1.2b
Block schematic of supervisory computer control for four loops.

many chemical processes such as distillation or boiler operation, obtaining an accurate process model is a difficult task. In some cases, particularly in old, existing plants, obtaining an accurate and complete model is not possible. When conventional methods of obtaining a model fail, heuristic models are advised.

Some of the heuristic models include the fuzzy logic–based model, the neural network–based model (see Section 2.18) and the genetic algorithm–based neural models. These models can be obtained by mapping a set of inputs and their corresponding outputs from the process. There are also neural or fuzzy controllers, which can generate their own optimal control algorithms. The behavior of these nonconventional models and controllers is similar to that of humans; these controllers are well suited for controlling complicated and nonlinear processes.

Conventional Models Process models can be obtained by conducting a process reaction test. Many higher-order processes have over-damped responses. Such a response is similar to the response of a first-order with dead time process. In other words, the higher-order process can often be approximated by models that are first order plus dead.

If there are oscillations in the system, then it can be approximated by an under-damped second-order + dead time model. The parameters of the dead time and the first- or second-order approximation can be experimentally determined.[1] The different methods available are impulse response methods, step response methods, and frequency response methods.[1]

For multivariable systems, if one can identify all the inputs and outputs and if they are measurable, then the least square method can be used to obtain a state model of the process. This will be an offline model or post-flight model. A number of experiments can be conducted for a sufficiently long time to obtain the input and output data, and those values are used in the least squares (LS) algorithm.[2,3] In systems where the parameters are likely to change with time, it is preferred to have online estimation of the system parameters. The recursive least square algorithm, discussed in References 2 and 3, can be used.

Optimization The main purpose of supervisory control is to obtain optimal performance of the overall process. When the supervisory computer works out and generates the set points for individual local controllers, coordinating the operation of the individual loops is an important task. The overall process performance will only be optimal if all the equipment constraints are taken into consideration and raw material availability, market needs, and management requirements are all satisfied.

When the supervisory computer generates the set points for individual analog controllers, it is important that these controllers be properly tuned. The tuning of PID and other controllers for various criteria are discussed in detail in Chapter 2 and are summarized in Table 1.2c.

In 1/4 decay ratio response, the oscillations of the controller output are such that for a small disturbance the second positive peak is one-fourth of the amplitude of the first positive peak. The PID controller settings are tuned to provide this output response. In the integral tuning criteria listed in Table 1.2c, the integral values are minimized.

COMPUTER-SUPERVISED DCS SYSTEMS

Most of the DCS software has evolved from the classical analog control. Therefore, many sophisticated supervisory control functions, such as calculating operating constraints for process units or determining heat transfer coefficient trends for maintaining heat exchangers, cannot be easily performed at the DCS level due to hardware or software restrictions. A review of supervisory control techniques and strategies is provided later in this section.

Production Monitoring and Control

Production monitoring and control for a given operation may include any or all of the following functions:

- Order entry/assignment
- Scheduling
- Production reporting

TABLE 1.2c
Criteria for Controller Tuning

1. Specified Decay Ratio, Usually $^1/_4$	$\text{Decay ratio} = \dfrac{\text{second peak overshoot}}{\text{first peak overshoot}}$
2. Minimum Integral of Square Error (ISE)	$\text{ISE} = \int_0^\infty [e(t)]^2 dt$, where $e(t)$ = (set point process output)
3. Minimum Integral of Absolute Error (IAE)	$\text{IAE} = \int_0^\infty \lvert e(t)\rvert\, dt$
4. Minimum Integral of Time and Absolute Error (ITAE)	$\text{ITAE} = \int_0^\infty \lvert e(t)\rvert\, t\, dt$

- Quality measurement and control by statistical process control or statistical quality control (SPC/SQC)
- Warehouse and shipping management
- Inventory management
- Customer service (order status, etc.)

Traditionally, these functions were either performed by manual operation or by the application of management information systems (without the availability of online data). As computers became more powerful and less costly, it became technically feasible to include many or all of the above functions in an integrated online information and control system that includes several computers linked by one or a number of sophisticated communication networks.

Because of the increasing pressure from worldwide competitions, these integrated systems, sometimes called CIM (Computer Integrated Manufacturing), are rapidly becoming a necessary tool for many major operations. One example is for a mature company to allocate each order to one of its three refineries in an optimum manner. In order to do this task correctly, the most current information must be available from all three refineries, including all processing unit loads and efficiencies, maintenance schedules, and inventories.

CIM systems are complicated and will not be discussed in detail in this section. However, it is important to note that a supervisory control computer may be only a small part of a network system, and "system integration" can be an important added task, demanding both technical and managerial attention.

Online Information System

An online information system may include any or all of the following functions:

- Data collection, checking, and verification
- Data reconciliation
- Data storage and retrieval

Many DCS systems include only limited online information functions, perhaps providing, for example, a history module as part of a standard DCS function. In most cases, such systems do not have sufficient capacity to meet users' needs, and a computer-based data archiving system is necessary.

Similarly, some DCS packages do not have sufficient storage capacity nor processing speed for processing a large quantity of data, and they normally do not support the desired database formats required by many users. In addition, many computer systems are supported by huge quantities of standard software packages, making the implementation of a real-time information system affordable. Many of the standard packages are not available in the DCS environments.

SUPERVISORY CONTROL TECHNIQUES

One of the most important jobs for an engineer responsible for implementing supervisory control is to make sure that the computer functions and DCS functions support each other.

Supervisory Control Algorithms

As was discussed earlier, before the DCS became popular in process industries, supervisory control was used to command single-loop analog controllers. These controllers served to achieve certain limited goals, such as to obtain a uniform temperature profile for a given multi-pass furnace or to determine the optimum blending for gasoline products.

The functions that the analog controllers could not accomplish were more-or-less delegated to the digital computer to perform. These included the necessary logic, sequence, or analytic computations to improve the process control operation.

From this experience, the practical value of writing the control algorithm in velocity form becomes clearer. Coordinated supervisory control with integrated feedback or feedforward combined in a velocity control algorithm can be activated or deactivated without creating perturbations to the process. The use of velocity algorithms in a computer-supervised DCS system is illustrated in Figure 1.2d and is explained below.

Advantage of Velocity Algorithm The velocity algorithm implemented in the supervisory computer can be converted to the position algorithm, which is usually applied at the DCS level. The control command, u, in the supervisory computer at the current sampling time, n, can be expressed as follows:

$$u(n) = \text{Sat}[u(n-1) + \Delta] \qquad \textbf{1.2(1)}$$

where Δ = incremental output from computer command; $u(n)$ = current computer position command at sampling instant n; $u(n-1)$ = past sampled position command; Sat(x) = upper limit if $x \geq$ upper limit, = lower limit if $x \leq$ lower limit, = x if lower limit $< x <$ upper limit.

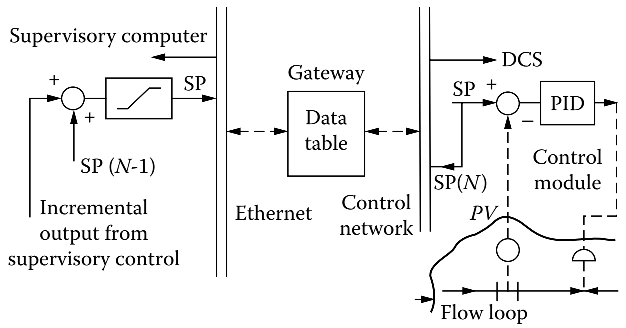

FIG. 1.2d
Velocity algorithm for supervisory control.

The incremental value can be the combination of feedforward or feedback as follows:

$$\Delta = \sum_i k_i \Delta fb_i = \sum_j k_j \Delta ff_j \qquad \mathbf{1.2(2)}$$

where Δfb_i = incremental value from the i^{th} feedback loop; Δff_j = incremental value from j^{th} feedforward loop; k_i = assignable constant for i^{th} loop; k_j = assignable constant for j^{th} loop.

The advantage of this algorithm for initialization of the control output command from the supervisory computer is that initialization can be obtained simply by setting Δ equal to 0 and making $u(n-1)$ equal the value obtained from DCS (for example, a set point value for a slave loop).

Antiwindup Control Strategy For supervisory control, the command from the supervisory computer to the set point for the control loop at the DCS level is essentially a form of cascade control. Caution is needed when control loops are in cascade. The upper or cascade master control command (supervisory computer command) requires information from the lower or secondary loop at the DCS level in order to command correctly. This information includes valve saturation status and lower loop current set point value at the DCS.

This information, which resides at the DCS level, requires constant monitoring by the supervisory computer of the real-time information communicated through interface modules on the DCS network. It is very important to prevent the computer command from causing set point windup at the DCS level. The block diagram for antiwindup is shown in Figure 1.2e.

This algorithm protects the upper loop command from windup. This protection is accomplished by freezing the supervisory control command output to the DCS set point at its last value if the DCS output to the valve is saturated and if the direction of the upper loop output increment would cause further valve saturation at the DCS level. Otherwise the upper loop within the supervisory computer will not be frozen at its last value.

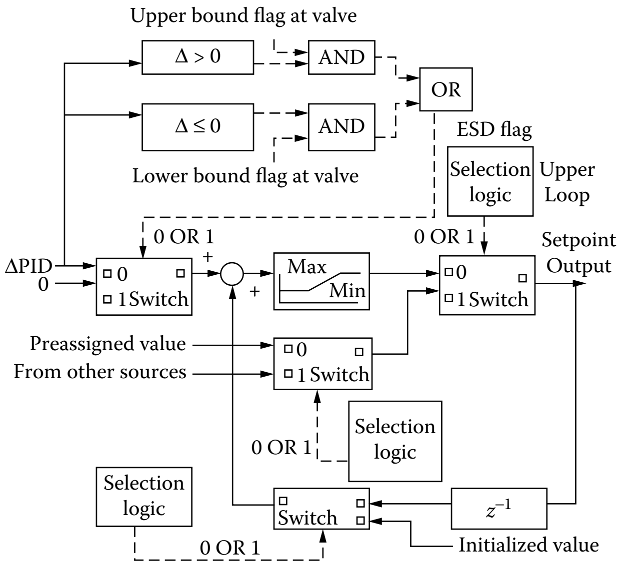

FIG. 1.2e
Supervisory control with antiwindup.

This antiwindup algorithm can be written by modifying Equation 1.2(1) as follows:

$$u(n) = \mathrm{Sat}[u(n-1) + (1 - sw) * \Delta] \qquad \mathbf{1.2(3)}$$

where $sw = 1$ if antiwindup logic is true and $sw = 0$ if antiwindup logic is false.

The switching logic is defined as:

$$I_+ = N_+ (\Delta > 0)$$
$$I_- = N_- (\Delta \le 0)$$
$$sw = (I_+ \text{ .AND. } I_u) \text{ .OR. } (I_- \text{ .AND. } I_1)$$

where

$$\begin{aligned} N_+ (\Delta > 0) &= 1 \quad \text{if} \quad > 0 \\ &= 0 \quad \text{if} \quad \le 0 \\ N_- (\Delta \le 0) &= 1 \quad \text{if} \quad \le 0 \\ &= 0 \quad \text{if} \quad > 0 \end{aligned}$$

I_u = 1 if valve8 position reaches upper bound
= 0 if valve position at upper bound is not reached
I_1 = 1 if valve position reaches lower bound
= 0 if valve position at lower bound is not reached

Combined Discrete and Continuous Algorithm For industrial process control, the control algorithm, if arranged in a structured manner, can be implemented by using a user-friendly configuration arrangement instead of writing program code for each special algorithm. Such an arrangement can be extremely useful to facilitate the implementation of supervisory control by control engineers.

Through the experience gained using several DCS systems implemented at the supervisory computer level, the generalized

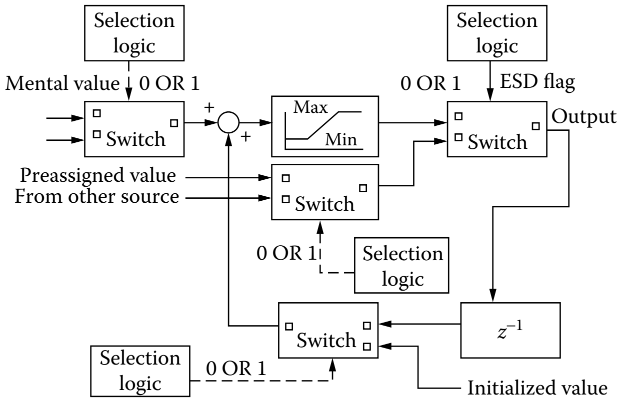

FIG. 1.2f
Generalized output control algorithm.

output control algorithm shown in Figure 1.2f was found to be useful and practical. It is designed to satisfy the application of control output for batch or continuous process control and is combined with emergency shutdown logic.

Algorithm Initialization For supervisory control, the upper-level (supervisory) control algorithm must be initialized when the output from the supervisory computer commanding the lower loops in the DCS is initiated or when an emergency process condition requires that the supervisory control command be prevented from acting in an unrealistic manner. Because the control algorithm is structured in the velocity algorithm form, initialization is simple and universal. That is, $\Delta = 0$, and $u(n-1)$ = initial value from destination loop at the DCS level.

System Failure When the supervisory computer fails, the control commands generated at the computer level cannot be transferred to the DCS level. The designer of the integrated control system should utilize a watchdog timer or communication link message to flag the lower DCS loops as a precautionary step, to prevent unnecessary disturbance to the process due to supervisory computer failure.

The intent of the supervisory control command should be designed so that fault-tolerant control can be achieved in the event that the computer fails. One approach, which can be utilized to achieve fault tolerance, is to implement the generalized output control algorithm at the DCS level, as shown in Figure 1.2f. Proper manipulation of the switch blocks and proper use of the "computer failed" flag at the DCS level ensures that the process control actions at the DCS level will not be perturbed by a computer failure.

DCS and Supervisory Computer Displays In order to judge whether or not the supervisory computer or DCS is performing properly, the displays on the CRT screen become the only man-machine interface that can be utilized for performance evaluation.

There are typically hundreds of display page screens provided in both DCS and the supervisory computer. These operational display pages can be easily accessed through the keyboard, touch screen, mouse, or trackball to arrive at the destination screen for display. The display access method and the display architecture should be similar for both the supervisory computer and the DCS screen displays. The supervisory control monitor and the operator console at the DCS level should have consistent operating procedures and should be easy for the operators to use.

Display Access Method The access methods should be designed such that a minimum number of keystrokes are required to arrive at the destination display, where the controller of interest resides. One convenient access method is to use a tree-structured, multilevel display architecture. This is shown in Figure 1.2g.

For example, if a two-level structure is used for 16 elements (pages) in each level, then the total number of pages of screen will be 16 × 16 = 256 pages. In such case, each screen page at the second level can cover 16 elements, and each element can be any digital or analog input/output combination. Therefore, a total of 4096 combined I/O points can be displayed at the second level. If the correct search path is selected, only two keystrokes are required to arrive at the destination controller for operation.

Display Feature for Supervisory Control Traditional analog controllers on the panel board are arranged in cluster of rows or columns. In the DCS, controllers are usually arranged in groups of 8, 12, 16, or 32 for screen displays in a one-dimensional horizontal arrangement or a two-dimensional matrix arrangement (Figures 1.2i and 1.2j). However, if the same type of the group display for DCS is used for a supervisory control application, the information that resulted from the supervisory computer calculations cannot be properly displayed to inform the operators.

A typical example is the multi-input/multi-output control commands from the supervisory computer to the lower loops in DCS. This type of control algorithm does not exactly fit

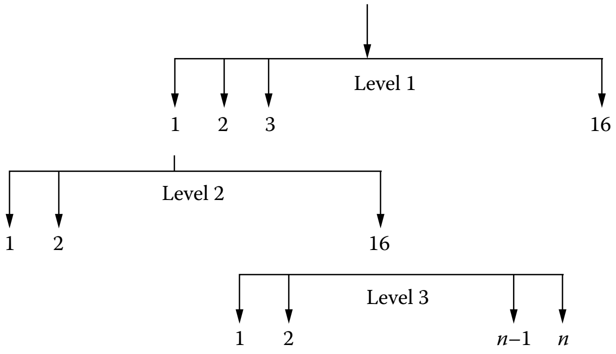

FIG. 1.2g
Multilevel display architecture.

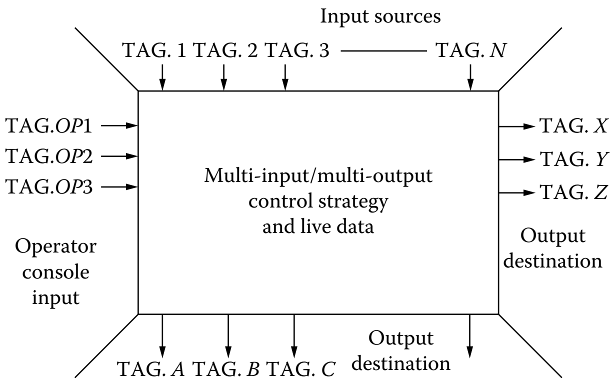

FIG. 1.2h
Multi-input/multi-output strategy display.

the conventional single-input, single-output structure. For this reason a new type of display for the multi-input/multi-output control display structure should be created. This display would indicate the source and destination of information for different locations, magnitude, type of process signals, etc.

One of the simplest ways to represent the information for supervisory strategies is to create a multi-input/multi-output control strategy display. This display is shown in Figure 1.2h.

Alarm Access Architecture Several types of alarms exist for each process variable from the DCS, including high, low, high-high, low-low, and high rate of change. These alarms will appear on the alarm screen at the DCS operator's console in chronological order with tag names, time of occurrence, magnitude of alarmed variable, alarm limit, and so on. The alarm buffer can be created to accommodate the burst of alarms occurring in a short period of time.

For supervisory computers, the alarm management program should be created differently in order to speed the alarm access and to assist the alarm diagnostic operation (to help the operators pinpoint alarm cause and location). To do so, the priority classification or grouping of the pertinent process alarm information is required.

Tag names belonging to an important process unit or equipment should be grouped to give a group alarm flag so that any individual alarm or alarms within that group can be identified logically. This will help speed the decision making of the operator when time is critical. The alarm access architecture can also be grouped according to geographical regions of the process plant or unit so that field operators can be informed (by the control room console operator) to take precautionary measures when necessary.

Voice Input Man-Machine Interface In process control, voice input and output can be an important method for conveying pertinent information about real-time process conditions to the operator. The cause or location of alarms can be announced without viewing the screen display, which clearly can be an advantage when the operator is away from the console. When process variables are approaching an alarm limit, voice output can be generated to alert the operator of the impending alarm condition.

Because of the parallel nature of process control activities, the input methods for man-machine interface should be improved to take advantage of both hands and feet to speed up the operational maneuver.

Advanced Control Strategies

Advanced control, as it is defined here, refers to the multi-input/multi-output control algorithm. The computations usually involve a combination of continuous and discrete algorithms. These algorithms can be implemented either at the DCS or at the supervisory level or at a combination of both of these levels.

Simple PID control algorithms are usually implemented at the DCS level. Those algorithms are structured with single-input/single-output characteristics. Robust multi-input/multi-output algorithms are often implemented at the supervisory computer level and should be carefully structured to satisfy multi-periodic sampled data control requirements.

Advanced Control at the DCS Level Advanced control strategies may fit into the software architecture of DCS systems with sophisticated controllers. Such control modules usually include multi-input and multi-output capabilities inside the control module. Therefore, if the advanced control algorithm is programmed with multi-input/multi-output that have assignable sequence computation steps, and the periodic computation is synchronous with the periodic execution of the control module (such as less than a 30-s range), then the advanced control should be implemented at the DCS level. Examples include ratio controls, feedforward controls, logical sequencing, and start-up and shutdown ramping operations during the transition period.

A typical application of the multi-input/multi-output algorithm is heater pass temperature balancing control combined with the total feed-flow control. The multi-input/multi-output algorithm in this case is structured to fit the single-input/single-output type, suitable for implementation at the DCS level with single-input/multi-output algorithm structure combined to form the multi-input/multi-output algorithm.

The execution of the multi-input/multi-output control period in this case is identical with that of the DCS controller. The control period is usually a multiple basic scan rate of the given controller module in the DCS. The size of the program is usually small. Consequently, the CPU time limit can be satisfied easily.

Advanced Control in the Supervisory Computer For control strategies requiring substantial computation time to complete the program execution, the regular DCS controller is not suitable. This function may involve a process model or iterative computations to obtain the convergent solution. In this case a dedicated computer is required.

To accomplish this computation task, the periodic execution of the program is typically greater than a 30-s period. This period is a function of such process response dynamic parameters as the time constant, pure transportation delay, program execution elapse time, interaction with the lower loop control execution frequencies, DCS network speed, update frequency of the gateway data table, and external periodic interrupt.

Because of the physical distances between the input sources at the DCS and the supervisory computer and because of the multiple scan frequencies involved, the precise timing for the arrival for the commands at the DCS loop set points cannot easily be predicted. It is up to the designer of the advanced control strategy to minimize the timing problem.

An example of advanced control being implemented in supervisory computers and using the multi-input/multi-output concept is gasoline blending with optimal product cost control. The criteria for optimal cost can be minimum product quality, maximum profit subject to the availability of the blend component tank inventories, or delivery time constraints.

An online optimization algorithm, such as a linear programming method or gradient method, can be utilized to obtain the solution for commands that can be manipulated. The commands to the set points of the flow ratio parameters can be so directed by the supervisory computer that optimum volume ratios are maintained for the components.

Mixed Implementation For certain situations, the DCS control module cannot facilitate the advanced control algorithm because of the infrequent execution or the excessive size of the program. In such a situation it is necessary to partition the multi-input/multi-output structure to fit the actual hardware constraint. An example of such a partitioned structure is batch control, where the sequence control can be handled by a supervisory computer, while regulatory and ramping controls can be handled by the DCS control.

COMPUTER INTERFACE WITH DCS

Hardware

Supervisory computers are interfaced to the DCS through a gateway, which is constructed to receive the data or messages from an originating source (see Chapter 4). The gateway resides on nodes of the local control network or data communication network of the DCS. Usually, the communication network topology is either a ring or bus type.

The nodes on the communication network consist of the operator console, engineering console, process control unit, controller subsystem, and gateway. The gateways are usually configured through the DCS from the engineering console to establish a list of variables associated with the tag names of interest in the DCS node on the gateway data table. The gateway device collects the listed data from the DCS communication network or data highway and transfers them to the supervisory computer through a different communication link or network. At the same time, the gateway also receives the data from the supervisory computer or nodes on the computer local area network (LAN) and transfers these to the nodes of the DCS where the information was requested.

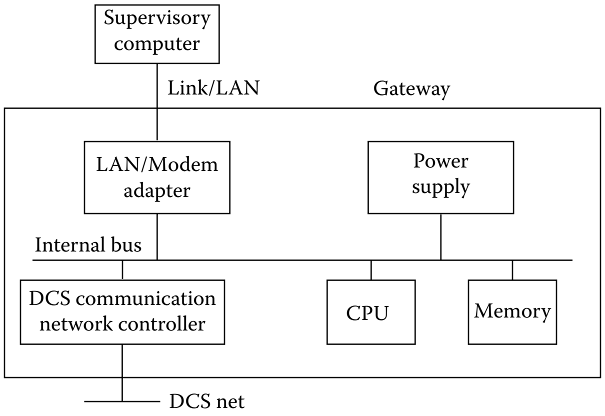

FIG. 1.2i
Generic gateway.

The generic hardware arrangement of the gateway with respect to the supervisory computer and the DCS network is shown in Figure 1.2i. Typical data transmission speeds for the DCS network are from 1 to 10 million bits per second (MBS).

Two types of computer connections are explained here using Honeywell's configuration of the gateway to illustrate the functionality of each type. Type one, called a computer gateway, communicates with a computer via a dedicated link, as shown in Figure 1.2j. Type two is the plant network module, which communicates with computers through LAN. The computer LAN usually differs from the proprietary DCS network in communication speed and protocol. This is shown in Figure 1.2k.

The physical connection of the LAN is typically a bus-type topology; however, the logical connection of the

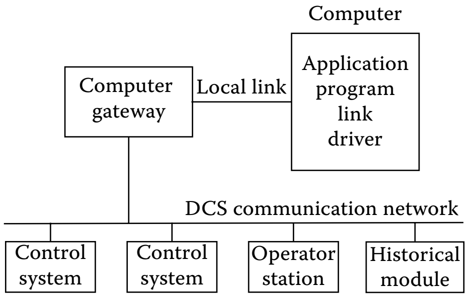

FIG. 1.2j
Gateway for supervisory computer and DCS.

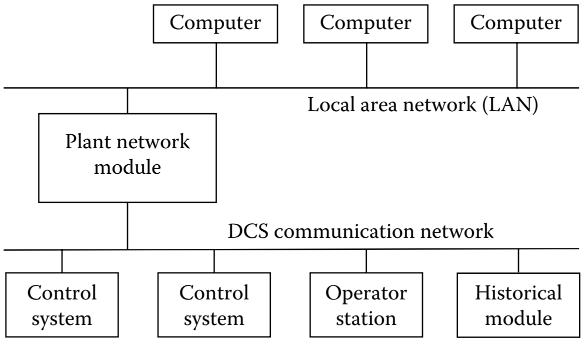

FIG. 1.2k
Gateway for computer LAN and DCS.

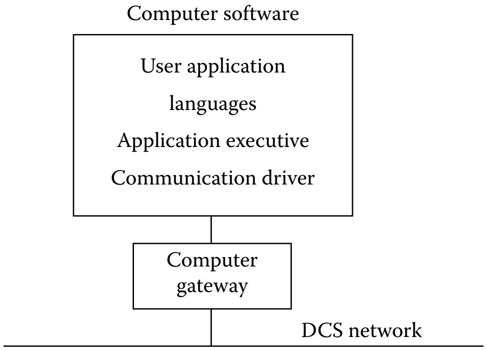

FIG. 1.2m
Computer software structure.

computer-to-computer gateway or to plant network modules can be of the star-type topology.

One approach for computer-integrated manufacturing is to design the hardware and software for the gateway such that integration of manufacturing or process data and plant management information can be achieved easily. Such an interface gateway or network module requires:

1. Highly efficient information communication between the DCS network data or messages and the data or messages in the computers on the LAN nodes
2. High security and reliability for both the DCS network access and the computer LAN access

The actual architecture to this type of hardware connection is shown in Figure 1.2l.

Software

The computer interface module or gateway functions such that the commands from the computer can be transmitted to accomplish read/write processing of data or messages in the data table at the interface module or at the nodes on the DCS. Usually, the data classified for reading are variables such as set points (SP), process variables (PV), control loop outputs (OP), digital inputs, digital outputs, control parameters, device status, controller status, or alarm status. However, the data to the DCS, which is classified for writing, usually are much more restrictive for security reasons.

For a computer, the structure of the software architecture is are shown schematically in Figure 1.2m. The data representation in the interface module is converted into the computer format for transmission.

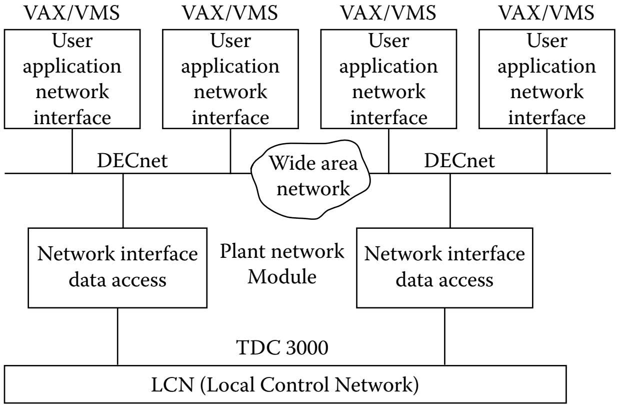

FIG. 1.2l
Honeywell TDC 3000 and VAX computers.

CONCLUSIONS

At the present time, most DCS vendors are able to interface their proprietary DCS systems with computers. The supervisory computer can be used for data analysis and control commands. Most of the supervisory computers are handling the time-critical tasks. However, some personal computers are able to access directly from historical files for engineering analysis of the process using a database software package.

The supervisory computer can assist the operator with the following tasks: performing the supervisory control; alarm classification and prediction; process performance evaluation; process diagnostics; communication routing to other host computers; and online optimization of production.

When the supervisory computer is used with conventional analog controllers, it can be used for data analysis and generation of set point control commands.

This section first describes the components and the operation of both analog and hybrid computers and then covers some of the simulation techniques for first order, second order, PID, and other applications.

The computer is a versatile tool for many applications ranging from simple calculation to sophisticated control of large-scale process plants. Computers are classified as analog and digital. Analog computers accept continuous signals and perform many operations on them, such as addition, subtraction, multiplication, integration, and simulation of systems.

THE ANALOG COMPUTER

Analog computers work on continuous signals and consist of operational amplifiers, capacitors, resistors, potentiometers, diodes, switches, squarer cards, and patch cards. All the fundamental functions of computation, such as addition, subtraction, multiplication, integration, differentiation, and generation of different functions, can be carried out with an analog computer.

The heart of an analog computer is the operational amplifier. The operational amplifier is a single-ended, high-gain DC coupled wide bandwidth unit, which has a very high open-loop gain, on the order of 10^5 to 10^8. All the computer signals are referenced to a common ground. Offsets, drifts due to temperature variation, aging, and electronic noise are the main problems in the operational amplifier circuits. Hence special precautions are taken to reduce or eliminate them. Special care should be taken to minimize the electromagnetic and static coupling between different computing units and signal sources.

The basic analog computing units are the inverter, summer, integrator, and multiplier.

Operational Amplifier

The main component of an analog computer is the operational amplifier, popularly called the op-amp, which is represented by a symbol shown in Figure 1.3a.

Its static gain μ is of the order of 10^5 to 10^8 and is a single-ended input and output representation. Its other special features are:

- High input impedance
- High DC gain
- Low power requirement
- Low noise and drift
- Stability and ruggedness

With the advent of integrated circuits (IC), operational amplifiers are now available as chips, such as the units IC741, IC741C, and IC LM 308. The ICs are quite compact, and many problems such as offset, drift, and noise associated with discrete component models have been minimized or eliminated.

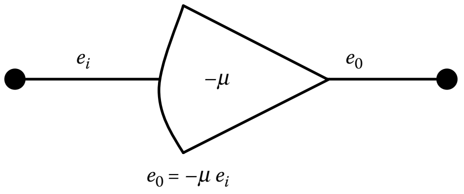

FIG. 1.3a
Symbol for the operational amplifier (OP-AMP).

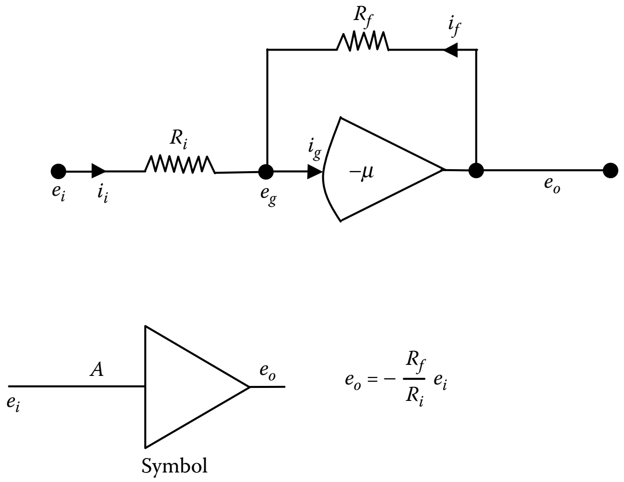

FIG. 1.3b
The circuit of and the symbol for an inverter.

In analog computers, operational amplifiers are used for three basic purposes:

- To generate the necessary computing functions
- To amplify the input signal level
- To provide isolation and unloading between the different input and output signals within the computing units

The Inverter

This operational amplifier can be used in conjunction with resistors to invert and multiply a signal. The circuit for and the symbol of the inverter are shown in Figure 1.3b. It may be noted that e_g is very near earth potential because of the large value of μ and a finite e_0 value. The current flowing into the op-amp grid is very small, on the order of micro amps.

According to Kirchoff's current law:

$$i_i + i_f = i_g \tag{1.3(1)}$$

when $i_g = 0$, $i_1 = -i_f$, $\frac{e_i}{R_i}$ and $i_f = \frac{e_0}{R_f}$.

Therefore

$$e_0 = -\frac{R_f}{R_i} e_i$$

If $R_f > R_i$, the input is inverted and amplified.

The Summer

The operational amplifier can be used as a summer by using the circuit shown in Figure 1.3c. Assuming μ to be large, i_g can

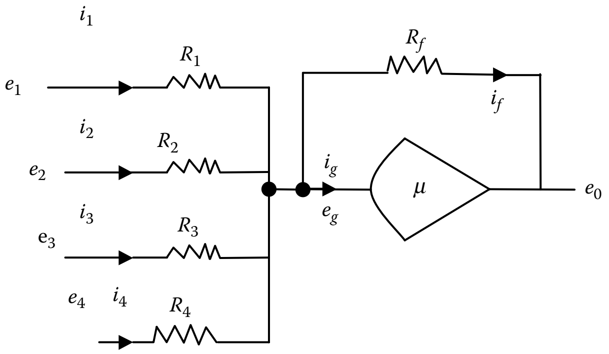

FIG. 1.3c
The circuit of a summer.

be neglected. Applying Kirchoff's equation, Equation 1.3(2) is obtained:

$$i_f = (i_1 + i_2 + i_3 + i_4) \qquad \textbf{1.3(2)}$$

As e_g is near ground potential

$$i_f = e_0/R_f,\ i_1 = e_1/R_1,\ i_2 = e_2/R_2,\ i_3 = e_3/R_3 \quad \text{and} \quad i_4 = e_4/R_4 \qquad \textbf{1.3(3)}$$

Then

$$e_0/R_f = -[e_1/R_1 + e_2/R_2 + e_3/R_3 + e_4/R_4] \qquad \textbf{1.3(4)}$$

$$e_0 = -[R_f/R_1e_1 + R_f/R_2e_2 + R_f/R_3e_3 + R_f/R_4e_4] \qquad \textbf{1.3(5)}$$

$$e_0 = -[g_1e_1 + g_2e_2 + g_3e_3 + g_4e_4] \qquad \textbf{1.3(6)}$$

The symbol for a summer is given in Figure 1.3d.

If the open loop gain μ is low, the summing junction potential e_g must be considered in Equation 1.3(2):

$$(e_0 - e_g)/R_f = -[(e_1 - e_g)/R_1 + (e_2 - e_g)/R_2 + (e_3 - e_g)/R_3 + (e_4 - e_g)/R_4] \qquad \textbf{1.3(7)}$$

Since

$$e_0 = -\mu e_g \qquad \textbf{1.3(8)}$$

Substituting 1.3(8) in 1.3(7), one obtains:

$$e_0\,(1/R_f + 1/\mu R_f) = -[e_1/R_1 + e_0/\mu R_1 + e_2/R_2 + e_0/\mu R_2 + e_3/R_3 + e_0/\mu R_3 + e_4/R_4 + e_0/\mu R_4] \qquad \textbf{1.3(9)}$$

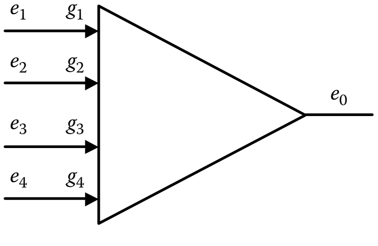

FIG. 1.3d
The symbol for a summer.

i.e.,

$$e_0\,[1/R_f + 1/\mu R_f + 1/\mu R_1 + 1/\mu R_2 + 1/\mu R_3 + 1/\mu R_4] = -[e_1/R_1 + e_2/R_2 + e_3/R_3 + e_4/R_4] \qquad \textbf{1.3(10)}$$

$$e_0 = -f_u\,[g_1e_1 + g_2e_2 + g_3e_3 + g_4e_4] \qquad \textbf{1.3(11)}$$

where

$$\begin{aligned} g_1 &= R_f/R_1,\ g_2 = R_f/R_2,\ g_3 = R_f/R_3,\ g_4 = R_f/R_4 \\ 1/f_u &= 1/\mu(1 + \mu + g_1 + g_2 + g_3 + g_4) \end{aligned} \qquad \textbf{1.3(12)}$$

f_u is the correction factor.

The analog computer circuits and their symbols, which are used for basic computation, are summarized in Figure 1.3e.

Frequency Response of the OP-AMP

It may be noted that the open loop amplification (open loop gain) of the OP-AMP decreases as the signal frequency increases. Hence the analog computation must be carried out within the corresponding frequency limits. For higher frequencies, the gain falls off. When the signal frequency is 100 kHz, the open loop gain becomes 10^2 as shown in Figure 1.3f. The correction factor for this gain is 101/100. That means the error in computation is 0.01%

Analog Circuits for Differential Equations

Consider the equation below, in which a is a positive constant and $f(t)$ is an arbitrary function of time:

$$dx/dt = ax + f(t) \qquad \textbf{1.3(13)}$$

Let us assume that $-dx/dt$ is available as voltage from some amplifier. This voltage is connected to an integrator as shown in Figure 1.3g. The output of this integrator is x. Then this output is connected to the summer as also shown in Figure 1.3g. The output of this summer is $-[ax + f(t)]$, which is equal to $-dx/dt$. By connecting the output of the summer to the input of the integrator, the equality of the equation 1.3(13) has been electrically established.

Figure 1.3g can be redrawn as in Figure 1.3h. Once this circuit is made and the circuit is switched on, $x(t)$ is obtained as a function of time, which is the solution of the differential equation. It may be noted that the initial condition is assumed to be zero.

The detailed circuit for a first-order differential equation is described in Figure 1.3i.

There is no fixed procedure for constructing computer circuits to solve differential equations. There are many satisfactory ways to arrive at a computer circuit to solve a given differential equation.

The analog computer circuit shown in Figure 1.3h is for solving a first-order differential equation with a zero initial condition. But normally, differential equations will have boundary conditions or initial conditions. A first-order differential equation will have one initial condition, a second-order will have two initial conditions, and so on.

Integrator with initial condition	 $e_0 = -\left[\frac{1}{R_3C}\int_o^t e_i dt + \frac{R_2}{R_1}e_s\right]$	 $e_o = -A\int_o^t e_i\,dt + e_o$ $A = \frac{1}{R_3c}$; $e_o(o) = -\frac{R_2}{R_1}e_s$	To have an initial condition for integration the capacitor is charged initially to a required value by choosing R_2 & R_1. The switch is initially at point 1 for a sufficient time so that the capacitor C is charged to $R_2/R_1\,e_s$. When we want to integrate the signal e_s the switch is moved from position 1 to position 2 and then the integration starts.
Squarer	 $e_0 = -Ae_i^2$ Square function generation	 $e_0 = -Ae_i^2$	This device approximates a function $y = f(x)$ by a number of straight line segments. The electrical components used in a square function generator are diodes, resistors, and potentiometers.
Multiplier		 $e_0 = -\,e_1\,e_2$	This circuit is known as a quarter square multiplier $e_0 = \frac{1}{4}\left[(e_1+e_2)^2 - (e_1-e_2)^2\right]$ $= e_1e_2$ Now the circuit is available as a device which produces a current proportional to the product of two voltages.
Signal divider		 $e_0 = \alpha\,e_1$ $0 \le \alpha \le 1$	

FIG. 1.3e
Summary of analog computer circuits and their symbols used for basic computation.

For the first-order system described by Equation 1.3(13), assume the initial condition to be $x(0) = x_0$. This requires that the voltage from the integrator be held at x_0 until the integration starts. There are two ways of obtaining the initial condition. One way is to connect a battery of the required initial condition value between the grid and the output as shown in Figure 1.3j.

Initially, the switch is closed for a sufficiently long time for the capacitor to become charged to the initial condition value x_0. Two relay-operated switches are placed in the circuit as shown in Figure 1.3j. When the initial condition is to be established, switch 1 is closed and switch 2 is simultaneously opened. When the equation is to be solved, a suitable relay system opens switch 1 and closes switch 2 at the same time.

Another way of obtaining the initial condition voltage is shown in Figure 1.3k. In this case, when the computer is put in the initial condition (IC) mode, the switches S_1 and S_2 are put in position 1. This is done simultaneously by a master switch. A voltage V_s of desired magnitude and polarity is connected to the R_1 and R_2 circuit. Normally, R_1 and R_2 values will be 0.1 MΩ. When the switch S_1 is in position 1, $e_0 = -(R_2/R_1)V_s$, and when $R_1 = R_2$, e_0 becomes the negative of V_s.

Then, according to the time constant of the RC circuit, the capacitor is charged to $-e_0$. In this case the time constant $RC = 0.1$ s, and hence one can expect that in five times the time constant or say in 0.5 s the capacitor will be charged to V_s voltage, which becomes the initial condition for the integrator.

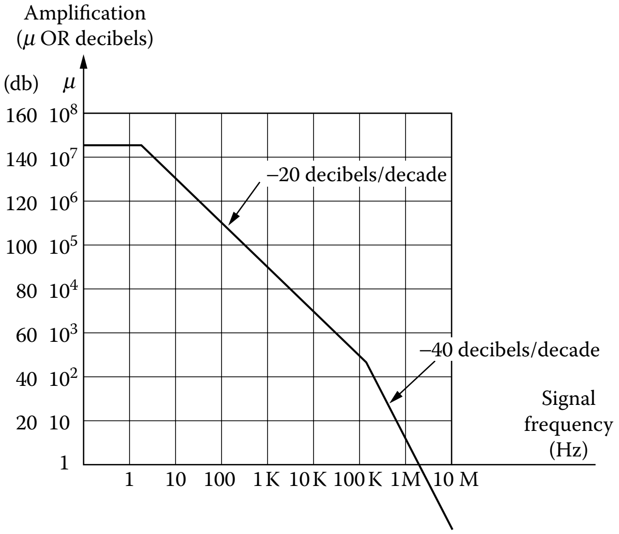

FIG. 1.3f
The open-loop gain characteristic is such that as the signal frequency increases, the open-loop gain (amplification) of the OP-AMP decreases.

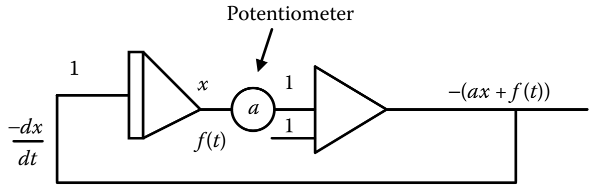

FIG. 1.3g
The circuit for solving Equation 1.3(13).

The computer circuit for solving first-order differential equations.

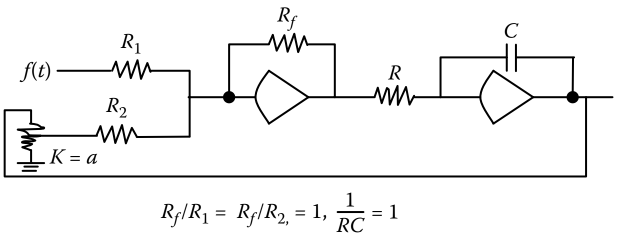

FIG. 1.3i
The detailed circuit for solving first-order differential equations.

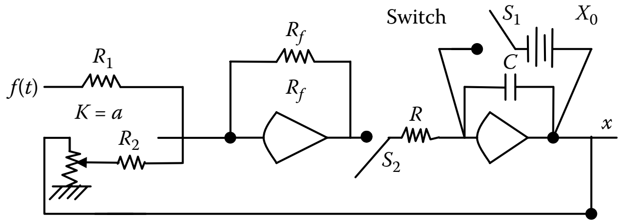

FIG. 1.3j
Analog computer circuit for solving the equation dx/dt = ax + f(t) with initial condition.

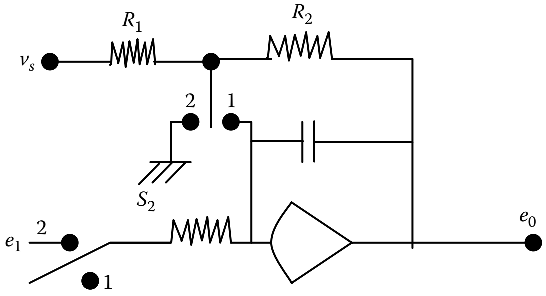

FIG. 1.3k
The circuit for an integrator with IC value.

When the computer is placed in the operate mode, switches S_1 and S_2 are switched to position 2 and the voltage is integrated. In this state, resistor R_1 provides a load for the initial condition voltage because one side of the resistor is grounded through switch S_1.

Figure 1.3l shows the symbol for an integrator with an IC value. It may be noted that the reference voltage is opposite in sign to the initial condition voltage because of the sign reversal at the amplifier.

Magnitude and Time Scaling

To get satisfactory results utilizing the analog computer, magnitude scaling and time scaling are needed.

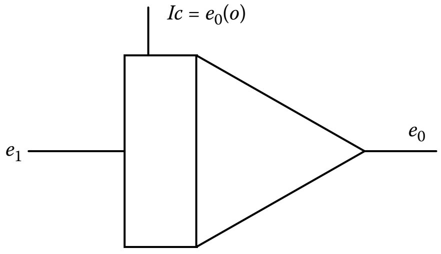

FIG. 1.3l
The symbol for an integrator with IC value.

Magnitude Scaling During the solution of a problem in an analog computer, the output voltage from any amplifier should not exceed the operating range of that amplifier. For many semiconductor analog computers the nominal voltage range is +15 to –15 V. If, at any point of the solution, the output voltage of any amplifier exceeds this value, the amplifier response may not be linear. Often, it is possible to estimate the maximum value of x, say x_m, which occurs during the solution. This maximum value should be reduced to the maximum output voltage of the amplifier, which is say 15 V, by selecting the suitable scaling factor of $k_x = 15/x_m$, so that the amplifier does not saturate.

For example, if $x_m = 5$ units, then $k_x = 15/5 = 3$.

By using magnitude scaling, full use is made of the voltage range available in an analog computer and also the overloading and saturation problems are taken care of. Scale factor for the derivates of the dependent variable

$$dx/dt, \qquad d^2x/dt^2$$

are also to be chosen by estimating their maximum values. To fully understand the concept of magnitude scaling, consider the second-order differential equation:

$$d^2x/dt^2 + a\,dx/dt + bx = f(t) \tag{1.3(14)}$$

where x is the dependent variable and t is the independent variable. The coefficients a and b are positive constants. The dependent variable and its derivates are available as voltages at the output of amplifiers on the computer. Magnitude scale factors are used to correlate the voltages from amplifiers to the dependent variable and its derivates.

In case of a vibration problem, x may represent displacement, dx/dt can stand for velocity, and d^2x/dt^2 for acceleration.

for acceleration.

$$\text{Let } x1 = dx/dt \quad \text{and} \quad x2 = \frac{d^2x}{dt^2}$$

if the maximum anticipated values for x_m, $x1_m$, and $x2_m$. In that case the scale factors are:

$$k_1 = 15/x_m,\ k_2 = 15/x1_m, \quad \text{and} \quad k_3 = 15/x2_m \tag{1.3(15)}$$

Equation 1.3(14) can be rewritten as:

$$\frac{d^2x}{dt^2} = -a\frac{dx}{dt} - bx + f(t) \tag{1.3(16)}$$

Using the scale factors, the variables at the output of the amplifiers are $[k_1x]$, $[k_2x1]$, and $[k_3x2]$. Rewriting the equation using $[k_1x]$, $[k_2x1]$, and $[k_3x2]$, we get

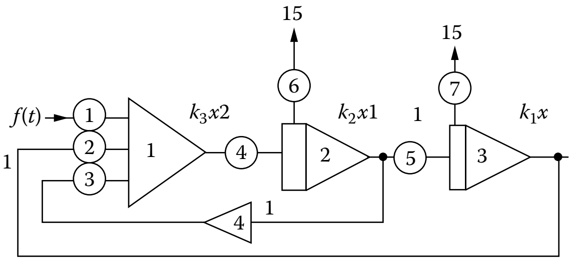
$$[k_3x2]/k_3 = -a[k_2x1]/k_2 - b[k_1x]k_1 + f(t) \tag{1.3(17)}$$

or

$$[k_3x2] = -a(k_3/k_2)[k_2x1] - b(k_3/k_1)[k_1x] + k_3f(t) \tag{1.3(18)}$$

The analog computer circuit for Equation 1.3(18) is shown in Figure 1.3m, which is a generalized circuit for solving a second-order differential equation with magnitude scaling.

Time Scaling It may be noted that the analog computer integrates with respect to time measured in seconds. But the independent variable in a differential equation representing a real time problem may be time in minutes or length in feet. The time needed for the solution of a particular problem may be 30 minutes, in which case 30 minutes of operators' time and the computer time would be needed, if time scaling was not used to speed up the solution.



Potentiometer number	1	2	3	4	5	6	7	
Values of its setting	k_3	$b\,k_3/k_1$	$a\,k_3/k_2$	k_2/k_3	k_1/k_2	$k_2x/1(0)/15$	$k_1x/(0)/15$	← Magnitude scaling
Values of its setting	k_3	$b\,k_3/k_1$	$a\,k_3/k_2$	$k_2/b\,k_3$	$k_1/b\,k_2$	$k_2x1(0)/b15$	$k_1x/(0)/15$	← Magnitude and time scaling

FIG. 1.3m
A generalized analog computer circuit for solving a second-order differential equation with magnitude scaling (Equation 1.3[18]).

For some fast-acting processes, such as transients in circuit breakers, slowing down the problem is needed to capture and record the variation. Hence time scaling is needed whenever it is necessary to speed up or slow down the process when it is studied in an analog computer.

If one designates the computer time as t and the real time as τ, then the time scale factor can be defined as the ratio of $t/\tau = \beta$. The steps in the procedure that was adopted for time scaling are listed below:

Step 1. Assuming $\beta = 1$, magnitude scale the problem as described earlier.
Step 2. Choose β, $\beta > 1$ when speeding up the solution or $\beta < 1$ to slow down the solution. The actual values can be selected from knowing the real process.
Step 3. Multiply the gain of each input to an integrator by I/β
Step 4. Modify the time in the forcing function from $f(t)$ to $f(\tau/\beta)$.

The above procedure can be applied to Equation 1.3(18) to implement the time scaling:

$$\left[\beta^2 k_3 d^2 x/d^2\tau\right] = -a(k_3/k_2)\left[\beta k_2 \frac{dx}{d\tau}\right] - b(k_3/k_1)[k_1 x] + k_3 f(\tau/\beta) \qquad \textbf{1.3(19)}$$

The initial conditions for potentiometer settings are given in the table at the lower part of Figure 1.3m.

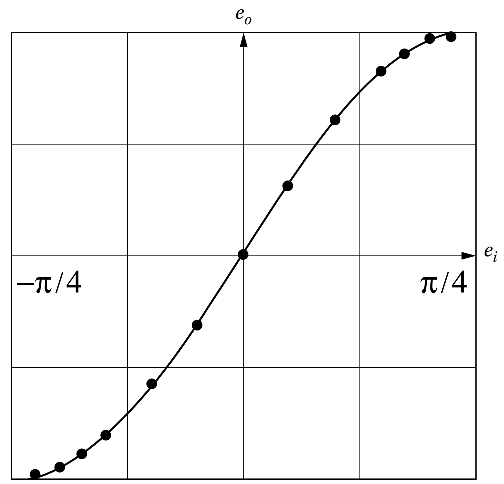
Nonlinear Components

For solving nonlinear equations using analog computers, one needs nonlinear components[1] such as function generators, multipliers, dividers, and switches. These nonlinear elements significantly extend the usefulness of a computer by allowing nonlinear equations to be solved with the same ease as linear ones.

Function Generator The most common function generator used is a diode function generator.[2] This circuit approximates a function $y = f(x)$ by a number of straight-line segments of different scopes. To generate a functional relationship $e_o = \sin(2e_i)$, a number of line segments with different slopes are needed, as shown in Figure 1.3n.

Multiplier To obtain the instantaneous product of two time-varying voltages, a multiplier is needed. A convenient symbol for the multiplication block is shown in Figure 1.3e. Three types of multipliers are used in computers.[2] They are:

1. The quarter-square multiplier
2. The servo mechanical multiplier
3. The time division multiplier



Example of function $e_0 = \sin(2\,e_i)$

FIG. 1.3n
The response of a sine function generator.

Quarter-Square Multiplier The identity of the quarter-square multiplier can be described as:

$$xy = 1/4[(x+y)^2 - (x-y)^2] \qquad \textbf{1.3(20)}$$

The analog computer circuit that corresponds to the above equation is shown in Figure 1.3o. Today, the quarter-square card is available from many manufacturers; this card gives a current output, which is proportional to the product of two voltages divided by 10.

The Analog Computer Unit

Commercially available analog computer equipment is box-type equipment with an orderly collection of amplifiers, power supplies, potentiometers, reference power supplies, diodes, switches, and some function generators, quarter-square cards, etc. The connections from the various components are brought to a panel called a patch board. The patch board is removable, and many spare patch boards are available. This facility is for wiring a computer circuit when the computer is to operate on another problem. The wired computer circuits can also be stored and used later.

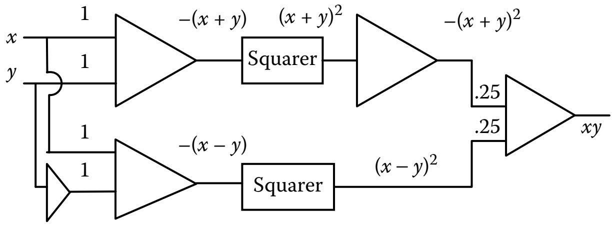


FIG. 1.3o
Analog computer circuit for a quarter-square multiplier.

In many analog computers, the resistors and capacitors used to construct summers and integrators are not accessible to the user. They are located inside the computer, and only their terminals are brought out to the patch board.

A reference power supply is provided for establishing initial conditions on the integrators. X-Y plotters, oscilloscopes, and strip chart recorders are used to record or observe the response or solution.

HYBRID COMPUTERS

A hybrid computer is a combination in hardware and software of one or more analog and digital computers. It aims at providing faster, more efficient, and more economical computational power than is available with computers of either type alone. The results depend to a large extent on the exchange of information between the analog and the digital computers and on the compatibility in operations and mutual interactions between the two parts.

A hybrid computer provides for the rapid exchange of information between the parallel and simultaneous computations and simulations within the analog computer and the serial and sequential operations of the digital computer. This information exchange links the two computational domains and offers the combined advantages of the fast and flexible analog computer with the precise and logic-controllable digital computer.

The extent of the information exchange between the two parts and the sophistication of the control structures and instruction repertoires determine the capability and the capacity of the hybrid computer. Best results are obtained when both computers are designed and developed with hybrid applications as the major purpose. If a hybrid computer is made up of general-purpose analog and digital computers, with an interface tailored to these, the resulting hybrid computer often poses severe limitations in equipment complement and operational features.

Hardware

The distinguishing feature of a hybrid computer is the interface that connects the analog and digital computers. The interface consists of data communication channels in which information is passed between the two computational parts. The interface does not carry out computations, but it may contain equipment that incorporates computational units, such as multiplying digital-to-analog converters.

The interface contains a number of conversion channels in which information is converted between an analog signal (voltage) and an encoded numerical (discrete) digital computer representation, according to programmed instructions and hardware executions. The number of conversion channels states the total parallel capacity of the interface, for conversions in both directions. In practice, the number of A/D (analog-to-digital) channels may differ from the number of D/A channels, depending on applications and implementations.

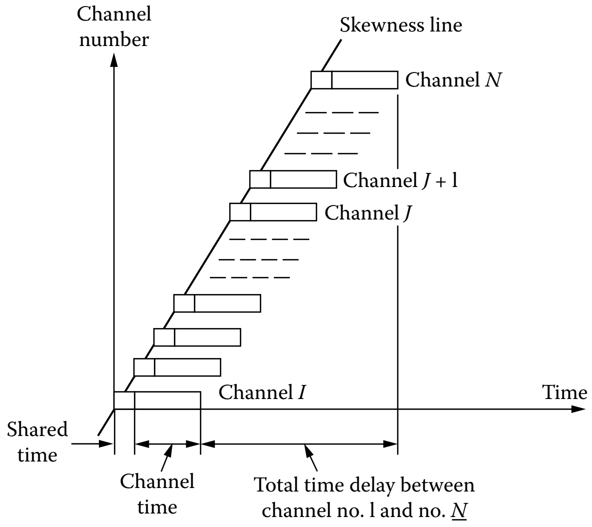

FIG. 1.3p
The skewness of converted data.

Since the conversion channels link parallel and concurrent analog computer variables with serial and sequential program steps in the digital computer, the interface must provide storage facilities, by which information (variables) can be stored, while all channels are being prepared (loaded). This way, all conversions can take place simultaneously, in terms of analog variables, and sequentially, in terms of digital variables.

If the converted information is not buffered, it reflects computational variables or conditions that are not concurrent or coreferenced in time. Such skewness is indicated in Figure 1.3p, showing the effect of a sequential conversion capability (among several time-shared units). To a degree, and at the cost of computer time, the skewness effects may be reduced by a common hold mode for all analog computing units, during which hold the information conversion may take place. Fast, accurate mode control facilities that allow rapid computer interruption and resumption of the analog program are necessary for this.

Figure 1.3q shows an example of an A/D conversion channel in which the analog signal is tracked and stored in analog form. The conversion channel utilizes a multiplexer and converter that are shared among a number of channels, typically 24 to 36, and it reads the converted information into a programmed (controlled) memory location in the digital computer. From this memory location the digital program can then obtain the converted information.

An example of a D/A conversion channel is shown in Figure 1.3r. It consists of a buffer register for the digital information and converter unit. The buffer register holds the digital information until the moment of conversion, when it is loaded into the converter with other D/A channels. For single-channel or continuous D/A conversion, the buffer register is sometimes bypassed, and the digital information read directly (jammed) into the converter.

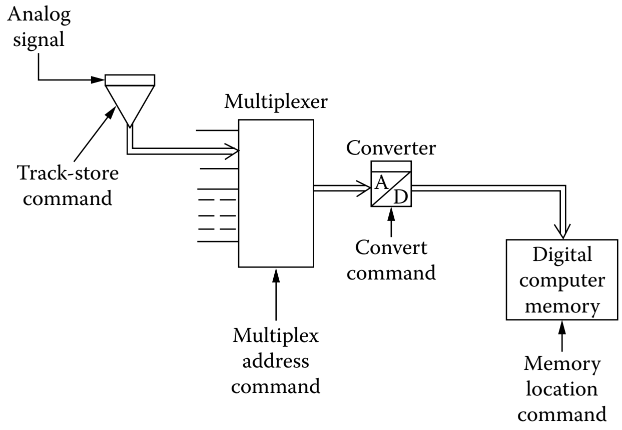

FIG. 1.3q
The components of an A/D channel.

The analog conversion output is a direct signal output or, as in a multiplying D/A, the product of an analog signal input and the converted D/A information. The conversion moment is only triggered by digital computer instructions, or indirectly, by interrupts form the analog computer through the digital computer program.

A number of status channels in the interface provide binary information exchange between the analog and digital computers. This information relates to the status of particular computational variables or computing units and to the condition and progress of the programmed functions. Status channels are used to ensure proper relationships in terms of operation sequences, timing of program events, steps, and coordination of the two hybrid computer parts.

There are three main types of status channels, depending on the importance or immediacy of the reported conditions:

1. Status indicating, which at all times corresponds in status to the condition of its input variable
2. Status retaining, which will retain the predetermined status of the input variable from the first time it is set or activated until the status channel is interrogated by the receiving computer and the channel is reset or deactivated
3. Status responding, which will respond immediately to the condition of the input variable when this is set or activated and will cause the receiving computer to interrupt its task or change its modes or functions according to the programmed actions

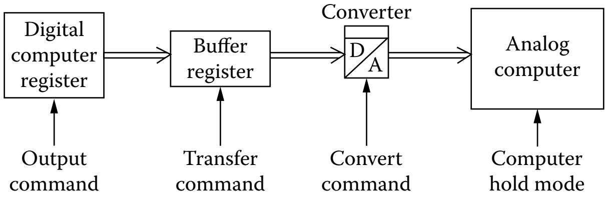

FIG. 1.3r
The components of a D/A channel.

Status channels are generally furnished in the interface as one-way signal lines, which must be assigned to the conditions or computing units that are to be reported during the programming.

The interaction and control of operations between the two computers are handled by binary command channels. The command channels represent direct, fixed interactive links between the control systems or command sources of the two computers. They control the executions of programs, such as start and stop computations and iterations, and the initialization or reset of programmed functions and routines.

Operation

The operational efficiency of a hybrid computer depends on the command and control (instruction) structures of the two computers. Analog and digital computers are sufficiently different in organization and operation to present profound problems in terms of command characteristics and functional orientation. In a hybrid computer, the analog and digital computers are linked together on the fundamental control level, providing facilities for mutual interruption and interaction of tasks.

In terms of analog computer control, the hybrid computer permits the digital computer program to carry out the control system functions previously outlined. These functions span the setup and checkout of analog and hybrid programs, the initialization and presetting of conditions for the computations and simulations, and the measurement, recording, and monitoring of the analog computer variables and functions during productive runs. Of prime importance in a hybrid computer is the ability of the computer programs to govern the progress of the computations and to take the appropriate control actions, depending on the obtained results and responses.

The digital computer instruction repertoire normally includes many bit-handling instructions designed to facilitate the exchange of information through the status channels, command channels, and direct mode control and command channels. These instructions permit multiple-level priority assignments and convenient handling of the exchanged information, which can be either in a converted data format or in single-bit format.

The fast access to information in the digital computer memory through direct access or cycle stealing is important for high-speed conversion channel utilization and efficient hybrid computations.

Software

Good and complete software is required to attain the optimum operational efficiency and utilization of the hybrid computer. This is especially important in hybrid computer applications since the complexity and extent of many hybrid programs and the sophistication of the instruction repertoire and control routines in the computers otherwise limit the usefulness and understanding of the computer capabilities.

The software is designed with practical problem-solving objectives in mind, such as handling the system's functions and presenting conditions and variables in concise and efficient formats. For best results, the software is written for a particular hybrid computer and is defined and specified according to the characteristics of the hardware configuration. The software consists of three types of system programs:

1. Batch-oriented hybrid computer operation programs, organized and utilized for large, complex hybrid problems, with extensive program setup and checkout demands
2. Conversational computer operation programs, designed for experimental and development-oriented type hybrid computations and simulations
3. Utility routines designed for efficient and convenient setup, checkout, and documentation of intermediate or limited hybrid computer programs, such as test programs, experimental circuit evaluations, and hybrid program developments

The software enables the operator to carry out a hybrid computation or simulation of the specific problem with a minimum of effort. In a hybrid application, this includes determining the signal connections and tie-lines, calculating the scale factors and coefficients of analog variables, adjusting coefficient units to the appropriate values prior to or during computations, and selecting the states or modes of the analog computing units.

An important aspect of the software is its capabilities for readout and documentation. It must be able to obtain the values within the hybrid program and to decode or interpret these in the language of the problem (such as in engineering units or mathematical terms). Finally, it must be able to make this information available to the operator, either on CRT, graphic display, trend curve, or in other forms.

PROCESS SIMULATION

The simulation of most processes, reactions, and plants requires the developing of a representation or building a model of common elements. For this model, each element is adapted to the particular functions it must simulate. When all the parts have been defined and assembled, the overall effects and constraints may be imposed, such as material and energy balances, operating modes, limitations, instrumentation, and control system characteristics.

Laplace Transforms

For linear control systems, Laplace transforms can be used to obtain their transfer functions. Laplace impedances can be used when working with Laplace transfer functions for system simulation. Information on Laplace impedance is available in most books on circuit theory or network analysis,[3] while these Laplace impedances are referred to as complex impedances in control system books.[4]

For the two terminal elements like resistance, capacitance, and inductance the impedance are given by R, $1/Cs$ and Ls, respectively. If these complex impedances are connected in series, the total impedance is the sum of the individual complex impedances, and if these are connected in parallel, then the parallel resistance rule is applied. It may be noted that complex impedances are valid only for such transfer function approaches where the initial conditions are assumed to be zero. For example, a series combination of R and C has a total impedance of

$$Z = R + 1/Cs = (RCs + 1)/Cs \qquad \textbf{1.3(21)}$$

The impedance of R and C connected in parallel is obtained by equating the reciprocal of the parallel impedance, i.e.,

$$1/Z = 1/R + Cs = (1 + Rcs)/R$$

Then

$$Z = R/(1 + RCs) \qquad \textbf{1.3(22)}$$

First-Order System Simulation The first-order transfer function $A/(1 + sT)$ can be simulated by the circuit shown in Figure 1.3s:

$$Y/X = Z_f/Z_i = R/R_1(1 + Rcs) = A/(1 + Ts) \qquad \textbf{1.3(23)}$$

where $A = R/R_1$ and $T = RC$.

Another way of obtaining a simulation circuit is as follows: First convert the Laplace function into a time function:

$$(1 + Ts)Y = AX \qquad \textbf{1.3(24)}$$

Then, in order to get the time domain equation, replace s and d/dt in Equation 1.3(24):

$$\begin{aligned} y + Td/dt\ y &= Ax \\ d/dt\ y &= -y/T + A/Tx \end{aligned} \qquad \textbf{1.3(25)}$$

The computer circuit for this given in Figure 1.3t.

Second-Order System Simulation In order to simulate a second-order system, which is in the form of $K/(1 + sT_1)(1 + sT_2)$,

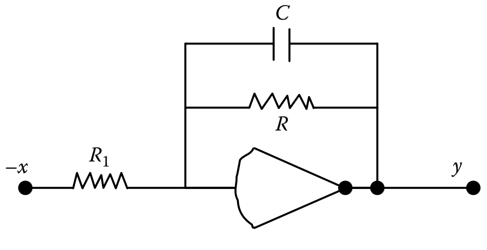

FIG. 1.3s
This circuit simulates a first-order transfer function A/(1 + sT).

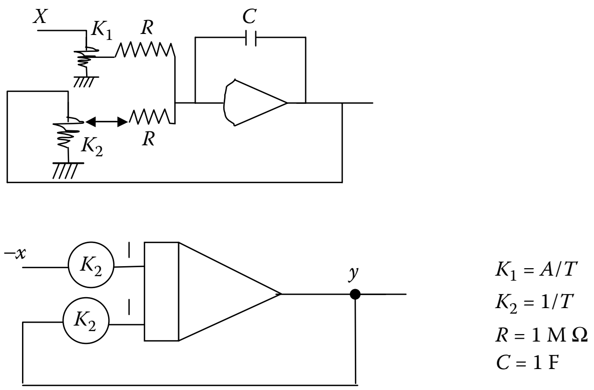

FIG. 1.3t
This alternate circuit also simulates a first-order transfer function A/(1 + sT).

one can connect two first-order system circuits (which are shown in Figure 1.3s) in cascade, but such a circuit cannot be used to simulate underdamped systems.

In order to simulate a second-order system of the form

$$G(s) = Y/X = k\left(s^2 + 2\xi w_n s + w_n^2\right) \qquad \mathbf{1.3(26)}$$

where $\xi < 1$, then the circuit shown in Figure 1.3u can be used. To obtain this circuit, one can first rewrite the transfer function into a differential equation form, using the following steps.

Cross-multiplying Equation 1.3(26)

$$s^2Y + 2\xi w_n sY + w_n^2 Y = kX \qquad \mathbf{1.3(27)}$$

and replacing s by d/dt, one obtains:

$$\frac{d^2}{dt^2}y + 2\xi w_n \frac{dy}{dt} + w_n^2 y = kx \qquad \mathbf{1.3(28)}$$

Keeping d^2/dt^2

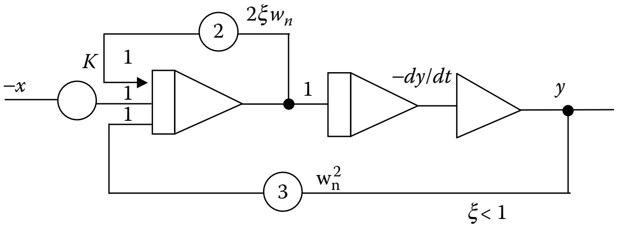

FIG. 1.3u
This circuit simulates an underdamped second-order system.

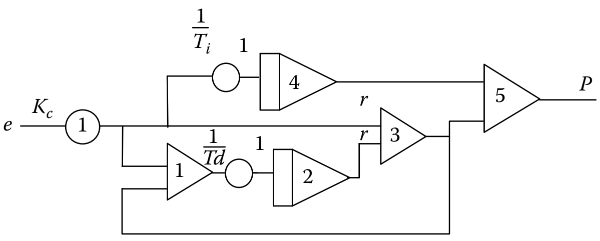

FIG. 1.3v
Analog simulation of a PID controller.

on the left-hand side and shifting all other terms to the right and multiplying the whole equation by −1, we obtain:

$$-\frac{d^2}{dt^2}y = 2\xi w_n \frac{dy}{dt} + w_n^2 y - kx \qquad \mathbf{1.3(29)}$$

For Equation 1.3(29), the circuit is shown in Figure 1.3u.

Simulation of PID Controller The transfer function that represents a proportional, integral, and derivative (PID) controller is:

$$\frac{P(s)}{E(s)} = K_c\left[\frac{1 + T_D s}{1 + T_D s/r} + \frac{1}{T_1 s}\right] \qquad \mathbf{1.3(30)}$$

When r is made very large, the transfer function reduces to

$$\frac{P(s)}{E(s)} - = k_c\left[1 + T_D s + \frac{1}{T_1 s}\right] \qquad \mathbf{1.3(31)}$$

This is the transfer function of an ideal PID controller.[4] The analog computer circuit that simulates it is shown in Figure 1.3v.

Lag Functions

A common element in the process and plant simulations is the lag, defined by the transfer function (in Laplace notation) as:

$$H(s) = \frac{Y(s)}{X(s)} = \frac{K}{1 + \tau s} \qquad \mathbf{1.3(32)}$$

where K is the steady-state gain and τ is the time constant. In general, the gain and time constant will vary with other simulation variables, such as flows, temperatures, and pressures. A generalized circuit for the lag function is shown at the top of Figure 1.3w. Other versions of the lag are also shown in the figure with different aspects and advantages, such as independent adjustment of gain and time constant, bipolar output, and simplicity and independent adjustment (but poorly scaled in many cases).

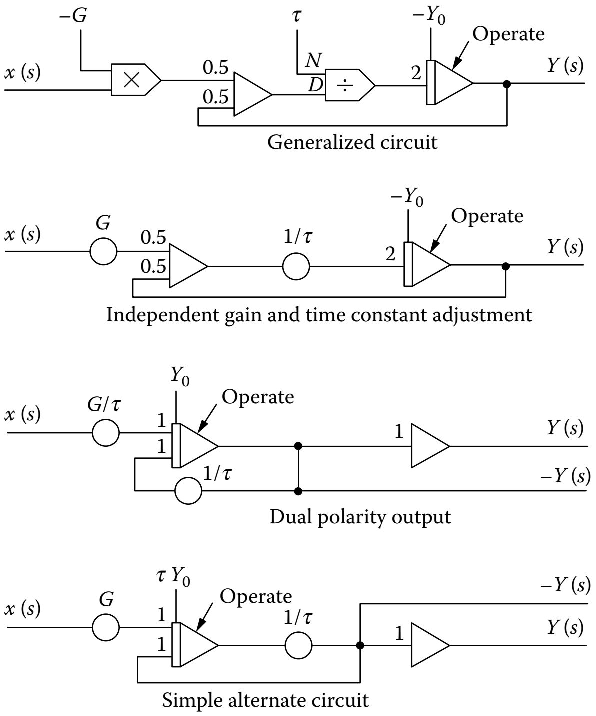

FIG. 1.3w
The lag function.

Lead-Lag Element Another commonly used element is the lead-lag, for which the transfer function is:

$$H(s) = K\frac{s}{1+\tau s} \tag{1.3(33)}$$

or

$$H(s) = K\frac{1+\tau_1 s}{1+\tau_2 s} \tag{1.3(34)}$$

Figure 1.3x shows a generalized circuit for the transfer function described in Equation 1.3(33), with variable gain K and time constant τ.

The class of lead-lag transfer functions described by Equation 1.3(33) may be simulated with circuits of the type shown in Figure 1.3y. The generalized arrangement used for individual time constants and gain variations by signal inputs often results in poor integrator scaling, especially for large τ_2 values. The common circuit permits the ratio between τ_1 and τ_2 to be adjusted over a wide range.

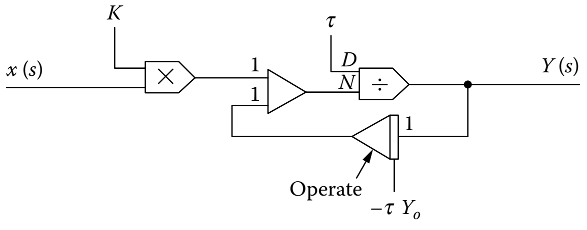

FIG. 1.3x
The lead-lag function for Equation 1.3(33).

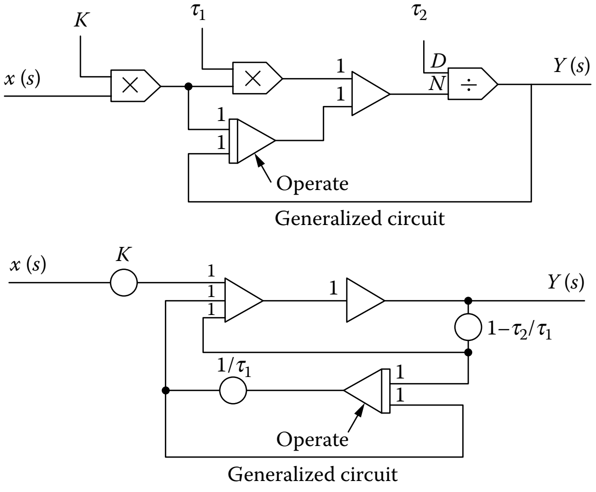

FIG. 1.3y
The lead-lag function for Equation 1.3(34).

Delays, Transport Lags In many analog computer simulations, a signal delay effect, or simulation of a transport lag, such as the flow of fluids through pipes or the movement of material on a conveyor, is desired. Delays or dead times such as this often represent important dynamic factors and influence the stability and operation of the plant or process. In general, there is no true analog computer "model" for a transportation delay, and for most applications some form of approximation of the delay function must suffice.

The most commonly known approximations are the Padé functions. These are often unsatisfactory in process and plant simulations, and other empirically determined functions are used in their place. Figure 1.3z shows a delay approximation, for which the time domain responses are better than those of the Padé functions and give more stable, damped, and consistent performance. The delay approximation is the low-pass type, with the transfer function:

$$H_2(s) = \frac{3.45 - 0.345(\tau s)}{3.45 + 3.18(\tau s) + (\tau s)^2} \tag{1.3(35)}$$

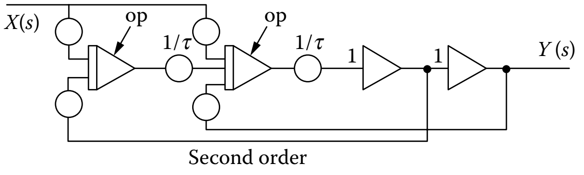

FIG. 1.3z
Approximation of the transport lag.

In Figure 1.3z, the transportation delay time (τ) can be varied by adjusting the coefficient potentiometers. If the delay time is a function of a simulation variable, such as the flow rate in a pipe, multipliers must replace the potentiometers. For the circuit described, the range of variation is generally limited to less than 100 : 1, without rescaling or rearranging the gain distributions. The shortest delay is determined by the highest input gains available (or by gain–integrator speed combinations).

Control System Simulation

The simulation of instrumentation control systems includes measuring or detecting devices, the controllers, and the actuating or manipulating output elements. Most measuring devices may be simulated by one or more simple lags for dynamic representation, with added nonlinearities for device characteristics, sensitivity, or operating point modeling.

For special functions, such as logarithmic input–output relationships (such as pH measurements), the general-purpose function-generating units may be used or the functions generated by implicit techniques. When the measuring device puts out a discontinuous (pulse-type) signal, signal-generating circuits may be used, as discussed later in this section.

Interacting PID Controller A direct, three-mode (PID) controller has the transfer function:

$$M(s)=\frac{100}{\text{PB}}\left[1+\frac{1}{T_i s}\right]\left[1+\frac{T_d s}{1+T_0 s}\right][R(s)-C(s)] \qquad \textbf{1.3(36)}$$

where $M(s)$ = controller output in Laplace representation; $C(s)$ = measured (controlled) input variable; $R(s)$ = reference (set point); PB = proportional band (in percent); T_i = reset (integration) time; T_d = derivative (rate) time; and T_0 = stabilizing (filtering) time constant.

The filter time constant is usually made as small as possible and is often a fraction of the derivative time T_d (such as $T_d/16$).

Figure 1.3aa shows simulation circuits for direct and reverse acting three-mode controllers, with the initial value M_0 corresponding to the controller output when it was in "manual."

The controller transfer function in Equation 1.3(36) is of the interacting type, which is the common case for most industrial applications.

Noninteracting PID Controller A mathematically noninteracting controller is expressed by:

$$M(s)=\left[\frac{100}{\text{PB}}+\frac{1}{T_i s}+\frac{T_d s}{1+T_0 s}\right][R(s)-C(s)] \qquad \textbf{1.3(37)}$$

Here all the three modes can be independently adjusted.

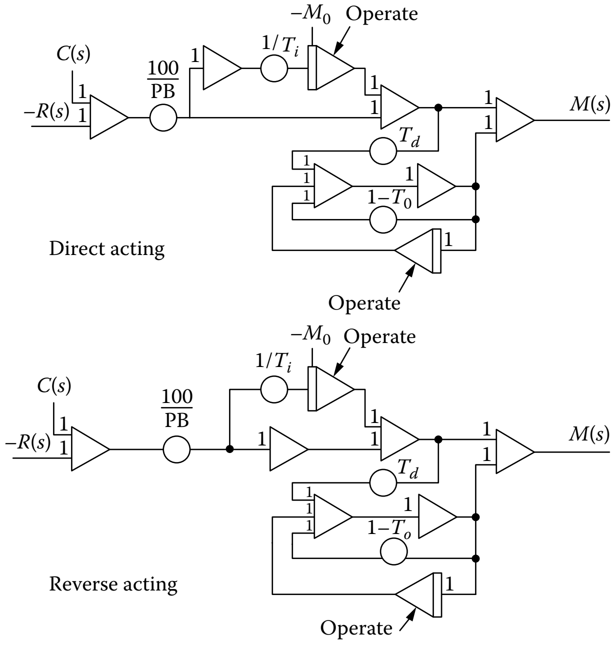

FIG. 1.3aa
Interacting PID controller described by Equation 1.3(36).

In general, the proportional band should have an *overall* adjusting effect, which leads to the practical noninteracting controller with the transfer function:

$$M(s)=\frac{100}{\text{PB}}\left[1+\frac{1}{T_i s}+\frac{T_d s}{1+T_0 s}\right][R(s)-C(s)] \qquad \textbf{1.3(38)}$$

This circuit arrangement is shown in Figure 1.3bb.

More modern controllers often limit the derivative action so that it will respond only to changes in the measured variable and not to rapid set point changes, which could upset the process. This characteristic is described in the modified transfer function:

$$M(s)=\frac{100}{\text{PB}}\left[1+\frac{1}{T_i s}\right]\left[R(s)-\left(1+\frac{T_d s}{1+T_0 s}\right)C(s)\right] \qquad \textbf{1.3(39)}$$

which is of the interacting kind.

Hybrid Simulation

A hybrid controller can simulate direct digital control of a process. In that case the individual PID control algorithms can be simulated by the digital computer, while the process is simulated using an analog computer, and the two are interconnected for system analysis and design.

Simulation of Direct Digital Control Direct digital control may be simulated with a controller circuit as shown in Figure 1.3cc, where the measured variable $C(s)$ and the set point $R(s)$ are sampled at fixed intervals (Δt) and held in

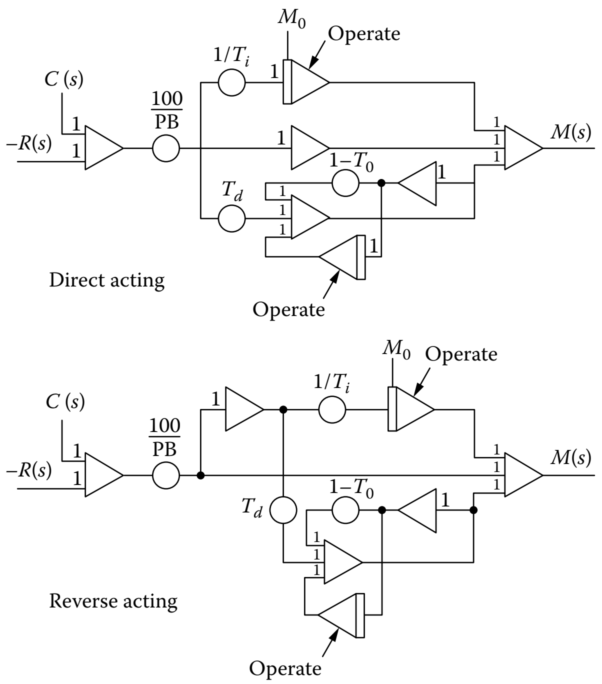

FIG. 1.3bb
Practical noninteracting controller described by Equation 1.3(38).

track-store units. The controller algorithm for this case is given by Equation 1.3(40):

$$\Delta m = \frac{100}{\text{PB}}\left[\left(1+\frac{\Delta t}{T_i}\right)(r_n - c_n) - r_{n-1} + c_{n-1} - \frac{T_d}{\Delta t}(c_n - 2c_{n-1} + c_{n-1})\right] \qquad \textbf{1.3(40)}$$

with Δm being the change in the output, which is computed in the time interval. This control corresponds to the one given in Equation 1.3(39), with derivative action responding to the measured variable only. The track-store operation is controlled by the pulse P occurring once during each time interval Δt to produce an output pulse Δm of amplitude (height) corresponding to the desired change in the control variable.

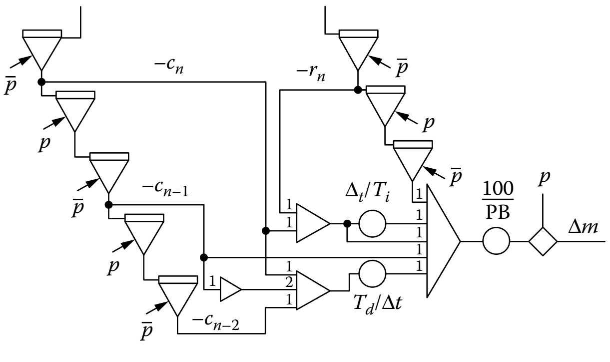

FIG. 1.3cc
Analog simulation of direct digital control based on Equation 1.3(40).

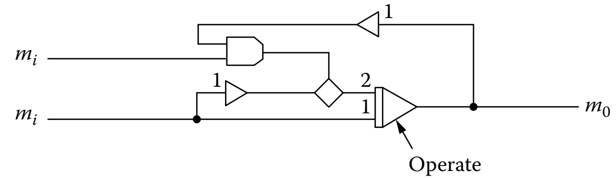
Simulation of Control Valves The most important manipulating output element is the control valve, which can have several distinct functional aspects in an analog computer simulation. The flow characteristics can be linear, equal percentage, quick opening, or butterfly type.

Except for the linear valve, the flow characteristics must be generated by a special analog computer circuit (by implicit techniques), or programmed in a function-generating unit, for a true representation (see Chapter 3 for details). Additional effects such as velocity limiting or backlash in valve stem movements must be included in the model.

The dynamic performance of the control valve may be represented by a time lag of first or second order, with a limited velocity in stem movement. The time lags are simulated by circuits that were described under transfer functions, lags, and lead-lags. Velocity limiting may be expressed by the equation

$$\frac{dm_0}{dt} = \text{LOW}\left(m_L; \frac{dm_i}{dt}\right) \qquad \textbf{1.3(41)}$$

where m_0 is the stem position, m_L the velocity limit, and m_i the input stem position of an ideal, unconstrained valve. The simulation circuit for velocity limiting is shown in Figure 1.3dd.



Common limiting

1.4 Electronic vs. Pneumatic Instruments

H. L. FELDMAN (1969) **R. K. KAMINSKI** (1985) **B. G. LIPTÁK** (1995, 2005)

The debate concerning the relative merits of electronic versus pneumatic instrumentation took place in the middle of the 20th century. As can be seen from the references for this section, most of the arguments were published during that period, and little additional knowledge has been obtained in more recent decades. Although the debate has been concluded, and the process control industry has decisively moved into the electronic and digital age, knowing the arguments — the advantages and disadvantages of pneumatics versus electronics — can still be educational. For this reason, and because pneumatics are still used in the heating, ventilation, and air conditioning industry and in the control valve portion of control loops, this section has not been deleted from this handbook.

FACTORS TO BE CONSIDERED

The main advantages of pneumatic systems over electronic instruments lies in their safety in hazardous locations and in the availability of qualified maintenance personnel. However, electronic systems are favored when computer compatibility, long transmission distances, or very cold ambient conditions are expected, or when long-term maintenance is to be minimized (Figure 1.4a).

Perhaps "Pneumatics versus High Technology" would have been a better title for this section. If a process plant uses digital electronic control, it is very difficult to justify the use of pneumatics. Naturally, when evaluating the advisability of pneumatics, one must evaluate the options of analog electronics, digital controllers with or without computers, distributed control systems, and programmable logic controllers. The relative merits of analog vs. digital controls are covered in Section 1.1 of this volume. In the discussion here, references are provided for further reading on the subject.

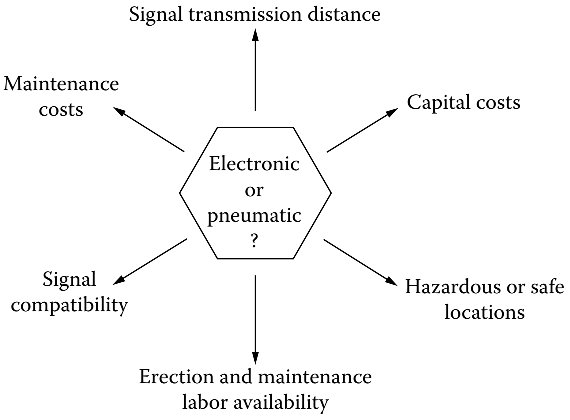

FIG. 1.4a
Electronic versus pneumatic systems.

THE OLD DEBATE

In the debate some decades ago, some authors promoted electronics[1–4] and others pneumatics.[5–9] Table 1.4b summarizes the views on both pneumatic and electronic instruments that are expressed in the first nine referenced articles.

In the area of maintenance, the referenced literature[1–18] does not present convincing evidence that electronics guarantees reduced maintenance costs, but it does suggest that electronic instrumentation is easier to maintain and that the life of electronic instruments is longer. This is because of the wear on the pivot points, the change in spring elasticity and diaphragm stretch in pneumatic designs. Maintenance publications, such as those of ISA, have contributed to making maintenance easier by promoting modular component designs and self diagnostics.

The argument that pneumatic instruments need dry, clean air but electronic systems do not is not correct because many electronic control system include I/P (current-to-air) converters and electro-pneumatic valve positioners, which also require dry and clean air. Deuschle,[14] in his detailed cost comparison, points out that the capacity required for the air compressor serving an electronic control system is about 60% of that required for a pneumatic system. For a specific application, the rating approach proposed by Tompkins[17] can be considered for comparing the choice of pneumatics versus electronics.

HVAC DAMPER ACTUATORS

The relative performance of electronic and pneumatic damper actuators will be discussed below.

Pneumatic Actuators

Pneumatic dampers are usually throttled over a 5 PSI spring range such as from 8 to 13 PSIG. Over this range, the damper will move from the closed to the open position if there is no

TABLE 1.4b
Viewpoints Expressed on Electronics versus Pneumatics†

Features	*Electronics Superior*	*Pneumatics Superior*	*About Equal*	*Remarks*
Lower initial hardware cost		11,12,13,14,15,16,17*		
Lower installation cost	10, 12, 13, 14		11	Ref. 13: Cost for either varies all over the map
Lower total installed cost			12, 14, 15, 16*	
Simpler system design		13, 15, 16*		
Shorter check-out and start-up		11*		
Shorter training period		11*		
Higher dependability (reliability)			11, 15, 16*	
Less affected by corrosive atmospheres		13, 14, 17*		Ref. 14: Air acts as a purge
Lower maintenance	12, 14, 17	11	*	Ref. 12 cites user experience
More compatible with control valves		13, 14, 18*		
Greater accuracy	11, 12, 16*			
Superior dynamic response	11, 12, 13, 14, 15, 16, 17, 18*			Ref. 13: Normally, the fastest response is not necessary
Better suited for long transmission distances	11, 12, 13, 14, 15, 17, 18*			
Superior computer capability	11, 12, 13, 14, 17, 18*			Ref. 13: This is the primary reason for selecting electronic instruments

† Numbers refer to the references listed at the end of this section.
* An asterisk marks the preference of this author.

friction and no process load, which resist the movement of the damper. Usually both are present.

Hysteresis

Resistance forces (F_R) are present, not only because there is friction between the stem and the hole through which it passes but because there also is linkage stiffness and axle bind at the rotary joints. Therefore, because the air is both the control signal and the power source, its pressure must rise beyond that required to break free and initiate movement, which results in overshoot. On the return stroke, the air signal pressure must drop below the spring force (F_S) before the spring will overcome friction and start returning the damper. On an actuator with a 4” stroke, this can result in a hysteresis of 1”.

Spring Range Shift

When a process load (F_L) exists on the damper, it will shift the throttling range of the damper. If the actuator area is 15 in.^{2}, each pound of air signal pressure will generate 15 lb of added force on the diaphragm (F_A). Therefore, if the process load (F_L) is, say, 45 lb, that load will shift the throttling range of the damper by 3 PSIG. Depending on the failure position of the damper, either the lower or the upper limit of the range will be shifted. Consequently, if the process load (F_L) is 45 lb, the throttling of a fail closed (FC) damper will not occur between 8 and 13 PSIG, but the damper will throttle between 5 and 13 PSIG. Similarly a fail open (FO) damper will throttle between 8 and 16 PSI.

Direct Coupled Electronic Actuator

When a 2- to 10-VDC signal, generated by a 4- to 20-mADC signal passing through a 500-ohm resistor, directly operates the damper, performance is improved. This is because the direct coupled electronic actuator has a resolution of 160:1, allowing a positioning accuracy that can be as high as 120:1,[28] which is much superior to that of a pneumatic actuator. This actuator uses an internal potentiometer to verify its position with respect to the control signal. Consequently, it is unaffected by friction and process load forces and obeys the relationship between control signal and internal potentiometer within +/–0.05 VDC.

Pneumatic vs. Electronic

If the pneumatic actuator has no positioner, the problems of hysteresis and spring range shift will make its performance inferior to that of a direct coupled electronic design. If the pneumatic actuator is furnished with a positioner, its performance is improved. The amount of improvement depends on the quality of the positioner, which will determine how close the loop performance will approach that of the electronic actuator. In any case, it is not likely that the positioning accuracy of a pneumatic actuator will approach or reach that of an electronic one.

The relative costs of the installed pneumatic and electronic actuators are a function of the quality of the pneumatic positioner used. If the positioner is of reasonably high quality, the installed costs will be similar.

CONTROL SIGNALS

Putting together a pneumatic system can be relatively simple. The 3- to 15-PSIG (0.2- to 1.0-bar) air pressure signal range permits the teeing in of different manufacturers' equipment with very few problems. Other pressure ranges are seldom used, except when there is reason to amplify the range, such as to 6 to 30 PSIG.

Much has been written about pneumatic transmission lags.[19–23] In this regard the electronic system is superior; however, pneumatics systems have been successfully operated with 250- to 500-ft (75- to 150-m) lines. When boosters are used, distances of 1000 ft (300 m) and more can be considered.[21, 22] The longer distances can be attained by specifying such requirements as higher air capacities and the use of volume boosters and 3/8 in. (9.38 mm) OD tubing. In order to reduce transmission distances, field-mounted controllers can also be used. According to Buckley,[22] serious limitations on performance are caused by:

1. Control valves without positioners
2. The use of 1/4 in. (6.25 mm) rather than 3/8 in. (9.38 mm) OD tubing
3. Restrictions in manual/automatic switch blocks and plug-in manifolds
4. Inadequate valve positioner air capacities
5. Single-acting (instead of double-acting) positioners on cylinder operators
6. Inadequate field air supplies
7. Multiple process lags

The most common analog electronic control or transmission signal is 4 to 20 mA DC. Considerable engineering must go into all-electronic systems because of impedance restrictions and polarity, power supply, shielding, and grounding requirements. In digital control systems, the buses and networks require substantial engineering, particularly in the area of the interfacing of different suppliers' products.

The transmission range of the electronic system can be a mile or more with no time lag. However, this feature is important only in a minority of control loops.

With regard to electrical noise, pneumatic instruments are, of course, immune. Electronic systems do experience problems if shielding and grounding are inadequate. In recent years, many manufacturers have designed instruments protected against RFI (radio frequency interference).

CONVERTERS

A pneumatic system does not need additional hardware to operate an air-operated control valve, whereas an I/P converter must be installed if an electronic loop is to operate a pneumatic control valve. Because many transmitter outputs are inherently electronic, pneumatic loops also require I/P converters for applications involving such transmitters on temperature, flow, or analytical measurements.

Electronic systems are superior for data loggers, computers, distributed control, and/or programmable controller applications. The pneumatic system would require I/Ps, P/Is, and pneumatic scanning devices for these applications.

ELECTRICAL SAFETY

In many process industries, some locations are hazardous because of the presence of flammable gases, combustible dusts, and ignitable fibers. Therefore, equipment in hazardous areas must be designed so that it will not cause a fire or explosion (see Section 7.1 in Volume 1 of this handbook for details). Manufacturers and users agree that pneumatic instruments are inherently safe to use in installations in hazardous areas. On the other hand, analog and digital electronic instruments require special protection features if they are to operate in a hazardous environment.

If the area is Class I explosion-proof, where explosive or ignitable mixtures (in air) of flammable gases or vapors constitute the hazard, the electronics must meet different requirements. Divisions 1 and 2 are defined below:

Division 1: Location is likely to have flammable mixtures present under normal conditions or the operating process equipment is likely to require frequent maintenance
Division 2: Location is likely to have flammable mixtures present only under abnormal conditions

The initial and installed costs for electronic systems will be a function of the electrical classifications and of the selected approaches, which are used to meet the requirements of the

National Electrical Code. The choices include explosion-proof housings, purging, and intrinsically safe designs. For Division 2, nonincendiary, nonarcing, and hermetically sealed equipment can also be considered. (Refer to Chapter 7 in the *Measurement* volume and to References 24 to 26 in this section for more information.)

THE MODERN DEBATE

In selecting a control system one must examine the advantages and drawbacks of both analog and digital alternatives,[27] which was the topic of Section 1.1 in this chapter. Digital controls are compatible with computers, distributed control systems, programmable controllers, and digital controllers.

1.5 Human Engineering

M. C. TOGNERI (1985, 1995) **B. G. LIPTÁK** (2005)

THE CONTROL ROOM OF THE 21ST CENTURY

Human–machine interfaces (HMI) can allow a single operator to monitor thousands of control loops from a single operator's station. The HMI is the operator's window on the process that is being controlled. The information content of the early HMIs was that of the faceplates of analog controllers, while today's computer displays can provide not only data on the process parameters and alarms but can also furnish trend charts and historical data, in addition to generating reports and analyzing or diagnosing complex systems.

Modern control rooms and their equipment will be discussed in more detail in Chapter 4. They serve to simultaneously enhance efficiency and safety by providing advanced alarm systems, compact workstations, and large display panels (Figure 1.5a). Another essential feature of modern control systems is their ability to allow smooth growth, which is referred to as their scalability. This capability is very important in process control, because processing plants are ever expanding and therefore their control systems must also grow with them. A modular approach to operator stations can conveniently serve this purpose (Figure 1.5b), as will also be discussed in more detail in Chapter 4.

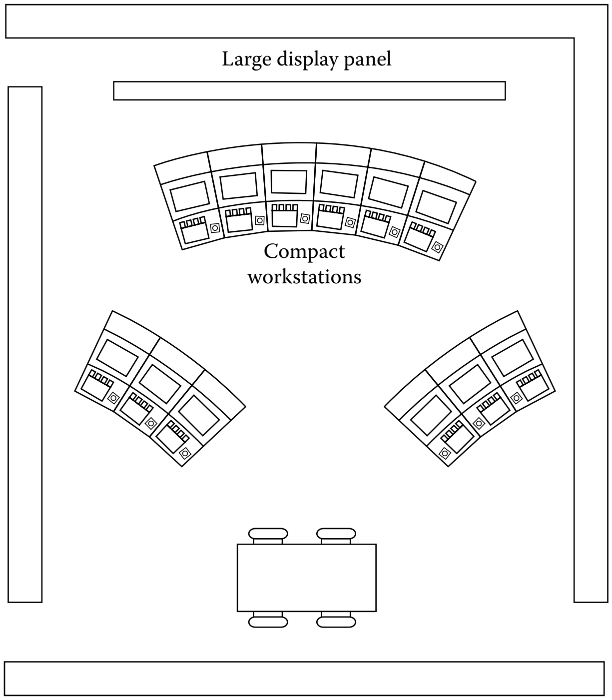

FIG.1.5a
The layout of a modern control room.

The value of these modern tools depends on the human operator's ability to use them. The hand, psychological characteristics, hearing, and color discrimination capability of the human operator must all be part of human engineering, which is the topic of this section.

INTRODUCTION

Human engineering, also known as engineering psychology, human factors engineering, and ergonomics, is probably the most basic form of engineering because the fashioning of any tool to suit the hand is the goal of human engineering. The discipline began as a feedback system in the sense that modification was left to future modification as needed instead of being made part of the original design. This approach sufficed when technological progress was sufficiently slow to allow the sequential development of several generations of improved

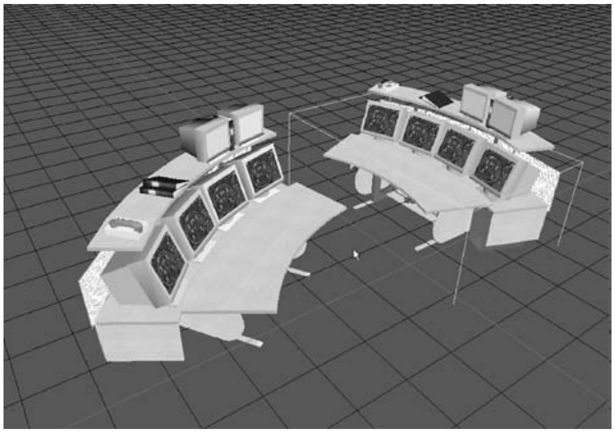

FIG. 1.5b
The growth of control rooms is served by the availability of modular operator's workstations.

equipment. The efficiency and cost of tools were such that improper original design was tolerable.

Current technology has supplied highly efficient, complex, and therefore expensive tools, the ultimate success of which rests with our ability to use them. Today's tools are required not only to fit the human hand but also to reinforce many physiological and psychological characteristics, such as hearing, color discrimination, and signal acceptance rates. The complexity and cost of tools make the trial-and-error feedback approach to improvement unacceptable.

World War II introduced the first attempt at technical innovation and the first serious effort to treat human engineering as a discipline. Postwar economic pressures have been almost as grudging of critical mistakes as war has been; thus, the role of human engineering has increased with technological progress. A few highlights of human engineering described in this section will aid the instrument engineer in evaluating the impact of this discipline in process plants.

Applicability extends from instruments as sophisticated as those used in the Apollo moon flight to those as prosaic as the kitchen stove.

Man–Machine System

The man–machine system is a combination of people and equipment interacting to produce a desired result. The majority of industrial control systems are indeed sophisticated man–machine systems.

Because the purposes of an instrument and control system are limited, a satisfactory definition is difficult to make. Subdividing the purpose into its constituent goals is an important first step in clarifying the goals. Many operators cannot supply much more information than to criticize that which is currently used or available. Learning from mistakes, although necessary, is not a desirable engineering approach.

The backbone of a man–machine system is a flow chart of man-related activities. This approach concentrates the design efforts on improving the capability of the operator to handle information and control — not just on improving instruments. Proper design criteria are obtained by asking what should be done, not what has been done. The machine should be adapted to the man. Two constraints exist:

1. The abilities of the average operator
2. The amount of information and control required by the process

Sight, hearing, and touch allow the operator to control information storage and processing, decision making, and process control. Information is processed by man and by machine in a similar manner (Figure 1.5c).

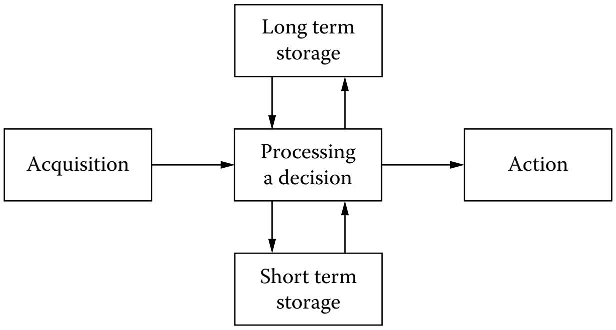

FIG. 1.5c
Information processing: man or machine.

Although people and machines process information similarly, their abilities to execute diverse functions vary greatly. Humans are better than machines at qualitatively processing information, an aptitude that develops on the basis of experience or judgment. The ability of humans to store enormous quantities of data (10^{15} bits) and to use these facts subconsciously in decision making allows them to reach decisions with a high probability of being right, even if all necessary information is not available. Machines are suited for quantitative processing and storage of exact data and provide rapid access. Machine decisions must be based on complete and exact data.

In a process control system, the differences are best applied by training the operator in emergency procedures and letting the machine store data on limits that, when exceeded, trigger the emergency. Table 1.5d summarizes the characteristics of men and machines. Since information is the primary quantity processed by a man–machine system, a brief account of informational theory is necessary.

Information Theory

The discipline of information theory defines the quantitative unit of evaluation as a binary digit or "bit." For messages containing a number of equal possibilities (n), the amount of information carried (H) is defined as:

$$H = \log_2 n, \qquad \textbf{1.5(1)}$$

and the contact of a pressure switch (PS) carries one bit of information. Therefore:

$$H_{\text{PS}} = \log_2^2 \text{(alternatives)} = 1 \qquad \textbf{1.5(2)}$$

The nature of most of the binary information in process control is such that probabilities of alternatives are equal. If this is not so, as with a pair of weighted dice, the total information carried is reduced. In an extreme case (if the switch were shorted), the probability of a closed contact is 100%, the probability of an open contact is 0%, and the total information content is zero.

CHARACTERISTICS OF MAN

Much has been learned about man as a system component since organized research in human factors was initiated during World War II. Anthropometric (body measurement)

TABLE 1.5d
Comparing the Characteristics of Man to Machine

Man Excels in	*Machines Excel in*
Detection of certain forms of very low energy levels	Monitoring (of both men and machines)
Sensitivity to an extremely wide variety of stimuli	Performing routine, repetitive, or very precise operations
Perceiving patterns and making generalizations about them	Responding very quickly to control signals
Detecting signals in the presence of high noise levels	Exerting great force, smoothly and with precision
Ability to store large amounts of information for long periods — and recalling relevant facts at appropriate moments	Storing and recalling large amounts of information in short periods
Ability to exercise judgment when events cannot be completely defined	Performing complex and rapid computation with high accuracy
Improvising and adopting flexible procedures	Sensitivity to stimuli beyond the range of human sensitivity (infrared, radio waves, and so forth)
Ability to react to unexpected low-probability events	Doing many different things at one time
Applying originality in solving problems, e.g., alternative solutions	Deductive processes
Ability to profit from experience and alter course of action	Insensitivity to extraneous factors
Ability to perform fine manipulation, especially when misalignment appears unexpectedly	Ability to repeat operations very rapidly, continuously, and precisely the same way over a long period
Ability to continue to perform even when overloaded	Operating in environments that are hostile to man or beyond human tolerance
Ability to reason inductively	

and psychometric (psychological) data are now available to the designer of control systems, as are many references to information concerning, for instance, ideal distances for perception of color, sound, touch, and shape. The engineer should keep in mind that generally the source of data of this sort is a selected group of subjects (students, soldiers, physicians, and so on), who may or may not be representative of the operator population available for a given project.

Body Dimensions

The amount of work space and the location and size of controls or indicators are significant parameters that affect operator comfort and output and require knowledge of body size, structure, and motions (anthropometry).

Static anthropometry deals with the dimensions of the body when it is motionless. Dynamic anthropometry deals with dimensions of reach and movement of the body in motion.

Of importance to the instrument engineer is the ability of the operator to see and reach panel locations while he or she is standing or seated. Figure 1.5e and Table 1.5f illustrate dimensions normally associated with instrumentation. The dimensions given are for the American male population. When operator populations other than American males are involved, the dimensions must be adjusted accordingly.

Information Capability

Human information processing involves sensory media (hearing, sight, speech, and touch) and memory. The sensory channels are the means by which man recognizes events (stimuli). The range of brightness carried by a visual stimulus, for example, may be considered in degrees and expressed in bits, and discrimination between stimulus levels is either absolute or relative. In relative discrimination, the individual compares two or more stimuli; in absolute discrimination, a single stimulus is evaluated.

Man performs much better in relative than in absolute discrimination. Typically, a subject can separate 100,000 colors when comparing them with each other; the number is reduced to 15 colors when each must be considered individually. Data in Table 1.5g deal with absolute discrimination encountered in levels of temperature, sound, and brightness.

In addition to the levels of discrimination, sensory channels are limited in the acceptance rates of stimuli. The limits differ for the various channels and are affected by physiological and psychological factors. A study by Pierce and Karling suggests a maximum level of 43 bits per second.

Several methods of improving information transmission to man include coding (language), use of multiple channels (visual and auditory), and organization of information (location of lamps; sequence of events). Simultaneous stimuli, similar signals with different meanings, noise, excessive intensity, and the resulting fatigue of the sensors — stimuli that approach discrimination thresholds — are all detrimental to the human information process.

The limit of the operator's memory affects information processing and is considered here in terms of long and short span. Work by H.G. Shulmann indicates that short-term memory

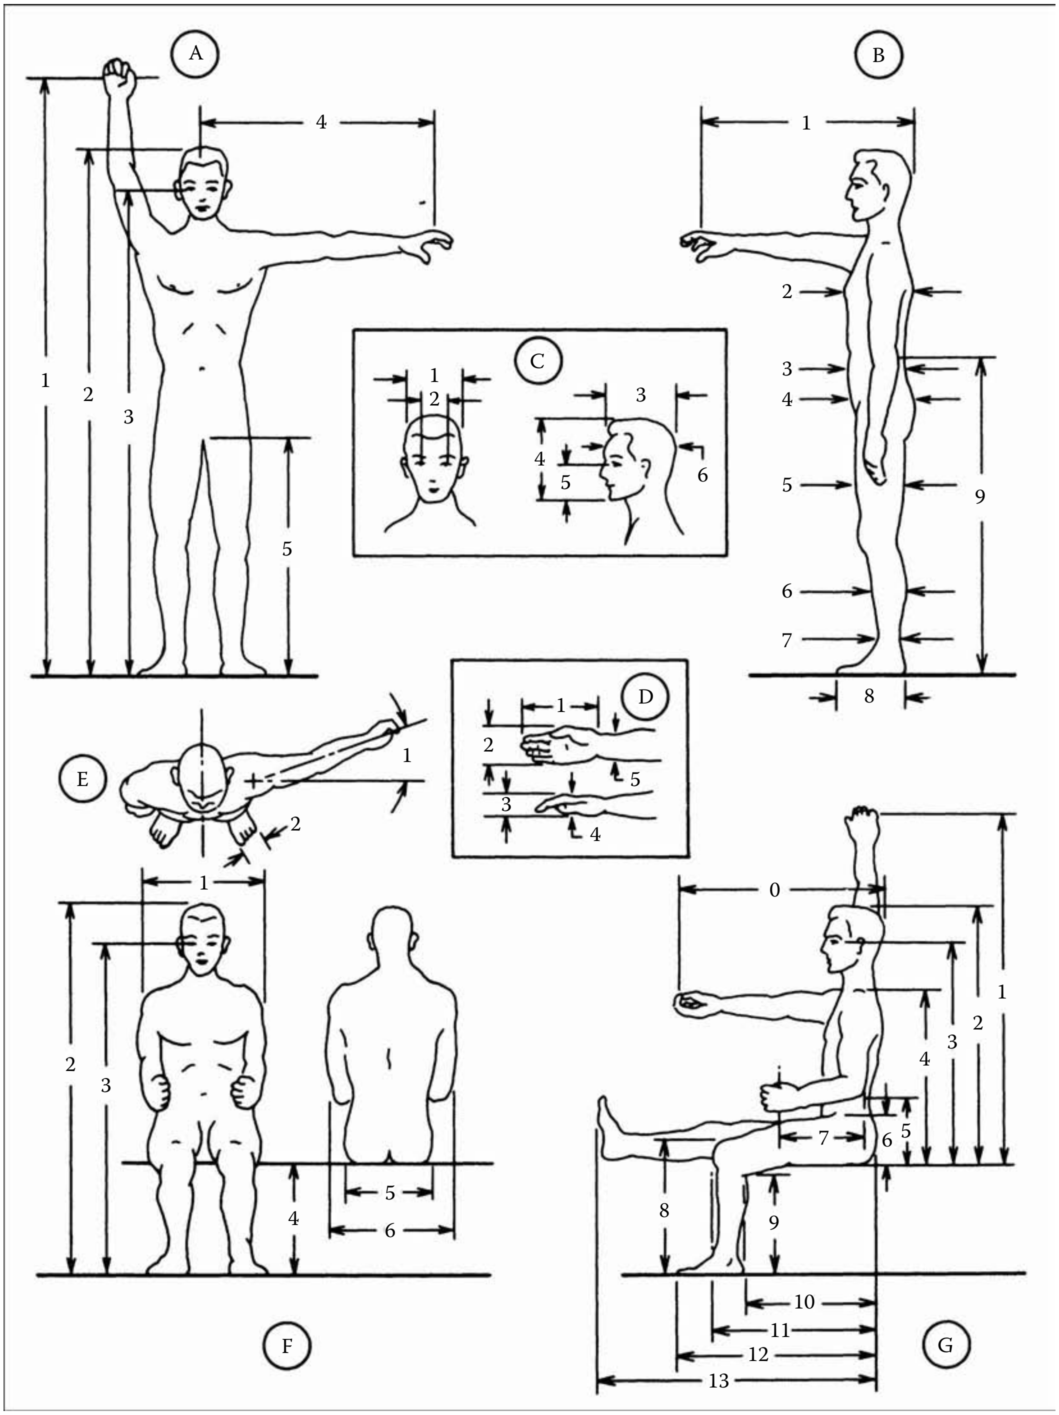

FIG. 1.5e
Body dimension chart. Dimensions are summarized in Table 1.5f.

uses a phonemic (word sounds) and long-term memory uses a semantic (linguistic) similarity. These approaches tend to make codes that are phonemically dissimilar less confusing for short-term recall and make codes that are semantically different less confusing for long-term recall. Training, for example, uses long-term memory.

Performance (Efficiency and Fatigue)

Motivation, annoyance, physical condition, and habituation influence the performance of primarily nonphysical tasks. These influences make the subject of efficiency and of fatigue controversial. Both the number and frequency of occurrence

TABLE 1.5f

Male Human Body Dimensions

Selected dimensions of the human body (ages 18 to 45). Locations of dimensions correspond to those in Figure 1.5e.

			Dimension in Inches (Meters) Except Where Noted	
		Dimensional Element	*5th Percentile*	*95th Percentile*
		Weight in pounds (kg)	132 (59.4)	201 (90.5)
A	1	Vertical reach	77.0 (1.9)	89.0 (2.2)
	2	Stature	65.0 (1.6)	73.0 (1.8)
	3	Eye to floor	61.0 (1.5)	69.0 (1.7)
	4	Side arm reach from center line of body	29.0 (0.7)	34.0 (0.8)
	5	Crotch to floor	30.0 (0.75)	36.0 (0.9)
B	1	Forward arm reach	28.0 (0.7)	33.0 (0.8)
	2	Chest circumference	35.0 (0.87)	43.0 (1.1)
	3	Waist circumference	28.0 (0.7)	38.0 (0.95)
	4	Hip circumference	34.0 (0.8)	42.0 (1.1)
	5	Thigh circumference	20.0 (0.5)	25.0 (0.6)
	6	Calf circumference	13.0 (0.3)	16.0 (0.4)
	7	Ankle circumference	8.0 (200 mm)	10.0 (250 mm)
	8	Foot length	9.8 (245 mm)	11.3 (283 mm)
	9	Elbow to floor	41.0 (1.0)	46.0 (1.2)
C	1	Head width	5.7 (143 mm)	6.4 (160 mm)
	2	Interpupillary distance	2.27 (56.75 mm)	2.74 (68.5 mm)
	3	Head length	7.3 (183 mm)	8.2 (205 mm)
	4	Head height	—	10.2 (255 mm)
	5	Chin to eye	—	5.0 (125 mm)
	6	Head circumference	21.5 (0.54)	23.5 (0.59)
D	1	Hand length	6.9 (173 mm)	8.0 (200 mm)
	2	Hand width	3.7 (92.5 mm)	4.4 (110 mm)
	3	Hand thickness	1.05 (26.25 mm)	1.28 (32 mm)
	4	Fist circumference	10.7 (267.5 mm)	12.4 (310 mm)
	5	Wrist circumference	6.3 (39.7 mm)	7.5 (186 mm)
E	1	Arm swing, aft	40 degrees	40 degrees
	2	Foot width	3.5 (87.5 mm)	4.0 (100 mm)
F	1	Shoulder width	17.0 (0.4)	19.0 (0.48)
	2	Sitting height to floor (std chair)	52.0 (1.3)	56.0 (1.4)
	3	Eye to floor (std chair)	47.4 (1.2)	51.5 (1.3)
	4	Standard chair	18.0 (0.45)	18.0 (0.45)
	5	Hip breadth	13.0 (0.3)	15.0 (0.38)
	6	Width between elbows	15.0 (0.38)	20.0 (0.5)
G	0	Arm reach (finger grasp)	30.0 (0.75)	35.0 (0.88)
	1	Vertical reach	45.0 (1.1)	53.0 (1.3)
	2	Head to seat	33.8 (0.84)	38.0 (0.95)
	3	Eye to seat	29.4 (0.7)	33.5 (0.83)
	4	Shoulder to seat	21.0 (0.52)	25.0 (0.6)

TABLE 1.5f Continued
Male Human Body Dimensions

Selected dimensions of the human body (ages 18 to 45). Locations of dimensions correspond to those in Figure 1.5e.

		Dimension in Inches (Meters) Except Where Noted	
	Dimensional Element	*5th Percentile*	*95th Percentile*
5	Elbow rest	7.0 (175 mm)	11.0 (275 mm)
6	Thigh clearance	4.8 (120 mm)	6.5 (162 mm)
7	Forearm length	13.6 (340 mm)	16.2 (405 mm)
8	Knee clearance to floor	20.0 (0.5)	23.0 (0.58)
9	Lower leg height	15.7 (393 mm)	18.2 (455 mm)
10	Seat length	14.8 (370 mm)	21.5 (0.54)
11	Buttock to knee length	21.9 (0.55)	36.7 (0.92)
12	Buttock to toe clearance	32.0 (0.8)	37.0 (0.93)
13	Buttock to foot length	39.0 (0.98)	46.0 (1.2)

Note: All except critical dimensions have been rounded off to the nearest inch (mm).

TABLE 1.5g
Absolute Discrimination Capability

(Maximum Rates of Information Transfer)

Modality	*Dimension*	*Maximum Rate (Bits/Stimulus)*
Visual	Linear extent	3.25
	Area	2.7
	Direction of line	3.3
	Curvature of line	2.2
	Hue	3.1
	Brightness	3.3
Auditory	Loudness	2.3
	Pitch	2.5
Taste	Saltiness	1.9
Tactile	Intensity	2.0
	Duration	2.3
	Location on the chest	2.8
Smell	Intensity	1.53
	Multidimensional Measurements	
Visual	Dot in a square	4.4
	Size, brightness, and hue (all correlated)	4.1
Auditory	Pitch and loudness	3.1
	Pitch, loudness, rate of interruption, on-time fraction, duration, spatial location	7.2
Taste	Saltiness and sweetness	2.3

of stimuli to which the operator responds affect efficiency and fatigue.

Performance increases when the number of tasks increases from a level of low involvement to one of high involvement. When rates of information processing are raised beyond the limits of the various senses, performance rapidly deteriorates.

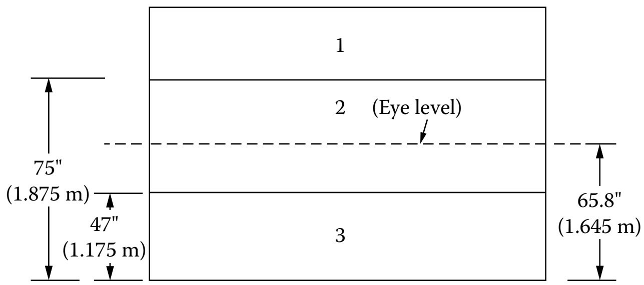
APPLICATION OF HUMAN ENGINEERING

The seemingly commonplace task of defining the man–machine system is more difficult to formalize than expected because:

1. Operators themselves are too closely involved for objectivity.
2. Engineers tend to make assumptions based on their technical background.
3. Equipment representatives focus their attention mainly on the hardware.

The definition can be more highly organized around the purpose, components, and functions of the system. The purpose of the system is its primary objective; it significantly affects design. In a system for continuous control of a process, operator fatigue and attention span are of first importance. Attention arousal and presentation of relevant data are important when the objective is the safety of personnel and equipment, and the operator must reach the right decision as quickly as possible.

Components of the system are divided into those that directly confront the operator and those that do not. The distinction is used to locate equipment. For example, a computer process console should be located for operator convenience,



Variables are grouped by function

- Indication and controls in area 2.
- Seldom used controls or push buttons in area 3.
- Indicators (analog or digital) only in area 1.
- Alarm and on/off indication in area 1.

FIG. 1.5h
Panel for standing operator. Variables are grouped by function, with indication and controls in area 2, seldom-used controls or pushbuttons in area 3, indicators (analog or digital) only in area 1, and alarm and on-off indicators in area 1.

but maintenance consoles should be out of the way so as to reduce interference with operation.

System functions are primarily the operator's responsibility, and operator function should be maximized for tasks that involve judgment and experience and minimized for those that are repetitive and rapid. Table 1.5d is an efficient guideline for task assignment.

Statistics of Operator Population

As was mentioned in the introduction to this section, the statistical nature of human engineering data influences individual applications. A specific problem demands full evaluation of the similarity among operators. For example, if color blindness is not a criterion for rejecting potential operators, color coding must be backed by redundant means (shape) to ensure recognition because one of four subjects has some degree of color blindness.

Variations and exceptions are to be expected and recognized since people are significantly different in physical size, native aptitude, and technical acculturation. Control systems and instruments should be designed for the user. A frequent mistake made by the instrument engineer is to assume that the operator will have a background similar to his or hers.

Some operators may have never ridden a bicycle, much less driven a car or taken a course in classical physics. In Arctic regions, massive parkas and bulky gloves change all the figures given in body dimension tables. It is only in Western culture that left-to-right motion of controls and indicators is synonymous with increasing values.

Setting Priorities

The diverse functions of the system confronting the operator vary in importance. The most accessible and visible areas should be assigned to important and frequently used items. Vertical placement is critical and dependent on the normal operating mode (standing, sitting, or mixed). Determination of optimum viewing zones is centered on the average eye level for standing (approximately 66 in. or 1.65 m) and sitting (approximately 48 in. or 1.2 m). Above these areas, visibility is still good, but accessibility falls off (Figures 1.5h and 1.5i). At the lower segment, even grocers know that objects are virtually hidden. Canting the panel helps to make subordinate areas more usable. (For more on control panel design, refer to Chapter 4).

Instruments should be arranged from left to right (normal eye scan direction) in (1) spatial order, to represent material movement (storage and distribution); (2) functional order, to represent processing of material (distillation, reaction, and so on); and (3) sequential order, to modify the functional order approach to aid the operator in following a predetermined sequence even under stress.

Wrap-around consoles (now in common use with the advent of distributed control systems) with multifunction displays (such as cathode ray tubes) do not require operator movement; however, the primary (most used or critical) displays and controls should be centered in front of the sitting operator with auxiliary or redundant instruments on either side. Reach considerations are much more important when the operator is normally sitting (Figure 1.5j).

Locating similar functions in relatively the same place gives additional spatial cues to the operator by associating locating with function. On this account it is advisable to divide alarms into groups related to meaning, including (1) alarms requiring immediate operator action (for example, high bearing temperatures), which must be read when they register; (2) alarms for abnormal conditions that require no immediate action (standby pump started on failure of primary), which must be read when they register; and (3) status annunciator for conditions that may or may not be abnormal. These are read on an as-needed basis.

Alarms can be separated from other annunciators, have a different physical appearance, and give different audible cues. For example, group 1 alarms can have flashing lamp windows measuring 2 × 3 in. (50 × 75 mm) with a pulsating tone. Group 2 alarms can have flashing lamp windows measuring 1 × 2 in. (25 × 50 mm) with a continuous tone, and group 3 can have lamp windows measuring 1 × 1 in. (25 × 25 mm) without visual or auditory cues.

Alarms are meaningless if they occur during shutdown or as a natural result of a primary failure. Whether usable or not, they capture a portion of the operator's attention. Several alarms providing no useful information can be replaced by a single shutdown alarm. Later, the cause of the shutdown will be of keen interest to maintenance personnel; to provide detailed information about the cause, local or back-of-panel annunciators can be used. CRT displays are generally multifunctional, and rapid operator association (especially in emergencies) with a particular situation or function can be visually facilitated by unique combinations of shapes, colors, or sounds.

Hardware Characteristics

Digital indicators are best when rapid reading or obtaining accurate values is of utmost concern. However, they give only a useless blur at a high rate of change. Analog indications allow rapid evaluation of changing values. The reading can be related to zero and full-scale for interpretation of rate of change (estimated time to reach minimum or maximum levels). Correspondingly, analog information is difficult to read when exact values are needed.

Display patterns should be natural to the eye movement—in most cases, left-to-right. An operator scanning only for abnormal conditions will be aided by this arrangement. The horizontal scan line approach proved successful in several major lines of control instruments and is now widely used by “overview” displays in distributed control systems (Figure 1.5k).

An alternative system is shown in Figure 1.5l, in which two rows are combined to give the effect of one line containing twice the number of readings. In our culture, horizontal scanning is eight times faster than vertical scanning.

Viewing distances with cathode ray tubes depend on resolution (the number of scan lines) and size of characters used in the display. Normal broadcast uses 525 scan lines, which translates to approximately 1.8 lines per millimeter. Color CRTs used as operator displays vary widely, from 38 to 254 lines per inch (1.52 to 10 lines per millimeter). As a general rule, 10 lines per character provide optimal character recognition. Words can be identified with a smaller number of lines per character. Typical color CRTs associated with process control have eight lines per character.

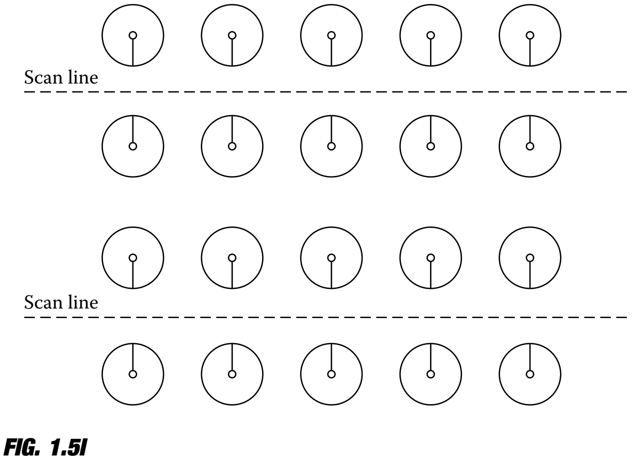

FIG. 1.5l
Dial orientation enabling two rows of instruments to be scanned at one time.

Viewing distance as it relates to character height can be determined using the following formula:

$$\text{optimum viewing distance (inches)} = \frac{\text{character height (inches)}}{0.00291} \tag{1.5(3)}$$

The interactive effect of color, contrast, and lines per character adversely influences the viewing distance.

Black-and-white screens are visible at nearly any light level, provided that reflected light is eliminated by a hood or a circularly polarized filter. Flicker resulting from slow refresh rate is a potential fatigue factor. Rates above 25 flickers per second are reasonably stable. Color CRTs require a lighting level above 0.01 lumen to ensure that color vision (retinal rods) is activated and color discrimination is possible.

Display of information through cathode ray tubes can be graphic (pictorial or schematic representation of the physical process) or tabular (logical arrangement of related variables by function). The graphic format is useful when the controlled process changes in operating sequence or structure (batch reactors, conveyor systems, and so forth) or if the operator is not familiar with the process. The tabular display format conveys large quantities of information rapidly to an experienced operator in continuous processes (distillation columns, boilers, and so forth).

Operator response in modern control systems occurs predominantly through specialized keyboards. Key activation can be sensed by the operator through tactile, audible, or visual feedback. Tactile feedback is usually found in discrete or conventional pushbutton keys and is well suited for rapid multiple operations, such as entry of large quantity of data. Membrane-, laminate-, or capacitance-activated keyboards do not provide adequate tactile feedback; therefore, audible feedback, such as a “beep” or “bell” sound, is usually provided. Keyboards with audible feedback are well suited for low-frequency usage, such as may be encountered in the operation of a process control system. Audible feedback may be confusing if adjacent keyboards with identical audible feedback are used simultaneously.

Visual feedback is useful when several operations use multiple select keys and a common activate key. Blinking or color change of the selected operation reduces the probability of an operator error.

Information Coding

Several factors affect the ability of people to use coded information. The best method to predict difficulty is by the channel center load, which uses the basic information formula of Equation 1.5(1). By this method the informational load is determined by adding the load of each character.

In a code using a letter and a number, the character load is:

$$\text{Letter (alphabet) } L_h = \text{Log}_2\ 26 = 4.70$$
$$\text{Number (0 to 9) } N_h = \text{Log}_2\ 10 = 3.32$$
$$\text{Code information } (C_h) = 4.70 + 3.32 = 8.02$$

This method applies when the code has no secondary meaning, such as when A 3 is used for the first planet from the sun, Mercury. When a code is meaningful in terms of the subject, such as O 1 for Mercury (the first planet), the information load is less than that defined by the formula.

Typical laboratory data indicate that when a code carries an information load of more than 20, a person has difficulty in handling it. Tips for code design include:

1. Using no special symbols that have no meaning in relation to the data
2. Grouping similar characters (HW5, not H5W)
3. Using symbols that have a link to the data (M and F, not 1 and 2, for male and female)
4. Using dissimilar characters (avoiding zero and the letter O and I and the numeral one)

The operator environment can be improved by attending to details such as scale factor, which is the multiplier relating the meter reading to engineering units. The offset from midscale for the normal value of the value of the variable and the desired accuracy of the reading for the useful range are constraints. Within these constraints, the selected scale factor should be a one-digit number, if possible. If two significant digits are necessary, they should be divisible by (in order of preference) 5, 4, or 2. Thus, rating the numbers between 15 and 20 as to their desirability as scale factors would give 20, 15, 16, 18 (17, 19).

Operator Effectiveness

The operator is the most important system component. His or her functions are all ultimately related to those decisions that machines cannot make. The operator brings into the system many intangible parameters (common sense, intuition, judgment, and experience) — all of which relate to the ability to extrapolate from stored data, which sometimes is not even consciously available. This ability allows the operator to reach a decision that has a high probability of being correct even without all the necessary information for a quantitative decision.

The human engineer tries to create the best possible environment for decision making by selecting the best methods of information display and reducing the information through elimination of noise (information type), redundancy (even though some redundancy is necessary), and environmental control.

Operator Load

The operator’s load is at best difficult to evaluate because it is a subjective factor and because plant operation varies. During the past 30 years, automation and miniaturization have exposed the operator to a higher density of information, apparently increasing operator efficiency in the process. Since increases in load increase attention and efficiency, peak loads will eventually be reached that are beyond the operator’s ability to handle.

Techniques for reducing operator load include the simultaneous use of two or more sensory channels.

Vision is the most commonly used sensory channel in instrumentation. Sound is next in usage. By attracting the operator’s attention only as required, it frees the operator from continuously having to face the display and its directional

TABLE 1.5m
General Illumination Levels

Task Condition	*Level (foot candles [lux])*	*Type of Illumination*
Small detail, low contrast, prolonged periods, high speed, extreme accuracy	100 (1076)	Supplementary type of lighting; special fixture such as desk lamp
Small detail, fair contrast, close work, speed not essential	50 to 100 (538 to 1076)	Supplementary type of lighting
Normal desk and office-type work	20 to 50 (215 to 538)	Local lighting; ceiling fixture directly overhead
Recreational tasks that are not prolonged	10 to 20 (108 to 215)	General lighting; random room light, either natural or artificial
Seeing not confined, contrast good, object fairly large	5 to 10 (54 to 108)	General lighting
Visibility for moving about, handling large objects	2 to 5 (22 to 54)	General or supplementary lighting

message. The best directionality is given by impure tones in the frequency range of 500 to 700 Hz.

Blinking lights, pulsating sounds, or combination of both effectively attract an operator's attention. The relative importance of these stimuli can be greatly decreased if their use is indiscriminate. (Blinking, as an example, should not be used in normal operator displays on a CRT.)

Increased frequency of a blinking light or a pulsating sound is normally associated with increased urgency; however, certain frequencies may have undesirable effects on the operator. Lights changing in intensity or flickering (commonly at frequencies of 10 to 15 cycles) can induce epileptic seizures, especially in stressful situations.

Information quantity can be decreased at peak load. In a utility failure, for example, more than half the alarms could be triggered when many of the control instruments require attention. It would be difficult for the operator to follow emergency procedures during such a shutdown. A solution gaining acceptance in the industry involves selectively disabling nuisance alarms during various emergencies. Some modern high-density control rooms have more than 600 alarms without distinction as to type or importance.

Environment

The responsibilities of human engineering are broad and include spatial relations — distances that the operator has to span in order to reach the equipment and fellow operators. Controlling temperature and humidity to maintain operator and equipment efficiency is also an important responsibility of the human engineer.

Light must be provided at the level necessary without glare or superfluous eye strain. Daylight interference caused by the sun at a low angle can be an unforeseen problem. Last-minute changes in cabinet layout can create undesirable shadows and glare from glass and highly reflective surfaces. Flat, brushed, or textured finishes reduce glare. Poor illumination can be reduced by light colors, low light fixtures, and special fixtures for special situations. Fluorescent lighting, because of its 60-Hz flicker rate, should be supplemented by incandescent lamps to reduce eye fatigue, particularly important in the presence of rotating equipment, in order to eliminate the strobing effect. Table 1.5m and Table 1.5n give detailed information on typical lighting applications.

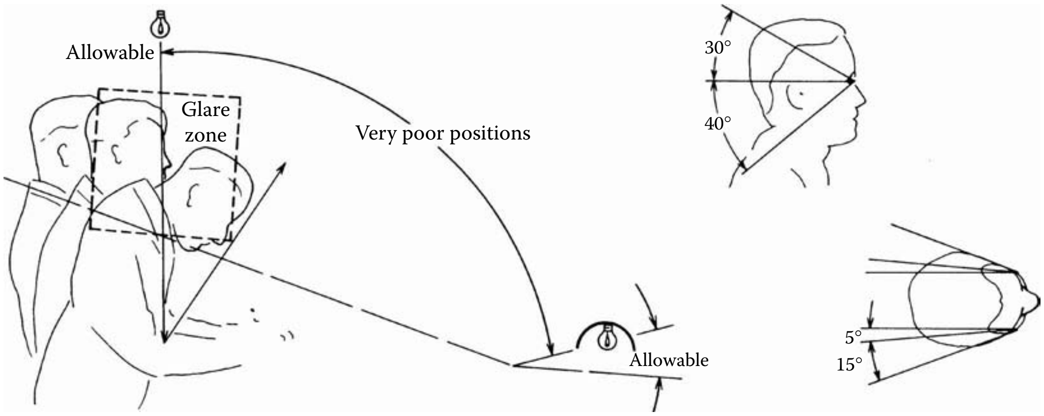

FIG. 1.5o
Typical lighting chart.

Glare is the most harmful effect of illumination (Figure 1.5o). There is a direct glare zone that can be eliminated, or at least mitigated, by proper placement of luminaires and shielding, or, if luminaires are fixed, by rearrangement of desks, tables, and chairs. Overhead illumination should be shielded to approximately 45 degrees to prevent direct glare. Reflected glare from the work surface interferes with most efficient vision at a desk or table and requires special placement of luminaires.

Eyeglasses cause disturbing reflections unless the light source is 30 degrees or more above the line of sight, 40 degrees or more below, or outside the two 15-degree zones, as shown in Figure 1.5o.

Noise and vibration affect performance by producing annoyance, interfering with communication, and causing permanent physical damage. Prolonged exposure to high sound levels causes hearing loss, both temporary and permanent. The noise exposure values in Table 1.5p are those stated in the Walsh Healy Public Contracts Act as being permissible. They are derived from the curves in Figure 1.5q and reflect the variation in sensitivity with frequency.

Annoyance and irritability levels are not easily determined because they are subjective factors, and habituation significantly affects susceptibility. A quantitative tolerance limit has not yet been established. One aspect of background noise is deterioration of speech communication.

Noise reduction may take the form of reducing noise emission at the source, adding absorbent material to the noise path, or treating the noise receiver (having operators wear protective equipment, such as ear plugs and ear muffs). The last precaution reduces both speech and noise, but the ear is afforded a more nearly normal range of sound intensity and thus can better recognize speech. Figure 1.5r illustrates typical speech interference levels.

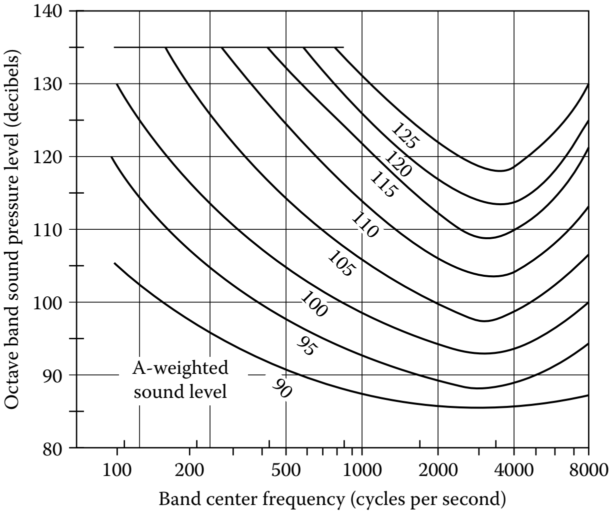

FIG. 1.5q
Equivalent sound level contours.

TABLE 1.5p
Permissible Noise Exposures[*]

Duration per Day (hours)	*Sound Level (dBA)*	*Duration per Day (hours)*	*Sound Level (dBA)*
8	90	1½	102
6	92	1	105
4	95	½	110
3	97	¼ or less	115
2	100		

[*] When the daily noise exposure is composed of two or more periods of noise exposure of different levels, their combined effect should be considered, rather than the individual effect of each. If the sum of the following fractions: $C1/T1 + C2/T2 \ldots Cn/Tn$ exceeds unity, then the mixed exposure should be considered to exceed the limit value. Cn indicates the total time of exposure at a specified noise level, and Tn indicates the total time of exposure permitted at that level.

Exposure to impulsive or impact noise should not exceed 140 dbA peak sound pressure level.

The speech interference level should be less than that given in order to have reliable conversation at the distance and voice levels shown.

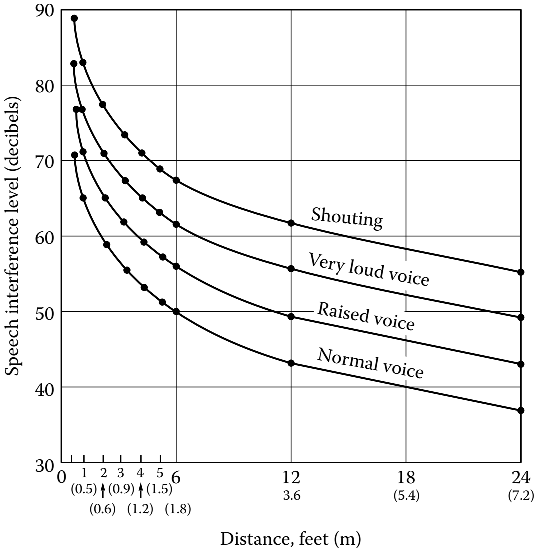

FIG. 1.5r
Speech interference levels.

SUMMARY

This section has described not only the tools needed, but the solutions that will fulfill the engineer's mandate from the industrial sector which must come out of his or her own creativity. The engineer must develop an original approach to each new assignment and introduce creative innovations consistent with sound engineering practices. Decisions must not be based solely on data from current projects reflecting only what has not worked, and human engineering must not be left to instrument manufacturers who, however well they fabricate, still do not know how the pieces must fit together in a specific application. Complications of data on mental and physical characteristics must be approached cautiously because they may reflect a group of subjects not necessarily like the operators in a specific plant.

It is the engineer's task to ensure that the limitations of men and machines do not become liabilities and to seek professional assistance when means of eliminating the liabilities are not evident.

1.6 Process Alarm Management

M. S. MANNAN, H. H. WEST (2005)

INTRODUCTION

Recently, major incidents have been caused or worsened by the excessive and undisciplined growth in the quantity of alarms and for that reason, effective alarm management (A.M.) has moved to the top of many plant project lists.

Many currently installed computer control systems provide only limited information regarding abnormal operation. The operator information is often not enhanced by the computer control system, and the operator is forced to search out trends and use intuition and experience to evaluate abnormal plant status.

Alarm growth is a natural outcome of the increased information load provided by modern control systems. However, if alarms are not managed in a disciplined manner, uncontrolled alarm growth can result, leading to ineffective and potentially dangerous alarm situations.

A structured approach to alarm management has emerged to increase alarm effectiveness and thereby overall plant safety.

History of Alarm Systems

In the not-too-distant past, alarm systems consisted of a few selected process measurements, which were hard-wire connected to panel board mounted annunciators or indicator lights, which activated when the measurements exceeded some predefined limits. These panels provided alarm annunciation to the plant operator. The panels were large but limited in capacity and thereby tended to limit the number of configured alarms.

Modern distributed control systems (DCS) and programmable electronic systems (PES) are capable of defining limits for each field measurement. Furthermore, calculated parameters, such as rate of change or a combination of field measurements could also have defined limits. Therefore, computer-based control systems have the capability to vastly increase the number of configured alarms.

Alarms not only increase the amount of information provided to the operator but can often also be a source of operator overload and confusion. There have been a number of major incidents that might have been prevented if the plant operator had recognized critical alarms among the flood of alarms that were activated.[1] One notable example of an alarm problem was the Three Mile Island accident in 1979, where important alarms were missed because of the flood of alarms received. Another example of alarm overload was the Texaco refinery explosion at Milford Haven in 1994, where, in the last 10 minutes prior to the explosion, the operators had to respond to alarms that were annunciating at a rate of about three per second.

Definitions

The most common definition of an alarm is “a signal designed to alert, inform, guide or confirm deviations from acceptable system status.” Similarly, an alarm system is defined as a system for generating and processing alarms to be presented to users.

Another common definition is that an alarm system is designed to direct the operator’s attention toward significant aspects of the current plant status. In other words, an alarm system should serve to help the operator to manage his time.

Because the DCS system processes information on a tag point-by-tag point basis, alarms and non-safety related events, such as condition monitoring alerts, equipment fault status, or journal logging events for engineering or maintenance attention, have often been described as alarms.

Hence, the A.M. system must address events that need operator attention and various other non-safety related events. Figure 1.6a provides a graphic description of the relationship between alerts and safety-related alarms. The distinction that is emerging between the two can be stated as follows: An *Alarm* requires operator action, while an *Alert* is informational in its nature and may not require a specific action by the operator.

Alarm Basics

The purpose of alarm systems is to alert operators to plant conditions that deviate from normal operating limits and thereby require timely action or assessment. Hence, the purpose of an alarm is action.

Matters that are not worthy of operator attention should not be alarmed but rather placed into a logging journal database for the potential use by other plant staff.

An alarm is useless if the operator does not know what action is required in response to it. Similarly, if the operator knows the correct action but cannot implement the action, the alarm is also useless. Useless alarms should not exist.

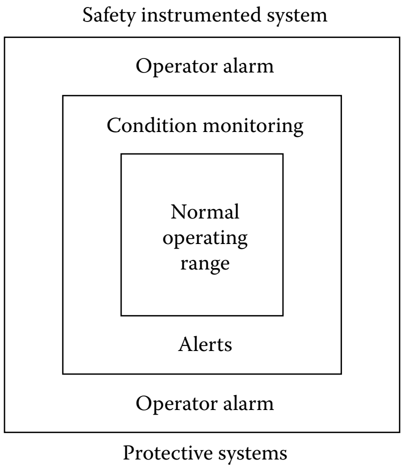

FIG. 1.6a
Graphic description of the relationship between alerts and safety-related alarms.

Logging may be a suitable alternative to be used to record non-safety related discrepancy events to prevent the unnecessary sounding of alarms. A system for assessing the significance of logged events to ensure timely intervention by maintenance personnel is absolutely required.

A.M. COSTS AND DESIGNS

The Honeywell Abnormal Situation Management Consortium[2] members estimated that a medium-sized petrochemical company consisting of about six facilities (refineries, chemical plants, etc.) might accumulate \$50 million to \$100 million in yearly losses due to plant upsets and other production-related incidents. They also noted that losses caused by plant upsets cost about 3 to 5% of the total throughput of the plant. The US National Institute of Standards and Technology estimated that plant upsets cost the national economy about \$20 billion annually. These estimates may actually underestimate the real situation. Not included in these cost estimates are the rare tragic incidents such as the Phillips Pasadena disaster or the Piper Alpha tragedy.

A.M. and Safety Instrumentation

Although alarm systems may not always have safety implications, they do have a role in enabling operators to reduce the need for automatic shutdowns initiated by safety systems. However, in cases where a risk reduction factor of 10^{-1} failures on demand is claimed, the safety system includes both the alarm system and the operator. Hence, the total safety system requires a suitable safety integrity level.[3,4]

Many Layers of Protection Analysis (LOPA) safety integrity level determination studies have incorporated alarm management as an existing layer of protection, thereby assigning the alarm system components some designated level of reliability.

Alarms that are not designated as safety should be carefully designed to ensure that they fulfill their role in reducing demands on the safety-related systems.

For all alarms, regardless of their safety designation, attention is required to ensure that under abnormal conditions or under severe emergency situations, the alarm system remains effective and the limitations of the speed of human response are recognized in its design.

Alarm Set Points

The type of alarm and its set point must be established to enable the operator to make the necessary assessment and take the required timely action.

Engineering analysis of the potential timing of events that generate alarms requires good control system engineering. Then alarm set points must be documented and controlled in accordance with the alarm system management control. Timing of alarms and potential operator reaction time are both critical. Figure 1.6b illustrates how alerts can progress into alarms and eventually into safety shutdowns.

The recommended best practice is that the engineering analysis of alarm set points be coordinated with the plant hazard and operability (HAZOP) studies.

Alarm Presentation

The alarm interface provided for the operator must be effective.[5] Alarms may be presented on annunciation panels, individual indicators, CRT screens, or programmable display devices. Alarms lists should be carefully designed to ensure that high-priority alarms are readily noted and recognized, while low-priority alarms are not overlooked, and that the list remains readable even during times of high alarm activity or when alarms occur repeatedly.

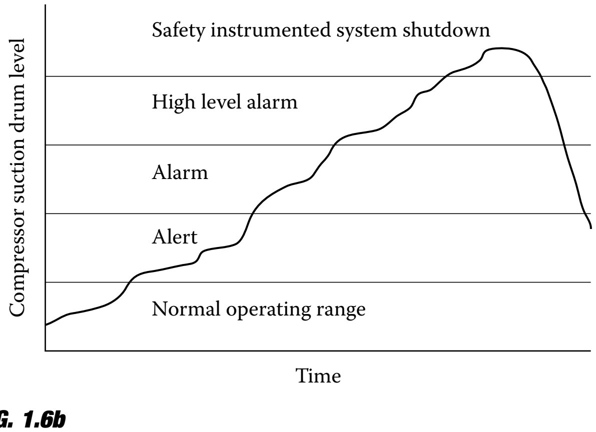

FIG. 1.6b
Alerts can progress into alarms and eventually into safety shutdowns.

Alarms should be prioritized in terms of which alarms require the most urgent operator attention. Alarms should be presented within the operators' field of view and use consistent presentation style (color, flash rate, inscription convention). The alarms should be presented in an explicit manner, should be distinguishable from other alarms, have the highest priority, and when activated, remain on view all the time.

The presentation of alarms should not exceed that which the operator is capable of acting upon, or alternatively the alarms should be prioritized and presented in such a way that the operator may deal with the most important alarms first and without distraction from the others.

Each alarm should provide sufficient information to the operator so that the operator will know the condition that caused the alarm, the plant affected, the corrective action that is required, priority of the alarm involved, the time of alarm initiation, and the alarm status.

The visual display device may be augmented by audible warnings. Where there are multiple audible warnings, they should be designed so that they are readily distinguished from each other and from emergency alarm systems. They should be designed to avoid distraction of the operator in high workload situations.

Alarm Processing

The alarms should be processed in such a manner as to avoid operator overload at all times (avoiding alarm floods). The alarm processing should ensure that fleeting or repeating alarms do not result in operator overload even under the most severe conditions. Alarm processing techniques such as filtering, the use of dead-band, de-bounce timers, and shelving have been successfully exploited by industry. For shelving alarms, a rule of thumb that has been used by some plants is that an alarm is shelved if it is repeated 10 times in 10 minutes.

Applicable alarm processing techniques include grouping and first-out alarms, suppression of lower-priority alarms (e.g., suppressing the high alarm when the high-high activates) suppression of out-of-service plant alarms, suppression of selected alarms during certain operating modes, automatic alarm load shedding, and shelving.

Care should be taken in the use of shelving or suppression to ensure that controls exist to ensure that alarms are returned to an active state when they are relevant to plant operation.

IMPROVING THE PLANT'S A.M.

In order to improve alarm management (A.M.) in a plant, it is first necessary to identify the symptoms of the problems that exist. Next it is desirable to note available elements of A.M. as the potential tools of correction. Once this been done, an A.M. improvement and rationalization project can be initiated. An example of such a project will be described later in this section.

Symptoms of A.M. Problems

The list below identifies some of the symptoms that might signal problems with the design of the A.M. system:

- Minor operating upsets produce a significant number of alarm activations.
- Routine operations produce a large number of alarm activations that serve no useful purpose.
- Alarm activations occur without need for operator action.
- Major operating upsets produce an unmanageable number of alarm activations.
- Operators do not know what to do when a particular alarm occurs.
- Occasional high alarm activation rates occur.
- A large number of configured high-priority alarms occur.
- Alarm conditions are not corrected for long periods of time.
- Alarms chatter or are frequently repeated transient.
- No plant-wide philosophy for the alarm system management has been established.
- There are no guidelines for when to add or delete an alarm.
- Operating procedures are not tied to alarm activations.
- There are active alarms when the plant is within normal operating parameters.
- There is a lack of documentation on alarm set points.
- The system does not distinguish safety, operational, environmental, and informational events.
- The schedule of alarm testing is erratic.
- A large number of defeated alarms occurs.
- Any operator or engineer can add an alarm or change the set points on his or her own authority.

The Tools and Elements of A.M.

Some of the essential elements of alarm management are:

- An alarm management philosophy document
- Written operating procedures for alarm response
- Ownership of the alarm system
- Alarm prioritization
- Alarm configuration records
- Alarm presentation
- Alarm logical processing, such as filtering and suppression
- Informational alert management
- Operator training
- Alarm testing
- Management of changes made to the alarm system

Management systems should be in place to ensure that the alarm system is operated, maintained, and modified in a controlled manner. Alarm response procedures should be available, and alarm parameters should be documented.

The performance of the alarm system should be assessed and monitored to ensure that it is effective during normal and abnormal plant conditions. The monitoring should include evaluation of the alarm presentation rate, operator acceptance and response times, operator workload, standing alarm count and duration, repeat or nuisance alarms, and operator views of operability of the system. Monitoring may be achieved by regular and systematic auditing.

A.M. Improvement and Rationalization Project

Alarm rationalization is a systematic procedure for the analysis and improvement of the DCS capability used to alert operators of alarm conditions. This process normally results in a reduction in the total number of configured alarms. Rationalization may occasionally identify the need for new alarms or changes in the alarm priority. Alarm rationalization is a structured procedure that involves a project team, with representatives from operations, maintenance, engineering, and safety.

The rationalization procedure includes a dozen essential steps, each of which is listed and described under separate titles in the paragraphs that follow:

Assessing the Current Alarm System Performance Typical metrics needed to assess the current and then later the improved alarm system include:

- Rate of alarm activation
- Pattern of alarm activations
- Priority alarm activations
- Number of standing alarms
- Time before acknowledge
- Spread between trip points
- Time before clearing
- Chattering alarms
- Correlated alarms
- Number of disabled alarms
- Total number of alarms
- Alarms per operator
- Alarm frequency by shift
- Alarm rate during emergencies
- Fraction of unacknowledged alarms
- Average time to return to normal
- Nuisance alarms
- Disabled alarms
- Bypassed alarms
- Shelved alarms

Operational metrics must also be used, such as production rate, off-quality production, number of upsets, and any other factors that the plant considers important or relevant. Safety and environmental metrics that must be used are the number of plant shutdowns, number of incidents/near misses, releases to the atmosphere, and pressure relief activations or releases to flare.

The amount of information needed to develop these metrics is daunting, thereby requiring special software to sort the alarm journals in an efficient manner. Many DCS and Supervisory Control and Data Acquisition (SCADA) systems and vendors provide alarm management features or products. However, some of these are either primitive or do not provide the necessary purpose by themselves, though they are generally improving.

There also are some add-on alarm software products on the market that enhance a control system's basic alarm capabilities by providing online A.M., advanced logical processing of alarms, alarm pattern recognition, and dynamic reconfiguration of the alarm system for varying operating conditions.

Developing an A.M. Philosophy Document A consistent, comprehensive alarm management procedure/philosophy is necessary before beginning an alarm rationalization project.

This procedure typically covers alarm type (quality, safety, environmental, maintenance information), method of prioritization of alarms, alarm logical processing methods, and testing requirements.

Reviewing the Basis for Alarm Set Points Evaluation of the alarm configuration file and the accompanying engineering reports is required to verify the basis for the alarm set points. If not available, then an engineering study must be made to recreate the basis for the alarm set points.

Identifying the purpose of the alarm and its correlation to other alarms is particularly important. Analysis of the alarm purpose includes defining the consequences of inaction to alarm notification.

Analyzing Alarm Histories Dynamic analysis of the alarm journals of several previous months is required to get a statistically valid sample. Disadvantages include correlation with operational, process, or equipment events which may not be available in the electronic database.

Prioritizing the Alarms The significance of the alarm must be determined through a ranking scheme or identified during the HAZOP study. The process hazard/risk analysis must determine the level of importance that is associated with the operator detecting the alarm and performing the expected action. Prioritization helps ensure that the operator understands the importance of the alarm itself as well as the importance of the alarm in relationship to other alarms.

The prioritization scheme is generally limited to the control systems capabilities along with third-party alarm management software on the system. The number of prioritization levels should be kept to a minimum to minimize operator confusion. Typical alarm priority categories can be critical, high, medium, and low.

Incorporating Operator Actions in Procedures In addition to ensuring that each alarm has a defined operator response, operator reliability must be enhanced by lowering the workload, reducing the number of false alarms, and making the alarm displays obvious and the operator responses simple. Management should be made responsible to ensure that the operators are well trained and that their performance is tested.

Considering Advanced Logical Processing Techniques In addition to grouping alarms, various suppression techniques and artificial intelligence techniques may be piloted and then incorporated into the alarm system.

Updating the Alarm Presentation Techniques The latest techniques in DCS graphic design and control system design should be considered to enhance operator effectiveness.

Implementing the Rationalization Project Since the rationalization may add or remove alarms and change presentation techniques or configuration parameters, it is necessary to have an implementation plan that involves the participation of the appropriate personnel, such as the operators and operating staff.

Benchmarking the New Alarm System Once the alarm rationalization is implemented, the final system should be evaluated to determine the degree of success of the rationalization effort.

For example, the alarm rate should be less than one per 10 minutes (some plants suggest that one per 5 minutes is manageable). Similarly the distribution of priority alarms should be less than five high alarms per shift and less than two such alarms per hour. Journal alerts should not exceed 10 per hour.

Auditing The goal of a good audit process is to keep the alarm system manageable and in control. Online dynamic alarm monitoring systems can assist in this. If the plant is not following a comprehensive alarm management procedure, the alarm system may go out of control again in the future.

Managing the Change Including the alarm system within the scope of the plant Management of Change program will assist in retarding uncontrolled alarm growth.

1.7 Speech Synthesis and Voice Recognition

D. H. F. LIU (1995) **B. G. LIPTÁK** (2005)

THE NATURE OF SOUND

Sound normally reaches the ear through pressure waves in the air. Vibratory motion at frequencies between 16 Hz and 20 kHz is recognized as audible sound. Sound pressure levels and velocities are quite small, as listed in Table 1.7a. Sound pressures are measured in root-mean-square (RMS) values. The RMS values are arrived at by taking the square root of the arithmetic mean of the squared instantaneous values.

The RMS pressure of spherical sound waves in a free field of air can be described as:

$$P_r = P_0/r \text{ dynes/cm}^2$$

where P_r is the RMS sound pressure at a distance r from the sound source and P_0 is the RMS pressure at a unit distance from the source.

INTRODUCTION

Several companies and universities have developed voice recognition systems. These systems and others built under grants from the Defense Advanced Research Projects Agency (DARPA) couple the ability to convert speech into electronic text with the artificial intelligence to understand the text. In these systems the computer acts as an agent that knows what the users want and how it is to be accomplished, including the voice output. Altogether, this type of speech synthesis allows untrained manufacturing workers the uninterrupted use of their hands, which could translate into increased productivity and cost savings.

SPEECH SYNTHESIS

Figure 1.7b shows the components of a computer voice response system. A synthesis program must access from a stored vocabulary a description of the required sequence of words. It must put them together, with the proper duration, intensity, and inflection for the prescribed text. This description of the connected utterances is given to a synthesizer device, which generates a signal for transmission over a voice circuit. Three different techniques can be used for generating the speech: (1) adaptive differential pulse-code modulation (ADPCM), (2) formant synthesis, and (3) test synthesis. Their typical bit rates for vocabulary storage are shown in Table 1.9c.

Adaptive Differential Pulse-Code Modulation (ADPCM)

Figure 1.7d shows the schematic of a simple ADPCM decoder. The synthesis program pulls the digitally coded words from the disk, where they are stored in the required sequence, and supplies them to an ADPCM decoder, which produces the analog signal. The only control of prosody (accent and voice modulation) that can be effected in the assembling of the message is the adjustment of time intervals between successive words, and possibly of their intensities. No control of voice pitch or merging of vocal resonance at word boundaries is possible.

This technique is suitable for messages requiring modest vocabulary size and very lax semantic constraints. Typical messages are voice readouts of numerals, such as telephone numbers, and instructions for sequential operations, such as equipment assembly or wiring.

Formant Synthesis

Formant synthesis uses a synthesis model in which a word library is analyzed and parametically stored as the time variations of vocal-tract resonance, or formants. Speech formants are represented as dark bars on sound spectrogram in the bottom panel of Figure 1.7e. These frequency variations and voice pitch periods can be analyzed by computer, as shown in the upper two panels of the figure.

TABLE 1.7c

Features of the Different Coding Techniques Used in Speech Generation

Coding Technique	*Data Rate (bits/s)*	*Duration of Speech in 10 Bits of Storage (min)*
ADPCM	20k	1
Formant synthesis	500	30
Text synthesis	700	240

In formant synthesis, the synthesizer device is a digital filter, as shown in Figure 1.7f. The filter's transmission resonance or antiresonance are controlled by the computer, and its input excitation is derived by programmed rules for voice pitch and for amplitudes of voiced sounds and noise-like unvoiced sounds. The parametric description of the speech information provides the control and modification of the prosodic characteristics (pitch, duration, intensity) of the synthetic speech and produces smooth formant transitions at successive word boundaries. This technique has also been

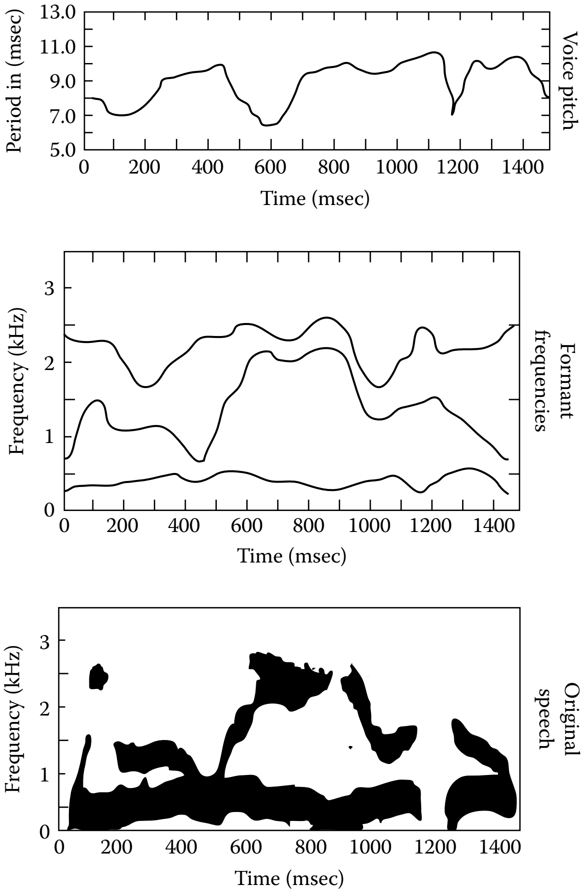

FIG. 1.7e

Analysis of the sentence "We were away a year ago." The sound spectrogram in the bottom panel shows the time variation of vocal-tract resonances or formants (dark areas). Computer-derived estimates of the formant frequencies and the voice pitch period are shown in the top two panels. (Courtesy of Bell Laboratories.)

used experimentally for generating automatic-intercept messages and for producing wiring instructions by voice.

Text Synthesis

Text synthesis is the most forward-looking voice response technique. It provides for storing and voice-accessing voluminous amounts of information or for converting any printed message into spoken form. It generates speech from an information input corresponding to a typewriter rate. In one design, the vocabulary is literally a stored pronouncing dictionary. Each entry has the word, a phonetic translation of the word, word stress marks, and some rudimentary syntax information.

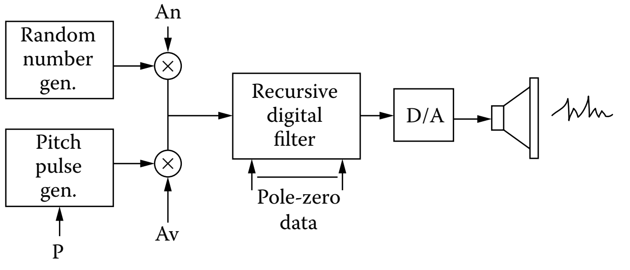

FIG. 1.7f

Block diagram of a digital formant synthesizer. (Courtesy of Bell Laboratories.)

The synthesis program includes a syntax analyzer that examines the message to be generated and determines the role of each word in the sentence. The stored rules for prosody then will calculate the sound intensity, sound duration, and voice pitch for each phoneme (the sound of human voice) in the particular context.

Figure 1.7g shows a dynamic articulatory model of the human vocal tract. The calculated controls cause the vocal-tract model to execute a sequence of "motions." These motions are described as changes in the coefficients of a wave equation for sound propagation in a nonuniform tube. From the time-varying wave equation, the formants of the deforming tract are computed iteratively. These resonant frequencies and the calculated pitch and intensity information are sent to the same digital formant synthesizer shown in Figure 1.7f. The system generates its synthetic speech completely from stored information. Language text can be typed into the system and the message can be synthesized online.

VOICE RECOGNITION

Figure 1.7h illustrates one general structure for a machine to acquire knowledge of expected pronunciations and to compare input data with those expectations. A precompiling stage involves the user's speaking sample pronunciations for each allowable word, phrase, or sentence, while identifying each with a vocabulary item number. Later, when an unknown utterance is spoken, it is compared with all the lexicon of expected pronunciations to find the training sample that it most closely resembles.

Word Boundary Detection

Silent pauses permit easy detection of word onsets at transitions from no signal to high energy and word offsets as energy dips below the threshold. Word boundary confusions can occur, when short silences during stop consonants (/p,t,k/) may resemble intended pauses. A word such as "transportation" could appear to divide into three words: "trans," "port," and "ation." Recognizers must measure the duration of the pause to distinguish short consonantal silences from longer deliberate pauses.

Feature Extraction

Acoustic data provide features to detect contrasts of linguistic significance and to detect segments such as vowels and consonants. Figure 1.7i shows a few typical acoustic parameters used in recognizers. One can extract local peak values, such as 1 in the top panel, as an amplitude measure. The sum of the squares

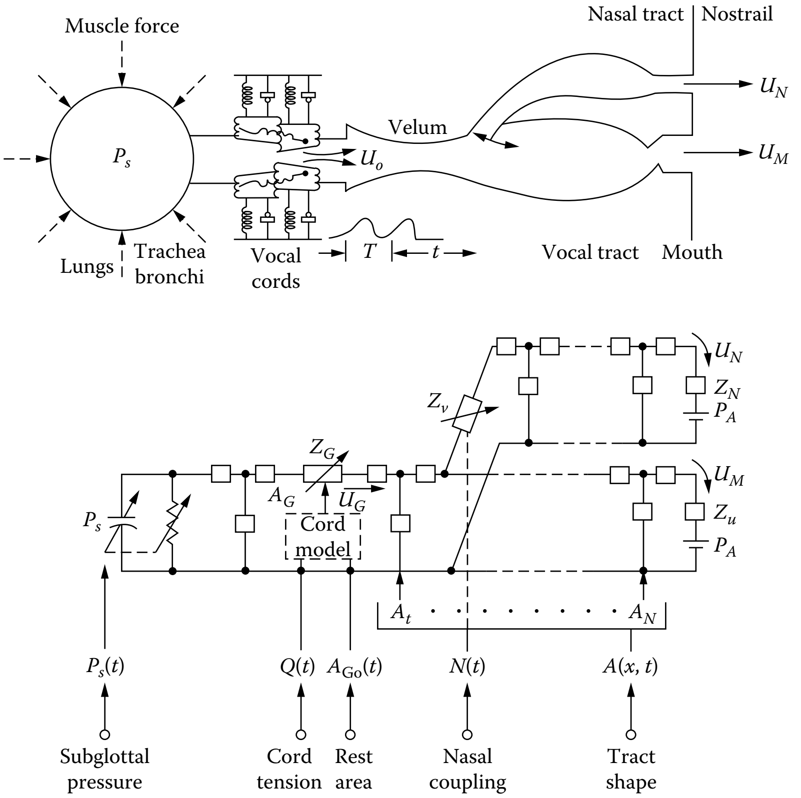

FIG. 1.7g

Speech synthesizer based upon computer models for vocal cord vibration, sound propagation in a yielding-wall tube, and turbulent flow generation at places of constriction. The control inputs are analogous to human physiology and represent subglottal air pressure in the lungs (P_s); vocal-cord tension (Q) and area of opening at rest (A_{Go}); the cross-sectional shape of the vocal tract $A(x)$; and the area of coupling to the nasal tract (N). FIG. 1.7i

Typical acoustic parameters used in speech recognizers. (a) Time waveform showing parameters that can be extracted. (b) Frequency spectrum of the waveform of a, with the detailed frequency spectrum derived from a fast Fourier transform (FFT) smoothed by linear predictive coding (LPC) to yield a smooth spectrum from which formants can be found as the spectral peaks. (c) Smoothed LPC spectra for five successive short time segments, with formants F_1, F_2, and F_3 tracked as the spectral peaks.

of all waveform values over a time window provides a measure of energy. Vowel-like smooth waveforms give few crossings per unit time; noiselike segments give many crossings per unit time.

The time between the prominent peaks at the onsets of pitch cycles determines the pitch period T_0, or its inverse, the rate of vibration of the vocal cords, called fundamental frequency or F_0. Resonance frequencies are indicated by the number of peaks per pitch period. The third pitch period shows seven local peaks, indicating a ringing resonance of seven times the fundamental frequency. This resonance is the first formant or vocal tract resonance of the /a/-like vowel. It is the best cue to the vowel identity.

The frequency content of the short speech is shown in panel (a). The superimposed results of two methods for analyzing the frequency of speech sample are given in panel (b). The jagged Fourier-frequency spectrum, with its peak at harmonics of the fundamental frequency, is determined using a fast Fourier transform (FFT), and the exact positions of major spectral peaks at the formants of the speech are determined using an advanced method called linear predictive coding (LPC). The peaks indicate the basic resonance of the speaker's vocal tract and can be tracked as a function of time in panel (c). This indicates the nature of the vowel being articulated.

Pattern Standardization and Normalization

A word spoken on two successive occasions has different amplitudes. A recognizer must realign the data so that proper portions of utterance are aligned with corresponding portions of the template. This requires nonuniform time normalization, as suggested by the different phonemic durations. Dynamic programming is a method for trying all reasonable alignments and yields the closest match to each template. Another pattern normalization involves speaker normalization, such as moving one speaker's formants up or down the frequency axis to match those of a "standard" speaker that the machine has been trained for.

Word Matching

The above processes yield an array of feature values versus time. During training, this array is stored as a template of expected pronunciation. During recognition, a new array can be compared with all stored arrays to determine which word is closest to it. Ambiguities in possible wording result from error and uncertainties in detecting the expected sound structure of an utterance. To prevent errors in word identifications, recognizers will often give a complete list of possible words in decreasing order of agreement with the data.

High-Level Linguistic Components

Speech recognizers need to limit the consideration of alternative word sequences. That is the primary purpose of high-level linguistic components such as prosodics, syntax, semantics, and pragmatics. Prosodic information such as intonation can help distinguish questions from commands and can divide utterances into phrases and rule out word sequences with incorrect stress patterns.

A syntactic rule can disallow ungrammatical sequences, like "plus divide" or "multiply clear plus." A semantic rule might disallow meaningless but grammatical sequences such as "zero divide by zero." A pragmatic constraint might eliminate unlikely sequences, such as the useless initial zero in "zero one nine."

It is possible to restructure the recognizer components to avoid propagation of errors through successive stages of a recognizer by having all the components intercommunicate directly through a central control component that might allow syntax or semantics to affect feature-extraction or word matching processes, or vice versa.

PRACTICAL IMPLEMENTATION

Figure 1.7j illustrates a typical circuit-board implementation of a method of word recognition using LPC coding for spectral data representation and dynamic programming for time alignment and word matching. An analog-to-digital converter

	F	A	Y	Y	V

A	8	1	5	5	6
F	1	7	7	7	2
F	1	7	7	7	2

FIG. 1.7j

Practical speech synthesizer based on linear predictive coding (LPC) and dynamic programming. (a) Major components of a circuit-board speech recognizer using LPC analysis. (b) Matrix of speech sound differences between reference words and word portions of unknown inputs. Alternative alignments are allowed within the parallelogram, and the path with least accumulated distance (heavy line) is chosen for best alignment of reference and input words.

chip amplifies and digitizes the microphone handset signal. An LPC chip performs the acoustic analysis and determines the necessary coefficients for specifying an inverse filter that separates such smooth resonance structure from the harmonically rich impulses produced by the vocal cords.

A matrix of these LPC coefficients versus time represents the articulatory structure of a word. Word matching can be based on comparing such coefficients with those throughout each word of the vocabulary for which the recognizer is trained.

As shown in Figure 1.7j, the analysis frames of the input are on the horizontal axis; those of a candidate reference word from the training data are on the vertical axis. The distances between the respective frames of the input and reference words are entered into the corresponding intersection cells in the matrix. The distances along the lowest-accumulated-distance alignment of reference and input data are accumulated. If that distance is less than the distance of any other reference word inserted in the illustrated reference word, then that reference word is accepted as the identity of the input.

Dynamic programming is a method of picking that path through all successive distance increments that produces the lowest accumulated distance. As shown in the heavy line in Figure 1.7j, a couple of frames of "f"-like sounds of the reference word may be identified with a single "f"-like frame of the input, or two inputs framed of "y"-like sounds may be associated with one such frame in the reference.

Dynamic programming is also applicable to word sequences, looking for beginning and end points of each word, and matching with reference words by best paths between such end points. The same procedure can be applied to larger units in successive steps, to yield "multiple-level" dynamic programming, which is used in some commercial recognition devices.

1.8 Wiring Practices and Signal Conditioning

C. H. KIM (1970) **R. G. DITTMER** (1985) **B. G. LIPTÁK** (1995, 2005)

INTRODUCTION

Although a variety of signal transmission methods are discussed in Chapter 3 of this handbook, the majority of measurement signals are still transmitted over wires. These wires can be dedicated or shared as in the case of buses in digital networks, which are described in Volume 3 of this handbook.

Consequently, proper wiring practices play an important role in the total performance of process control systems, and this section is dedicated to that topic. The goal of signal conditioning is to protect the information content of the signal from various forms of noise and interference. The types of noise and some methods of noise protection have already been discussed in Volume 1, in Section 4.13, which covers the subject of thermocouple noise protection.

In this section, a systematic discussion of the many aspects of electric signal protection and conditioning will be provided. It will start with the definitions of the types of noise encountered and will continue with the description of many applications of noise reduction. These discussions will cover the protection of grounds and wiring, the guarding of amplifiers and power transformers, common-mode rejection in amplifiers, and the protection of some specific components, such as thermocouples, multiplexers, and A/D (analog-to-digital) converters. The discussion will follow a system approach, which will start from the transducer through the signal transmission line to the signal conditioner, multiplexer, and/or A/D converters.

ELECTRIC NOISE

The ability of a process control system to perform is directly dependent upon the quality of the measured variables. This quality is dependent upon the elimination or attenuation of noise that can deteriorate the actual transducer signal. The amount of noise present is expressed as the signal-to-noise ratio, which is the ratio of signal amplitude to noise amplitude, where these amplitudes are expressed as either peak or RMS values. In the worst case, the noise can actually be of higher amplitude than the transducer signal. This type of signal, of course, would be of no value, because its useful control information content is undetectable. The wiring practices and signal conditioning techniques described here are meant to remove the noise signal from the transducer signal, ensuring an accurate measured variable signal for process control.

Although a multitude of signal noise sources exist, the four main sources are:

1. Uncontrollable process disturbances that are too rapid to be reduced by control action
2. Measurement noise resulting from such factors as turbulence around flow sensors and instrument noise
3. Stray electrical pickup, such as from AC power lines, pulses from power switching, or RF (radio frequency) interference
4. A/D conversion error

Reduction of Noise

Noise adversely affects both analog and digital electronic equipment, but in digital systems the noise effects are compounded because of the scanning or snapshot nature of digital systems.

The typical frequency ranges of some noise components are shown in Figure 1.8a. Stray electrical pickup can be minimized by good engineering and installation practices such as proper shielding, screening, grounding, and routing of wires. Even so, noise will still exist at the input, but its effect on the controlled and manipulated variables can be significantly reduced through judicious selection of filtering.

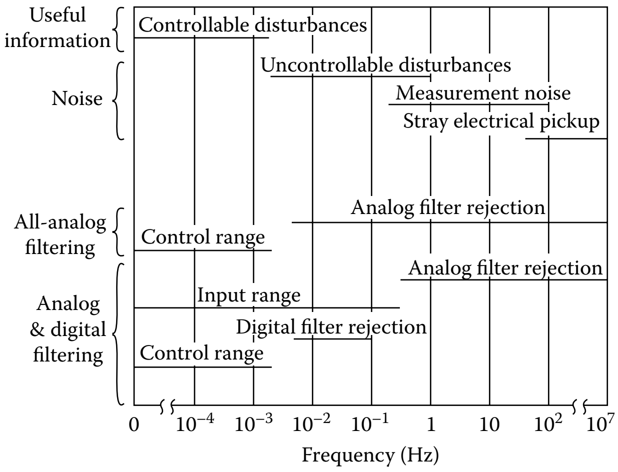

FIG. 1.8a
Frequency ranges of normal input signals, noise, and different filter types.

In most cases, relatively high-frequency noise (i.e., above approximately 5 Hz) is removed by conventional analog filters while the remaining noise occupying the range of 0.002 to 5 Hz may require either special analog filtering and/or digital filtering.

It is good practice to follow these three steps to reduce noise:

1. Estimate the dynamic characteristics (amplitude and bandwidth) of the noise.
2. Determine its effect on the controlled and manipulated variables.
3. Select the best filtering option (analog and/or digital filtering).

This section is devoted to a close examination of noise suppression techniques. Noise suppression is a system problem, and its discussion therefore should not be limited to signal transmission only but must be applied consistently from the transducer through the signal transmission line to the signal conditioner, multiplexer, and/or analog-to-digital converters.

There are several ways to reduce the effects of noise on control systems, including line filtering, integrating, digital filtering, and improving the signal-to-noise ratio, but none of these will completely solve the problem without proper cable selection and installation.

Careful examination of the various sources of noise shows that some can be eliminated by proper wiring practice. This implies good temperature compensation, perfect contacts and insulation, carefully soldered joints, use of good-quality solder flux, and use of the same wire material. However, additional precautions are needed to eliminate pickup noise entirely.

Noise Types

As shown in Figure 1.8b, signal leads can pick up two types of external noises: normal-mode and common-mode interference.

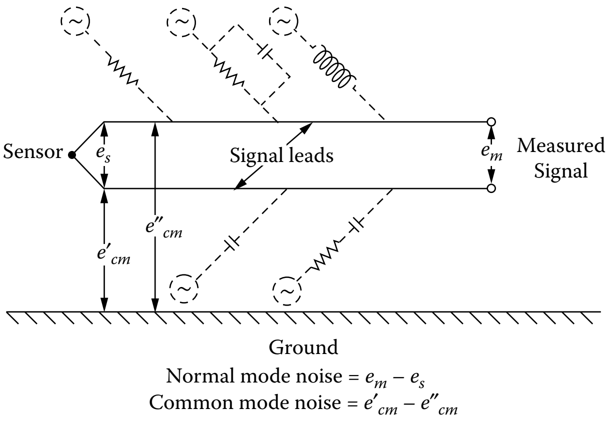

FIG. 1.8b
Electrical noise interference on signal leads.

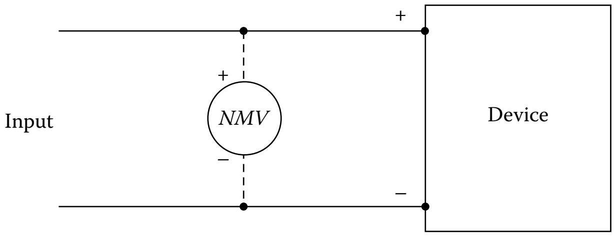

FIG. 1.8c
Definition of normal-mode voltage (NMV).

Interference that enters the signal path as a differential voltage across the two wires is referred to as normal-mode interference (Figure 1.8c). The normal-mode noise cannot be distinguished from the signal, which is coming from the transducer.

Common-mode voltage is a voltage of the same polarity on both sides of a differential input relative to ground (Figure 1.8d). Interference that appears between ground and both signal leads, as an identical voltage, is referred to as common-mode interference. Common-mode rejection is the ability of a circuit to discriminate against a common-mode voltage. This can be expressed as a dimensionless ratio, a scalar ratio, or in decibels as 20 times the $\log_{10}$ of that ratio.

Noise Sources

The most common sources of noise interference are described below:

Inductive Pickup This category includes 60-Hz noise from power lines and 120-Hz noise from fluorescent lighting, as well as high-frequency noise generated by electric arcs and pulse transmitting devices. The worst man-made electrical noise results from the opening or closing of electrical circuits that contain inductance. The amplitude of the transients generated in an inductive circuit is given in Equation 1.8(1) below:

$$E_i = L(d_i/d_t) \qquad \textbf{1.8(1)}$$

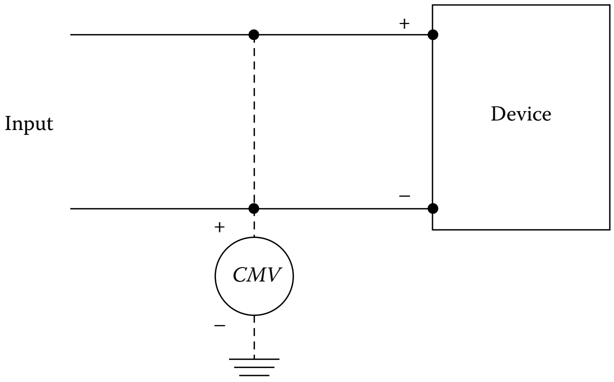

FIG. 1.8d
Definition of common-mode voltage (CMV).

TABLE 1.8e
Average Noise Conditions in Various Industries

Description		Industry Chemical	 Steel	 Aerospace
Normal signal levels (mV)		10 to 100	10 to 100	10 to 1000
Possible or expected noise level	Normal mode (mV)	1 to 10	2 to 7	1 to 10
	Common mode (V)	4 to 5	4 to 5	4 to 5
Desired noise rejection	Normal mode	10^3:1	10^3:1	10^3:1
	Common mode	10^6:1	10^6:1	10^6:1

This amplitude is calculated as the inductance (L) times the rates of change in the switched current. Closing an inductive circuit can cause a transient of twice the input voltage, and opening such a circuit can cause a transient as high as 10 times the supply voltage. When switching inductive loads from an AC supply, the noise transients are proportional to the instantaneous value of the AC supply.

Common-Mode Noise Inadequate common-mode rejection due to line unbalance will convert the common-mode noise interference into a normal-mode noise signal.

Table 1.8e shows the average noise conditions that exist in various industries. Some chemical plants have experienced as high as 60 volts common-mode noise interference. Electrical noise interference can be a severe problem in industries such as steel, power, and petroleum, where power consumption is high and complex electrical networks exist.

Other Noise Sources Other noise sources include:

Failure to distinguish between a ground and a common line. The ground currents that exist in a "daisy-chain" equipment arrangement are primarily noise signals induced into the equipment, or perhaps generated by some equipment, and they find their way back to earth. The resulting voltage drops in the ground wire place each piece of equipment at a different potential with respect to earth. This potential difference is easily coupled into the signal lines between equipment.

Common impedance coupling "ground loops." Placing more than one ground on a signal circuit produces a ground loop that is a very good antenna, and noise signals induced in the loop are easily coupled into the signal lines. This can generate noise that will completely obscure the useful signal.

Electrostatic coupling to AC signals. The distributed capacity between signal conductors and from signal conductors to ground provides a low-impedance path for cross-talk and for signal contamination from external sources.

Ineffective temperature compensation. Ineffective temperature compensation in transducers, lead wire systems, amplifiers, and measuring instruments can create changes in system sensitivity and drift in their zero. This is especially important in strain gauge transducers, resistance-type temperature sensors, and other balanced-bridge devices.

Loading the signal source. When a transducer or other signal source is connected in parallel with an amplifier or measuring device with low input impedance, the signal voltage is attenuated because of the shunting effect. This can considerably decrease the sensitivity of the system.

Variable contact resistance. All resistance-type transducers, as well as bridge-type circuits, are susceptible to changes in contact resistance. The measuring instrument is unable to distinguish between a resistance change in the sensor and a resistance change in the external wiring.

Conducted AC line transients. Large voltage fluctuations or other forms of severe electrical transients in AC power lines (such as those caused by lightning) are frequently conducted into electronic systems by AC power supply cords.

Conduction pickup. Conduction pickup refers to interfering signals that appear across the input terminals of the receiver, because of leakage paths caused by moisture, poor insulation, etc.

Thermoelectric drift. The junction of two dissimilar metal wires will create thermoelectric drift, which varies with changes in temperature. This is more critical in DC circuits, which operate at the micro volt level.

Electrochemically generated corrosion potentials. These potentials can often occur, especially at carelessly soldered junctions.

Use of the same common line. Using the same common line for both power and signal circuits or between two different signal lines can cause the appearance of transients on the signal and can also cause cross-talk between the two signals.

GROUNDING, WIRING, FILTERING

Ground Systems

Good grounding is essential for normal operation of any measurement system. The term "grounding" is generally defined as a low-impedance metallic connection to a properly designed ground grid, located in the earth. In large equipment, it is very difficult to identify where the ground is.

On standard all-steel racks less than 6 ft (1.8 m) in length, differences in potential of up to 15 volts peak to peak have been measured. Stable, low-impedance grounding is necessary to attain effective shielding of low-level circuits, to provide a stable reference for making voltage measurements, and to establish a solid base for the rejection of unwanted common-mode signals.

In a relatively small installation, two basic grounding systems should be provided. First, all low-level measurements and recording systems should be provided with a stable system ground. Its primary function is to assure that electronic enclosures and chassis are maintained at zero potential. A satisfactory system ground can usually be established by running one or more heavy copper conductors to properly designed ground grids or directly to earth grounding rods.

Signals can be measured with respect to the system reference ground only if the input signals are fully floating with respect to ground. In this case, the stable system ground fulfills the task of providing a base for common-mode noise rejection.

Signal Ground The other important ground is the signal ground. This system is necessary to ensure a low-noise signal reference to ground. This ground should be a low-impedance circuit providing a solid reference to all low-level signal sources and thus minimizing the introduction of interference voltages into the signal circuit.

The signal ground should be insulated from other grounding systems, and it is generally undesirable to connect it to the system ground at any point (Figure 1.8f). In a single-point grounding system, no current flows in the ground reference, and if the signal cable is properly selected, noise due to large and hard-to-handle low-frequency magnetic fields will not exist. It should be emphasized that a signal circuit should be grounded at one point and at one point only, preferably at the signal source (Figure 1.8g).

By connecting more than one ground to a single signal circuit, as shown in Figure 1.8f, a ground loop is created. Two separate grounds are seldom, if ever, at the same potential. This differential generates a current flow that is in series with the signal leads. Thus the noise signal is combined with the useful signal. These ground loops are capable of generating noise signals that can be 100 times larger than the typical low-level signal.

In off-ground measurements and recording, the cable shield is not grounded, but it is stabilized with respect to the useful signal though a connection to either the center tap or the low side of the signal source. Appropriate insulation is needed between the shield and the outside of the cable because the shield is driven by a voltage, which is off ground.

It is important that electric racks and cabinets be connected to a proper system ground and not be allowed to contact any other grounded element in the building. Guidelines on grounding can be summarized as follows:

1. Intentional or accidental ground loops in either the signal circuit or the signal cable shield will produce excessive electrical noise in all low-level circuits and will destroy the useful signal.
2. Every low-level data system should have a stable system ground and a good signal ground.
3. The signal circuit should be grounded at only one point.
4. The signal cable shield should not be attached to more than one grounding system.
5. A floating signal circuit and its signal cable shield should always be grounded at the signal source only.

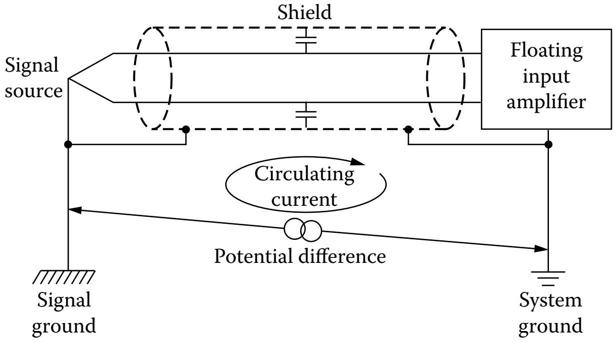

FIG. 1.8f
An example of the incorrect grounding of floating signal circuit. The ground loop is created by multiple grounds in a circuit and by grounding the shield at both ends.

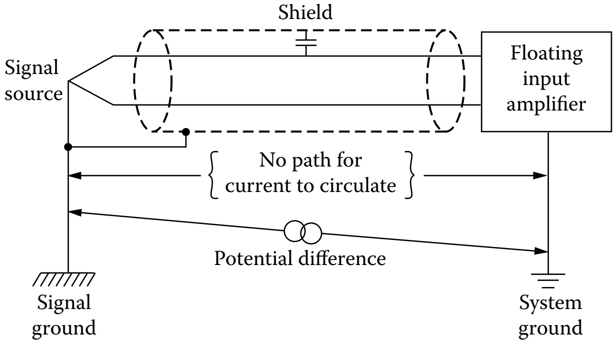

FIG. 1.8g
Illustration for showing the correct grounding of a floating signal circuit. By grounding the shield at the signal end only, the ground loop through the signal lead is eliminated.

Grounding and Safety A low-resistance, noncurrent-carrying metallic connection to ground should be established and maintained from every exposed metallic surface that can possibly become connected to an electrical circuit. Electrical connection could occur because of a fault, such as a loose wire making electrical contact, or as a result of leakage of current through insulation.

Grounding is usually accomplished by bonding all elements together in a system terminated at the ground connection where power enters the premises. It may be a bare or green insulated wire. More often it is the conduit enclosing the wires. It must be securely joined, electrically and mechanically, to each piece of equipment. It is connected at the service entrance to the grounded circuit conductor (white wire) and to ground. Instead of connection to a ground at the entrance connection, other suitable earth ground connections are acceptable. Equipment mounted directly on the structural steel of a building is considered effectively grounded. Water pipes have been considered effective grounds. However, because of the increasing use of plastic pipe for water connection, this is no longer an unquestionable ground.

Grounding serves two distinct safety-related purposes. First, since the ordinary power circuit has one side grounded, a fault that results in electrical contact to the grounded enclosure will pass enough current to blow a fuse. Second, the possibility of a shock hazard is minimized since the low-resistance path of a properly bonded and grounded system will maintain all exposed surfaces at substantially ground potential.

Grounding is effective against hazards from leakage currents. All electrical insulation is subject to some electrical leakage. This may rise to a significant level as insulation deteriorates with age or as layers of conductive dust accumulate in the presence of high humidity. A proper grounding system with low electrical resistance will conduct leakage currents to ground without developing significant potential on exposed surfaces.

Grounding of exposed metal surfaces is distinct from the grounded conductor of ordinary power wiring. The latter is a current-carrying ground, capable of developing significant potential, particularly on long lines and with surge or even short-circuit currents. Grounding systems are substantially noncurrent carrying, except for possible leakage currents.

Potential can build up only during the time required for a fuse to blow as a result of a specific fault that results in direct contact between power and grounding systems. Grounding is customarily not required for signal circuits where either maximum voltage is 30 V, or maximum current under any circumstance cannot exceed 5 mA.

Wiring

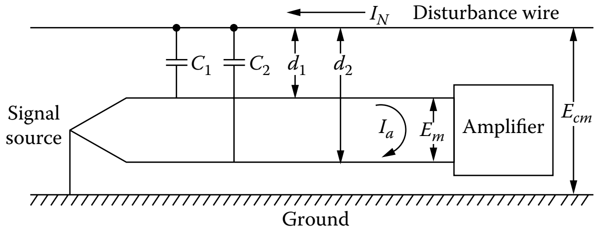
Another important aspect of reducing noise pickup involves the wiring system used to transmit the signal from its source to the measuring device or computer.

In less demanding low-frequency systems, where the signal bandwidth is virtually steady state and system accuracy requirements are not very high, two-wire signal leads will normally suffice. Otherwise, a third wire, or shield, becomes necessary.

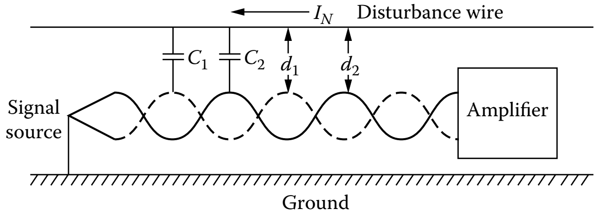
Shielding Where top performance is required, the shield is run all the way from the signal source to the receiving device. As already mentioned, the shield should be grounded at the signal source and not at the receiver because this arrangement provides maximum rejection of the common-mode noise.

The cable shield reduces electrostatic noise pickup in the signal cable, improves system accuracy, and is indispensable in low-level signal applications where high source impedance, good accuracy, or high-frequency response is involved. As the signal frequency approaches that of the noise, which is usually at 60 Hz, filtering can no longer be used to separate noise from the useful signal. Therefore, the only practical solution is to protect the signal lines and prevent their noise pickup in the first place.

Elimination of noise interference due to magnetic fields can be accomplished by wire-twisting (transpositions). If a signal line consisting of two parallel leads is run along with a third wire carrying an alternating voltage and an alternating current, the magnetic field surrounding the disturbing line will be intercepted by both wires of the signal circuit. Since these two wires are at different distances from the disturbing line, a differential voltage will be developed across them. If the signal wires are twisted (Figure 1.8h), the induced disturbing voltage will have the same magnitude and cancel out.



Where $d_1 \neq d_2$. Thus, $C_1 \neq C_2$, $\therefore$ difference in distance from disturbance wire creates a differential voltage, and a noise signal will be induced into the signal leads.



Where $d_1 = d_2$. Thus $C_1 = C_2$, $\therefore$ the induced disturbing voltages will have the same magnitude and cancel out when twisted wires are used.

FIG. 1.8h
The use of twisted wires eliminates the noise interference that might otherwise be caused by the magnetic fields of disturbing wires.

In order to prevent noise pickup from electrostatic fields, an effective shield must surround the low-level signal conductors. One type of shield consists of a woven metal braid around the signal pair, which is placed under an outside layer of the insulation. This type of shield gives only 85% coverage of the signal line and is adequate for some applications if the signal conductors have at least ten twists per foot (33 twists per meter). Its leakage capacity is about 0.1 picofarad per foot (0.3 picofarad per meter).

At the microvolt signal levels, this kind of shielding is not satisfactory. Another type of signal cable is shielded with a lapped foil (usually aluminum-Mylar tape) type shield, plus a low-resistance drain wire. This type of shielding provides 100% coverage of the signal line, reducing the leakage capacity to 0.01 picofarad per foot (0.03 picofarads per meter). To be most effective, the wires should have six twists per foot (20 twists per meter).

The lapped foil shield is covered with an insulating jacket to prevent accidental grounding of the shield. Care should be exercised to prevent the foil from opening at bends.

This type of low-level signal cable provides the following benefits:

1. There is an almost perfect shield between the signal leads and ground.
2. Magnetic pickup is very low because the signal leads are twisted.
3. Shield resistance is very low because of the low-resistance drain wire.

Feedback Currents and Shield Grounding In most measurements a voltage difference is detected relative to a reference potential. This is usually achieved by sending the signal through an amplifier, which provides the required gain. Such single-ended amplifiers will change the measurement signal in relation to the same reference potential, which is maintained both at their inputs and outputs.

With charge- and voltage-detecting single-ended amplifiers, the nonsignal related and unbalanced current flow, which is normal-mode noise pickup and is flowing in the zero reference conductor, must be limited. When such an amplifier and its power supply are suspended within a shield that they do not contact, capacitive couplings will occur. As it is shown in Figure 1.8i, because these couplings are at different voltages, they will cause a current flow back to the inputs (feedback) of the amplifier.

If the signal zero reference is grounded (as in Figure 1.8j) and allowing the shield to float does not solve the problem. This is because a current flow will be produced in the input side of conductor 3 by the potential difference of the earth between conductor 3 and the shield capacitance at the opposite end.

Figure 1.8k shows the solution to eliminating such feedback currents. Directly referencing the signal common to the shield will eliminate the capacitive feedback to the amplifier.

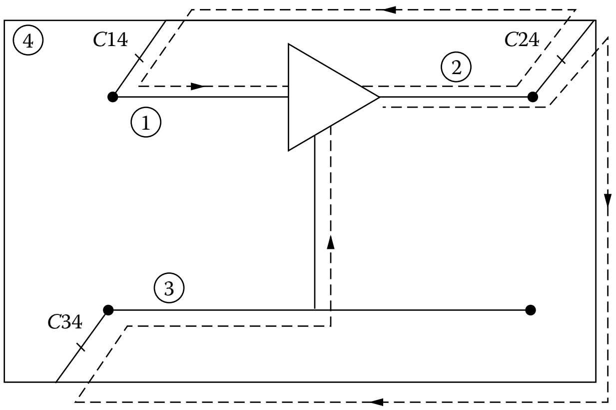


FIG. 1.8i
When the shield is ungrounded, the single-ended amplifier will receive feedback currents.

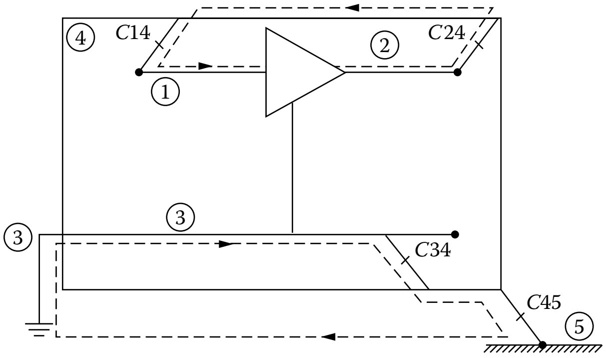

FIG. 1.8j
The feedback current problem is not solved by grounding the common conductor if the shield is not grounded.

Digital Communication Shielding Some 20 digital control system buses are in use worldwide. Table 1.81 lists their requirements for shielding. Most use unshielded twisted pair wiring (UTP). While only a minority requires the use of shielded twisted pairs (STP), shielding will improve the performance of all of them.

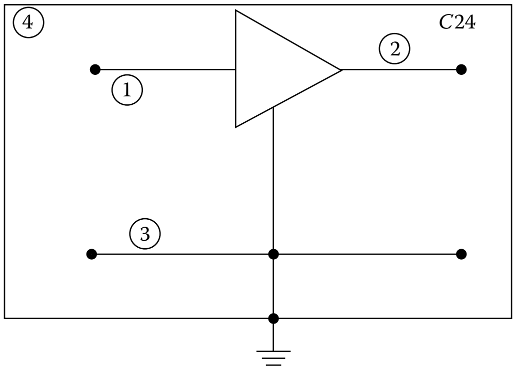

FIG. 1.8k
The solution is to properly ground both the shield and the common conductor.

Often, whole cabinets or complete rooms are also shielded. Raised computer floors with electrically bonded stringers are regularly used to help with this task. Zero signal reference grids (ZSRG) are also provided by such building structural elements as Q-decking and rebar. The proper bonding of non-continuous grids, the use of special gaskets, and wave-guide ventilation covers are usually also desirable.

Shielded rooms should usually be grounded at a single point with respect to the outside world. This requires the installation of surge protectors so that bridging is provided for the isolation gaps during lightning strikes.

Wire Costs and Installation Typical costs of the three types of twisted signal wires are shown in Table 1.8m. The use of ordinary conduit is not likely to reduce noise pickup. Its serious limitation is in obtaining or selecting a single ground point. If the conduit could be insulated from its supports, it would provide a far better electrostatic shield. The following general rules should be observed in installing low-level signal circuits:

TABLE 1.8m
Costs of Three Twisted Signal Wire Designs

Recommended for the Following Type Noise Source	*Single Pair Cable Type*	*Cost ($) per Foot (per Meter)*
Magnetic fields	Twisted	.20 (.60)
Magnetic and electrostatic	Twisted with metal braid; 85% shield coverage	.40 (1.20)
Magnetic and electrostatic	Twisted with aluminum/Mylar; 100% shield coverage	.25 (.75)

1. Never use the signal cable shield as a signal conductor, and never splice a low-level circuit.
2. The signal cable shield must be maintained at a fixed potential with respect to the circuit being protected.
3. The minimum signal interconnection must be a pair of uniform, twisted wires, and all return current paths must be confined to the same signal cable.
4. Low-level signal cables should be terminated with short, untwisted lengths of wire, which expose a minimum area to inductive pickup.
5. Reduce exposed circuit area by connecting all signal pairs to adjacent pins in the connector.
6. Cable shields must be carried through the connector on pins adjacent to the signal pairs.
7. Use extra pins in the connector as a shield around signal pairs by shorting pins together at both ends and by connecting to the signal cable shield.
8. Separate low-level circuits from noisy circuits and power cables by a maximum physical distance of up to 3 ft (0.9 m) and definitely not less than 1 ft (0.3 m).
9. Cross low-level circuits and noisy circuits at right angles and at the maximum practical distance.

10. Use individual twisted shielded pairs for each transducer. Thermocouple transducers may be used with a common shield when the physical layout allows multiple pair extension leads.
11. Unused shielded conductors in a low-level signal cable should be single-end grounded with the shield grounded at the opposite end.
12. High standards of workmanship must be rigidly enforced.

Filtering

Filtering is required to stabilize the input signal and to remove AC noise components (particularly 60-Hz noise) resulting from direct connection of normal-mode AC signals, from normal-mode noise pickup, or from conversion of common-mode noise to normal-mode noise due to line unbalance.

A reliable, low-cost, and effective filter for analog inputs is the balanced resistance–capacitance filter, shown in Figure 1.8n. Its ability to eliminate AC components increases exponentially with the frequency of the noise signal components. Common-mode noise rejection of about 40 decibels is possible with this type of filter, with decibel defined as

$$\text{decibel} = 20\log\frac{\text{inlet noise amplitude}}{\text{outlet noise amplitude}} \qquad \mathbf{1.8(2)}$$

Filtering action causes a time delay (time constant, $T = RC$) between a signal change at the transducer and the time of recognition of this change by the measuring device. As the time delay may be on the order of 1 s or more, there are situations in which this has to be reduced (systems with high-frequency response). In order to decrease only the time delay but not the filtering efficiency, inductance–capacitance filters may be used (Figure 1.8o). This increases the filter cost.

Since a filter limits the bandwidth of the transmitted signal, it might be desirable to use more complicated and expensive filters when higher-frequency AC transducer signals are involved. Fortunately, this type of situation seldom occurs.

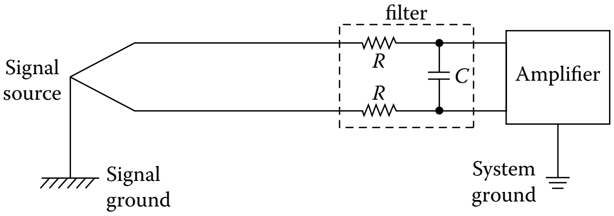

FIG. 1.8n
For analog signals, a low-cost and effective filter design is the balanced resistance–capacitance one.

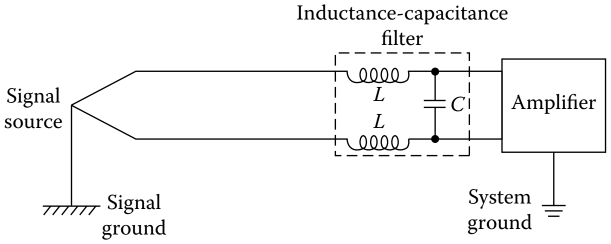

FIG. 1.8o
The use of an inductance–capacitance filter reduces the time delay while maintaining filtering efficiency.

APPLICATIONS

The following paragraphs discuss the application of noise protection techniques to transducers, thermocouples, multiplexers, and A/D converters.

Transducer Signals

The common-mode rejection of a good low-level signal amplifier is on the order of 10^6 to 1. This value is always decreased when the signal source and input signal leads are connected to the amplifier. Signal source impedance and signal lead impedance have a shunting effect on the signal input to the amplifier. From the point of view of maximum power transfer, equal impedance on both sides of a circuit is an ideal termination.

In the transmission of voltage signals, however, current flow has to be reduced to as close to zero as possible. This is achieved by selecting amplifiers with high input impedance and using transducers with low output impedance. Good instrumentation practice dictates that the input impedance of the amplifier be at least ten times the output impedance of the signal source.

However, low signal source impedance has an adverse effect on the pickup signal, because the low impedance of the transducer will shunt it. An additional step is to ground the transducer whenever possible and to run a balanced signal line to the amplifier input.

There are three basic techniques to condition transducers with high output impedance: high-impedance voltage amplifiers, charge amplifiers, and transducer-integrated unloading amplifiers.

Voltage Amplifiers Voltage amplifiers must have an amplifier input impedance that is very high compared with the source impedance. In this way, the amplifier's effect on the phase and amplitude characteristics of the system is minimized. A typical transducer with output amplifier is shown in Figure 1.8p. High impedance is practical for an amplifier, but an equally significant portion of the load is in the interconnecting cable itself, and it does not take much cable to substantially lower the available voltage.

In applying a voltage amplifier, low-frequency system response must be considered. The voltage amplifier input

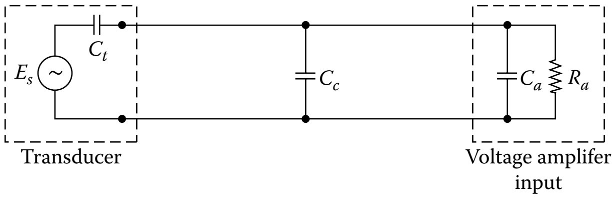

FIG. 1.8p
A typical transducer with voltage output amplifier. E_s = transducer voltage source; C_t = transducer capacitance; C_c = signal cable shunt capacitance; C_a = amplifier input capacitance; R_a = amplifier input resistance.

resistance (R_a) in combination with the total shunt capacitance forms a high-pass first-order filter with a time constant (T) defined by

$$T = R_a(C_t + C_c + C_a) \qquad \textbf{1.8(3)}$$

Cut-off frequency can become a problem when it approaches information frequency at low source capacitance (short cable or transducers with very low capacitance) or at lower amplifier-input resistance.

Charge Amplifiers Charge amplifiers have been widely used in recent years. This approach avoids the cable capacitance effects on system gain and frequency response. The typical charge amplifier shown in Figure 1.8q is essentially an operational amplifier with integrating feedback. A charge amplifier is a device with a complex input impedance that includes a dynamic capacitive component so large that the effect of varying input shunt capacitance is swamped, and the output is the integral of the input current.

Filtering of the resultant signal on both the low and high ends of the information band is desirable at times so that it is possible to get a rather high order of rejection without affecting information by using band pass filters. The addition of a resistor in parallel with the feedback capacitor in a charge amplifier will decrease the closed-loop gain at low frequencies, resulting in the desired high-pass filter characteristics.

Unloading Amplifiers Unloading amplifiers integrally mounted in a transducer housing (Figure 1.8r) have become available from transducer manufacturers because neither voltage amplifiers nor charge amplifiers offer a very satisfactory solution to the conditioning problem for systems with very high input capacitance (usually a result of very long lines).

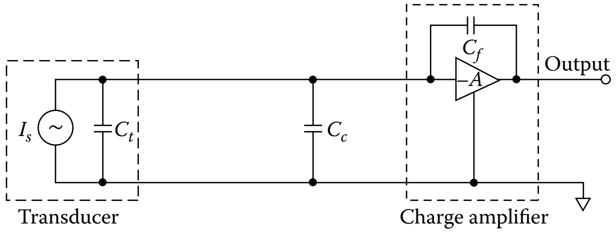

FIG. 1.8q
Transducer with charge output amplifier. I_s = transducer current source; C_f = feedback capacitance; C_t = transducer capacitance; C_c = signal cable shunt capacitance.

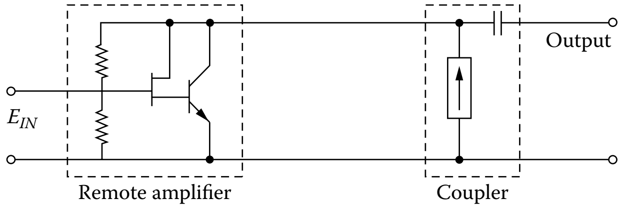

FIG. 1.8r
In comparison to voltage or to charge amplifiers, the unloading amplifier, which is located at the transducer, reduces the input capacitance.

With the voltage amplifier, signal-to-noise ratio suffers, because capacitance loading decreases the available signal. In a charge amplifier, the signal-to-noise ratio suffers because of the increased noise level (input noise is a direct function of input capacitance). Thus, remote signal conditioning appears to offer a satisfactory solution to the accommodation of long data lines. If closely located to the transducer, voltage-responding or charge-responding amplifiers are equally effective.

However, these techniques decrease the dynamic range capability (changing input amplifier gain to accomplish a range change is not possible) and restrict the high-frequency response signal amplitudes due to the limited current capability of the remote amplifier. When these two limitations are overcome, almost all of the signal-conditioning equipment will be at the remote location.

In summary, the following steps are recommended for low-level signals:

1. Select a signal source with low output impedance.
2. Select an amplifier (or measuring device) with high output impedance.
3. Use a balanced line from signal source to amplifier input (maximum allowable unbalance is 100 ohm/1000 ft or 0.33 ohm/m).
4. Keep signal cables as short as possible.
5. Use remotely located amplifiers when long signal cables are required (except for thermocouple and RTD signals).
6. Select a signal source that can be grounded (thermocouples, center-tapped sensors, etc.).

It is evident that common-mode rejection must be maintained at a high level in order to attain noise-free results from low-level signal sources.

Differential Amplifier An example where two zero references exist is a detector in a self-powered transmitter, which is interfaced to a digital I/O system. Other systems requiring

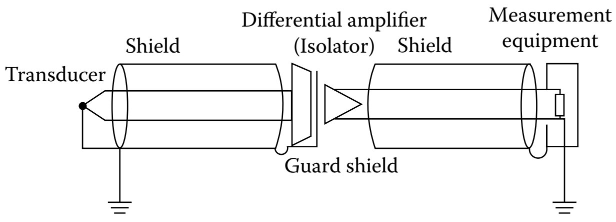

FIG. 1.8s
The application of a differential amplifier, which is also called an isolator.

differential amplifiers are grounded thermocouples, strain gauges, and data link applications.

It often happens that a common signal is the I/O reference to earth, while a self-powered transmitter generates an output, which is referenced to the ground of its own power supply. The difference between the zero references of the I/O and the transmitter's power supply will appear as common mode noise, which can cause normal-mode pickup.

In such cases, one should use a differential and not a single-ended I/O. If a differential I/O cannot be used, an external differential amplifier, also called an isolator, can be installed in the signal lines. In that case, each side of this isolator should be independently shielded and each shield should be grounded to its respective signal ground. Figure 1.8s illustrates the application of a differential amplifier.

Amplifier Guard In a normal measuring device, a signal line is connected to a differential DC amplifier with floating inputs. Generally, these amplifiers are provided with an internal floating shield that surrounds the entire input section, as shown in Figure 1.8t. This floating internal shield is called a "guard shield" or simply a "guard."

The guard principle requires that the amplifier guard be driven at the common-mode voltage appearing at the amplifier inputs. The most effective way to do this is as follows:

1. Connect the amplifier guard to the signal cable shield and make sure that the cable shield is insulated from the chassis ground or from any extension of the system ground.
2. Connect the ground of the signal source to the signal cable shield. In this way, the amplifier guard and signal cable shield are stabilized with respect to the signal from the source.
3. Connect the signal cable shield and its tap to the signal source and also to the signal ground, which should be as close as possible to the signal source. This will limit the maximum common-mode voltage. The signal pair must not be connected to ground at any other point.
4. Connect the amplifier chassis, the equipment enclosure, the low side of amplifier output, and the output cable shield to the system ground.

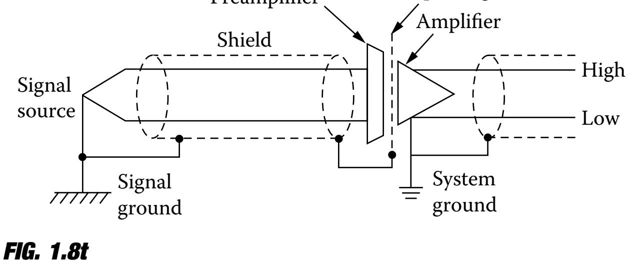

FIG. 1.8t
Correct grounding of an isolating amplifier.

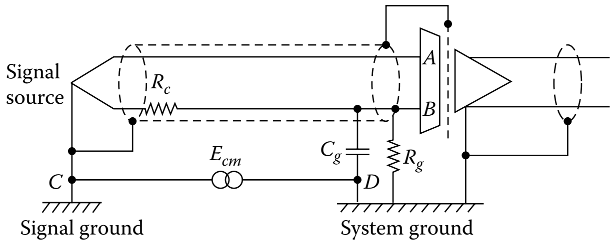

FIG. 1.8u
The design of a guard-shielded measuring system. R_c = cable unbalance resistance; C_g = measuring circuits/system ground capacitance; R_g = measuring circuits/system ground resistance; E_{cm} = common-mode voltage.

Power Transformer Guard It is important to avoid strong magnetic fields emanating from the power supply transformer. To avoid capacitive coupling, the transformer should be provided with at least two or three shielding systems. The third or final shield should be connected to the power supply output common. The inner shield should be connected to the signal ground.

Common-Mode Rejection Measurement

A typical configuration of a guard-shielded measuring system is shown in Figure 1.8u. The common-mode rejection of the system is measured by taking the ratio of the common-mode voltage (E_{cm} between points C and D) divided by the portion of E_{cm} that appears at the amplifier inputs A and B. Almost all of the remainder of the voltage E_{cm} will appear across C_g and R_g, in which case the common-mode rejection (CMR) is approximately:

$$CMR_{\mathrm{AC}} = 1/2FC_gR_c \qquad \mathbf{1.8(4)}$$

$$CMR_{\mathrm{DC}} = R_g/R_c \qquad \mathbf{1.8(5)}$$

It can be seen from these relations that the common-mode rejection is dependent on the value of R_c, which is the unbalance of the transducer and signal lines. In an ideal case, when R_c is zero, the common-mode rejection will be infinite.

Measuring by direct methods that portion of E_{cm} that appears across R_c is not possible since it is unlikely that any instrument could be connected to the source to measure the voltage across R_c without also changing the current through it. Thus, when testing the guarding of a system, the component

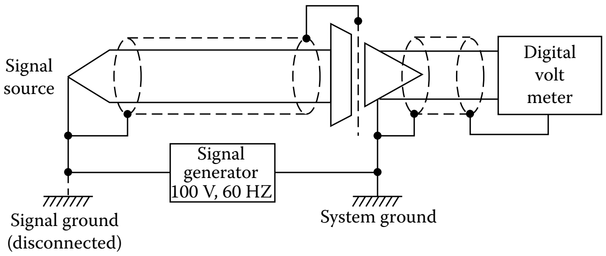

FIG. 1.8v
A method for measuring common-mode rejection.

due to E_{cm} at the amplifier output is measured. This value is divided by the amplifier gain, and it is assumed that the quotient is a good measure of the voltage across R_c.

A practical setup for measuring rejection in a common-mode system is shown in Figure 1.8v. With the signal source disconnected from the signal ground, a 100-V, 60-Hz signal from a signal generator is applied between the system ground and signal source. The change in the digital voltmeter (DVM) reading will show the effect of this common-mode signal on the system. To obtain the effective voltage across the amplifier inputs, this change is divided by the amplifier gain. The common-mode rejection is then obtained by dividing the signal generator voltage with the assumed voltage at the amplifier input. For example,

Amplifier gain (G) = 1000
Signal generator voltage (E'_{cm}) = 100 V
DVM reading before applying E_{cm} (e'_{cm}) = 2.0 V
DVM reading after applying E_{cm} (e''_{cm}) = 2.1 V

The increase in voltage at the amplifier output (e_{cm}) due to E_{cm} is:

$$e_{cm} = e''_{cm} - e'_{cm} = 2.1 - 2.0 = 0.1 \text{ volts} \tag{1.8(6)}$$

The voltage at the amplifier input (e'_{cm}) due to E_{cm} is:

$$e'_{cm} = \frac{e_{cm}}{G} = \frac{0.1}{1000} = 0.0001 \text{ volts} \tag{1.8(7)}$$

Therefore, the common-mode rejection of the system is:

$$CMR = \frac{E_{cm}}{e'_{cm}} = \frac{100}{0.0001} = \frac{1{,}000{,}000}{1} = 10^6:1 \tag{1.8(8)}$$

When dealing with AC common-mode signals applied to DC measuring instruments, it is important to consider the effect of inherent noise rejection in the measuring instrument (or amplifier). Many DC instruments have an input filter that allows the undisturbed measurement of DC signals in the presence of AC noise. Such instruments are said to have normal-mode interference rejection.

Thus, if common-mode rejection is measured by the indirect method just described, the apparent common-mode rejection will be the product of the actual common-mode rejection and the filter rejection. In the earlier example, if a filter with 10:1 normal-mode rejection were inserted in front of the amplifier input, the apparent common-mode rejection would increase to 10^7:1 (Ref. 2).

Thermocouple Signals

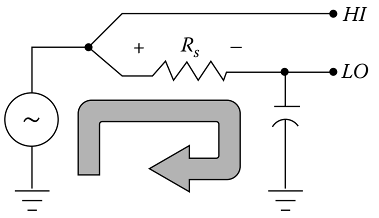
The thermocouple signal is very weak — a 1-degree change in temperature results in only a few millionths of a volt change in output. Because of this, precautions must be taken against errors due to stray currents resulting from the proximity of electrical wiring (common-mode noise) or from capacitive secondary grounds (normal-mode interference).

Common-Mode Noise Common-mode noise (Figure 1.8w) appears on both thermocouple signal wires and therefore can be filtered out as 60-Hz (or 50-Hz) harmonic noise.

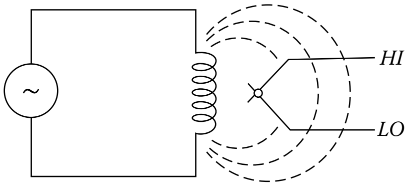
The filter does reduce the interference dramatically, but it also causes the voltmeter to be sluggish when responding to a step change. It is also possible to eliminate the common-mode interference by using twisted wire leads, because each time the wire is twisted, the flux-induced current is inverted.

Another recommended form of protection against any type of common-mode noise is guarding and shielding. If the shield surrounding the lead wires is connected to the guard surrounding the voltmeter, the interfering current caused by AC interference does not flow through the thermocouple lead resistance but instead is shunted.

Naturally, when thermocouples are scanned, the scanner guard must be switched to the shield of the thermocouple being read to eliminate ground loops. Harmonics can also be removed by integrating the incoming signal over the power line cycle in an integrating analog-to-digital converter or



Normal mode



Common mode

FIG. 1.8w
Normal-mode noise that enters only one of the lead wires is more difficult to remove than common-mode noise, which acts on both leads.

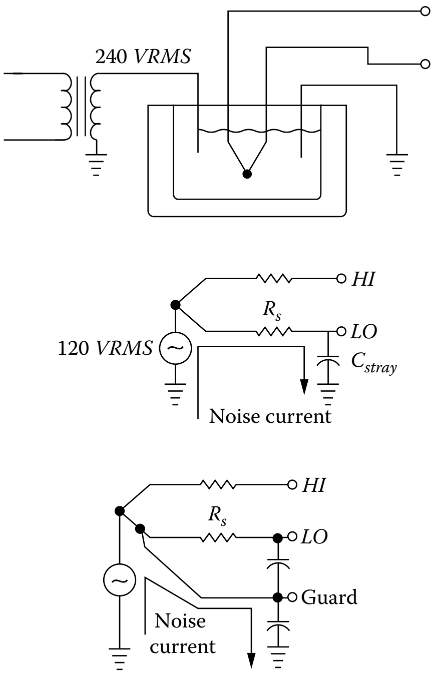


FIG. 1.8x
The normal-mode noise is reduced by the addition of a guard wire.[3]

voltmeter. In short, common-mode noise is relatively easy to remove.

Normal-Mode Noise The same cannot be said about normal-mode noise. Normal-mode noise interference can occur in the measurement of the temperature in a molten metal bath, which is heated by electric current. In this case, the thermocouple junction is in direct contact with a common-mode noise source. In addition, the capacitive ground (C-stray) from the LO terminal of the thermocouple to the chassis causes a current flow in the low lead and an associated normal-mode noise voltage across the resistance R_s (Figure 1.8x).

If a guard lead wire is connected directly to the thermocouple, the current flowing in the LO lead through the resistance R_s is drastically reduced. Therefore, the worst form of interference is DC offset caused by a DC leakage current; whatever normal-mode noise remains in the system cannot be distinguished from the measurement and, in case of weak signals, even a small amount of noise can represent a large amount of interference.

Complex TC Conditioning One of the important practices in eliminating noise in low-level signal systems is the arrangement of external circuits so that noise pickup will appear equally on both sides of the signal pair, remain equal, and appear simultaneously at both input terminals of the differential amplifier (or measuring device). In this case it can be rejected by common-mode protection without affecting the frequency response or the accuracy of the system. If a noise signal is allowed to combine with the useful signal, it can only be separated from the useful signal by selective filtering.

Thermocouple signals are susceptible to noise problems because they are often in contact with the process or structure being measured. Additional thermoelectric potentials developed in the bimetallic leads should be accounted for when measuring a signal from a thermocouple. The best thermocouple materials are not the best electrical conductors, yet lead wires must be made of thermocouple materials all the way back to the reference junction.

To eliminate the need to account for each bimetallic wire junction, one can compare the output of the thermocouple with the output of an identical thermocouple in a controlled-temperature environment. The balance of the circuit in that case can be made of copper wires creating an identical couple in each lead and producing a zero net effect when both couples are at the same temperature.

The use of a constant-temperature reference junction is the most accurate method of compensation, but it is not the most convenient. A simulated constant-temperature reference can be obtained with devices containing compensating junctions, millivolt sources, and temperature-sensitive resistors. These devices can also permit the use of copper lead wires instead of thermocouple leads.

A more complex conditioning circuitry is shown in Figure 1.8y, which performs the functions of thermocouple signal conditioning, noise discrimination, balancing, ranging, and standardizing. This circuit must be tied to a calibration scheme for the system output. The balance circuit shown accomplishes both variable offset and calibration.

The signal-conditioning circuitry makes it possible to convert the transducer output to make use of the optimum range of the measuring system for the best linearity, accuracy, and resolution.

Because thermocouples are often in electrical contact with the device or structure of which the temperature is being measured and with an intentional ground at the sensor, differential input amplifiers with very good common-mode rejection are required to effectively discriminate against noise in the structure or grounding system.[1]

Low-Level Signal Multiplexing

Conventional noise rejection techniques, such as twisting leads, shielding, and single-point grounding, have been discussed. It was pointed out that input guarding involves isolating the transducer input signal from the common-mode voltage between signal leads and ground. This change from differential to single-ended signal can occur at any place in the system after the multiplexer. Early versions of multiplexing systems employed crossbar switches, relays, and similar electromechanical devices for low-level input signal multiplexing.

Electromechanical Multiplexing Mercury-wetted relays, which are actuated by rotating magnets, can be used as electromechanical multiplexers. They have the advantage of high

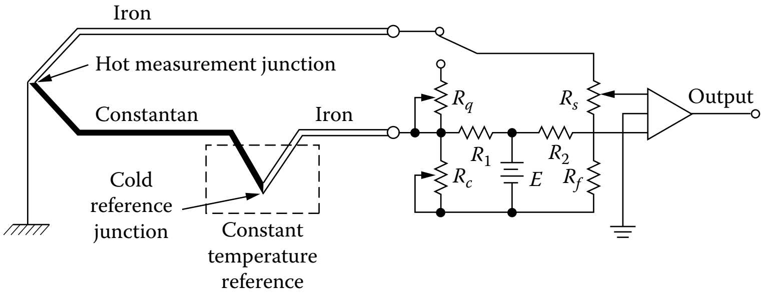

FIG. 1.8y
A complex thermocouple conditioner performs the functions of TC signal conditioning, noise discrimination, balancing, ranging, and standardizing. E = a precision isolated power supply; R_1 and R_2 = precision bridge resistors, low values (5 or 10 ohms); R_c = balance control variable resistor, large resistance value; R_f = reference resistor, large resistance value; R_q = equivalent line resistor for use during stabilizing and calibrating; R_s = span adjustment potentiometer.

cross-talk isolation, because of their high (10^{14}) ratio of open-circuit to closed-circuit resistance. They are also accurate because of their very low contact resistance.

Their disadvantages include their low speed (a few hundred points per second) and their vibration sensitivity, if it exceeds 0.75 g. DCS multiplexers, operating on analog process signals, in the past often used such electromechanical multiplexers.

Passive Filter Multiplexing A simple passive filter (RC) circuit, as shown in Figure 1.8z, can be designed to reject common-mode noise from about 40 decibels, at the selected frequency. More sophisticated passive networks (such as parallel T or notch filters) improve noise rejection, but it is hard to obtain 60-decibel noise rejection with passive circuits.

Because of deficiencies in the noise rejection capabilities of the earlier approaches, the limitations in scan rates, and the ever-increasing use of data acquisition systems, many devices have been developed with extended capability to cover the spectrum of present-day requirements. Each general category contains subsets of devices using the same basic switching element but offering application-dependent variations. The most important variations are the programmable range (i.e., gas chromatograph signal) switching and input grounding.

Three multiplexing techniques are commonly used: (1) flying capacitor multiplexer, (2) three-wire multiplexer, and (3) solid-state multiplexer.

Flying Capacitor Multiplexing The capacitive-transfer (flying capacitor) switching arrangement, shown in Figure 1.8aa, is simple, economical, and capable of great noise rejection (including random noise spikes). This system is limited to applications where signal bandwidth requirements are narrow (on the order of 0.5 to 1 Hz), due to a necessarily large transfer capacitance to minimize the effect on system resolution of charge losses and of delays during charging, settling, and digitizing.

In the capacitive transfer circuit, between scans, a set of normally closed contacts connects the low-leakage transfer capacitor across the input signal. Common practice is to short the amplifier input during this between-scan period to avoid stray pickup (due to a high-impedance open circuit).

When the multiplexer selects the input for scan, the amplifier input short is removed, and the contacts switch to connect the transfer capacitor to the amplifier input. This transfer circuit introduces input attenuation and phase lag, which must be considered in circuit design. An additional

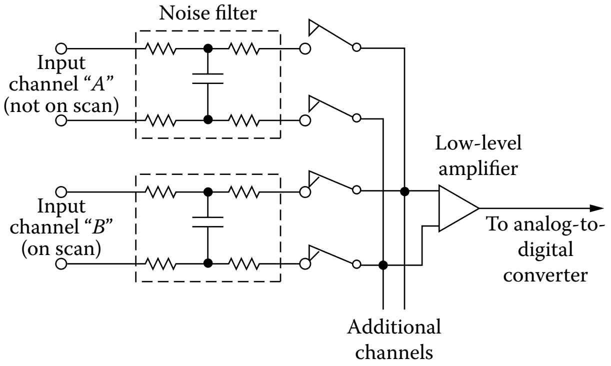

FIG. 1.8z
Circuit showing the passive filter multiplexer.

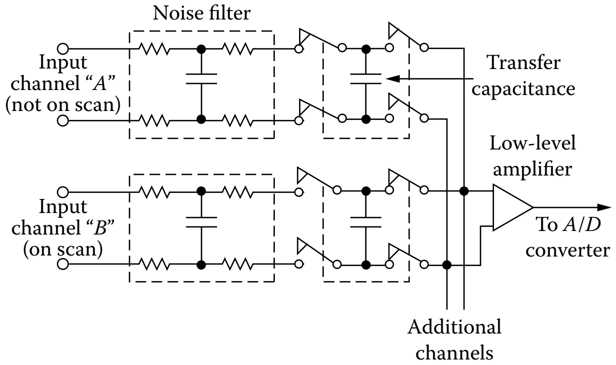

FIG. 1.8aa
Circuit describing the flying capacitor multiplexer.

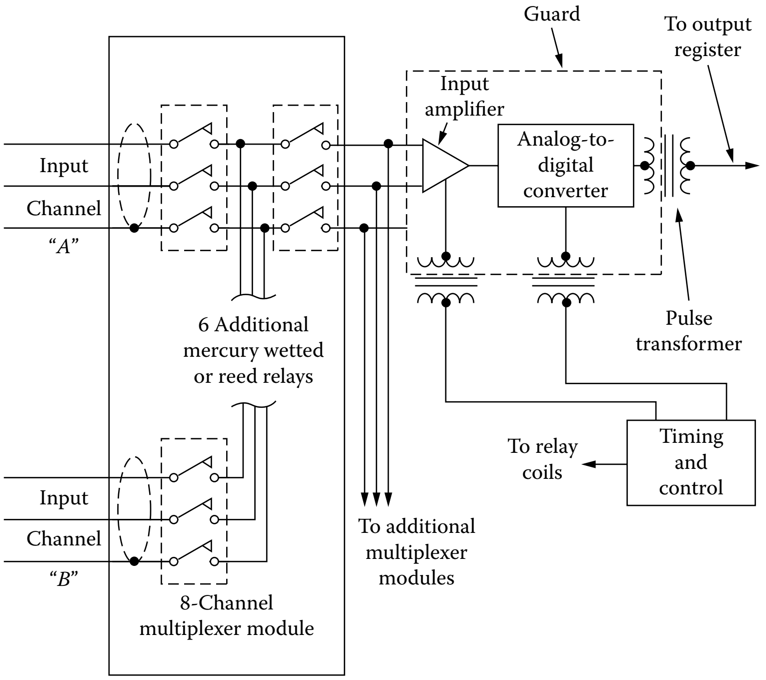

FIG. 1.8bb
Circuit describing the three-wire multiplexer, which provides high common-mode voltage rejection.

RC filter is usually necessary to achieve acceptable common-mode rejection of 100 to 120 decibels.

Three-Wire Multiplexing The three-wire multiplexing system requires the transducer lead wires to be shielded with the shield terminated at the signal ground. This guard shield must be carried through the multiplexer, at each point, up where the differential signal is transferred to a ground-referenced signal.

In Figure 1.8bb the input amplifier and analog-to-digital converter are enclosed within the guard. The serial digital data are transmitted through a shielded pulse transformer to an output register for presentation in parallel form. Relay coils are matrixed and controlled by address logic.

This system is used when input signal bandwidths of several hertz are required, since filtering is not essential to obtain good common-mode rejection. Common-mode rejection from DC to 60 Hz is about 100 decibels at reduced input bandwidth.

Solid-State Multiplexing Compared to electromechanical multiplexers, solid-state units do not have speed- or vibration-related limitations, but their early models did suffer from cross-talk due to their low open-circuit resistance. The switches in most newer multiplexers are MOSFET (metallic oxide semiconductor field-effect transistor) and are satisfactory for multiplexing digital signals. The costs of solid-state multiplexers using large-scale IC (integrated circuitry) circuits is lower than that of the electromechanical ones. Similarly, their power consumption and size are also smaller. Another advantage is that because their switching is electronic, the address of the next channel can be programmed in any order desired.

A solid-state multiplexing system is shown in Figure 1.8cc. In a typical high-performance solid-state multiplexer, each input has a matched pair of transistor switches terminating at the primary of shielded input transformers, which are driven through an isolation transformer. One cycle of a square wave of peak amplitude equal to the input signal level is transferred across the transformer by alternately pulsing the switches.

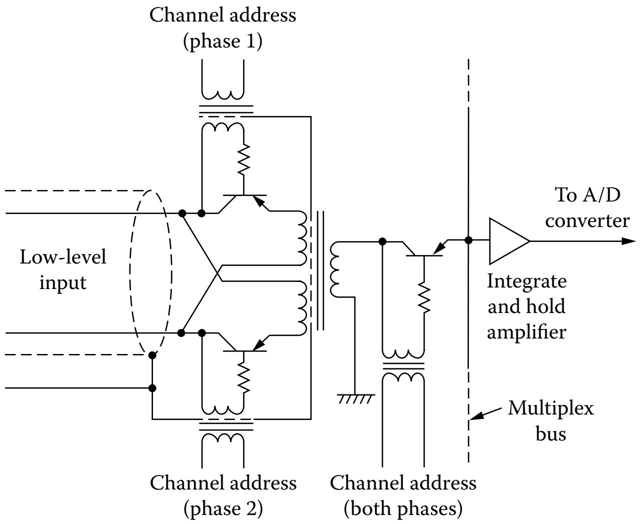

FIG. 1.8cc

TABLE 1.8dd
Feature Summary of Commonly Used Multiplexers

Features	*Capacitive-Transfer*	*Three-Wire*	*Solid-State*
Cost	Low	Low	High
Input signal ranges	±50 to ±500 mV	±5 mV to ±5 V	From 5 mV full scale to 100 mV full scale
Scan rates (points per second)	Up to 200	Up to 200	Up to 20,000[a]
Operable common-mode environment (volts)	Up to 200 to 300	Up to 200 to 300	Up to 500
Common-mode rejection from DC to 60 Hz (decibels)	100 to 120[b]	100 to 120	120
Accuracy	±0.1% full scale at 1 to 10 samples per second scan rate; ±0.25% full scale at 10 to 50 samples per second	±0.1% full scale for all scan rates	±0.1% full scale[c]

[a] 10-mV resolution in high common-mode environments.
[b] With a two-section filter.
[c] Overall accuracy.

This signal is synchronously rectified to preserve original input polarity integrated over the cycle period, and it is amplified and held for digitizing by an integrator and hold amplifier. The cost of the system is relatively high, making the application economically impractical unless high common-mode tolerance is required. Common-mode rejection from DC to 60 Hz of 12 decibels is easily obtained.

Selection of any multiplexing system should be based on the performance, reliability, and cost of a particular application. Table 1.8dd summarizes the features of the discussed systems.

Digital Multiplexing When there are many channels, the multiplexer must be fast even if the incoming signals are slow. Figure 1.8ee illustrates such a fast multiplexer configuration, where one analog-to-digital converter (ADC) is used for each channel. The outputs of the converters are connected to a common bus through interface units.

In such a configuration, the digital processor, which is used to process the digital outputs of the converters, uses the same bus. This way the digital processor can alternately access the outputs of each ADC and thereby can multiplex their output signals.

Data Acquisition Boards The data acquisition board allows a computer to access a set of analog signals that are connected to that plug-in board. Most of these boards operate on signals that have already been filtered and amplified, although some boards can directly accept the output signals of sensors.

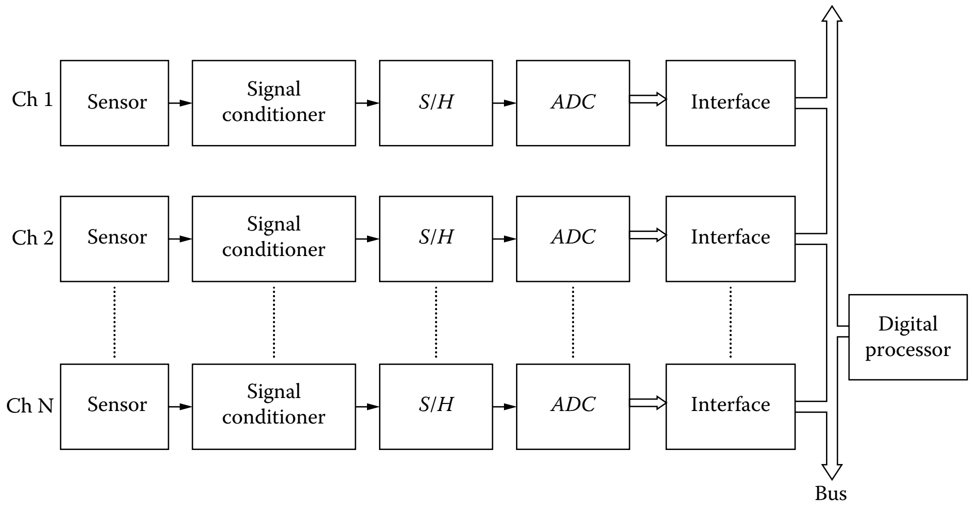

FIG. 1.8ee
Multi-channel data acquisition using digital multiplexing.

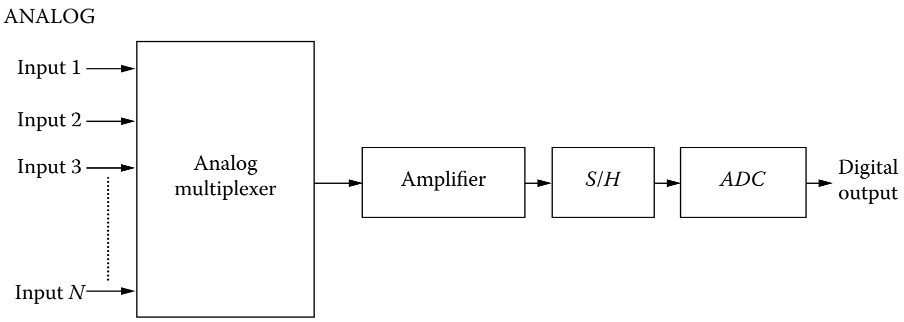

FIG. 1.8ff
Data acquisition boards commonly allow access digital computers to reach 8 or 16 analog inputs.

Such boards are provided with the required signal conditioning circuits.

Usually 8 or 16 analog inputs can be connected to a data acquisition board. Figure 1.8ff illustrates such a system, which consists of an analog multiplexer, an amplifier, a sample and hold circuit, and an analog-to-digital converter. Some data acquisition boards also provide (usually two) analog output channels for control purposes.

A/D Converters

Just as microprocessors have evolved in sophistication, so have A/D converters. Eight-bit resolution devices common in the 1960s provided a resolution of about +/– 0.4%. In the year 2000 the first 21-bit resolution A/D was used in a temperature transmitter, providing a resolution of +/– 0.00005%. D/A converters have also evolved with resolutions increasing from 8-bit up to the 18-bit versions used in the better transmitters beginning in the year 2000.

The result of combining these technologies is a universal transmitter that accepts inputs from any TC, RTD, mV, resistance, or potentiometer signal, checks its own calibration on every measurement cycle, has minimal drift over a wide ambient temperature range, incorporates self-diagnostics, and is configured using pushbuttons or simple PC software. The reconfiguration process is quick and convenient, and it tends to allow for lower inventories by making the transmitters interchangeable.

Noise Rejection in A/D Converters The dominant noise in A/D converters is line frequency noise. One approach toward reducing this noise is to integrate the input signal. The integrating technique relies on A/D converter hardware. The operation of the A/D converter is such that it converts the continuously monitored measurement into a pulse train and totals the number of pulses it receives. If the measurement time is equal to the period of the line frequency, integration yields the true value of signal level, and the line frequency noise effect becomes zero, as shown in Figure 1.8gg.

This method is usually applied to slow multiplexers (e.g., 40 points per second scan rate) and is suitable for applications in process monitoring and control where high sampling frequencies are not required. In appropriate situations, it provides noise rejection of about 1000 to 1 (or 60 decibels) at 60 Hz and offers good rejection of other frequency noises.

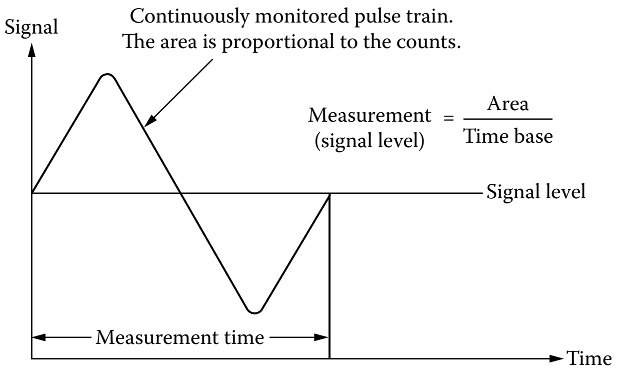

FIG. 1.8gg
Line frequency noise reduction by integrating the input signal of an A/D converter.

CONCLUSIONS

Electrical noise problems are not unique to new installations. Even systems that were in satisfactory operation can develop noise as a result of burned or worn electrical contacts, defective suppressors, loose connections, and the like. Any equipment used to identify the noise source must have the frequency response and rise time capability to display noise signals. Minimum requirements would be 10 MHz bandwidth and 35 nanosecond rise time.

Once the noise signal or a shielding problem is identified, its elimination involves applying the basic rules discussed earlier. The most important ones are listed below:

1. Select signal sources with low output impedance and with grounding capability. Never use the shield as a signal conductor and never splice a low-level circuit.

2. Use only top-quality signal cable, in which the signal pair is twisted and protected with a lapped foil shield, plus a low-resistance drain wire. Low-level signal cables must be terminated with short, untwisted wire, which expose a minimum area to inductive pickup.
3. Provide a good low-resistance system ground and a stable signal ground located near the signal source. Use individual twisted shielded pairs for each transducer. Unused shielded connector in a low-level signal cable should be single-end grounded with the shield grounded at the opposite end.
4. Ground the signal cable shield and signal cable circuit at the source only, and keep them from contacting ground at any other point. Signal cable shield must be maintained at a fixed potential with respect to the circuit being protected.
5. Thermocouple transducers may be used with common shield when the physical layout allows multiple pair extension leads.
6. Connect all signal pairs to adjacent pins in a connector and carry the cable shields through it on adjacent pins. Provide shield around signal pairs in the connector by shorting pins together at both ends and by connecting to signal cable shields.
7. Separate low-level circuits from power cables by 3 ft if possible (1 ft minimum), and cross noisy circuits at right angles and at a maximum practical distance.
8. Select appropriate multiplexing and amplifier circuits having input guarding systems of at least 10^6:1 common-mode rejection at 60 Hz.
9. Provide triple-shielded power supplies for measuring devices.
10. Measure the common-mode rejection of the system by an indirect method whenever the rejection capability is in doubt.
11. Pay particular attention to the quality of the workmanship and system wiring practices.
12. Perform the analog-to-digital conversion as close to the signal source as practical.

INTRODUCTION

This section begins with some control-related definitions of some basic terms and concepts. This is followed by some introductory discussion of process dynamics and closed loop feedback control. For an in-depth discussion of analog and digital PID (proportional-integral-derivative) variations, closed loop responses, and the various model-based expert and optimizing control systems, the reader should turn to the later sections of this chapter.

During the first industrial revolution, the work done by human muscles was gradually replaced by the power of machines. Process control opened the door to the second industrial revolution, where the routine functions of the human mind and the need for the continuous presence of human observers were also taken care of by machines. Today, during the third industrial revolution, we are designing computers that can optimize and protect the safety of our processes not only by self-tuning, but also by applying neural networks capable of self-learning the characteristics of the controlled process, similar to the way a baby learns about the outside world.

This way, the human operator is relieved of the bulk of tedious and repetitive physical and mental tasks and is able to concentrate on the more creative aspects of the operating industry. In the third industrial revolution the traditional goal of maximizing the quantity of production will be gradually replaced by the goal of maximizing the quality and durability of the produced goods, while minimizing the consumption of energy and raw materials and maximizing recycling and reuse. Optimized process control will be the motor of this third industrial revolution.

HISTORY OF PROCESS CONTROL

The fly-ball governor was the first known automatic control system. It was installed on Watts' steam engine over 200 years ago in 1775. As shown in Figure 2.1a, the fly-balls detected the speed of shaft rotation and automatically opened up the steam supply when a drop was registered in that speed. The users of the fly-ball used it without understanding why it works. Another century went by before James Clark Maxwell in 1868 prepared the first mathematical analysis of the fly-ball governor.

The spreading use of steam boilers contributed to the introduction of other automatic control systems, including various steam pressure regulators and the first multiple-element boiler feed water systems. Here again the application of process control was ahead of its theory, as this first feedforward control system was introduced at a time when even the term "feedforward" had not yet been invented, let alone understood. Actually, the first general theory of automatic control, written by Nyquist, did not appear until 1932.

In 1958 Donald P. Eckman's classic *Automatic Process Control* was published, and even after that, for several decades, most universities, and academia as a whole, treated the teaching of process control as if it were just another course in mathematics. Some still do and teach process control as if we lived in the frequency and not in the time domain.

It was not until the late 1960s that the first edition of this handbook and F. G. Shinskey's classic *Process Control Systems* started to give recognition to process control analysis in the time domain. This is no surprise as progress was always made by the practical users and not by the mathematically oriented theoreticians. One should also understand that before one can control a process one must fully understand the process, and for this reason this section will start with the description of the "personalities" of different processes.

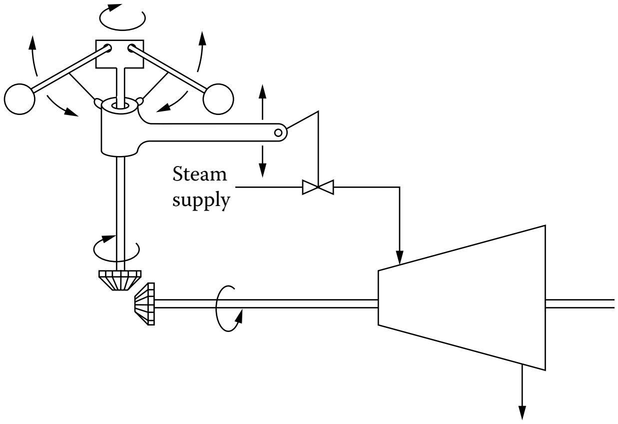

FIG. 2.1a
The fly-ball governor keeps shaft rotation constant by opening the seam supply valve when rotation slows and closing it when the rotation rises.

PROCESS DYNAMICS[1]

It is self-evident that the pilots of an ocean liner and a supersonic airplane need to have different personalities because the natures and the characteristics of their vehicles are different. This is also true in industrial process control. The pilot (the controller) must be correctly matched to the process that it controls. In order to do that, the designer of a process must understand the "personality" of the process.

Most processes contain resistance, capacitance, and deadtime elements, which determine their dynamic and steady-state responses to upsets. Before the control of processes is discussed, these three elements of the "personalities" of processes will be described.

To describe the personalities of processes, block diagrams are used (Figure 2.1b). The two main symbols used in any block diagram are a circle and a rectangular box. The circle represents algebraic functions such as addition or subtraction and is always entered by two lines but exited by only one.

The rectangular box always represents a dynamic function, such as a controller, where the output is the controlled variable (c) and is a function of both time and of the input or manipulated variable (m). Only one line may enter and only one line may leave a rectangular block. The "system function," the "personality" of the process component, is placed inside the block, and the output is determined by product of the system function and the input.

Resistance-Type Processes

Pressure drop through pipes and equipment is the most obvious illustration of a resistance-type process. Figure 2.1c illustrates the operation of a capillary flow system, where flow is linearly proportional to pressure drop. This process is described by a steady-state gain, which equals the resistance (R). Therefore as the input (m = flow) changes from zero to m, the output (c = head) will go in an instantaneous step from zero to $c = Rm$.

Laminar resistance to flow is analogous to electrical resistance to the flow of current. The unit of resistance is sec/m^2 in the metric and sec/ft^2 in the English system and can be calculated using Equation 2.1(1):

$$R = \frac{dh}{dq} = \frac{128\nu L}{g\pi D^4} \quad \text{sec/ft}^2 \qquad \textbf{2.1(1)}$$

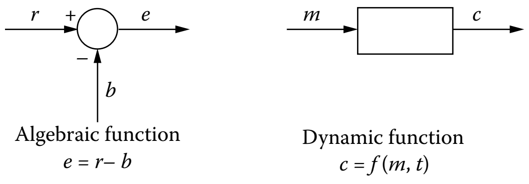

FIG. 2.1b
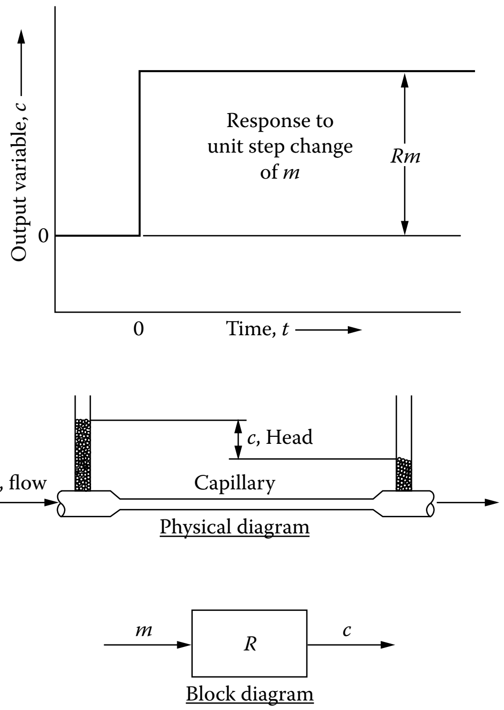
Block diagram descriptions of algebraic and dynamic functions.



$c = Rm$

Where c = Output variable (head)
R = Resistance
m = Input variable (flow)

FIG. 2.1c
Physical example of a resistance element and its block diagram.

where h = head, ft; ν = kinematic viscosity, ft^2/sec; L = length of tube or pipe, ft; D = inside diameter of pipe, ft; q = liquid flow rate, ft^3/sec; μ = absolute viscosity, lb-sec/ft^2 = $\gamma\nu/g$; γ = fluid density, lb/ft^3.

When the flow is turbulent, the resistance is a function of pressure drop, not of the square root of pressure drop, as was the case with laminar (capillary) flow. A liquid flow process usually consists of a flow-measuring device and a control valve in series, with the flow (c) passing through both. Figure 2.1d illustrates such a process. As can be seen from the block diagram, the flow process is an algebraic and proportional (resistance) only process. The manipulated variable (m) is the opening of the control valve, while the controlled variable (c) is the flow through the system. A change in m results in an *immediate and proportional* change in c. The amount of change is a function of the process gain, also called process sensitivity (K_a).

The load variables of this process are the upstream and downstream pressures (u_0 and u_2), which are independent, uncontrolled variables. A change in either load variable will also result in an *immediate and proportional* change in the controlled variable (c = flow). The amount of change is a function of their process sensitivity or gain (K_b).

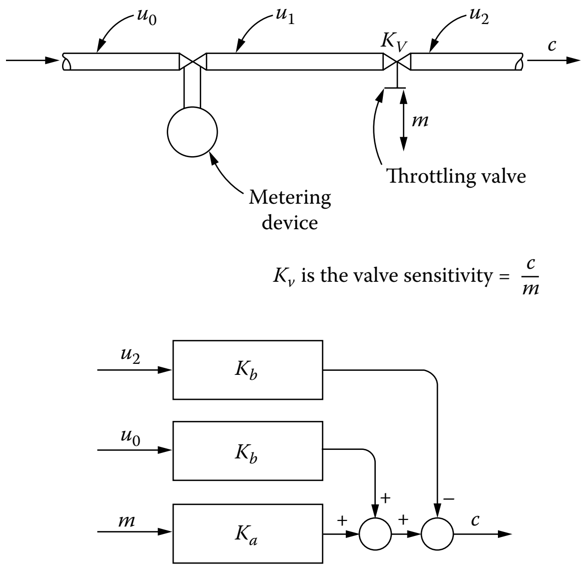


FIG. 2.1d
The relationship between the manipulated variable (m) and the controlled variable (c) in a resistance (flow) process, shown both in its physical and in its block diagram representations.

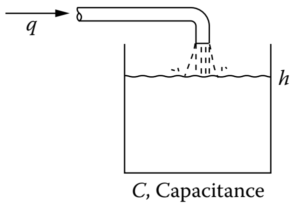
Capacitance-Type Processes

Most processes include some form of capacitance or storage capability. These capacitance elements can provide storage for materials (gas, liquid, or solids) or storage for energy (thermal, chemical, etc.). Thermal capacitance is directly analogous to electric capacitance and can be calculated by multiplying the mass of the object (W) with the specific heat of the material it is made of (Cp). The units of thermal capacitance are BTU/°F in the English or Cal/°C in the metric system.

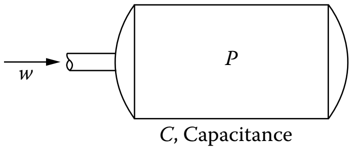
The capacitance of a liquid or a gas storage tank can both be expressed in area units (ft^2 or m^2). Figure 2.1e illustrates these processes and gives the corresponding equations for calculating their capacitances. The gas capacitance of a tank is constant and is analogous to electric capacitance. The liquid capacitance equals the cross-sectional area of the tank at the liquid surface, and if the cross-sectional area is constant, the capacitance of the process is also constant at any head.

A tank having only an inflow connection (Figure 2.1f) is a purely capacitive process element. In such a process the level (c) will rise at a rate that is inversely proportional to the capacitance (cross-sectional area of the tank) and after some time will flood the tank. The level (c) in an initially empty tank with a constant inflow can be determined by multiplying the inflow rate (m) with the time period of charging (t) and dividing that product with the capacitance of the tank ($c = mt/C$).

Figure 2.1f illustrates such a system and describes both the system equations and the block diagram for the capacitive element. In arriving at the system function the operational notation of the differential equation is used, using the substitution of $s = d/dt$. The system function therefore is $1/Cs$ and the output (c = head) is obtained by multiplying the system function with the input (m).



Liquid capacitance is defined by $C = \frac{dv}{dh} ft^2$



Gas capacitance is defined by

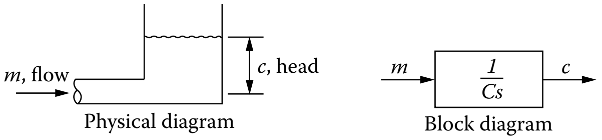
$$C = \frac{dv}{dp} = \frac{V}{nRT} ft^2$$

Where v = Weight of gas in vessel, LB.
V = Volume of vessel, ft^3
R = Gas constant for a specific gas, ft/deg
T = Temperature of gas, deg
p = Pressure, lb/ft^2
n = Polytropic exponent is between 1.0 & 1.2 for uninsulated tanks

FIG. 2.1e
Definitions of liquid and gas capacitance.

Resistance and Capacitance

Resistance and capacitance are perhaps the most important effects in industrial processes involving heat transfer, mass



$$C\frac{dc}{dt} = m = (Cs)c = m \therefore c = \left(\frac{1}{Cs}\right) m$$

Where C = Capacitance
c = Output variable (head)
t = Time
m = Input variable (flow)
$s = \frac{d}{dt}$ = differential operator

FIG. 2.1f
Example of a pure capacitance element.

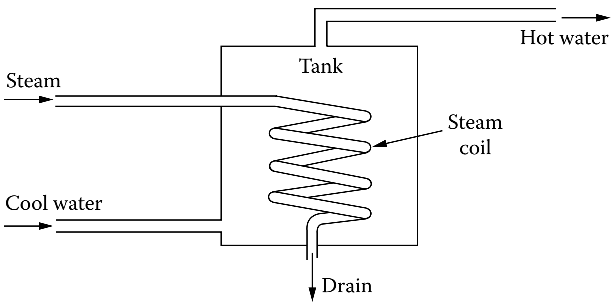


FIG. 2.1g
A water heater has both resistance and capacitance effects.

transfer, and fluid flow operations. Those parts of the process that have the ability to store energy or mass are termed "capacities," and those parts that resist transfer of energy or mass are termed "resistances." The combined effect of supplying a capacity through a resistance is a time retardation, which is very basic to most dynamic systems found in industrial processes.

Consider, for example, the water heater system shown in Figure 2.1g, where the capacitance and resistance terms can be readily identified. The capacitance is the ability of the tank and of the water in the tank to store heat energy. A second capacitance is the ability of the steam coil and its contents to store heat energy. A resistance can be identified with the transfer of energy from the steam coil to the water due to the insulating effect of a stagnant layer of water surrounding the coil.

If an instantaneous change is made in the steam flow rate, the temperature of the hot water will also change, but the change will not be instantaneous. It will be sluggish, requiring a finite period of time to reach a new equilibrium. The behavior of the system during this transition period will depend on the amount of material that must be heated in the coil and in the tank (determined by the capacitance) and on the rate at which heat can be transferred to the water (determined by the resistance).

Process Gain

The system function is the symbolic representation of how a process component changes its output in response to a change in its input. For example, if the system function is only a gain, only a constant (K_c, G, or some other symbol) would appear inside the block. The process gain is the ratio between the change in the output (*dc*) and the change in the input that caused it (*dm*). If the input (*m*) to the block is a sinusoidal, the output (*c*) will also be a sinusoidal.

The process gain can be the product of a steady-state gain (*Kp*) and a dynamic gain (*gp*) component. If the gain varies with the period of the input (exciting) sinusoidal, it is called dynamic gain (*gp*), while if it is unaffected by this period it is called steady-state gain (*Kp*). Therefore, if the process gain can be separated into steady-state and dynamic components, the system function can be given inside the block as (*Kp*)(*gp*).

The dynamic gain (*gp*) appears as a vector having a scalar component *Gp* and a phase angle. It will be shown shortly that capacitance-type process elements do introduce phase shifts in such a way that the peak amplitude of an input sinusoidal does not cause a simultaneous peak amplitude in the output sinusoidal.

Process Time Constant

Combining a capacitance-type process element (tank) with a resistance-type process component (valve) results in a single time-constant process. If the tank was initially empty and then an inflow was started at a constant rate of *m*, the level in the tank would rise as shown in Figure 2.1h and

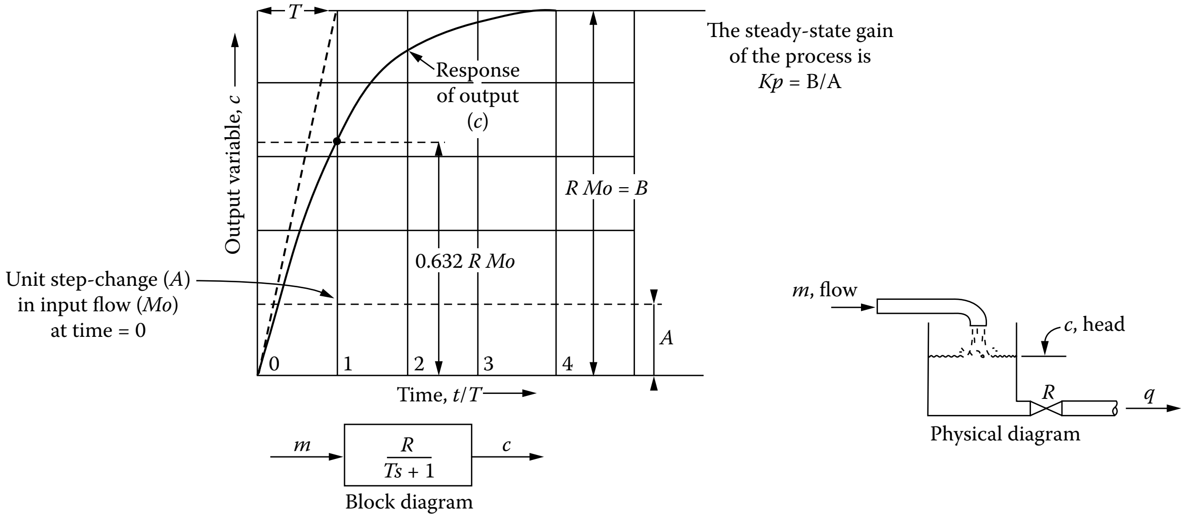

FIG. 2.1h
A single time-constant process consists of a capacitance and a resistance element. The time it takes for the controlled variable (c) to reach 63.2% of its new steady-state value is the value of the time constant.

would eventually rise to the steady-state height of $c = Rm$ in the tank.

In order to develop the overall system function, one has to combine the capacitance element of Figure 2.1f with a resistance element. If the input variable is the inflow (m) and the output variable is the level (c), the tank capacitance equals the difference between inflow (m) and outflow (q):

$$C(dc/dt) = m - q \qquad \textbf{2.1(2)}$$

In the fluid resistance portion of the system, the output (the head c) equals the product of the outflow (q) and the resistance (R). Because $c = qR$, therefore $q = c/R$. Substituting c/R for q in Equation 2.1(2) and multiplying both sides by R gives

$$RC(dc/dt) + c = Rm \qquad \textbf{2.1(3)}$$

The unit of R is time divided by area and the unit of C is area; therefore, the product RC has the unit of time. *This time (T) is called the time constant of the process.* It has been found experimentally that after one time constant the value of the output variable (c) of a single time-constant process will reach 63.2% of its final value.

Process elements of this description are common and are generally referred to as first-order lags. The response of a first-order system is characterized by two constants: a time constant T and a gain K. The gain is related to the amplification associated with the process and has no effect on the time characteristics of the response. The time characteristics are related entirely to the time constant. The time constant is a measure of the time necessary for the component or system to adjust to an input, and it may be characterized in terms of the capacitance and resistance (or conductance) of the process.

In their responses (Figure 2.1h), two characteristics distinguish first-order systems:

1. The maximum rate of change of the output occurs immediately following the step input. (Note also that if the initial rate were unchanged the system would reach the final value in a period of time equal to the time constant of the system.)
2. The actual response obtained, when the time lapse is equal to the time constant of the system, is 63.2% of the total response.

These two characteristics are common to all first-order processes.

Characteristic Equations of First-Order Systems A first-order system is one in which the system response to a constant change in the input is an exponential approach to a new constant value. Such a system can be described by a first-order differential equation:

$$\frac{dy(t)}{dt} + ay(t) = bu(t) \qquad \textbf{2.1(4)}$$

where $u(t)$ and $y(t)$ are the deviations of the inputs and outputs, respectively, and a and b are constants. The response of such a system with $a = 1$ and $b = 2$ to a unit step change (value 1 for $t \geq 0$ and 0 for $t < 0$) in the input is shown in the top panel of Figure 2.1i.

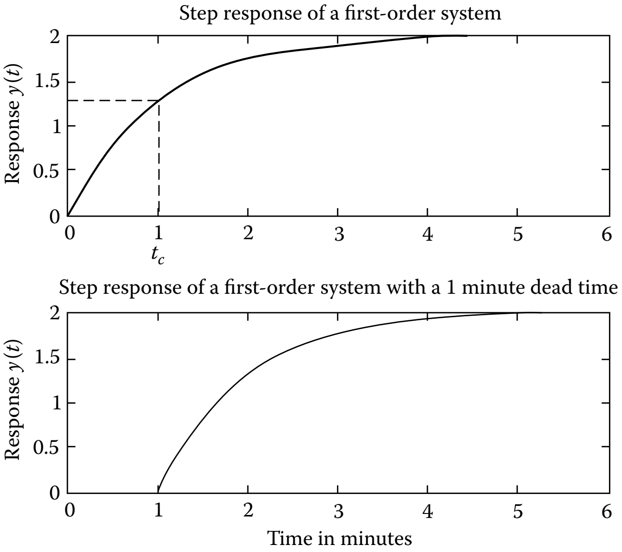

FIG. 2.1i
Step response of a first-order system with and without dead time.

This result can be demonstrated from the solution of the differential equation in Equation 2.1(4). The solution of this differential equation is important because it provides insight into the operation of the system and nature of the control problem.

The solution of any linear differential equation can be broken into the sum of two parts: the homogeneous and the particular solution. The homogeneous solution is that expression that when substituted for $y(t)$ in the left-hand side of Equation 2.1(4) produces the value zero. The particular or steady-state solution is that part of the total solution that is strictly due to the forcing input, $u(t)$.

To establish the homogeneous solution, assume the solution to be of the form

$$y_h(t) = Ke^{pt} \qquad \textbf{2.1(5)}$$

with $u(t) = 0$ in Equation 2.1(4). Substituting Equation 2.1(5) into the left-hand side of Equation 2.1(4) imposes the following condition on p:

$$p + a = 0 \qquad \textbf{2.1(6)}$$

which is satisfied with $p = -a$. It is clear from Equation 2.1(5) that for $a < 0$, the homogeneous solution becomes unbounded. The total solution, which is the sum of the homogeneous and particular solutions, becomes dominated by the homogeneous solution and not the particular solution.

Systems in which the homogeneous solutions grow without bound are said to be *unstable*. The homogeneous solution does not depend on the form of the forcing input and hence it is a characteristic of the system. In fact, a polynomial equation such as Equation 2.1(6) that defines $y_h(t)$ is called the *characteristic equation.*

The particular solution, $y_p(t)$, is that part of the total solution that is due entirely to the forcing function, $u(t)$. To establish $y_p(t)$, assume that it has the same functional form as $u(t)$, provided that the homogeneous solution does not have the forcing function as part of it. For example, if $u(t)$ is a ramp, assume that $y_p(t)$ is also a ramp with unknown intercept and slope. If $y_h(t)$ contains a term that is a ramp, then assume that the particular solution is quadratic in time with unknown coefficients. Substitute the assumed form into Equation 2.1(4) and solve for the unknowns.

Example

As an example, suppose that $u(t)$ in Equation 2.1(4) is a unit step. Assuming that the system is stable, the output will eventually reach a constant. Therefore, the particular solution is assumed to be a constant, α. Substituting α for $y(t)$ and 1 for $u(t)$ in Equation 2.1(4), yields that $\alpha = b/a$. Note that in Figure 2.1i, the particular solution is 2, obtained with $b = 2$ and $a = 1$.

The speed of response of a first-order system is determined by the *time constant, t_c*. The time constant is the time at which the exponent in the homogenous solution is −1. From Equation 2.1(5) and Equation 2.1(6), this corresponds to $1/a$. Figure 2.1i illustrates the time constant and output for the first-order system given in Equation 2.1(4).

If t_c is small, then the particular solution decays rapidly and the steady-state solution is quickly reached. Such a system is said to be "fast." On the other hand, if t_c is large, then the system reaches the steady state very slowly and is said to be "slow" or "sluggish."

First-Order System with Dead Time A first-order system coupled with dead time, or process delay, makes an excellent model for many process systems. The bottom panel of Figure 2.1i illustrates a first-order system with a 1-min dead time. Furthermore, this model is not difficult to determine. A simple step test in which the input to the system is changed from one value to another while the system is at some steady-state output gives sufficient information to determine the model.

Suppose the input is changed by an amount Δ. Let the output reach its new steady-state value, and divide the difference between the new and old steady-state outputs by Δ. This computed response is called the *step response.* The dead time is the time at which the output first starts to respond to the change in the input. If the exponent in the solution is evaluated at the time constant, the exponent of the particular part would be −1. This corresponds to the decay of 63.2% or $1-e^{-1}$ of the initial contribution of the particular solution. Thus, the time constant can be determined as the difference between the time at which the response is at 63.2% of the final value and the dead time.

In Figure 2.1i, 63.2% of the final response, denoted by the horizontal dashed line, has a value of 1.264 and yields a time constant of one. Experience shows that first-order plus dead time systems can be controlled by proportional plus integral (PI) controllers.

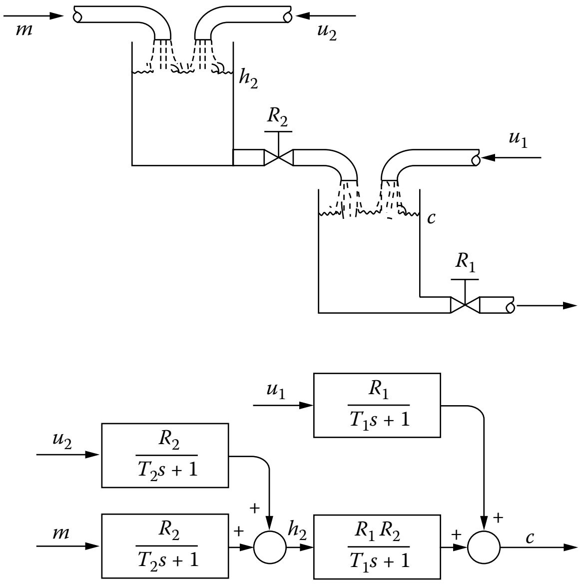

FIG. 2.1j
The physical equipment and the block diagram of a process with two time constants in series.

Multiple Time-Constant Processes Figure 2.1j illustrates a process where two tanks are connected in series and therefore the system has two time constants operating in series. The response curve of such a process ($r = 2$ in Figure 2.1k) is

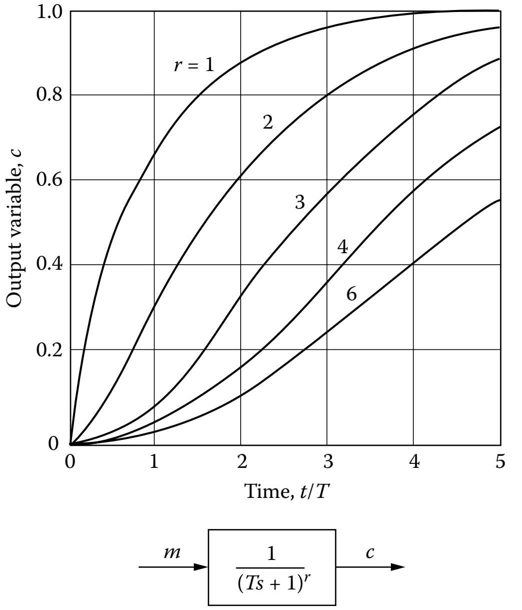

FIG. 2.1k
The responses of processes slow as the number of their (equal size) time constants in series increases.

slower than that of the single time-constant process ($r = 1$ in Figure 2.1k) because the initial response is retarded by the second time-constant. Figure 2.1k illustrates the responses of processes having up to six time constants in series. As the number of time constants increases, the response curves become slower (the process gain is reduced), and the overall response gradually changes into an S-shaped reaction curve.

Characteristic Equations of Second-Order Systems Second-order systems are characterized by second-order differential equations. These systems are more complex than first-order ones. A second-order system might be viewed as the solution of the following differential equation:

$$\frac{d^2y(t)}{dt^2}+2\xi\omega_n\frac{dy(t)}{dt}+\omega_n^2y(t)=\omega_n^2u(t) \qquad \textbf{2.1(7)}$$

Again, $y(t)$ is the process output (controlled variable) and $u(t)$ is the input, which is usually the reference input function. The parameters ξ and ω_n in this equation dictate the nature of the solution. The quantity ξ is called the *damping ratio* and ω_n is the *natural frequency.* If ξ is zero, then the solution is a sinusoid that oscillates at ω_n radians per second (Figure 2.1l). Thus, the system is an oscillator producing a sinusoidal response at the natural frequency of the oscillator.

The damping ratio is the ratio of the *damping constant* to the natural frequency. The damping constant determines the rate at which the oscillations decay away. As the damping constant increases, the speed of response increases and the oscillations decay more rapidly.

Figure 2.1m illustrates the effect of the damping ratio on the response of a second-order system. The top left panel of Figure 2.1m corresponds to the case of the damping ratio being zero. Note that the oscillations will continue forever and the steady-state solution is embedded in the response. This is an *undamped* response.

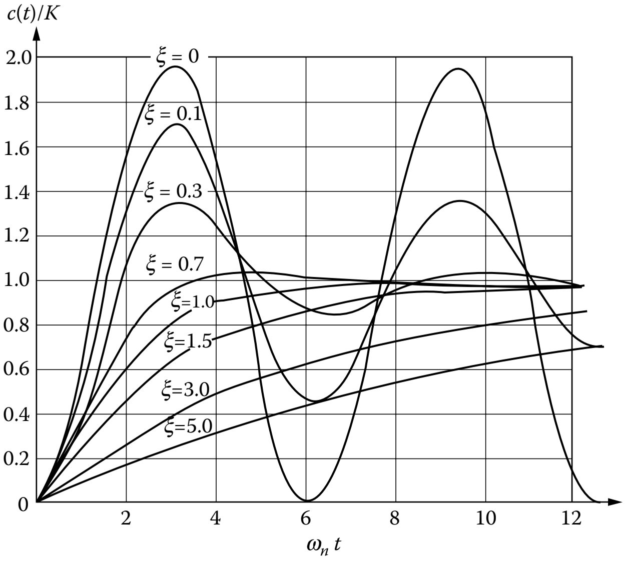

FIG. 2.1l
Illustration of the effect of damping ratio variations from 0 to 5 on a second-order system.

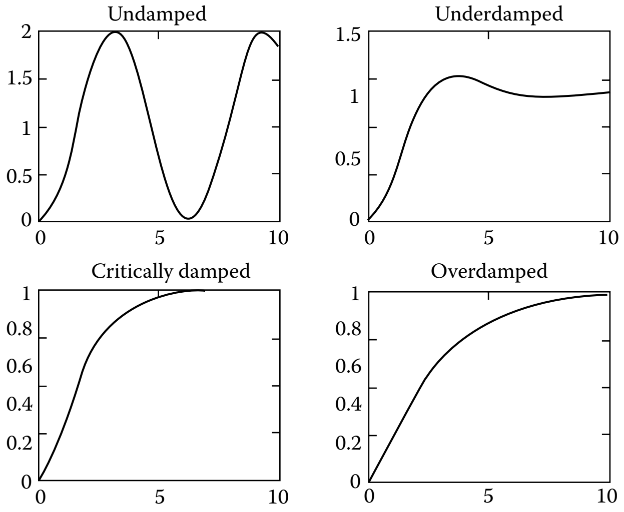

FIG. 2.1m
The effect of the damping ratio on second-order systems.

The top right panel corresponds to $0 < \xi < 1$ and produces an *underdamped output.* The speed of the response has deteriorated slightly in that the output $y(t)$ is a little slower in getting to the desired output 1. Note that the response oscillates, but the oscillation decays leaving only the steady-state solution.

The bottom left panel corresponds to being *critically* damped ($\xi = 1$). The response does not exceed the steady-state value of 1, but the speed of the system is noticeably slower than either the undamped or underdamped cases. The bottom right panel is the *overdamped* case ($\xi > 1$). Again, the response system is much slower.

From a control perspective, if the response is allowed to exceed the target value the system response is faster due to the underdamped nature of the system behavior. In fact, many heuristic tuning methods seek parameters that produce an underdamped response provided that the overshoot, or the amount that the output exceeds its steady-state response, is not too large.

If the second-order system also has dead time associated with it, then its response is not unlike that of the first-order system. That is, the response is delayed by the dead time, but the overall approach to steady state for different values of the damping ratio remains the same. A first-order system controlled with a PI controller may produce underdamped second-order system behavior.

Dead-Time Processes A contributing factor to the dynamics of many processes involving the movement of mass from one point to another is the transportation lag or dead time.

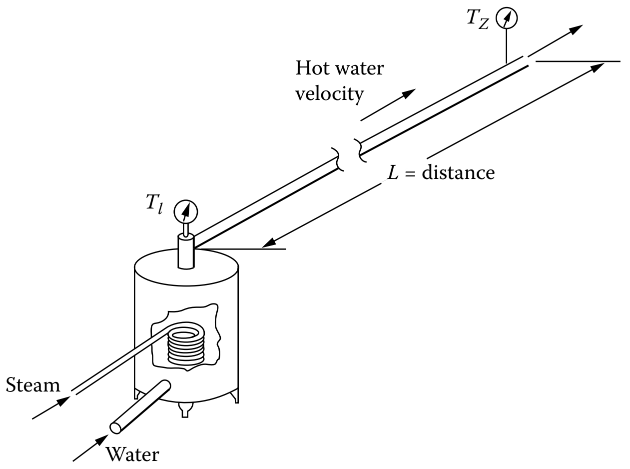

FIG. 2.1n
Transportation lag introduces a dead time in the water heater process.

Consider the effect of piping on the hot water to reach a location some distance away from the heater (Figure 2.1n).

The effect of a change in steam rate on the water temperature at the end of the pipe will not depend only on the resistance and capacitance effects in the tank. It will also be influenced by the length of time necessary for the water to be transported through the pipe. All lags associated with the heater system will be seen at the end of the pipe, but they will be delayed. The length of this delay is called the transportation lag (L) or dead time. The magnitude is determined as the distance over which the material is transported (l) divided by the velocity at which the material travels (v). In the heater example

$$L = v/l \qquad \mathbf{2.1(8)}$$

Dead time is the worst enemy of good control, and the process control engineer should therefore make a concentrated effort to minimize it. The effect of dead time can be compared to driving a car (the process) with closed eyes or with the steering wheel disconnected during that period. The goal of good control system design should be both to minimize the amount of dead time and to minimize the ratio of dead time to time constant (L/T).

The higher this ratio, the less likely it is that the control system will work properly, and once the L/T ratio reaches 1.0 ($L = T$), control by traditional PID (proportional–integral–derivative) strategies is unlikely to work at all. The various means of reducing dead time are usually related to reducing transportation lags. This can be achieved by increasing the rates of pumping or agitation, reducing the distance between the measuring instrument and the process, eliminating sampling systems, and the like.

When the nature of the process is such that the L/T ratio must exceed unity, or if the controlled process is inherently a dead-time process (a belt feeder for example), the traditional PID control must be replaced by control based on periodic adjustments, called sample-and-hold type control (see the next sections of this chapter).

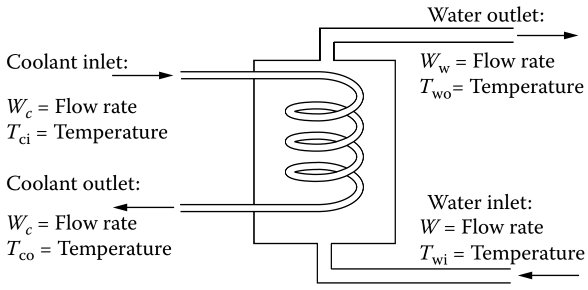

FIG. 2.1o
Process variables in a simple water cooler.

Process Variables Many external and internal conditions affect the performance of a processing unit. These conditions may be detected in terms of process variables such as temperature, pressure, flow, concentration, weight, level, etc. Most processes are controlled by measuring one of the variables that represent the state of the process and then by automatically adjusting another variable(s) that determine that state. Typically, the variable chosen to represent the state of the system is termed the "controlled variable" and the variable chosen to control the system's state is termed the "manipulated variable."

The manipulated variable can be any process variable that causes a reasonably fast response and is fairly easy to manipulate. The controlled variable should be the variable that best represents the desired state of the system. Consider the water cooler shown in Figure 2.1o. The purpose of the cooler is to maintain a supply of water at a constant temperature. The variable that best represents this objective is the temperature of the exit water, T_{wo}, and it should be selected as the controlled variable.

In other cases, direct control of the variable that best represents the desired condition is not possible. Consider the chemical reactor shown in Figure 2.1p. The variable that is

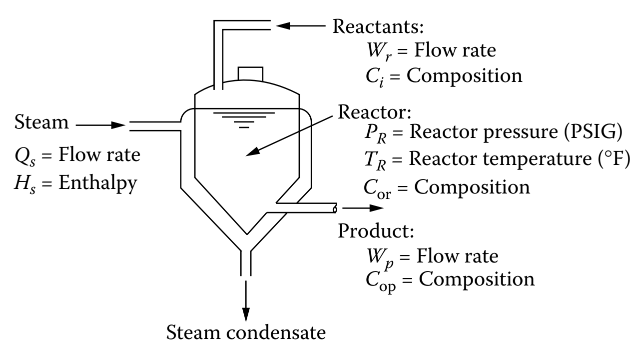

FIG. 2.1p
Process variables in a simple chemical reactor.

directly related to the desired state of the product is the composition of the product inside the reactor. However, in this case a direct measurement of product composition is not always possible.

If product composition cannot be measured, some other process variable is used that is related to composition. A logical choice for this chemical reactor might be to hold the pressure constant and use reactor temperature as an indication of composition. Such a scheme is often used in the indirect control of composition.

Degrees of Freedom To fully understand the "personality" of a process, one must also know the number of variables that can be independently controlled in a process. The maximum number of independently acting automatic controllers that can be placed on a process is the degrees of freedom (*df*) of that process. Mathematically, the number of degrees of freedom is defined as

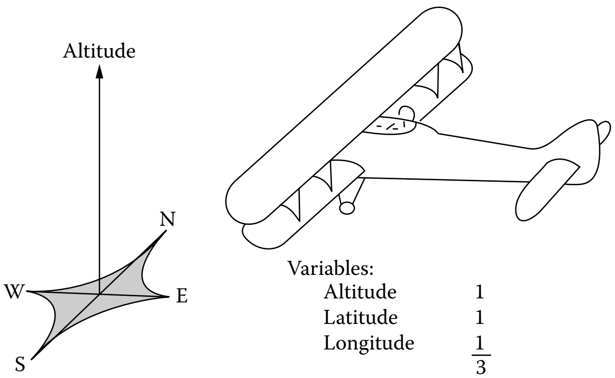
$$df = v - e \qquad \textbf{2.1(9)}$$

where df = number of degrees of freedom of a system; v = number of variables that describe the system; and e = number of independent relationships that exist among the various variables.

It is easy to see intuitively that a train has only one degree of freedom because only its speed can be varied, while boats have two and airplanes have three (see Figure 2.1q).

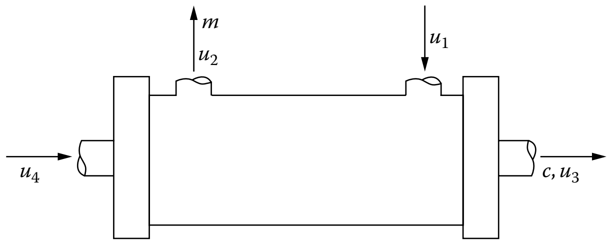
The degrees of freedom of industrial processes are more complex and cannot always be determined intuitively. In the case of a liquid-to-liquid heat exchanger, for example (Figure 2.1r), the total number of variables is six, while the number of defining equations is only one—the first law of thermodynamics, which states the conservation of energy.

Therefore, the degrees of freedom of this process are 6 – 1 = 5. This means that if five variables are held constant, this will result in a constant state for the sixth variable, the outlet temperature (c). Therefore, the maximum number of automatic controllers that can be placed on this process is five. Usually one would not exercise this option of using five controllers, and in the case of a heat exchanger of this type, one might use only one control loop.



Variables:	
Altitude	1
Latitude	1
Longitude	1
	3
Equations:	
None	–0
Degree of freedom:	3

FIG. 2.1q
The degrees of freedom of an airplane.



6 Variables:

c = heated fluid outlet temperature
m = heating fluid flow rate
u_1 = heating fluid inlet temperature
u_2 = heating fluid outlet temperature
u_3 = heated fluid flow rate
u_4 = heated fluid inlet temperature

FIG. 2.1r
The degrees of freedom of a liquid-to-liquid heat exchanger.

One would select the controlled variable (c) to be the process property that is the most important, because it has the most impact on plant productivity, safety, or product quality. One would select the manipulated variable (m) to be that process input variable that has the most direct influence on the controlled variable (c), which in this case is the flow rate of the heating fluid. The other *load variables* (*u_1 to u_4*) are uncontrolled independent variables, which, when they change, will upset the control system, and their effects can only be corrected in a "feedback" manner.

This means that a change in load variables is not responded to until it has upset the controlled variable (c). In order to fully describe this process, one would also consider such *system parameters* as the mass or the specific heat of the liquids, but such parameters are not considered to be variables.

When the process involves a phase change, the calculation of the degrees of freedom follows Gibbs's phase rule, stated in Equation 2.1(10):

$$n = n_c - n_p + 2 \qquad \textbf{2.1(10)}$$

where n = number of chemical degrees of freedom; n_c = number of components; and n_p = number of phases.

For example, if the process is a boiler producing *saturated* steam (Figure 2.1s), the number of components is one (H_2O), the number of phases is two (water and steam), and, therefore, the number of degrees of freedom is n = 1 – 2 + 2 = 1. Consequently, only one variable can be controlled: temperature or pressure, but not both. If a boiler produces

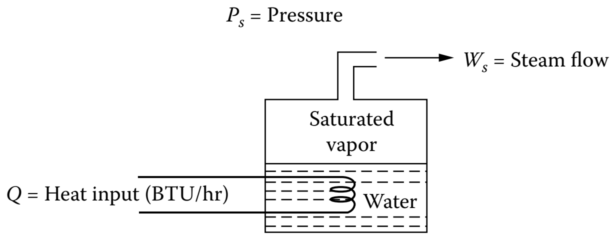


FIG. 2.1s
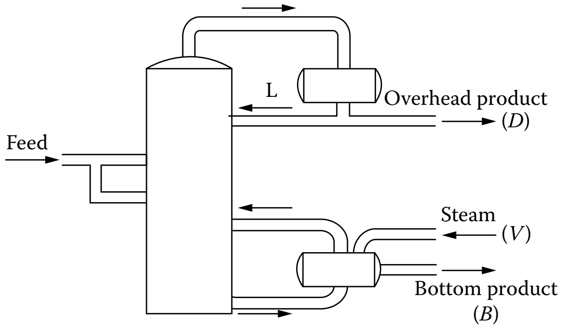
A saturated steam boiler has only one degree of freedom.

superheated steam, the number of degrees of freedom is two, and therefore both temperature and pressure can be independently controlled.

When the process is more complex, such as is the case of binary distillation, the calculation of the degrees of freedom also becomes more involved. Figure 2.1t lists 14 variables of this process, not all are independent. Since there are two components and two phases at the bottom, feed and overhead, Gibbs's law states that only two of the three variables (pressure, temperature, and composition) are independent. Therefore, the number of independent variables is only 11. The number of defining equations is two (the conservation of mass and energy), and therefore, the number of degrees of freedom for this process is 11 − 2 = 9. Consequently, not more than nine automatic controllers can be placed on this process.



Apparent variables:	Independent variables:
C_1 = Overhead temperature	2
C_2 = Overhead pressure	
C_3 = Overhead composition	
C_4 = Overhead flow rate	1
U_1 = Bottom temperature	2
U_2 = Bottom pressure	
U_3 = Bottom composition	
U_4 = Bottom flow rate	1
U_5 = Feed temperature	2
U_6 = Feed pressure	
U_7 = Feed composition	
U_8 = Feed percent vapor	1
U_9 = Feed flow rate	1
m = Steam flow rate (heat input)	1
	11

FIG. 2.1t
In a binary distillation process the number of independent variables is 11 and the number of degrees of freedom is nine.

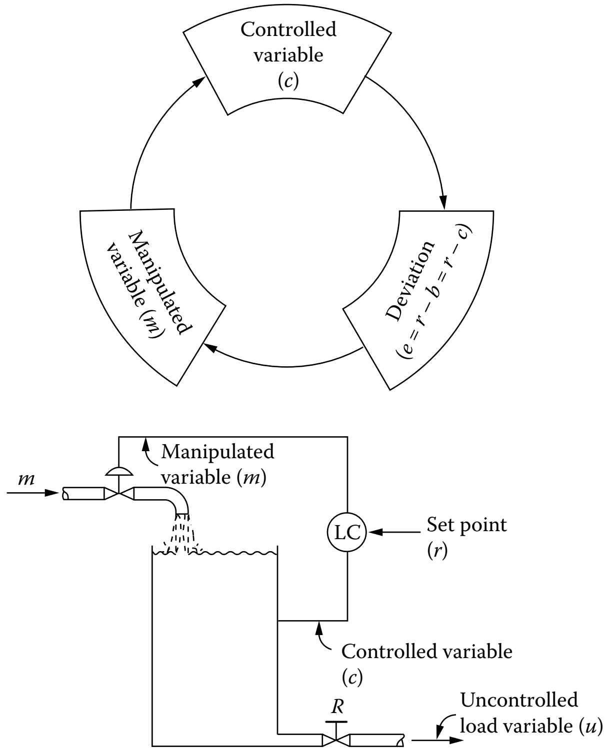


FIG. 2.1u
The addition of a controller closes the automatic control loop.

CLOSING THE LOOP[2]

After gaining a good understanding of the "personality" of the process and after having identified the controlled (*c*), manipulated (*m*), and uncontrolled load (*u*) variables, one can proceed to "close the loop" by installing an automatic controller onto the process.

The task of a controller is to measure the controlled variable *c* (say the level, in the case of Figure 2.1u), compare that measurement to some desired target value (*r* = set point), and, if there is an error (*c* does not equal *r*), modify its output signal (*m*) and thereby change the manipulated variable *m* (input to the process) in a way that will reduce the deviation from the set point.

Oscillation and Phase Shift

When a closed loop is in sustained oscillation, the period and amplitude of oscillation are constant, and therefore, the total phase shift in the loop must be 360 degrees. This state is called *sustained oscillation* or *marginal stability.*

In order to keep a ball bouncing at the same period and amplitude, it has to be struck at phase intervals of 360 degrees, when it is at its highest point. If it is struck sooner, the period of oscillation will be shortened. If the ball is the process and the hand is the controller, the goal is to push the ball back toward set-point whenever it is moving away from it.

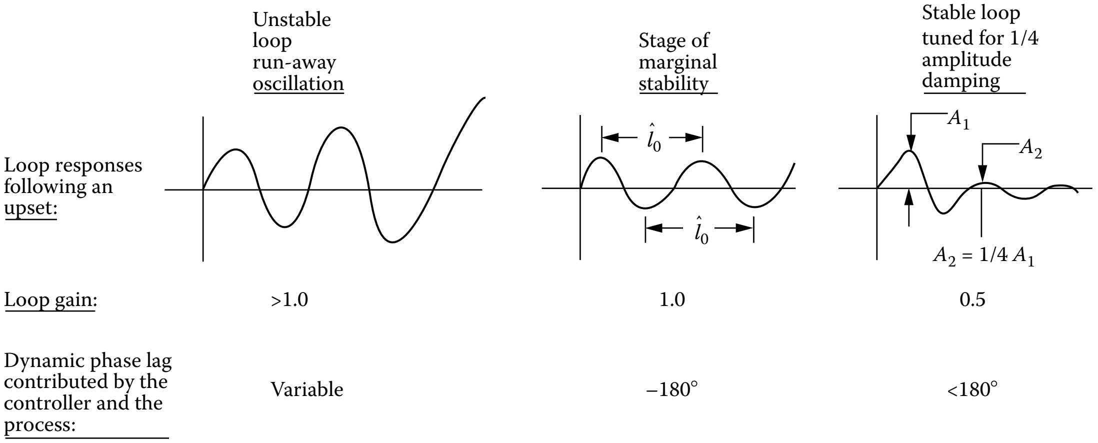

FIG. 2.1v
Control loops respond to upsets differently as a function of the loop gain and of the phase lag contributions of both the process and the controller.

Controlling a process is different from bouncing a ball only in that the force applied by the controller is applied continuously and not in periodic pulses. On the other hand, the two processes are similar from the perspective that in order to sustain oscillation the application of these forces must be displaced by 360 degrees (Figure 2.1v). The sources of this phase lag can be the process, the controller dynamics (modes), and the negative feedback of the loop.

The response of a process to a sinusoidal input is also sinusoidal if the process can be described by linear differential equations (a linear process). The phase shift in such processes is usually due to the presence of capacitance elements. For example, in the case of the process shown in Figure 2.1w, the process causes the output (c = outflow from the tank) to lag behind and oscillate with a smaller amplitude than the input of the process (m = inflow to the tank).

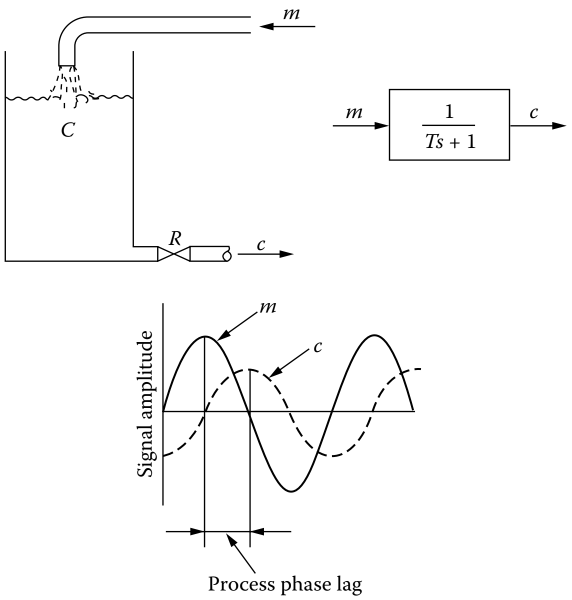

FIG. 2.1w
The outflow lags behind the inflow in this process because fluid must accumulate in the tank before the level will rise. This accumulation in turn will increase the outflow due to the resulting higher hydrostatic head.

Loop Gain and Tuning

It was shown in Figure 2.1v that sustained oscillation results if the loop gain is 1.0, and quarter amplitude damping results if the loop gain is 0.5. The goal of the tuning of most process control loops is to obtain quarter amplitude damping. This will result if the product of all the gains in the loop comes to 0.5. This end result is achieved through tuning, which is the process of finding the controller gain, which will make the overall gain product 0.5.

The controller gain (and most other gains also) consists of a steady-state component (K_c = the proportional setting), which is unaffected by the period of oscillation and the dynamic gain (gc), which varies with the period of the input (error) sinusoidal. The $(K_c)(gc)$ product is the total gain of the controller (Gc). Therefore, slow processes can be controlled with high-gain controllers, while controllers on fast processes must have low gains.

An example of a slow (low-gain) process is space heating, where it takes a long time (accumulation of the heat input provided by manipulated variable) to cause a small change in the controlled variable (the room temperature). If the combined gain of that process is 0.02, the controller gain required to provide quarter amplitude damping is 25 ($0.02 \times 25 = 0.5$).

If, on the other hand, the controlled process is a flow process, or a pH process near neutrality, the process gain is high. In such cases the controller gain must be low so that the total loop gain is 0.5.

The higher the controller gain, the more corrective action the controller can apply to the process in response to a small deviation from set point and the better the quality of the resulting control will be. Unfortunately, if the gain product of controller and process reaches unity, the process becomes unstable and undamped oscillations (cycling) will occur. Therefore, it is not possible to tightly control fast (high-gain) processes without cycling. It is easier to obtain tight control on slow, low-gain processes, because the use of high-gain controllers does not destroy stability.

The loop gain is the product of all the gains in the loop, including sensor, controller, control valve, and process. In a properly tuned loop, the product of all these gains is 0.5. What makes tuning difficult is that the process gain often varies with process load. For example, in heat transfer processes, when the heat load is low and the heat transfer surface available to transfer the heat is large, the transfer of heat is performed efficiently; therefore, under those conditions, this process is a high-gain process.

As the load rises, the same heat transfer process becomes a low-gain process because the fixed heat transfer area becomes less and less sufficient to transfer the heat. Therefore, as shown in Figure 2.1x, the gain of a heat transfer process (*Gp*) drops as the load rises.

Tuning such a system can be a problem because in order to arrive at an overall loop gain of 0.5, the controller should apply a high gain when the load is high and a low gain when the load is low. Standard controllers cannot do that because they have been tuned to provide a single gain. Therefore, if the loop was tuned (controller gain was selected) at high loads, the loop will cycle when the load drops, and if the loop was tuned at low loads, the loop will not be able to hold the process on set point (will be sluggish) when the load rises.

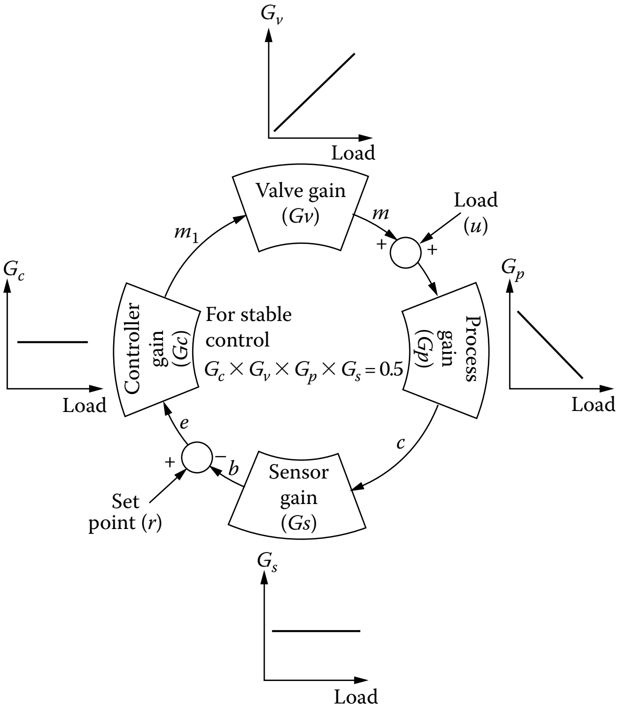

FIG. 2.1x

If the process gain varies with load, such as is the case of a heat transfer process, the gain product of the loop can be held constant by using a valve whose gain variation with load compensates for the process gain variation.

One way to compensate for this effect is to install a control valve in the loop (an equal percentage control valve), which increases its gain as the load rises. When the gain of the process drops, the gain of the valve increases and the total loop gain remains relatively unaffected.

Feedback Control

Two concepts provide the basis for most automatic control strategies: feedback (closed-loop) control and feedforward (open-loop) control. Feedback control is the more commonly used technique of the two and is the underlying concept on which most automatic control theory used to be based. Feedback control maintains a desired process condition by measuring that condition, comparing the measurement with the desired condition, and initiating corrective action based on the difference between the desired and the actual conditions.

The feedback strategy is very similar to the actions of a human operator attempting to control a process manually. Consider the control of a direct contact hot water heater. The operator would read the temperature indicator in the hot water line and compare its value with the temperature desired (Figure 2.1y). If the temperature was too high, he would reduce the steam flow, and if the temperature was too low, he would increase it. Using this strategy, he would manipulate the steam valve until the error is eliminated.

An automatic feedback control system would operate in much the same manner. The temperature of the hot water is measured and a signal is fed back to a device that compares the measured temperature with the desired temperature. If an error exists, a signal is generated to change the valve position in such a manner that the error is eliminated.

The only real distinction between the manual and automatic means of controlling the heater is that the automatic controller is more accurate and consistent and is not as likely to become tired or distracted. Otherwise, both systems contain the essential elements of a feedback control loop.

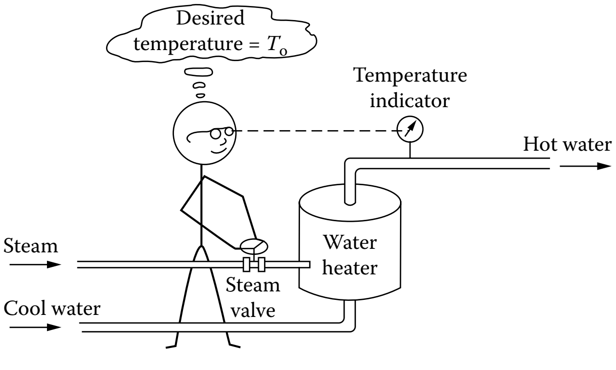

FIG. 2.1y

Manually accomplished feedback control.

Feedback control has definite advantages over other techniques in relative simplicity and potentially successful operation in the face of unknown contingencies. In general, it works well as a regulator to maintain a desired operating point by compensating for various disturbances that affect the system, and it works equally well as a servo system to initiate and follow changes demanded in the operating point.

Feedback Control Objectives

First, it is desirable that the output follow the desired behavior. Note that in all the subplots in Figure 2.1m, the response to a unit step change approaches the steady-state value of 1, which corresponds to the magnitude of the input step response. Because the output response eventually reaches the steady-state value, the *steady-state error,* or the difference between the desired final output and the actual one, is zero.

Second, almost always, the steady-state error should be zero to a step input, or constant targets, as inputs. In some cases, such as the case of a ramp input, it also is desirable for the steady-state error to be zero or nearly so. There may be an upper limit on the magnitude that is tolerable when no disturbances are present. However, in the presence of disturbances the steady-state error can become larger.

Third, the speed of response is important. From the discussion in connection with equation 2.1(7), viz. the solution of the differential equation, the steady-state is attained as the homogeneous portion of the solution of the differential equation approaches zero. A control system can affect the rate at which this happens. If the response of the system is sluggish, then the output (control action) of the controller is not changing enough in magnitude in response to the difference between the desired and actual output. By changing the parameters of the controller, the magnitude of the control action and the speed of response can be increased in response to control errors.

Fourth, the physical limitations of the plant constrain the ability of the controller to respond to input command changes. Another measure of the controller's speed is the *settling time.* The settling time is defined as the time after which the control system will remain within a given percentage of the desired final value when there are no outside disturbances. Figure 2.1z illustrates a "2% settling time," meaning the time it takes for a step response to approach the final steady-state value within 2%.

Lastly, note that (Figure 2.1l) the step change responses of a second-order system all have an overshoot, when the damping ratio of the system is less than one. Overshoot is defined as the percentage by which the peak response value exceeds the steady-state value (peak value of step response – steady-state value)/(steady-state value). A small overshoot can be acceptable, but large overshoots are not.

The PID Controller

In Sections 2.2, 2.3, and 2.4 detailed descriptions are provided of the various analog and digital PID algorithms and therefore only some of the basic aspects are discussed here.

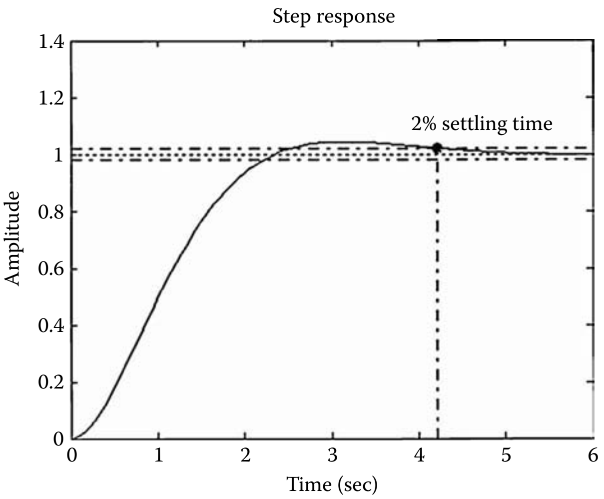

FIG. 2.1z
The step response shown has a 4.2-second "2% settling time."

As was shown earlier, the dynamic behavior of many processes can be modeled adequately as first- or second-order systems. Thus, the PID is an ideal tool with which to control such systems. Furthermore, the PID is easily understood and tuned by trained operators.

Consider the feedback control system with a plain proportional-only controller shown in Figure 2.1aa. Assume that the process to be controlled is a static system with a gain K_p. For a proportional-only controller, the controller output is the product of the error signal ($e = r - c$) and of the proportional gain K_c. That is,

$$u = K_c e \qquad \textbf{2.1(11)}$$

The closed-loop response is the relationship between the output (controlled variable), c, and the reference or set point input, r. This relationship is

$$c = \frac{K_c K_p}{1 + K_c K_p} r \qquad \textbf{2.1(12)}$$

Note that if r is a constant, say one, the controlled output is less than one. Thus, there is a nonzero steady-state error to constant inputs. This is not surprising because if $r = c$, then $e = r - c = 0$ and the output of the controller would also be

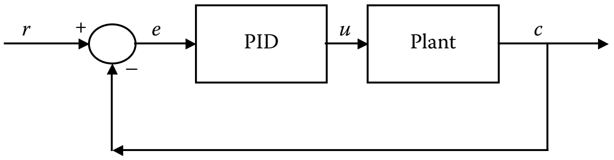

FIG. 2.1aa
Block diagram of a PID feedback control loop.

zero. This produces a contradiction in that c would be forced to zero, which, in general, is not the value of r.

Therefore, the plain proportional controller reduces but does not eliminate the error. Note from Equation 2.1(12) that as the controller gain increases, the controlled output, c, approaches the referenced input r more and more closely. Thus, the steady-state error, e, becomes smaller as K_c is made larger. But since K_c can never be infinite, the error is never zero.

The Derivative Mode To better understand the effect of derivative action, consider the situation in which the controller shown in Figure 2.1aa is proportional plus derivative (PD). In this case, the controller output is given by

$$u(t) = e(t) + T_d \frac{de(t)}{dt} \qquad \textbf{2.1(13)}$$

if the proportional gain K_c is 1 and the derivative gain is T_d, which is called the derivative time. Figure 2.1bb illustrates the controlled variable's step response, the error and derivative of the error signal, when the set point (reference) is $r = 1$.

The vertical lines in the top two plots of Figure 2.1bb are in locations where the controlled variable signal and the error signal have local maximums and minimums or points where the derivative is zero. Note that the controlled variable response has exceeded the set point (target value) of one. The excess overshoot is due to the presence of a certain momentum in the response of the system; the controller did not turn the input around in time to stop the system from exceeding the desired value.

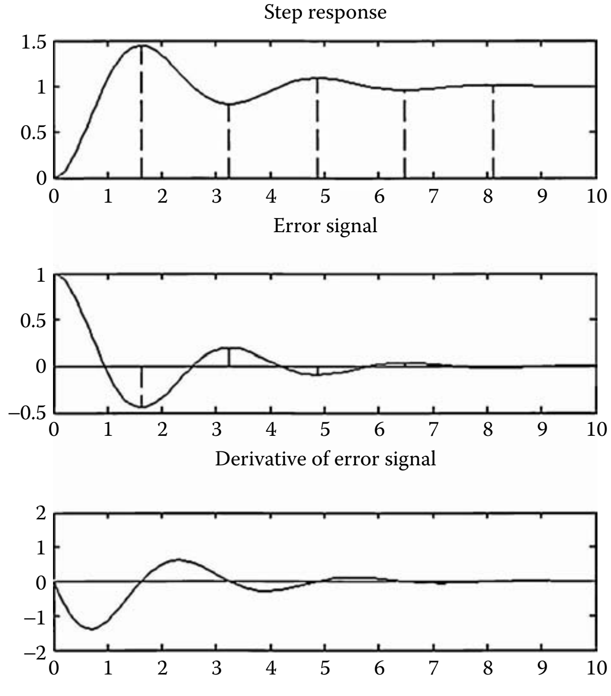

FIG. 2.1bb

The step response of a PD controller showing the responses of the controlled variable (top), the error (center), and the derivative of the error (bottom).

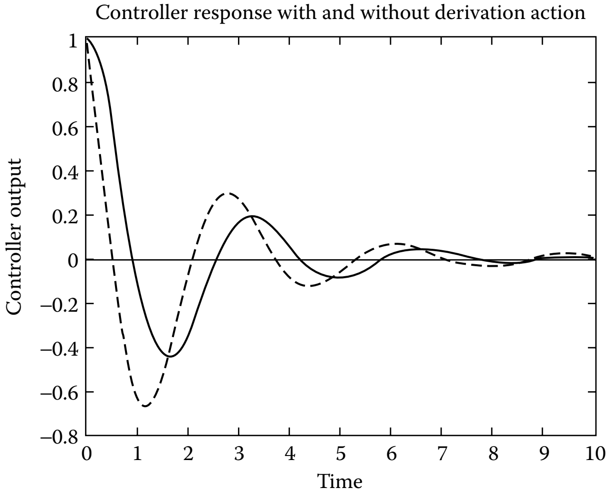

FIG. 2.1cc

The "anticipation" of the PD controller can be seen by noting the controlled variable response of a plain proportional controller (solid line) and that of a PD controller (dashed line) to the same step upset.

This is seen in the error signal that has not changed sign until the controlled variable output has exceeded the set point. Note also that the derivative is zero at the peak values and of opposite sign to the value of the error signal. When the error is added to a constant times the derivative, the result is a signal that changes sign earlier in time, that is, before the output has actually reached the steady-state value. Figure 2.1cc illustrates this.

The PD controller is used in applications where overshoot cannot be tolerated, such as pH neutralization. The reduction or elimination of overshoot can often be accomplished without significantly affecting the settling time of the closed-loop system. The primary disadvantage of derivative mode is its sensitivity to noise. Noise is generally of high frequency, and differentiating just amplifies it. The controller output can become cyclic or unstable, which can have a detrimental effect on the longevity of actuators such as valves or motors.

Integral Mode Nearly all controllers have some form of integral action. Integral action is important because it corrects based on the accumulated error, which is the area under the error curve. If the error goes to zero, the output of the integrator is the constant area that had accumulated up to that point.

Consider the feedback system illustrated in Figure 2.1aa. The task of the integral term in the PID algorithm is to find the manipulated variable (the input to the plant) needed to drive the steady-state error to zero when the set point (reference input) is constant.

When the error is zero, both the proportional term and the derivative term contribute nothing to the controller output.

Only the integral term provides any input to the controller output; only the integrator drives the manipulated variable to compensate for the area under the past error curve.

In summary, the PID controller produces an output defined as

$$u(t) = K_p\left(e(t) + \frac{1}{T_i}\int e(\tau)d\tau + T_d\frac{de(t)}{dt}\right) \qquad \textbf{2.1(14)}$$

where K_p is the proportional gain; T_d is the derivative time; and T_i is the integral time.

The integral time can be viewed as the amount of the time it takes for the integral component to make the same contribution as the proportional term. If the integral time is short, the integral contribution to the PID output is large and too much integral gain (T_i too small) can cause the system to become unstable.

Feedforward Control

Feedforward control is another basic technique used to compensate for uncontrolled disturbances entering the controlled process. Both feedback and feedforward control are discussed in detail in Section 2.8 and therefore only an introduction is given here. In this technique the control action is based on the disturbance input into the process without considering the condition of the process. In concept, feedforward control yields much faster correction than feedback control does, and in the ideal case compensation is applied in such a manner that the effect of the disturbance is never seen in the controlled variable, the process output.

A skillful operator of a direct contact water heater could use a simple feedforward strategy to compensate for changes in inlet water temperature by detecting a change in inlet water temperature and in response to that, increasing or decreasing the steam rate to counteract the change (Figure 2.1dd). This same compensation could be made automatically with an inlet temperature detector designed to initiate the appropriate corrective adjustment in the steam valve opening.

The concept of feedforward control is very powerful, but unfortunately it is difficult to implement in most process control applications. In many cases disturbances cannot be accurately measured, and therefore pure feedforward cannot be used. The main limitation of feedforward is due to our inability to prepare perfect process models or to make perfectly accurate measurements.

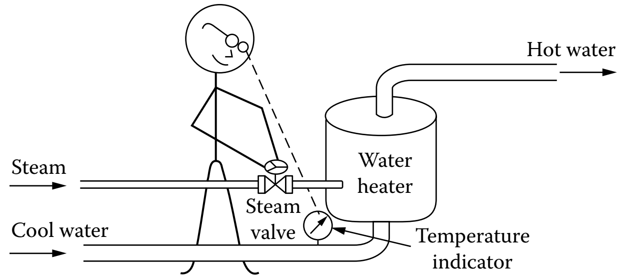

FIG. 2.1dd
The concept of feedforward control implemented by a human operator.

Because of these limitations, pure feedforward would accumulate the errors in its model and would eventually "self-destruct." The main limitations of feedback control are that feedback cannot anticipate upsets but can only respond to them after the upsets have occurred, and that it makes its correction in an oscillating, cycling manner.

It has been found that combining feedback and feedforward is desirable in that the imperfect feedforward model corrects for about 90% of the upset as it occurs, while feedback corrects for the remaining 10%. With this approach, the feedforward component is not pushed beyond its abilities, while the load on the feedback loop is reduced by an order of magnitude, allowing for much tighter control.

Feedforward Response

Ideally the feedforward correction would be so effective that a disturbance would have no measurable effect on the controlled variable, the process output. As an example, consider a first-order system in which there is a measurable disturbance. Suppose that a process disturbance occurs at time $t = 5$ seconds, as shown in the top segment of Figure 2.1ee, and causes the PID controller to generate a corrective action as shown in lower part of Figure 2.1ee. Note that while the controller will eliminate the disturbance, it will do that only after it has occurred.

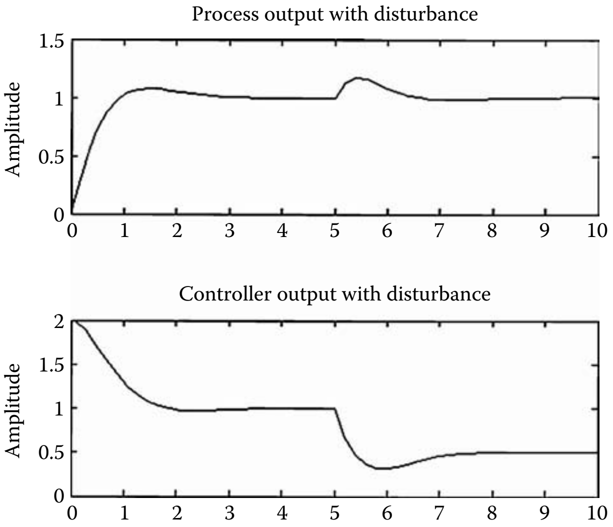

FIG. 2.1ee
If a step disturbance occurs at t = 5, the controlled variable of a first-order process responds to that upset as shown in the top portion of the figure. The bottom part shows the response of a feedback PID controller to such an upset, which generates the manipulated variable.

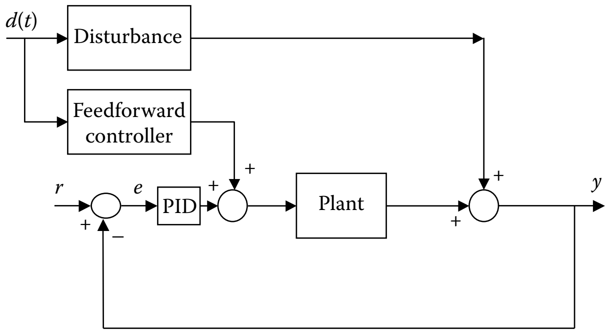

FIG. 2.1ff
Block diagram representation of a combination of a feedback PID control loop with a feedforward compensator.

Now consider a control system that includes a 100% effective feedforward controller as shown in Figure 2.1ff. The bottom part of Figure 2.1gg shows the response of a perfect feedforward compensator to an upset that has occurred at $t = 5$. The middle section of the figure shows the feedback PID output and the top portion shows the controlled variable, which remains undisturbed.

Note that the compensator does not respond until the disturbance occurs at time $t = 5$ seconds. With the feedforward compensation that is added to the PID controller output (Figure 2.1ff), the system exactly compensates for the disturbance. In practice, exact compensation is not possible. However, much of the effect of a disturbance can be mitigated by a judiciously designed feedforward compensator.

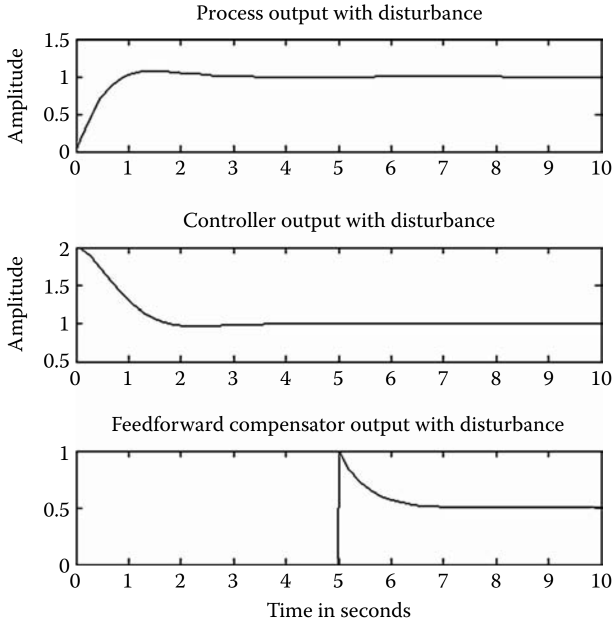

FIG. 2.1gg
The response of the control loop shown in Figure 2.1ff to a process upset that occurs at t = 5. In the bottom part, the output of the feedforward compensator is shown. When this is added to the output of the feedback PID controller, the upset is fully corrected and as shown in the top curve, the controlled variable is not upset at all.

Cascade Control

Section 2.6 discusses cascade control in detail; therefore, only an introduction is given here. In cascade control two controllers are used to control a single process variable. For example, consider the composition control of the product from a continuously stirred reactor in which an exothermic chemical reaction takes place. If the compensation is directly related to the temperature within the reactor and if the composition itself is difficult to measure online, then the reactor temperature is often chosen as the controlled variable. To control that temperature, the cooling water flow to the jacket is usually manipulated by the master (outer) temperature controller, which is adjusting the set point of the slave (inner) flow controller. Together these two controllers form a cascaded control loop, as shown in Figure 2.1hh.

The control loop for the cooling water flow is called the *inner loop.* The *outer loop* is the controller for the reactor temperature. The inner loop must have a response time that is faster than that of the outer loop. The outer loop controller provides the set point for the inner loop. The inner loop must be faster than the outer loop, so that the set point will not change too fast for the inner loop dynamics to follow; if it did, stability problems would result.

Filtering

Filters are needed to eliminate noise from such signals as the controlled variable. If the noise in the measurement signal is not reduced, it can pass through the controller and cause cycling and eventual damage to the control valve or other final control element.

Noise tends to be of a high frequency and changes more rapidly in time than does the controlled process variable. The task of a filter is to block the rapidly changing component of the signal but pass the slowly changing component, so that the filter output will have less noise than does the raw signal.

Filtering may have little or no effect on control performance if the closed-loop system response time is slow compared to the response time of the filter. In other words, if the

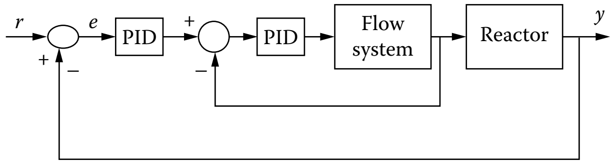

FIG. 2.1hh
Block diagram of a cascade control loop.

filter reaction time is assumed to be instantaneous compared to the speed of response of the closed-loop system, then there is no dynamic effect on the closed-loop system. On the other hand, if the closed-loop is fast relative to the speed of response of the filter, then the dynamic effects of the filter will have an effect.

Therefore, filtering can complicate the controller and can limit the response of a PID controller. One way to compensate for this is to tune the controller with the filter inserted into the feedback loop. Although the PID controller may give better performance without the filter, the effectiveness of the filter depends on the nature and amount of the noise and the desired closed-loop dynamics.

ADVANCED CONTROLS

The scope of the discussion in this first section was limited to basics of process control, and therefore such subjects as multivariable loops, interaction and decoupling, optimization, artificial intelligence, statistical process control, relative gain calculations, neural networks, model-based and model-free controls, adaptive control, fuzzy logic and statistical process control have not been covered. These topics and many others are discussed in the sections that follow.

2.2 Control Modes—PID Controllers

C. F. MOORE (1970, 1985) **B. G. LIPTÁK** (1995) **R. BARS, J. HETTHÉSSY** (2005)

INTRODUCTION

A controller compares its measurement to its set point (r) and, based on the difference between them (e = error), generates a correction signal to the final control element (e.g., control valve) in order to eliminate the error. The way a controller responds to an error determines its character, which significantly influences the performance of the closed-loop control system.

The different ways in which a controller may behave are the different control modes. They include on/off, floating, proportional (P), integral (I), differential (D), and many others. These control modes will be described in this section.

A controller is called direct acting if its output increases when its measurement rises and is called reverse acting if its output decreases when its measurement rises.

ON/OFF CONTROL

The oldest control strategy is to use a switch for control. For example, if the controlled process is the room temperature, the switch would turn on the heat source when the temperature is low and turn it off when the desired comfort level is reached.

A perfect on/off controller is "on" when the measurement is below the set point. Under such conditions the manipulated variable is at its maximum value. When the measured variable is above the set point, the controller is "off" and the manipulated variable is at its minimum value.

$$\text{if} \begin{cases} e > 0 & \text{then } m = \max \\ e < 0 & \text{then } m = \min \end{cases} \qquad \mathbf{2.2(1)}$$

In most practical applications, due to mechanical friction or to the arcing of electrical contacts, the error must exceed a narrow band (around zero error) before a change will occur. This band is known as the differential gap, and its presence is usually desirable to minimize the cycling of the process. Figure 2.2a shows the response of an on/off controller to a sinusoidal input.

The block diagram shown in Figure 2.2b can be used to analyze the behavior of an on/off controller. A dead time and a time constant can represent *the* control response. The on/off control of heating processes can be represented with such dynamics. The on/off controller can be implemented by a relay having a hysteresis of h. If the error signal is greater than h, the relay is switched on, providing output value u_o and if the error goes below $-h$, it is switched off.

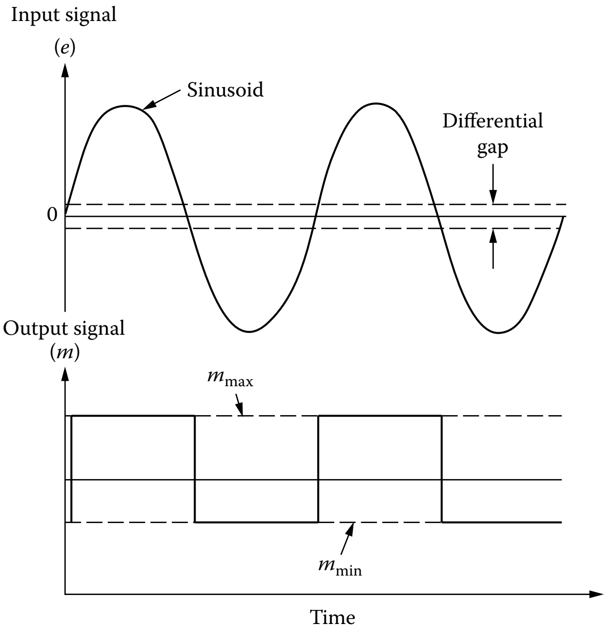

FIG. 2.2a
The response of a two-position controller.

Figure 2.2c shows the output (manipulated variable $-u$) and control (controlled variable $-y$) signals of the on/off control system. The relay is first switched on until the controlled variable (y) reaches the value $r + h$. At that point it

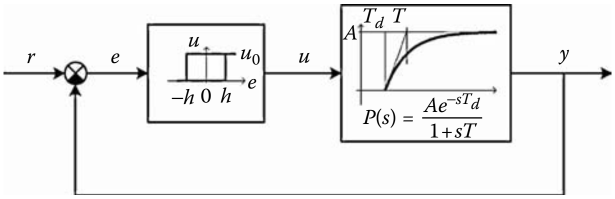

FIG. 2.2b
Block diagram of an on/off control system.

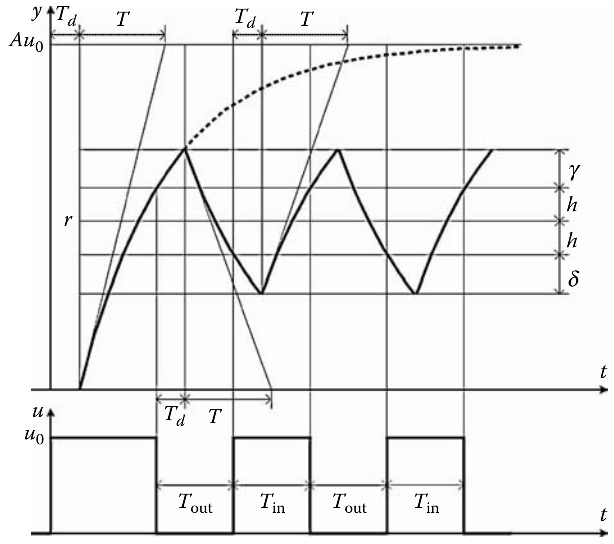

FIG. 2.2c
*The on/off output signal (*u*) of the controller results in a cycling response of the controlled variable (*y*).*

switches off, but the controlled variable keeps increasing through the duration of the switch's dead time by the amount γ. Then it starts decreasing exponentially. When the output (y) has dropped to $r - h$, the relay is switched on again, but the controlled variable (y) will continue to decrease for the period of the dead time by a value of δ.

This cycle is repeated as the controlled variable (y) is oscillating around a mean value. The amplitude of the oscillations is smaller if both the hysteresis band and the dead time are small. With a small hysteresis band the frequency of the oscillations becomes higher. It can be observed that the mean value of the controlled variable (y) is shifted a bit from the reference value (set point – r). This shift depends on the value of the reference signal.

The performance of the on/off control system can be improved by applying a negative feedback around the relay with a proportional lag element as shown in Figure 2.2d. This feedback causes the oscillations to have a higher switch-over frequency and a smaller amplitude range. The addition of an integrating (I) or a proportional-plus-integral (PI) mode to the on/off controller could further improve its performance.

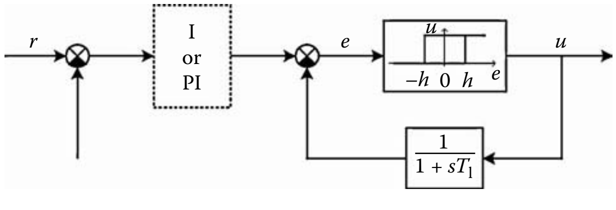

FIG. 2.2d
The performance of an on/off controller can be improved by the addition of an inner feedback.

SINGLE-SPEED FLOATING CONTROL

For self-regulating processes with little or no capacitance, the single-speed floating controller can be used. The output of this controller can either be increasing or decreasing at a certain rate. Such control is commonly used when the final control element is a single-speed reversible motor.

The controller is usually provided with a neutral zone (dead zone), and when the measurement is within that zone, the output of the controller is zero. This dead zone is desirable because otherwise the manipulated variable would be changing continually in one direction or the other.

With this controller, the output to the reversible motor is either forward, reverse, or off. Mathematically the single-speed floating control is expressed as

$$\text{if}\begin{cases} e > +\varepsilon/2 \\ e < -\varepsilon/2 \\ -\varepsilon/2 \le e \le \varepsilon/2 \end{cases} \quad \text{then}\begin{cases} m = +T_i t + M_{01} \\ m = -T_i t + M_{02} \\ m = M_{03} \end{cases} \qquad \mathbf{2.2(2)}$$

where t = time; m = controller output (manipulated variable); e = controller input (error signal); ε = constant defining neutral zone; T_i = controller speed constant; and M_{o1}, M_{o2}, M_{o3} = constants of integration.

The response of a single-speed floating controller to a sinusoidal input is shown in Figure 2.2e.

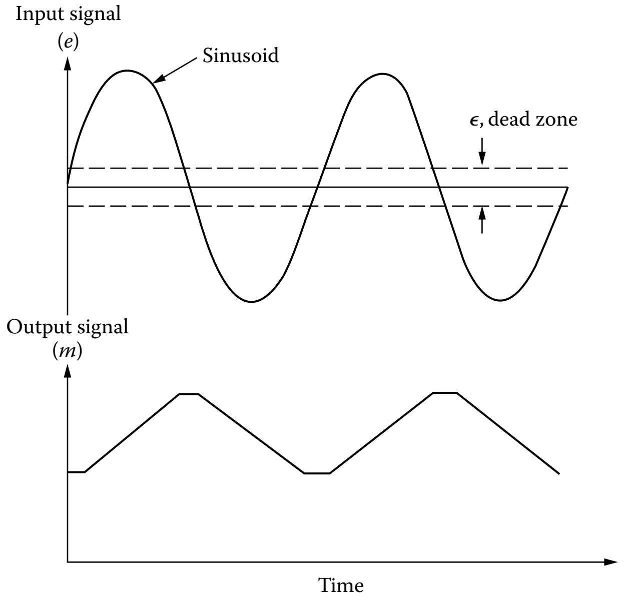

FIG. 2.2e
The response of a single-speed floating controller to a sinusoidal measurement signal.

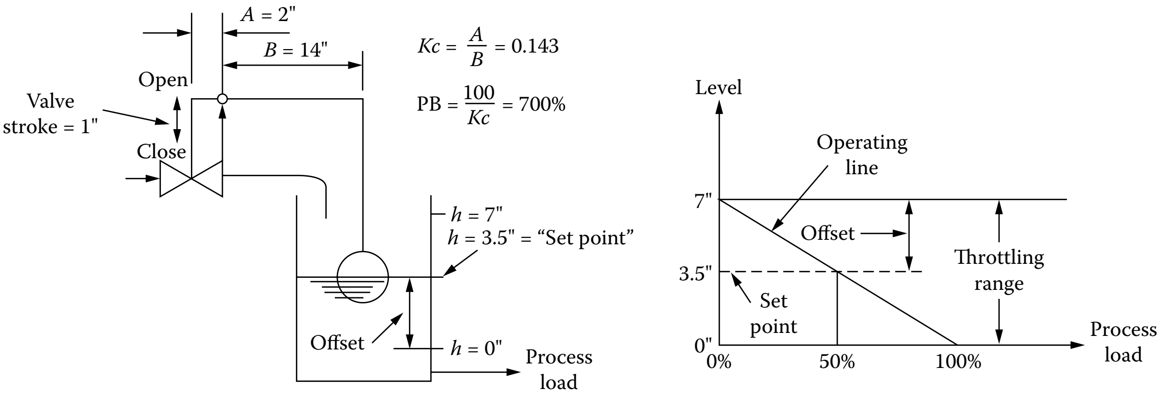

FIG. 2.2f

A plain proportional controller cannot maintain its set point because in order to operate at a load other than 50%, it first has to move the manipulated variable (inflow) away from 50%, which corresponds to its set point.

THE PROPORTIONAL CONTROL MODE

The proportional (P) mode alone is the simplest linear control algorithm. It is characterized by a constant relationship between the controller input and output. The adjustable parameter of the proportional mode, K_c, is called the proportional gain. It is frequently expressed in terms of percent proportional band, PB, which is inversely related to the proportional gain as shown below:

$$K_c = 100/\mathrm{PB} \qquad \mathbf{2.2(3)}$$

"Wide bands" (high PB values) correspond to less "sensitive" controller settings, and "narrow bands" (low PB percentages) correspond to more "sensitive" controller settings.

As the name "proportional" suggests, the correction generated by the proportional control mode is proportional to the error. Equation 2.2(4) describes the operation of the proportional controller.

$$m = K_c e + b = (100/\mathrm{PB})(e) + b \qquad \mathbf{2.2(4)}$$

where m = the output signal to the manipulated variable (control valve); K_c = the gain of the controller; e = the deviation from set point or error; PB = the proportional band ($100/K_c$); b = the live zero or bias of the output, which in pneumatic systems is usually 0.2 bars and in analog electronic loops is 4 mA.

The proportional controller responds only to the present. It cannot consider the past history of the error or the possible future consequences of an error trend. It simply responds to the present value of the error. It responds to all errors in the same manner, in proportion to them.

When a small error results in a large response, the gain (K_c) is said to be large or the proportional band (PB) is said to be narrow. Inversely, when a large error causes only a small response, the controller is said to have a small gain or a wide proportional setting. The gain in digital control system (DCS) control packages is usually adjustable from 0 to 8, while in analog controllers it can usually be adjusted from 0.02 to about 25.

Proportional Offset

The main limitation of plain proportional control is that it cannot keep the controlled variable on set point.

Let us consider the level control system shown in Figure 2.2f. The float-type proportional controller can only respond to a load change (change in the outflow of water) because it must experience a change in level before it can respond. Therefore, the only condition when this process will be on set point is when the load is 50%. In all other cases the level will have to travel up or down on its "operating line" as a function of the load. The difference between the actual value of the level and set point is called the offset, because this is the amount by which the process is off set point.

The gain of this mechanical controller is the ratio of the lengths of the two arms around the pivot. $K_c = A/B = 2/14 = 0.143$, or PB = 700%. One can increase the gain of this controller by moving the pivot to the right. This would result in requiring a smaller change in level to fully stroke the valve, which in turn would narrow the throttling range of the system and would make the operating line more horizontal.

It is evident that by increasing the gain, one can reduce (but not eliminate) the offset. If the controller gain is very high, the presence of the offset is no longer noticeable, and it seems as if the controller is keeping the process on set point.

Unfortunately, most processes become unstable if their controller is set with such high gain. The only exceptions are the very slow processes. For this reason the use of plain proportional control is limited to slow processes that can tolerate high controller gains (narrow proportional bands). These include the float-type valves, thermostats, and humidostats. In other processes, the offset inherent in proportional control (Figure 2.2g) cannot be tolerated.

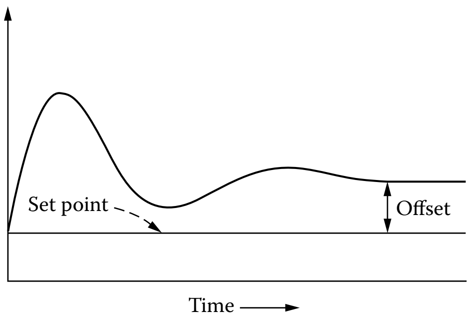

FIG. 2.2g
After a permanent load change, the proportional controller is incapable of returning the process back to the set point and an offset results. The smaller the controller's gain, the larger will be the offset.

THE INTEGRAL MODE

The integral (I) control mode is also sometimes called reset mode because after a load change it returns the controlled variable to set point and eliminates the offset, which the plain proportional controller cannot do. The mathematical expression of the integral-only controller is

$$m = \frac{1}{T_i}\int e\,dt + b \qquad 2.2(5)$$

while the mathematical expression for a proportional-plus integral (PI) controller is

$$m = K_c\left[e + \frac{1}{T_i}\int e dt\right] + b \qquad 2.2(6)$$

The term T_i is the integral time setting of the controller. It is also called reset time or repetition time, because with a step input, the output of a pure integrator reaches the value of the step input during the integral time, assuming $b = 0$.

The integral mode has been introduced in order to eliminate the offset that plain proportional control cannot remove. The reason proportional control must result in an offset is because it disregards the past history of the error. In other words, it disregards the mass or energy that should have been but was not added to (or removed from) the process, and therefore, by concerning itself only with the present, it leaves the accumulated effect of past errors uncorrected.

The integral mode, on the other hand, continuously looks at the total past history of the error by continuously integrating the area under the error curve and eliminates the offset by forcing the addition (or removal) of mass or energy that should have been added (or removed) in the past.

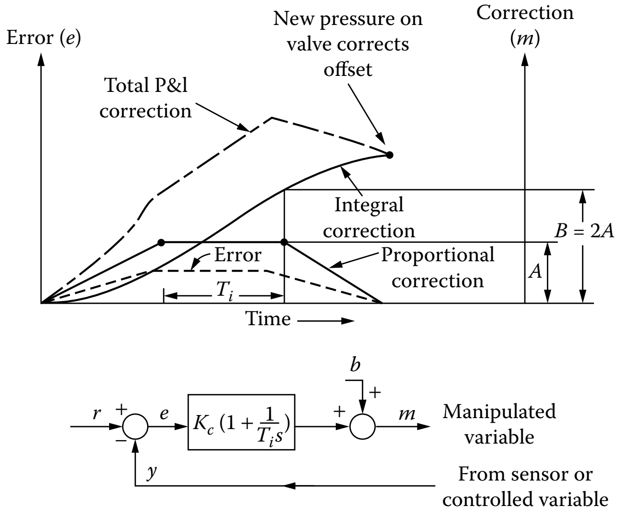

FIG. 2.2h
The contribution of the integral mode to the controller's output signal (m) is a function of the area under the error curve.

Figure 2.2h illustrates the correction generated by the integral mode in response to a supposed error curve indicated with a dotted line in the figure. It also shows the proportional and the combined (PI) correction.

Note that when the error is constant and therefore the proportional correction is also constant, the integral correction is rising at a constant rate because the area under the error curve is still rising. When the error and with it the proportional correction are both dropping, the integral correction is still rising because the area under the error curve is still rising. When the error reaches zero, the integral correction is at its maximum. It is this new signal level going to the control valve that serves to eliminate the offset.

The units of setting the integral time are usually given in "repeats/minute" or in "minutes/repeat." In DCS systems, the integral setting of control loops can usually be set from 0 to 300 repeats/minute, or from 0.2 seconds to about 60 minutes or more in units of minutes/repeat.

The meaning of the term "repeats/minute" (or its inverse) can be understood by referring to Figure 2.2h. Here, in the middle section of the error curve, the error is constant and therefore the proportional correction is also constant (A).

If the length of the duration of the middle section is one integral time (T_i), the integral mode is going to repeat the proportional correction by the end of the first integral time ($B = 2A$). The integral mode will keep repeating (adding "A" amount of correction) after the passage of each integral time during which the error still exists. The shorter the integral time, the more often the proportional correction is repeated (the more repeats/minute), and thus the more effective is the integral contribution.

Pure integral control (floating control) is seldom used, except on very noisy measurements as in some valve position or flow control systems, where the PI loop is usually tuned to have a low gain and lots of reset (integral). The proportional mode acts as a noise amplifier, while the integral mode

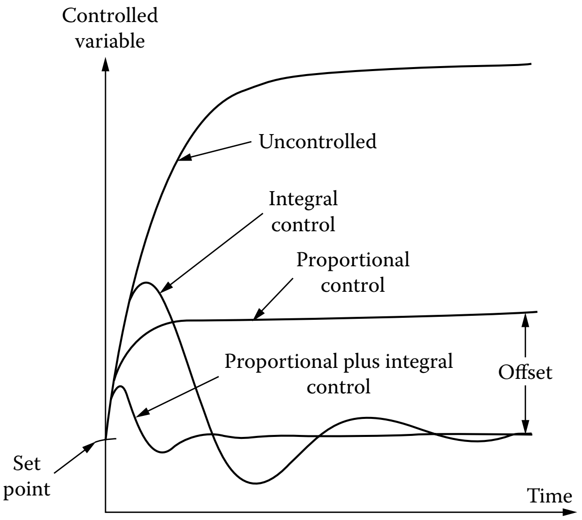

FIG. 2.2i
The different responses of a process variable to a load change in the process when it is uncontrolled and also when it is under P, I, and PI control.

integrates the area under the noisy error curve and gives a smooth average.

PI control is the most widely used control mode configuration and is used in all except the easiest applications, such as thermostats, and the most difficult applications, such as temperature or composition control. These difficult processes have large inertia that causes slow performance, and therefore the addition of rate (derivative) action accelerates the response of the control loop.

Figure 2.2i illustrates a process variable's response to a load change in the process when it is uncontrolled and also when it is under P, I, and PI control.

Reset Windup

It is often the case that the solving of one problem introduces another. While the introduction of the integral mode has solved the problem of offset, it has introduced another worry that has to do with the very nature of the integral mode. The fact that integral looks at the past history of the error and integrates it is good and useful when the loop is operational, but it can be a problem when the loop is idle.

When the plant is shut down for the night, the controllers do not need to integrate the errors under the error curves. Similarly, it would be desirable to "turn off" the integral mode in a surge controller when there is no surge or in a reactor temperature controller during heat-up. Other cases where integration of the error is undesirable include a selective control system, when a particular controller is not selected for control, or in a cascade master, if the operator has switched the loop off cascade, etc.

Under these conditions it is not desirable for the integral mode to stay active because if it does, it will eventually saturate, and its output will either drop to zero or rise to the maximum value of the air or power supply. Once saturated, the controller will not be ready to take control when called upon to do so but will actually upset the process by trying to introduce an equal and opposite area of error, which it has experienced during its idle state.

In all such installations the controller must be provided with either external reset, which protects it from ever becoming idle (see next section for details), or with an antireset windup feature, which protects it from saturating in its idle state. In selective and cascade control loops, external feedback is the most often applied solution. Here, instead of looking at its own output, which can be blocked, the integral mode of the controller looks at an external feedback signal (such as the opening of the valve), which cannot be blocked.

In surge control or reactor heat-up applications the chosen solution usually is to use the slave measurement as the external reset signal to prevent saturation. In some control systems, when a windup limit is reached, the integral (repeats/minute) is increased 8-, 16-, or even 32-fold, in order to speed the "unwinding" process and return the algorithm to normal operation. In DCS systems these functions are implemented in software.

THE DERIVATIVE MODE

The proportional mode considers the present state of the process error, and the integral mode looks at the past history of the error, while the derivative mode anticipates the future values of the error and acts on that prediction. This third control mode became necessary as the size of processing equipment increased and, correspondingly, the mass and the thermal inertia of such equipment also became greater. For such large processes it is not good enough to respond to an error when it has already evolved because the flywheel effect (the inertia or momentum) of these large processes makes it very difficult to stop or reverse a trend once it has evolved. The purpose of the derivative mode is to predict the process errors before they have evolved and take corrective action in advance.

Figure 2.2j describes the derivative response to the same error curve that has been used earlier. In the middle portion of the illustration where the error is constant, the derivative contribution to the output signal (to the control valve) is zero. This is because the derivative contribution given below by Equation 2.2(7) is based on the rate at which the error is changing, and in this region that rate of change is zero.

$$m = K_c\left[e + T_d \frac{d}{dt} e\right] + b \qquad \textbf{2.2(7)}$$

In a controller, derivative action is used not by itself, but in combination with the proportional (PD) or with the proportional and integral control modes (PID controller).

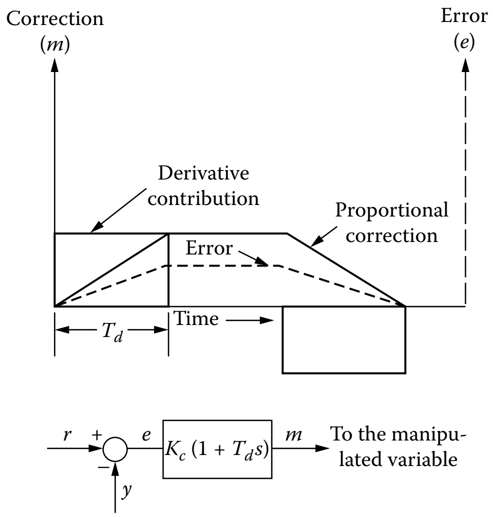

FIG. 2.2j
The contribution of the derivative mode to the total output signal (m) is a function of the rate at which the error is changing.

As illustrated in Figure 2.2j, when the error is rising (on the left of the figure), the derivative contribution is positive and is a function of the slope of the error curve.

The unit of the derivative setting is the derivative time (T_d). This is the length of time by which the D-mode (derivative mode) "looks into the future." In other words, if the derivative mode is set for a time T_d, it will generate a corrective action immediately when the error starts changing, and the size of that correction will equal the size of the correction that the proportional mode would have generated T_d time later. The longer the T_d setting, the further into the future the D-mode predicts and the larger its corrective contribution. When the slope of the error is positive (measurement is moving up relative to the set point), the derivative contribution will also rise, if the controller is direct-acting.

On the right side of Figure 2.2j, the error is still positive (measurement is above the set point), but the derivative contribution is already negative, as it is anticipating the future occurrence when the loop might overshoot in the negative direction and is correcting for that future occurrence now.

The derivative (or rate) setting is in units of time and usually can be adjusted from a few seconds to up to 10 hours or more. The applications for PD control loops (with proportional plus derivative effect) are few. They sometimes include the slave controller in temperature cascade systems, if the goal is to increase the sensitivity of the slave loop beyond what the maximum gain can provide.

Another application of PD control is batch neutralization, where the derivative mode protects against overshooting the target (pH = 7) while the P-mode reopens the reagent valve for a few droplets at a time as neutrality is approached.

PID control (with proportional plus integral plus derivative modes acting in) is more widely used, and its applications include most temperature and closed-loop composition control applications.

In most cases, when derivative action is used, the filtering of the measurement or error signal is also required, because otherwise it would respond to noise and to all abrupt input changes with excessively high changes in its output signal. The smaller the filter time constant is relative to the derivative time constant, the more effective will be the derivative mode.

Limitations of the Derivative Mode

Because the derivative mode acts on the rate at which the error signal changes, it can also cause unnecessary upsets because, for example, it will react to the sudden set point changes made by the operator. It will also amplify noise and will cause upsets when the measurement signal changes occur in steps (as in a chromatograph, for example).

In such situations special precautions are recommended. For example, it is necessary to change the control algorithm so that it will be insensitive to sudden set point changes. It is necessary to make sure that the derivative contribution to the output signal going to the control valve will respond not to them, but only to the rate at which the measurement changes. This change is aimed at making the derivative mode to act on the measurement only (Equation 2.2[8]), but *not* on the error (Equation 2.2[9]).

$$m = K_c\left[e + \frac{1}{T_i}\int e\,dt - T_d\frac{d}{dt}y\right] + b \qquad \textbf{2.2(8)}$$

$$m = K_c\left[e + \frac{1}{T_i}\int e\,dt + T_d\frac{d}{dt}e\right] + b \qquad \textbf{2.2(9)}$$

Some might prefer to eliminate the set point effect on the proportional contribution also. In that case, Equation 2.2(8) would be revised as follows:

$$m = K_c\left[-y + \frac{1}{T_i}\int e\,dt - T_d\frac{d}{dt}y\right] + b \qquad \textbf{2.2(10)}$$

Excessive noise and step changes in the measurement can also be corrected by filtering out any change in the measurement that occurs faster than the maximum speed of response of the process. DCS systems, as part of their software library, are provided with adjustable filters on each process variable.

Table 2.2k gives a summary of PID equations, while Figure 2.2l illustrates the responses to a step change in the set point of a pure P, a pure I, and a pure D control mode, and also gives the step responses of the PI, PD, and PID controllers.

The operation with a plain proportional controller (P) produces a large steady-state error. If an integral-only (I) controller is used, it continues to integrate the area under the error curve until the process variable is returned to set point. Adding the proportional mode to the integral mode provides a bit faster response. With a PD controller, the controller

TABLE 2.2k
Mathematical Descriptions of the Conventional Control Modes

Symbol	*Description*	*Mathematical Expression*
	One-Mode	
P	Proportional	$m = K_c e + b$
I	Integral (reset)	$m = \frac{1}{T_i}\int e\,dt + b$
	Two-Mode	
PI	Proportional-plus-integral	$m = K_c\left[e + \frac{1}{T_i}\int e\,dt\right] + b$
PD	Proportional-plus-derivative	$m = K_c\left[e + T_d\frac{d}{dt}e\right] + b$
	Three-Mode	
PID	Proportional-plus-integral-plus-derivative	$m = K_c\left[e + \frac{1}{T_i}\int e\,dt + T_d\frac{d}{dt}e\right] + b$

causes an initial overshoot and a steady-state error. A properly tuned PID controller reduces the initial overshoot and returns the controlled variable to set point.

Figure 2.2m separately describes the responses of the above controllers and control modes to a variety of disturbance inputs. Figure 2.2n shows the process responses of a closed loop with different control algorithms when they respond to a unit step change in set point. It can be seen that the integral mode returns the process to set point while the derivative amplifies transients.

Inverse Derivative Control Mode

A special-purpose control action used on extremely fast processes is the so-called inverse derivative mode. As the name implies, it is the exact opposite of the derivative mode. While the output of the derivative mode is directly proportional to the rate of change in the error, the output of the inverse derivative mode is inversely proportional to the rate of change in error.

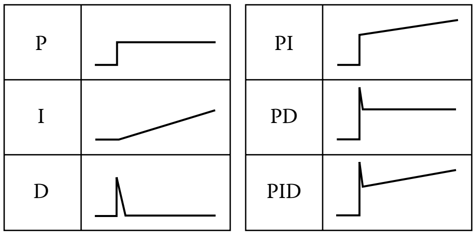

FIG. 2.2l
The responses to a step change in set point of the P, I, D control modes and of the PI, PD, and PID controllers.

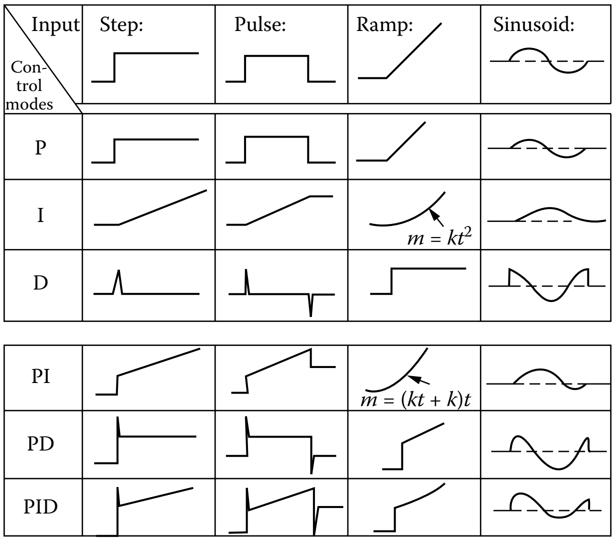

FIG. 2.2m
Responses of the P, I, D control modes and of the PI, PD, and PID controllers to a variety of input disturbances.

Inverse derivative is used to reduce the gain of a controller at high frequencies and is therefore useful in stabilizing a flow loop. The proportional-plus-inverse-derivative controller provides high gain to minimize offset at low frequency and low gain to stabilize at high frequency.

Inverse derivative can also be added to a proportional-plus-integral controller to stabilize flow and other loops requiring very low proportional gain for stability. One should add inverse derivatives only when the loop is unstable at the minimum gain setting of the proportional-plus-integral controller.

Since inverse derivative is available in a separate unit, it can be added to the loop when stability problems are encountered. Interestingly, the addition of the inverse derivative, if properly tuned, has little effect on the natural frequency of the loop.

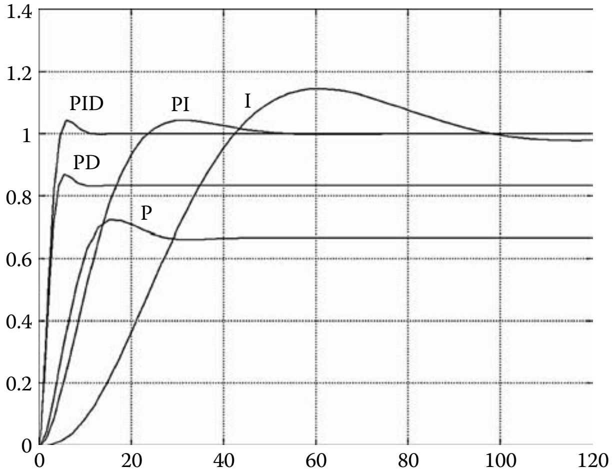

FIG. 2.2n
The unit-step responses of P, I, PI, PD, and PID controllers.

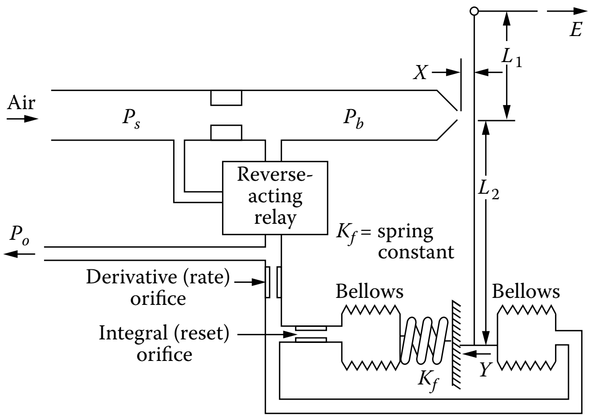

FIG. 2.2o
Interaction was unavoidable in the pneumatic PID controller because its components were physically interconnected, and a change in one tuning setting affected the others.

PID ALGORITHM VARIATIONS

Equations 2.2(8) and 2.2(9) are referred to as noninteracting PID equations. Such interacting behavior was unavoidable when pneumatic controllers were used because their three settings were physically interconnected (Figure 2.2o); if one setting changed, it affected all the others.

In these so-called interacting controllers, if we designate the PID settings on the controller knobs as PB_o (proportional band), T_{io} (minutes/repeat), and T_{do}, it can be shown that the actual "working" settings (PB, T_i, and T_d) that the process "sees" are as follows:

$$PB = PB_o/(1 + T_{do}/T_{io}) \qquad \mathbf{2.2(11)}$$

$$T_i = T_{do} + T_{io} \qquad \mathbf{2.2(12)}$$

$$T_d = (T_{do})(T_{io})/(T_{do} + T_{io}) \qquad \mathbf{2.2(13)}$$

While interaction is somewhat confusing, the interacting controller has a major advantage: the actual working derivative (T_d) can never become more than one-quarter of the T_i. This feature contributes to the safety of using this controller because if it were possible to make $T_d > T_i/4$, the controller action would reverse, which could cause accidents.

Nowadays, the different DCS and PLC suppliers use a variety of PID control algorithms. Table 2.2p illustrates the working principles of the three most widely used versions, the interacting, the noninteracting, and the parallel algorithms. It should be understood that on the one hand all of these are usable, but on the other hand their settings will mean different things, and the noninteracting and parallel algorithms do need software protection against an operator accidentally setting T_d to exceed $T_i/4$.

Digital Algorithms

When PID algorithms are implemented in the digital world by DCS systems, what used to be integration in the analog world becomes summation, and what used to be time differential in the analog world becomes difference. The scan period of DCS systems is fixed at around 0.5 seconds or is

Conversions and Relationships Between the Different PID Algorithms

Types of Algorithms	*Standard or Noninteracting*	*Interacting*	*Parallel*
Equation for Output (m) =	$K_c\left(e+\frac{1}{T_i}\int e\,dt+T_d\frac{de}{dt}\right)+b$	$K_c\left(e+\frac{1}{T_i}\int e\,dt+T_d\frac{d}{dt}e\right)+b$	$K_c e+\frac{1}{T_i}\int edt+T_d\frac{de}{dt}+b$
Block Diagram Representation	 	 	Working PB (100/K_c)	$PB = PB_0$	$PB=\frac{PB_0}{1+T_{do}/T_{io}}$	$PB = PB_0$
Working T_i (minutes/repeat)	$T_i = T_{io}$	$T_i = T_{do} + T_{io}$	$T_i = (T_{io})(K_c)$
Working T_d (minutes)	$T_d = T_{do}$	$T_d=\frac{(T_{do})(T_{io})}{T_{io}+T_{do}}$	$T_d = T_{do}/K_c$

Where: PB_o, T_{io}, and P_{do} are the proportional, integral, and derivative settings on the controller.

selectable for each loop from 0.1, 0.2, 0.5, 1.0, 5.0, 10, or 30 seconds.

The DCS system does not continuously evaluate the status of each measurement, but looks at them intermittently. This increases the dead time of the loop by two “scan periods” (the period between readings of a measurement) and bases its algorithm calculations on the “present” and the “previous” error.

There are two basic types of digital algorithms in use. One is called positional. This means that the full output signal to the valve is recalculated every time the measurement is looked at (Equation 2.2[14]).

$$m = K_c\left(e + \frac{1}{T_i}\sum_{o}^{n} e\,dt + \frac{T_d}{\Delta t}\Delta e\right) + b \qquad \textbf{2.2(14)}$$

where Δt = scan period; Δe = change between the previous and the present value of the error; and $\sum_0^n e$ = the sum of all previous errors between time zero and time n.

The other type of calculation is called a velocity algorithm. In that case, the value of the previous output signal (m) is held in memory, and only the required change in that output signal is calculated (Equation 2.2[15]).

$$\Delta m = K_c\left(\Delta e + \frac{1}{T_i}e\Delta t + \frac{T_d}{\Delta t}\Delta(\Delta e)\right) \qquad \textbf{2.2(15)}$$

where $\Delta(\Delta e)$ = the change in the change in the error between the previous and the present scan period.

The positional algorithm is preferred when the measurement is noisy because it works with the error and not the rate of error change when calculating its proportional correction. Velocity algorithms have the advantages of providing bumpless transfer, less reset windup (0 or 100%) and are better suited for controlling servomotor-driven devices. Their main limitations include noise sensitivity, likelihood to oscillate, and lack of an internal reference.

SAMPLE-AND-HOLD ALGORITHMS

When the dead time of a control loop exceeds the time-constant of that loop, the conventional PID algorithms cannot provide acceptable control. This is because the controller cannot distinguish between a nonresponding manipulated variable and one that is responding but whose effect cannot yet be detected because of the transportation lag (dead time) in the system.

This lack of response to a change in output during the dead-time period causes the controller to overreact and makes the loop unstable. For such applications the sample-and-hold type algorithms are used.

These algorithms are identical to the previously discussed PID algorithms except that they activate the PID algorithm for *only part of the time.* After the output signal (m) is changed to a new quantity, it is sealed at its last value (by setting the measurement of the controller equal to its set point) and it is held at that constant value until the dead time of the loop is exhausted.

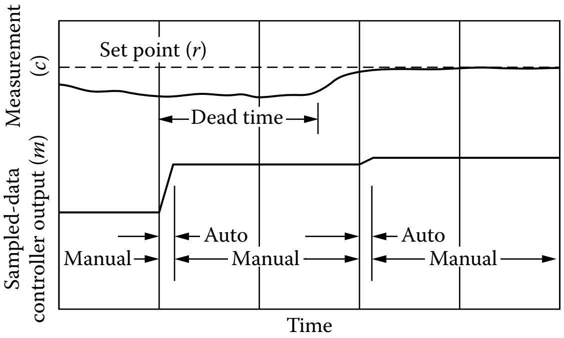

FIG. 2.2q
Sample-and-hold controllers are periodically switched from manual to automatic and back again. They are used mostly on dead time processes.

When the dead time has passed, the controller is switched back to automatic and its output (m) is adjusted based on the new measurement it “sees” at that time, using the PID algorithm. Figure 2.2q shows how these periods of manual and automatic operating modes are alternated. A timer sets the time period for which the controller is switched to manual. The timer setting is adjusted to exceed the dead time of the loop.

The only difference between conventional PID and its sample-and-hold variety is in the tuning of the loops: the sample-and-hold controller has less time to make the same amount of correction that the conventional PID would and therefore needs to do it faster. This means that the integral setting must be increased in proportion to the reduction in time when the loop is in automatic.

CONCLUSIONS

In this section the basic control modes and control algorithms were described. The next sections of this chapter will cover some of the more sophisticated analog and digital PID algorithm variations.

In summation one might say that on/off and plain proportional control is suited only to the easiest (fast with little dead time) processes, which do not need to be kept on a set point. The addition of integral action returns the controller to set point, but this PI controller must be protected from reset windup, usually by external reset. The addition of derivative provides anticipation into the future, but requires protection from noise and sudden set point changes.

Inverse-derivative is used to stabilize fast and noisy processes. Sample-and-hold algorithms are required if the dead time (transportation lag) of the process is long. Digital algorithms are discussed in more detail later, and it should suffice here to say that positional ones are better suited to the control of noisy processes, while velocity algorithms are preferred for the bumpless control of servomotor-driven devices.

2.3 Control Modes—PID Variations

R. R. RHINEHART (1995, 2005) **F. G. SHINSKEY** (2005) **H. L. WADE** (2005)

Although the PID form represented by Equation 2.3(1) is presented as the standard form, many controller manufacturers offer a variety of modified versions. Some modifications are improvements; some are leftovers from early pneumatic implementations, and some are more traditional in certain industries than others. Regardless, the basic proportional, integral, and derivative actions are retained, so there are no conceptual barriers to using the various vendor offerings. The main issue is that the tuning behavior varies from one form to another.

$$m = K_C\left(e + \frac{1}{T_I}\int e\,dt + T_D\frac{de}{dt}\right) \qquad \textbf{2.3(1)}$$

An experienced operator who is accustomed to tuning a controller having a particular PID algorithm will be baffled when another controller does not respond as expected. An operator or software program that follows a recipe procedure to determine K_C, T_I, and T_D for the standard algorithm (Equation 2.3[1]) can be startled by the response when applying the procedure to a manufacturer-specific version. A manufacturer's equipment usually offers a number of alternative controller forms. An unknowledgeable user may choose some of them on the whim of the moment, with the results that a variety of algorithms may exist in controllers mounted side by side or in the same control system. When various algorithms are used in the same control room, the operators will not experience consistent behavior patterns, and as a result may never become competent at tuning. A controller that "cannot be tuned" will be placed in manual.

Controller tuning is an ongoing necessity. It is needed whenever process operating conditions change, when process gains and time constants change, and often when previous controller settings no longer give the desired response. Tuning is required to maintain good control, and a rational understanding of the controller form and its behavior is required for effective tuning.

An understanding of the various forms of control algorithms, plus the configuration options that are offered, is also necessary to properly design and apply process control strategies.

PID ALGORITHMS

PID algorithms that continuously (in analog control systems) or repetitively (in digital processor systems) calculate the required position of the valve or other final actuator are called position algorithms. On the other hand, algorithms that calculate the required change in position of the final actuator are called velocity, or incremental, algorithms. Velocity algorithms, which are limited to digital implementation, are covered in Section 2.4. There are three basic forms of the position PID algorithm, plus variations on each of these forms.

Noninteracting Form

The standard form is shown by the block diagram in Figure 2.3a and is given by Equation 2.3(1), where for a reverse acting controller, $e = r - c$, the difference between set point and measurement. (For a direct acting controller, $e = c - r$.) The units of both error e and output m are percentages of full-scale transmitter and controller outputs, respectively, and time is usually expressed in minutes. (Some manufacturers are beginning to express time in seconds, rather than minutes.) Accordingly, K_C is dimensionless, the units of T_I are minutes per repeat, and the units of T_D are minutes. In this form the controller gain attenuates each of the controller modes.

The integration is from the last time the controller was switched from manual to automatic until the present time. The integrator must be initialized, however, to prevent a "bump" in the controller output when the mode is switched

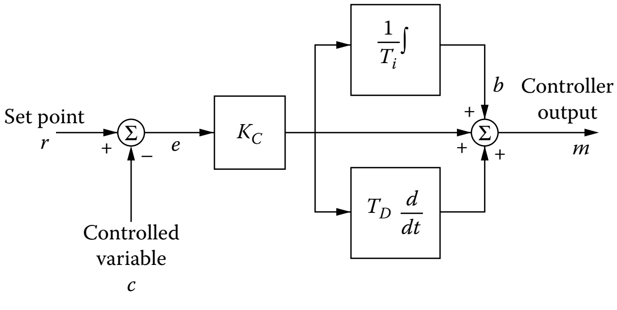

FIG. 2.3a
Block diagram, noninteracting PID controller.

from manual to automatic. If "*b*" represents the integral mode contribution to the controller output, that is,

$$b = \frac{K_C}{T_I}\int e\,dt \qquad \mathbf{2.3(2)}$$

then b_0, the initial value of b, must be set to

$$b_0 = m^* - \left(K_C e + T_D \frac{de}{dt}\right) \qquad \mathbf{2.3(3)}$$

where m^* is the operator-entered value of the controller output in the manual mode. Normally, b_0 tracks the right-hand side of Equation 2.2(3) continuously when the controller is in manual.

This form is often called the "ISA" form, although ISA has never sanctioned this or any other form of the PID. For reasons to be seen, it is also called the "noninteracting" form to distinguish it from the "interacting" form to be presented later. It is also called the "parallel" form, to distinguish it from the so-called "series" form, also to be presented later. Since there is no standard terminology among manufacturers, the user is cautioned to examine the mathematical expression representing the particular form, rather than relying on the manufacturer's nomenclature.

The proportional mode tuning parameter may be expressed as proportional band, PB, rather than controller gain, K_C. Proportional band is defined as the change in measurement required to produce a full range (100%) change in controller output due to proportional control action. The equations for conversion between PB and K_C are

$$K_C = \frac{100}{\text{PB}} \qquad \mathbf{2.3(4)}$$

$$\text{PB} = \frac{100}{K_C} \qquad \mathbf{2.3(5)}$$

The integral (reset) mode tuning parameter is often expressed as the reset rate, T_R, rather than as integral or reset time, T_I. The units of T_R are repeats/minute. The equations for conversion between reset time and reset rate are

$$T_R = \frac{1}{T_I} \qquad \mathbf{2.3(6)}$$

$$T_I = \frac{1}{T_R} \qquad \mathbf{2.3(7)}$$

Although there is no technological advantage in using either K_C or PB for the proportional mode tuning, or T_I or T_R for the integral mode tuning, the use of T_R has the psychological advantage that if faster integral action is desired, a larger number is set for T_R.

If both proportional and integral mode tuning parameters are changed, then Equation 2.3(1) becomes

$$m = \frac{100}{\text{PB}}\left(e + T_R\int e\,dt + T_D\frac{de}{dt}\right) \qquad \mathbf{2.3(8)}$$

Interacting Form

The interacting controller form is also called a "rate-before-reset" or "series" form algorithm. The "series" nomenclature arises from block diagram notation, in which the integral block is in series with the derivative block, whereas in the standard controller, the integral and derivative blocks are in parallel. The "parallel" nomenclature is also used in the next topic to describe an algorithm with independent gains on each mode. Therefore the "series/parallel" nomenclature can be misleading.

In the interactive controller, shown by the block diagram in Figure 2.3b and by

$$m = K'_C\left(e + T'_D\frac{de}{dt} + \frac{1}{T'_I}\int\left(e + T'_D\frac{de}{dt}\right)dt\right), \qquad \mathbf{2.3(9)}$$

integral action is taken on both the error and derivative terms. There is no technological advantage of Equation 2.3(9) over Equation 2.3(1), since with corresponding tuning, the performance of each is the same. Furthermore, if the derivative is not used ($T'_D = 0$), then the interacting and noninteracting controllers are identical in both form and performance. The interacting controller represents a physically realizable construction

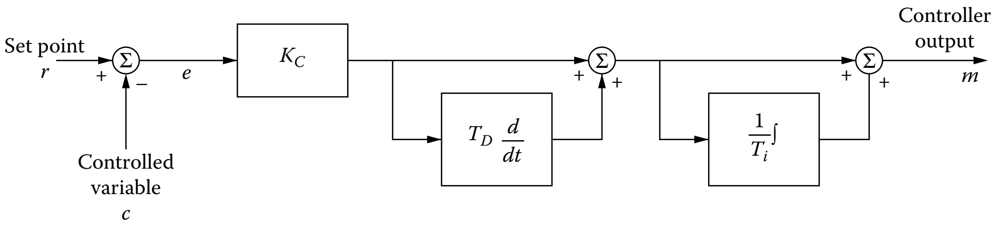

FIG. 2.3b
Block diagram, interacting PID controller.

of pneumatic devices, and is offered by vendors of electronic analog and digital systems so that new controllers will have a tuning response similar to certain pneumatic equipment that is being replaced.

Rearrangement of Equation 2.3(9) gives

$$m = K_C' \frac{T_I' + T_D'}{T_I'} \left(e + \frac{1}{T_I' + T_D'} \int e\,dt + \frac{T_I' T_D'}{T_I' + T_D'} \frac{de}{dt} \right) \tag{2.3(10)}$$

which shows exactly the same functional form as Equation 2.3(1). It also shows interactive behavior because adjustment of either T_I' or T_D' will affect the effective controller gain and both the effective integral and derivative times. K_C', T_I', and T_D' represent values actually entered for the noninteracting controller. The effective values of gain, integral, and derivative settings for an identical noninteracting, or standard, controller are given by

$$K_C = K_C' \frac{T_I' + T_D'}{T_I'} \tag{2.3(11)}$$

$$T_I = T_I' + T_D' \tag{2.3(12)}$$

$$T_D = \frac{T_I' T_D'}{T_I' + T_D'} \tag{2.3(13)}$$

If one has tuning parameters for a standard, or noninteracting, controller, Equation 2.3(1), then the corresponding tuning for Equation 2.3(10) is

$$K_C' = 0.5\,K_C\,(1 + \sqrt{1 - 4\,T_D/T_I}) \tag{2.3(14)}$$

$$T_I' = 0.5\,T_I\,(1 + \sqrt{1 - 4\,T_D/T_I}) \tag{2.3(15)}$$

$$T_D' = 0.5\,T_D\,(1 - \sqrt{1 - 4\,T_D/T_I}) \tag{2.3(16)}$$

Many conventional tuning rules define $T_D = T_I/4$. In this case, the corresponding tuning for the interacting controller is $K_C' = K_C/2$ and $T_I' = T_D' = T_I/2$. The interacting controller cannot duplicate a standard controller if $T_D > T_I/4$.

Noisy process signals should be smoothed or averaged before being applied to the control algorithm. A first-order filter (exponentially weighted moving average [EWMA]) is the standard offering. If the filter is used within the algorithm itself, it may be applied to the error signal, so that the filtered value of the error, e_f, replaces e in Equations 2.3(1) and 2.3(9). The filter equation is

$$T \frac{de_f}{dt} = e - e_f \tag{2.3(17)}$$

where T is the time constant of the filter. Since process noise is especially amplified by derivative action, some vendors make the filter time constant some multiple of the derivative time, T_D, so that

$$T = \alpha T_D \tag{2.3(18)}$$

Typical values for α range from 0.05 to 0.1. In pneumatic and electronic analog systems, α had a fixed value; in digital systems, α may or may not be accessible to the user. Some manufacturers refer to the reciprocal of α as “derivative gain.” Since filtering in essence averages new data with old data, the filtered value lags behind the process. The filtered variable dynamics are slower than the process, which means that (1) the controller must be tuned using the filtered data and (2) if the filter time constant is changed the controller may have to be retuned.

By combining Equations 2.3(17) and 2.3(9) and expressing the relationship in Laplace notation, the transfer function from error to controller output for an interacting controller with filter is

$$\frac{m(s)}{e(s)} = K_C \frac{(T_D s + 1)(T_I S + 1)}{(\alpha T_D s + 1) T_I S} \tag{2.3(19)}$$

Except for a modification that makes the derivative mode sensitive only to measurement changes, this transfer function is representative of most analog controllers and many implementations in digital systems.

Parallel Form

Whereas either the interacting or noninteracting forms of the PID are widely used in the process industries, the parallel form, also called the “independent gains” form, of PID is often used in power generation, drive control systems, robotics, and other applications. Figure 2.3c and Equation 2.3(20) presents the independent gains form of PID.

$$m = K_P\,e + K_I \int e\,dt + K_D \frac{de}{dt} \tag{2.3(20)}$$

K_P, K_I, and K_D are called the proportional gain, integral gain, and derivative gain, respectively. K_P is a dimensionless number, K_I is in units of time^{-1}, and K_D is in units of time.

There is no technological advantage of the parallel form of PID, since with corresponding tuning, the behavior of this form and either of the other forms will be identical. If one has tuning

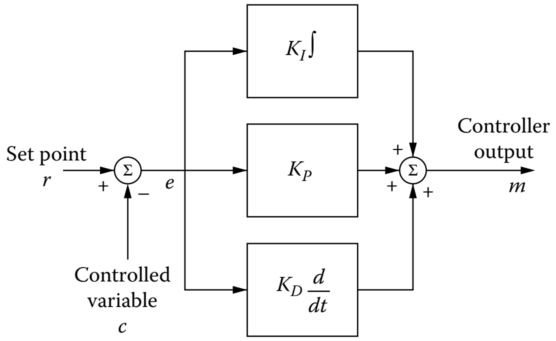

FIG. 2.3c
Block diagram, parallel PID controller.

parameters for a noninteracting controller, Equation 2.3(1), then the corresponding tuning parameters for Equation 2.3(20) are

$$K_P = K_C \tag{2.3(21)}$$

$$K_I = \frac{K_C}{T_I} \tag{2.3(22)}$$

$$K_D = K_C T_D \tag{2.3(23)}$$

A slight advantage of this form of configuration is that an integral-only controller can be obtained by simply setting K_C and K_D to zero. That cannot be done with either of the other forms if the integral tuning parameter is T_I, minutes/repeat.

SET-POINT RESPONSE SOFTENING

The algorithms presented previously may cause undesirable process effects whenever a set-point change is made. Each term acts on the error. Because the error is a deviation from set point, a sudden set-point change becomes a sudden change in error, which in turn causes an output spike — often an undesirable feature. Even if derivative is not being used, a set-point change will cause a "bump" in controller output; the size of this bump will be the magnitude of the set-point change times the controller gain. Another problem with set-point changes has to do with controller tuning. If a controller is tuned for optimum response to a set-point change, it will likely be too conservative for elimination of disturbances to the loop. The rate of recovery of the controlled variable will be much slower than its rate of departure. On the other hand, controller settings that produce optimum disturbance rejection tend to cause large overshoot on set-point changes. This is especially true of lag-dominant loops such as most liquid level, temperature, pressure, and composition loops. To avoid this undesirable behavior, several modifications that can soften the response to a set-point change can be used. In general, these modifications can be applied to any of the three forms of PID algorithm presented earlier.

Derivative and Proportional Actions

The algorithm can be modified so that either the derivative mode, or both the derivative and proportional modes, act only on the measurement. Output spiking due to the derivative mode and output bumping due to the proportional response are prevented, while the tuned controller response to a loop disturbance is unchanged. Derivative-on-error or -measurement and proportional-on-error or -measurement are often user-configuration choices. If both are chosen, the form of a noninteracting algorithm becomes

$$m = K_C\left(-c + \frac{1}{T_I}\int e\,dt - T_D\frac{dc}{dt}\right) \tag{2.3(24)}$$

Because of the elimination of output spikes and output bumps, the controller can be tuned for a more aggressive response to disturbances. Conventional tuning rules (e.g., Ziegler–Nichols) will produce a very sluggish response to set-point change if proportional-on-measurement is chosen. The response to a measurement disturbance will be the same if the proportional acts on the error or on measurement.

Set-Point Filtering

With proportional-on-measurement there may be a serious degradation in the response to a set-point change, since immediately following the set-point change, only the integral mode will act on the deviation. Since most modern PID controllers feature bumpless transfer between the manual and automatic modes, the response is the same as if the set point had been changed with the controller in manual, with the controller then switched to automatic.

To achieve the advantage of improved disturbance rejection due to more aggressive tuning of the PID yet avoid the degraded response following a set-point change, a lead-lag filter can be placed on the set point.

$$r'(s) = \left(\frac{\lambda T_I s + 1}{T_I s + 1}\right) r(s) \tag{2.3(25)}$$

Here, $r(s)$ is the (transform of) the actual set point; $r'(s)$ is the modified set point used by the PID algorithm; T_I is the integral time used by the PID, and λ is the lead-lag ratio. When λ is set to 1.0, there is no filtering; when set to zero, the filter is a first-order lag whose time constant is equal to the integral time. When Equation 2.3(25) is combined with the transform of Equation 2.3(1), using only the proportional and integral modes, the result is

$$m(s) = K_C\left(\lambda r(s) - c(s) + \frac{r(s) - c(s)}{T_I s}\right) \tag{2.3(26)}$$

Another way of viewing this modification is to consider taking a linear combination of proportional-on-error and proportional-on-measurement. From Equation 2.3(1), the proportional mode contribution to the output is $K_c(r - c)$. From Equation 2.3(24), the proportional mode contribution to the output is $-K_c c$. A linear combination of these becomes

$$\lambda K_C(r - c) - (1 - \lambda)K_C c = K_C(\lambda r - c) \tag{2.3(27)}$$

which, after transformation, is the same as the proportional mode contribution exhibited by Equation 2.3(26). A value for λ of 0.4 produces almost no set-point overshoot, whereas a value of 0.5 will produce a minimum integral of absolute error (IAE) response with about 10% set-point overshoot. These results will vary somewhat with the dynamics of the process and the tuning of the controller.

One manufacturer offers a "two-degree-of-freedom" controller in which linear combinations of both the proportional modes and derivative modes can be chosen.

$$m = K_C\left[(\lambda r - c) + \frac{1}{T_I}\int e\,dt + TD\frac{d(\delta r - c)}{dt}\right] \tag{2.3(28)}$$

Some manufacturers offer a set-point ramping option that prevents both output spikes and bumps by eliminating sudden set point changes.

Although any of the set-point softening techniques described here can be an advantage for single loop control or for the primary controller of a cascade configuration, neither set-point ramping nor proportional-on-measurement should be used on the secondary controller of a cascade loop, as that would degrade the responsiveness of the secondary loop.

WINDUP ACCOMMODATION

The integral is an accumulator that, in digital algorithms, continuously adds the deviation from set point to the previous sum. Whenever an error persists for a long time, the integral can grow to the largest value the assigned processor memory can hold. For analog systems, the integral can grow to the maximum signal value, usually beyond the limits of 0 or 100%. This is called integral or reset windup. Since the controller output is the sum of the three controller terms, the output will be dominated by the wound-up integral mode and will "max out" with the control valve either fully open or fully closed. When the error is subsequently removed or even changes sign, the integral windup continues to maintain the output saturated for a long time. This control action will persist until the negative error accumulation equals the previously accumulated positive error and thus permits the integral mode to "unwind."

Whenever a controller is not in control, the integral mode can wind up unless other provisions are made. Such situations include the controller being in the manual mode, a constraint being encountered (such as a valve stem at a limit), a primary controller of a cascade strategy being in automatic with its secondary in manual or local automatic, or the use of an override control strategy. Also, process conditions such as sensor failure, failure of control-loop communications, or a manual process bypass used for control or shutdown of a portion of the process can prevent a controller from being in control. Therefore it is desirable for every controller containing the integral mode to have antireset windup provisions. There are a variety of offerings.

Conceptually the simplest solution is to specify a limit on the integral contribution to the total output signal. The maximum and minimum reasonable values for the integral contribution correspond to the maximum and minimum controller outputs. For the standard controller:

$$I_{\max} = m_{\max}\ T_I/K_C \qquad \textbf{2.3(29)}$$

$$I_{\min} = m_{\min}\ T_I/K_C \qquad \textbf{2.3(30)}$$

Where integral limits are used, conventional practice uses 95% of the maximum:

$$I_{\text{U.L.}} = I_{\min} + .95(I_{\max} - I_{\min}) \qquad \textbf{2.3(31)}$$

$$I_{\text{L.L.}} = I_{\min} + .05(I_{\max} - I_{\min}) \qquad \textbf{2.3(32)}$$

However, the 95% value has been arbitrarily selected and can therefore be changed.

A closely associated strategy is to inhibit integral accumulation if the output hits a limit. With either of the mechanisms above, the integral windup will be limited to values corresponding to the fully open or fully closed valve positions. It is possible for the integral mode to wind up to fully open when the proper value should only be 30% open. In that case, the integral will keep the output excessively high, and until it unsaturates and has time to unwind, it will persist in introducing a process error in the opposite direction. To accelerate the return of the integral contribution to its proper value, some controllers will make the integral accumulation 16 times faster when coming off a limited value. These mechanisms generally work, but 95% limits, 16-times-faster recovery, and allowing some windup are not always the best solutions.

For digital systems, if a controller can detect when it is unable to control, then it can go into an "initialization" mode that forces the integral mode output to a value that will permit graceful recovery whenever the controller is again able to control. Situations when a controller can detect that it is unable to control include being in the manual mode, having the valve stem reach a limit (if valve stem position is detected and transmitted back to the controller) or, if the controller is a primary controller of a cascade configuration, having the secondary controller in some mode other than fully automatic cascade. If *b* represents the integral mode contribution to the output, then in the initialization mode, *b* can be reset using Equation 2.3(3), where m^* represents the operator-entered output value in the manual mode, the detected valve stem position, or the set point of the secondary controller.

RESET AND EXTERNAL FEEDBACK

Whereas Equations 2.3(1), 2.3(8), and 2.3(20) are good conceptual models for PID controller forms, they may not be representative of physical implementation. In essentially all analog controllers and in many digital control algorithms, the integral of the error is replaced with a first-order filter on the controller output; this is part of a positive feedback loop that computes the controller output. When the time constant of the filter is the same as the integral time, T_I, then the performance of the controller with reset feedback is the same as if it had pure integral mode. For the standard PI controller:

$$m(s) = K_C\ e(s) + \frac{1}{T_I s + 1} m(s) \qquad \textbf{2.3(33)}$$

which can be rearranged to

$$m(s) = K_C\left(1 + \frac{1}{T_I\, s}\right) e(s) \qquad \textbf{2.3(34)}$$

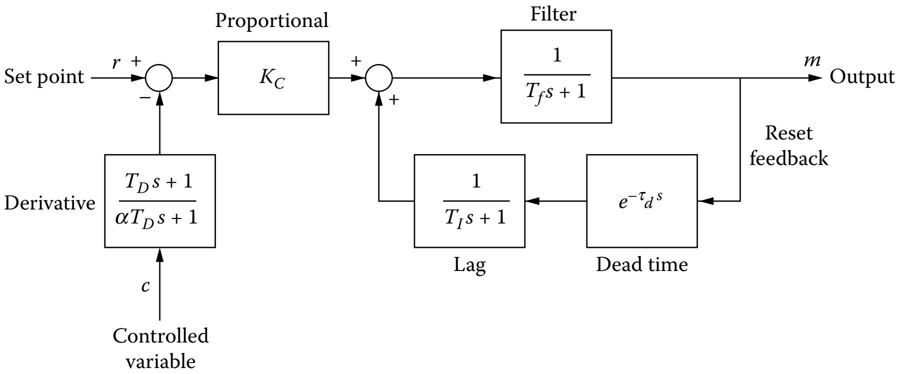

FIG. 2.3d
Block diagram, PIDτ_d controller.

Note that with reset feedback there is no integrator to wind up. The output of the filter, however, can wind up to the upper or lower limit of the controller output.

In addition to being a physically realizable method of construction, particularly for analog controllers, a key advantage of reset feedback is in override and cascade control structures, where the feedback is not directly from the controller output but from an external signal that would be identical to the controller output if the control loop were closed. With external reset feedback, the filter output “winds up” to the “right” value; when control is recovered there is no need for wind-down acceleration nor a need to guess at correct upper and lower integral limits.

PIDτ_d ALGORITHM

A relatively simple addition to a PID controller can significantly increase its performance, both to disturbances and to set-point changes. It involves delaying the integral mode of the controller in a manner similar to the delay or dead time that exists in the process being controlled. The structure of the PID-dead time (PIDτ_d) controller is not unlike that of model-based controllers—it may be considered a hybrid of PID and model-based technologies. A block diagram of the controller is shown in Fig. 2.3d. Without the dead time and filter blocks, this is a standard PID controller of the “interacting” or “series” type, with integration achieved by means of reset feedback as described earlier.

The PIDτ_d controller is capable of producing a phase lead, thereby substantially reducing the period of oscillation of a control loop. For lag-dominant processes, reducing the period of oscillation also reduces its dynamic gain, allowing a higher controller gain. This performance improvement comes with a price, however. Robustness is decreased, causing the loop to destabilize on rather small variations in process parameters unless the controller is precisely tuned. With deadtime-dominant processes, the dead time in the controller must match the process dead time. Any difference between process and controller dead times will produce a high-frequency oscillation with a period of twice their difference.

Robustness can be improved by the addition of the filter shown in Figure 2.3d. Its location lies in both feedback loops, making it doubly effective. However, performance is reduced by the ratio of filter time to dead time, so excessive filtering should also be avoided.

When the process contains lags as well as dead time, K_C can be increased further and derivative action added as well. In this role, it may be tuned much like a PID controller, with the dead time setting matched to the process dead time. But in the presence of noise, it may also be tuned as a PIτ_d controller, in which case optimum performance requires controller dead time to substantially exceed that of the process.

2.4 Control Modes—Digital PID Controllers

H. L. WADE (2005)

In the days of analog instrumentation, the term "controller" had a definite connotation. It referred to a stand-alone piece of equipment that received a signal, either pneumatic (3 to 15 psi [20 to 100 KpA]) or electric (4 to 20 mA), performed some control computation using a pneumatic mechanism or electronic circuitry, and then produced an output signal of the same type as the input signal. The controller output was usually connected to a valve or other final actuator but was sometimes connected to another controller (another separately identifiable piece of equipment) as the set point for a "slave" control loop. The controller was probably mounted on a panel board and was self-contained in terms of providing its own HMI (human-machine interface), which consisted of indicating gauges and recording means, plus switches and knobs by which an operator entered a set-point value, switched between manual and automatic, and remotely set a desired valve position when intervention into the control loop was necessary. In essence, a controller was "something you could put your finger on."

In digital technology, the concept of "a controller" is probably a misnomer. Although stand-alone devices (single loop controllers) exist that perform control computation using their own microprocessors rather than a pneumatic mechanism or electronic analog circuitry, the usual situation is to have a multi-loop digital processor, such as a distributed control system (DCS) or a programmable logic controller (PLC). Here both the section of code performing the control computation and the provisions for human-machine interface (HMI) are shared by many loops. The only thing that is unique to a particular loop is a data record in memory that contains an identification of the loop, designation of the particular subroutine to use for the control calculation, pointers to other memory locations as sources for its input values, and memory locations for holding tuning parameters, manual-automatic status parameters, configuration options, and so on. In essence, the "controller" in digital technology exists as a concept only, not as a physical entity. Nevertheless, it is beneficial as well as the customary practice to think of a digital controller as if it were a specific device, performing a specified function, interacting with other controllers, providing HMI services upon request, and being represented on a piping and instrumentation drawing (P&ID) by a function block symbol that has been assigned a unique identifying tag. This is the conceptual model we will use when speaking of a digital controller.

The heart of a digital controller is the control algorithm; this is the section of code that performs the computation that mimics one of the PID forms described in the previous section. Because of the versatility of a digital processor, however, many functions that were impossible with analog controllers, such as automated bumpless transfer, wind-up prevention, and interblock status communications, can now be performed as a part of a digital controller.

PID POSITION ALGORITHMS

The noninteracting PID form was given by Equation 2.3(1) of Section 2.3 as:

$$m = K_C \left(e + \frac{1}{T_I} \int e\,dt + T_D \frac{de}{dt} \right) \qquad \textbf{2.4(1)}$$

We will develop an analogous digital algorithm that operates repetitively in a sampling environment. The sampling interval is ΔT (such as 1/60 minute); everything is related to the nth sampling instant.

Corresponding to the proportional mode term, e, is the error at the nth sampling instant, $e_n = r_n - c_n$. The term $\int e\,dt$ will be approximated by summing the errors at each sampling instant. If S_{n-1} represents the previously accumulated sum, then

$$S_n = S_{n-1} + e_n \qquad \textbf{2.4(2)}$$

and the integral mode term is:

$$\frac{\Delta T}{T_I} S_n$$

The derivative will be approximated by two-point differencing, so that the derivative mode term is:

$$\frac{T_D}{\Delta T}(e_n - e_{n-1})$$

Putting these all together, the digital algorithm corresponding to Equation 2.4(1) is:

$$m_n = K_C \left[e_n + \frac{\Delta T}{T_I} S_n + \frac{T_D}{\Delta T}(e_n - e_{n-1}) \right] \qquad \textbf{2.4(3)}$$

The terms K_C, T_I, and T_D represent the conventional tuning parameters: controller gain, reset time in minutes/repeat, and derivative time in minutes; ΔT represents the sampling interval.

A similar approach can be used for the "parallel" (independent gains) form of PID. (See Equation 2.3[20] in the previous section.) The error is summed using Equation 2.4(2), then the control output is computed from

$$m_n = K_C e_n + K_I S_n \Delta T + K_D \frac{e_n - e_{n-1}}{\Delta T} \qquad \textbf{2.4(4)}$$

where K_C, K_I, and K_D are the proportional gain, integral gain, and derivative gain, respectively.

Equations 2.4(3) and 2.4(4) are called "position" algorithms because they compute the required position of the final actuator, m_n, at the nth sampling instant.

The modifications mentioned in Section 2.3 may also be applied here. For instance, if both the proportional and derivative modes are on measurement, rather than error, Equation 2.4(3) becomes

$$m_n = K_C \left[-c_n + \frac{\Delta T}{T_I} S_n - \frac{T_D}{\Delta T}(c_n - c_{n-1}) \right] \qquad \textbf{2.4(5)}$$

To achieve bumpless transfer from manual to automatic, or from any detectable condition where the PID is unable to control, the stored value of the error sum, S_{n-1}, is initialized by the equation:

$$S_{n-1} = \frac{T_I}{\Delta T}\left[\frac{m^*}{K_C} - \left(\left(1 + \frac{\Delta T}{T_I}\right) e_n + \frac{T_D}{\Delta T}(e_n - e_{n-1}) \right) \right] \qquad \textbf{2.4(6)}$$

where m^* represents the operator-entered output value in manual, the set point of a cascaded secondary PID, or the actual valve stem position, if the actual valve stem position is detected. After application of Equations 2.4(2) and 2.4(3), this initialization of S_{n-1} causes the controller output, m_n, to equal m^* at the time of switching from manual to automatic; thus, no bump to the process is incurred. If either the proportional or derivative modes is on measurement, rather than error, then the appropriate *en* terms in 2.4(6) must be replaced with *cn* and appropriate sign changes made. Equation 2.4(6) can be invoked at the first calculation cycle following a manual- to-automatic switch; alternatively, it may be processed on each calculation cycle as long as the controller is in manual. In this case no special procedure for the "first calculation cycle" is required.

Although the concept of bumpless transfer is widely recognized, the concept of "bumpless tuning" is virtually unknown. Yet a little reflection will show the need. If the proportional mode is on error, and if controller gain is changed at a time when there is a deviation from set point, there will be a bump in the controller output. A change in the derivative setting at a time when the measurement is changing will also cause a bump in the controller output. To prevent this, whenever the controller detects that a controller tuning parameter, either K_C or T_D, has been changed (no adjustment is necessary if T_I is changed), then, before the next algorithm processing cycle, the stored value of the error sum must be "fixed up" so that the new tuning parameters will produce the same controller output as would have been produced by the old tuning parameters. Had there been no gain change, the controller output would have been calculated as

$$m_n = K_C^{\text{old}} \left[e_n + \frac{\Delta T}{T_I}\left(S_{n-1}^{\text{old}} + e_n\right) + \frac{T_D}{\Delta T}(e_n - e_{n-1}) \right] \qquad \textbf{2.4(7)}$$

If a new value has been entered for K_C and the value for S_{n-1} has been adjusted, the controller output will be calculated as:

$$m_n = K_C^{\text{new}} \left[e_n + \frac{\Delta T}{T_I}\left(S_{n-1}^{\text{new}} + e_n\right) + \frac{T_D}{\Delta T}(e_n - e_{n-1}) \right] \qquad \textbf{2.4(8)}$$

Since we want the controller output to remain the same in spite of the tuning parameter change, we equate the right-hand sides of Equations 2.4(7) and 2.4(8) and solve for S_{n-1}^{new} :

$$S_{n-1}^{\text{new}} = \frac{K_C^{\text{old}}}{K_C^{\text{new}}} S_{n-1}^{\text{old}} + \frac{T_I}{\Delta T}\left(\frac{K_C^{\text{old}}}{K_C^{\text{new}}} - 1 \right) \times \left[\left(1 + \frac{\Delta T}{T_I}\right) e_n + \frac{T_D}{\Delta T}(e_n - e_{n-1}) \right] \qquad \textbf{2.4(9)}$$

If a new value has been entered for T_D, Equation 2.4(10) can be used for updating S_{n-1}.

$$S_{n-1}^{\text{new}} = S_{n-1}^{\text{old}} + \frac{\left(T_D^{\text{old}} - T_D^{\text{new}}\right) T_I}{(\Delta T)^2}(e_n - e_{n-1}) \qquad \textbf{2.4(10)}$$

If the derivative or proportional mode is on measurement rather than error, then the values of e must be replaced by values of c and appropriate sign changes made.

Once a new value of S_{n-1} has been determined, use Equation 2.4(2) to update S_n and Equation 2.4(3) or 2.4(5) to calculate the next value for controller output.

With the interacting algorithm (see Equation 2.3[9] in Section 2.3), the integral mode can be created by using a first-order lag filter in a positive feedback loop. The time constant of the filter is the integral time, T_I. The input to the filter is called the "reset feedback." If the algorithm is being used as an ordinary PID controller in the automatic mode, the reset feedback is connected directly to the controller output. An important application is in override control strategies, where the reset feedback is not connected directly to the controller output; instead, it is connected to another source, such as the output of a high or low signal selector between this and other controller outputs. This configuration prevents windup in the nonselected controller.

The equations for a PID controller with reset feedback involve a two-step process. The filter output is calculated first from previous values of the filter output and the controller output itself.

$$b_n = \frac{\Delta T}{T_I} b_{n-1} + \left(1 - \frac{\Delta T}{T_I}\right) m_{n-1} \qquad \textbf{2.4(11)}$$

Then the new controller output is computed:

$$m_n = K_C\left(e_n + \frac{TD}{\Delta T}(e_n - e_{n-1})\right) + b_n \qquad \textbf{2.4(12)}$$

If the controller is used in an override strategy, m_{n-1} in Equation 2.4(11) should be replaced by the output of the high or low selector.

When the PID algorithm is formulated with reset feedback, the term b_{n-1} can be adjusted to achieve bumpless transfer or bumpless tuning, similar to the use of S_{n-1} in Equations 2.4(6), 2.4(9), and 2.6(10). For instance, at the time of manual-to-automatic switching, b_{n-1} is initialized by the equation:

$$b_{n-1} = m^* - K_C\left(e_n + \frac{T_D}{\Delta T}(e_n - e_{n-1})\right) \qquad \textbf{2.4(13)}$$

where m^* is the operator-entered value for the controller output.

PID VELOCITY ALGORITHMS

A capability unavailable in analog control systems is that of velocity algorithms. Previously discussed algorithms have been positional. They calculated m_n, the required position of the valve or other final actuator. Velocity algorithms, on the other hand, calculate Δm_n, the increment by which the position of the final actuator should change. ("Incremental" algorithms would be better terminology; however, the term "velocity" is in traditional usage.)

Velocity algorithms were developed during the time of supervisory control when a computer output set the set point of an analog controller. A stepping motor was often used to drive the analog controller set point. The controller output, Δm_n, was converted to a pulse train that incremented the stepping motor by the required amount. Even though that technology is rarely used today, velocity algorithms are retained and offer certain advantages as well as disadvantages.

To develop a velocity algorithm that is the counterpart of Equation 2.4(3), the equation will first be rewritten for the previous calculation cycle. That is, the subscript "n" will be replaced by "$n - 1$" wherever it appears:

$$m_{n-1} = K_C\left[e_{n-1} + \frac{\Delta T}{T_I}S_{n-1} + \frac{T_D}{\Delta T}(e_{n-1} - e_{n-2})\right] \qquad \textbf{2.4(14)}$$

The required incremental change is given by $\Delta m_n = m_n - m_{n-1}$. Hence, to develop an equation for Δm_n, the right-hand side of Equation 2.4(14) will be subtracted from the right-hand side of Equation 2.4(3). In doing so, the term $S_n - S_{n-1}$ is encountered. By Equation 2.4(2), however, this is simply equal to e_n. Hence the final results are

$$\Delta m_n = K_C\left[e_n - e_{n-1} + \frac{\Delta T}{T_I}e_n + \frac{T_D}{\Delta T}(e_n - 2e_{n-1} + e_{n-2})\right] \qquad \textbf{2.4(15)}$$

In digital control systems that use velocity algorithms today, the previous required position of the final actuator, m_{n-1}, is stored in a separate memory location. After the velocity algorithm computes the required incremental change, this increment is added to the previous position, and the new required position overwrites the previous value in the memory location. The new value is then converted to an analog value, such as 4–20 mA, for transmission to the final actuator. This operation is described by Equation 2.4(16),

$$m_n \leftarrow m_{n-1} + \Delta m_n \qquad \textbf{2.4(16)}$$

where " ← " means "replaces."

An examination of Equation 2.4(15) reveals that it contains no integrator that is subject to windup. Therefore, a purported advantage of the velocity algorithm is that "it doesn't wind up." Whereas that is true of the algorithm itself, it does not mean that there cannot be windup in the overall control system. Suppose there is a sustained error, the situation that causes windup in a position algorithm. Each time the velocity algorithm is processed, it calculates an output change, Δm_n. These incremental changes accumulate in the output memory location due to Equation 2.4(16), so the windup occurs in the memory location, not in the algorithm itself. If the incremental change were applied to an external stepping motor, then the stepping motor would wind up. Therefore a better description of the velocity algorithm is "it moves the windup to someplace else."

Some true advantages can be attributed to the velocity algorithm. Bumpless transfer between the manual and automatic modes is simplified. When the algorithm is switched from automatic to manual, it simply stops calculating an incremental change. The output memory location is then freed for the operator to manually enter a required position of the final actuator. When the controller is returned to automatic, the algorithm resumes by calculating an incremental change, which is added to the last position set by the operator; this becomes the new required valve position:

$$m_n \leftarrow m^* + \Delta m_n \qquad \textbf{2.4(17)}$$

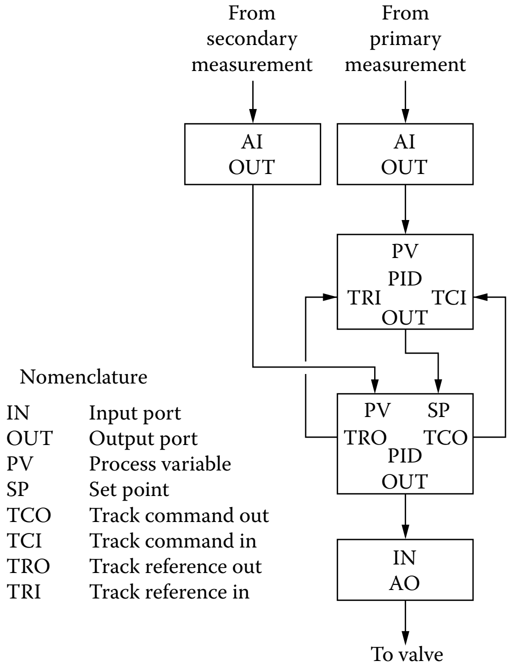
The problem of "bumpless tuning" is nonexistent. The velocity algorithm is inherently "bump free" when tuning parameters are changed.

Some true disadvantages of the velocity algorithm also exist. Reset feedback cannot be implemented with the velocity algorithm. Thus override control schemes that use reset feedback to prevent windup of the nonselected controller are not possible. Control systems that do use the velocity algorithm in override control strategies initialize the output memory location of the nonselected controller by the equation:

$$m = m^* + K_C\left(e_n + \frac{T_D}{\Delta T}(e_n - e_{n-1})\right) \qquad \mathbf{2.4(18)}$$

where, in this equation, m^* represents the output of the selected controller.

When operating in the automatic mode, and with a sampling rate that is relatively fast compared to the process dynamics (say, at least ten samples per dominant time constant), then there appears to be no performance advantage for either the velocity or position algorithms. With the DCS and PLCs in use today, sampling rate is rarely a problem. From the software developer's point of view, one form may have an advantage over the other due to the ease of developing the features to be included in a particular manufacturer's system. From an application developer's point of view, even though there may be no performance advantage to either, it is important to know which form is being used and the characteristics of that particular form.



Nomenclature

IN	Input port
OUT	Output port
PV	Process variable
SP	Set point
TCO	Track command out
TCI	Track command in
TRO	Track reference out
TRI	Track reference in

FIG. 2.4a
Function block structure for cascade control.

CONTROL STRUCTURES

Control strategies in digital systems are implemented by an organization of function blocks available from the manufacturer's function block library. Signals from one block to another are designated either graphically or in questionnaire format; other configuration choices are given in response to a questionnaire.

Using a cascade control strategy as an example, the signals that must be passed are:

- Primary process measurement from an analog input (AI) block to the primary PID
- Secondary process measurement from an AI block to the secondary PID
- Set point from the primary controller output to the secondary PID
- Controller output from the secondary PID to an analog output (AO) block

It is desirable to also pass status information between the blocks. For example, if the secondary block is manual or local automatic, the primary controller should be aware of this. Furthermore, the set point of the secondary should be passed back to the primary controller for initialization purposes; thus, when the secondary is returned to cascaded automatic, no bump will be created in the primary controller output.

This last requirement entails a form of interblock communication that was not present in analog control systems. The interblock communication can be implemented several ways, depending upon the manufacturer. One way is to configure specific forward and backward connections as shown in Figure 2.4a. The forward connections are:

Analog input (AI) "OUT" to PID "PV"—Floating point signal values
PID (primary) "OUT" to PID (secondary) "PV"—Floating point signal value
PID (secondary) "OUT" to analog output (AO) "IN"—Floating point signal value

TABLE 2.4b
PID Configuration Items (Minimum Set)

Block Identification	*Block Tag*
Block type	PID
Cascade?	Yes or No
If yes, set point source	Primary block tag
Set point track PV in manual?	Yes or No
Process variable source	AI block tag
Direct or reverse acting	DA or RA
Derivative mode on meas or error	M or E
Proportional mode on meas or error	M or E
Controller gain	K_C
Integral time, minutes/repeat	T_I
Derivative time, minutes	T_D

The backward connections are:

PID (secondary) "TCO" to PID (primary) "TCI" — Boolean signal
PID (secondary) "TRO" to PID (primary) "TRI" — Floating point signal value

Whenever the secondary controller is in manual or local set point, the status is communicated backward to the primary controller via the TCO–TCI communication link. At the same time, the set point of the secondary controller is communicated backward to the primary controller via the TRO–TRI communication link. The status notification puts the primary PID into an initialization mode. The primary is initialized using Equation 2.4(6). This forces the primary controller output to be the same as the secondary controller set point. (The secondary controller should be configured so that its set point tracks its measurement whenever it is in manual.)

A minimum set of configuration questions is given in Table 2.4b. Most systems would have many more questions covering loop description, engineering ranges, alarm limits, etc.

2.5 Control Modes—Closed-Loop Response

C. F. MOORE (1985, 1995) **J. HETTHÉSSY, R. BARS** (2005)

INTRODUCTION

In general, the aim of a control system is to maintain some desired conditions (signals) in a process. In case of a processing plant the measured conditions (signals) that are to be controlled are the *output signals* of the plant and the desired performance is to be achieved by manipulating the input variables of the plant, also called *control signals* or *manipulated variables.* The manipulation of some input variables will disturb the process, while others will not.

For example the maintaining of a comfortable temperature in a room can be considered a process control task, where the disturbances can come from ambient conditions, opening of windows, or from the number of people in the room, and the manipulation to achieve control is by varying the heat input. Other control examples can include driving a car within a lane on the road, maintaining the level of water in a tank, or controlling the speed or the position of physical equipment under different conditions.

The aim of this section is to outline the fundamental structure and properties of closed-loop control systems. The discussion will be limited to linear, single-input–single-output systems.

Control systems can be analyzed in the time domain or in the frequency domain by the use of transfer functions. Thus the section will start with a description of the alternative means of system analysis. Then the fundamental benefits of using feedback systems will be presented and the open-loop and closed-loop techniques will be compared. The roles of various transfer functions characterizing closed-loop systems will be discussed, and then some design guidelines will be given. Finally, the approach to control system analysis will be illustrated through an example.

LINEAR SYSTEMS

The behavior of a linear system can be described in the time domain, in the complex frequency (Laplace) operator domain, or in the frequency domain. In the time domain differential equations or state-space equations, which are derived on the basis of the physical operation, define the relationship between the output and the input signals of the controlled process.

In the Laplace operator domain, the differential equations are transformed to algebraic equations. The transfer function is defined as the ratio of the Laplace transforms of the output and input signals, respectively, assuming zero initial conditions.

In the frequency domain, the frequency function characterizes the quasi-stationary response of the system to a sinusoidal input signal, supposing that the transients have already decayed. An important property of linear systems is that in case of a sinusoidal input the output in the steady-state will also be sinusoidal and of the same frequency, but the amplitude and the phase angle of the output signal will differ from those of the input signal.

Amplitude and phase angle depend on frequency and provide two components with real values for the complex valued frequency function: *magnitude function* and *phase function.* The frequency function is formally obtained from the transfer function by substituting $s = j\omega$.

EXAMPLE

Consider a simple electrical circuit consisting of a resistance R and an inductance L as shown in Figure 2.5a. The input signal is the voltage u, the output signal is the current i.

The differential equation:

$$u = iR + L\frac{di}{dt} \qquad 2.5(1)$$

The transfer function:

$$G(s) = \frac{i(s)}{u(s)} = \frac{1}{R + sL} = \frac{1/R}{1 + sL/R} = \frac{A}{1 + sT} \qquad 2.5(2)$$

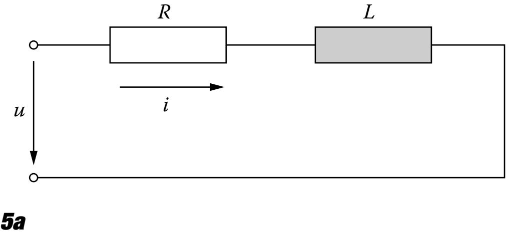

FIG. 2.5a
A simple electrical circuit.

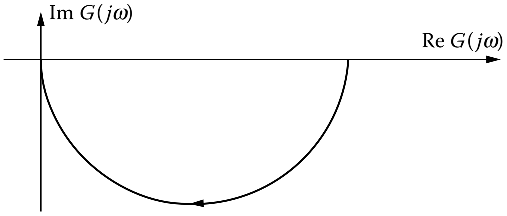

FIG. 2.5b
Nyquist diagram.

where s is the differential operator, A is the gain, and T is the time constant.

The unit step response is obtained by

$$i(t) = A(1 - e^{-t/T}), \qquad t \geq 0 \tag{2.5(3)}$$

while the frequency function becomes

$$G(j\omega) = \frac{A}{1 + j\omega T} \tag{2.5(4)}$$

The frequency function $G(j\omega)$ is a complex valued function, and it can be plotted in the complex plane, showing its values as ω changes from zero to infinity (Figure 2.5b). This polar plot is called the Nyquist diagram. The arrow indicates the direction of movement along the plot as the frequency increases.

Another possibility is to draw the magnitude and the phase angle of the frequency function versus the frequency separately. This technique is called *Bode diagram* (Figure 2.5c). Note that the Bode diagram uses a logarithmic scale for the frequency and *dB* values for the magnitude.

The performance of control systems can be evaluated in several ways. Analysis in the time domain requires solution of differential equations. Analysis in the complex frequency operator domain allows for much simpler mathematical calculations. However, it requires inverse Laplace transformation to obtain the results in the time domain. These same results in the time domain can also be obtained by simulation.

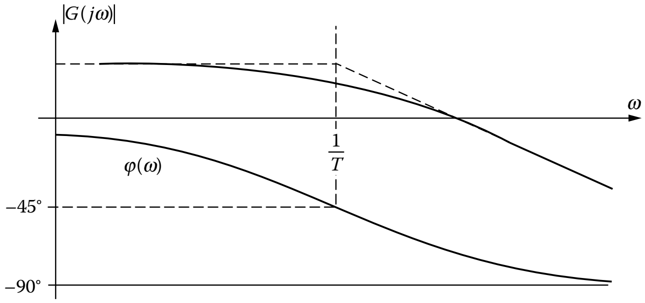

FIG. 2.5c
Bode diagram.

Analysis in the frequency domain — due to the relationship between the time and the frequency domain — gives an opportunity to draw conclusions for the essential system operation in the time domain.

Time and Frequency Domain Analysis

Control system signals can be analyzed by considering their frequency content. This means that they can be decomposed into an infinite number of sinusoidal signals of a given amplitude.

Periodic signals contain discrete frequencies (Fourier series), while aperiodic signals have a continuous frequency spectrum. The superposition theorem allows us to calculate the output signal of a linear system as a sum of the responses for the input signal components of individual frequencies.

This frequency response concept is illustrated by an example of a second-order system whose step response shows damped oscillations. The input u is a periodic rectangular signal. Figure 2.5d shows the input and its approximation versus time using only four of its sinusoidal components. The calculated accurate response y and the approximated response obtained as a sum of the individual responses for the four sinusoidal components are also given.

With more components, both the input and the output signals will be better approximated. Figure 2.5e shows the approximation with ten Fourier components.

Theoretically, if one knows the frequency response for all the frequencies in the whole frequency domain, the time

response of the system for a given input can also be obtained. The problem is that an infinite number of output components must be taken into account.

Higher frequencies usually are strongly attenuated, so considering a finite, truncated frequency range still gives acceptable results. Approximating relationships between the time and the frequency domain provides a good orientation for evaluating the system behavior.

For instance, the steady-state value for the step response of a system can be obtained from the magnitude response taken at zero frequency. Assuming a step function input, the initial value of the output signal can be directly calculated by considering the frequency response at infinitely high frequencies. Similarly, the middle-range frequency behavior will characterize the transient response in the time domain.

OPEN- AND CLOSED-LOOP CONTROL

In designing a control system, the components of the control system first have to be selected considering the actual operating conditions, such as the range of the measured process variable and the available sensors and actuators.

In order to obtain a model of the process, the signal transfer properties have to be analyzed based on physical principles governing the operation of the individual elements, which are described by mathematical relationships. Another way to obtain the model is the identification of the static and dynamic behavior of the process based on the information represented by the available process input–output records. The result is a model, typically a transfer function for linear systems, that can serve as an analytical description of the control system.

In *open-loop* control systems, the output signal has no effect upon the controlled variable(s). The control is executed, for example, on a time basis. A practical example is the operation of a washing machine, where the duration of soaking, washing, and rinsing are set in advance and on the basis of experience with how these settings affect the output signal, which is the cleanness of the clothes. In such an open-loop system, the output signal is not automatically measured.

The main tool utilized by *closed-loop* controllers is the negative feedback. Here, a detector measures the output signal of the controlled process and its value is compared to a reference value (set point). The difference between the reference signal and the output signal is the error signal, which is driving a *controller.* The output of the controller generates the manipulated variable, which throttles the final control element that influences the input of the process. This is how the control loop is closed.

The difference between the reference signal (set point) and the measured output signal — the error — is the basis for the control action to eliminate that error. The control action — due to the dynamics of the individual parts — takes time. An appropriately tuned controller takes the process dynamics into account and ensures stable closed-loop control.

In practice, both open-loop and closed-loop controls are utilized. For instance, the complex start-up and shut-down sequences are often governed by open-loop control, provided by intelligent PLCs (Programmable Logic Controllers) and closed-loop control loops in combination.

Open-Loop vs. Closed-Loop Control

Open-loop control is simple and cheap because it does not require any sensors. The characteristics of the operating elements, the relationships between the input and output signals, and the expected disturbances have to be known in advance, as this knowledge is needed to set up the rules that govern the system operation.

Open loop control cannot tolerate changes in the loop parameters or in the disturbances, thus, errors in the assumed data will lead to improper operation. However, designing an open-loop control system is simple and does not require stability analysis.

Closed-loop control is more expensive, but in addition to being able to keep the process variable on set point, it is also capable of correcting for process disturbances and compensating for the errors in the model, which is implemented by the controller. Figure 2.5f shows the block diagram of a closed-loop control system.

The block diagram is composed of units, which are characterized by transfer functions. The *external inputs* of the closed-loop system are the *reference signal* (*set point*), the

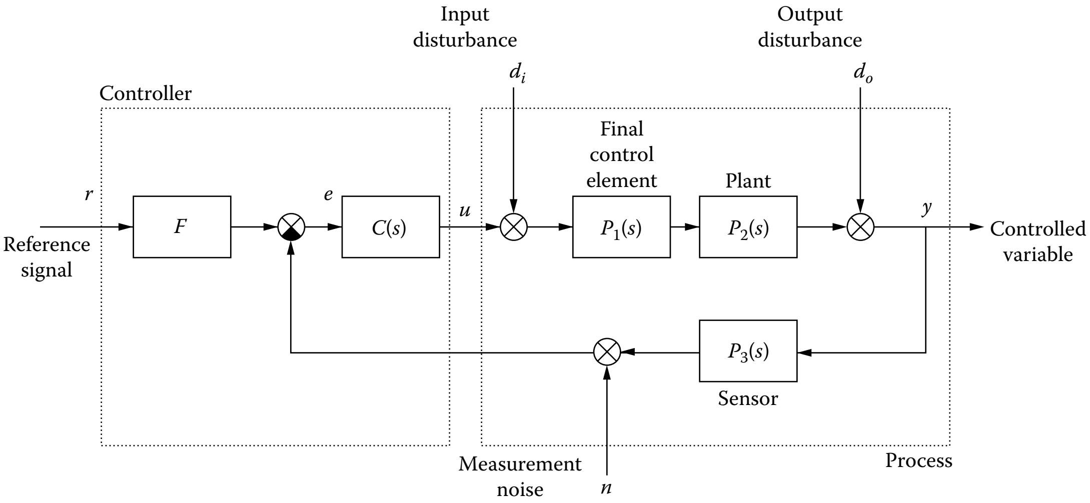

FIG. 2.5f
The structure of a closed-loop control system.

disturbances (sometimes called process load variations) and the *measurement noise.* The output is the *controlled variable,* measured by a sensor whose output (y) may be corrupted by measurement noise.

A simplified block diagram is shown in Figure 2.5g. The block diagram is an abstract model of a real closed-loop control system. In this model only the main system components are considered while others are neglected. At this point signal transfer properties are emphasized, and technology-dependent, practical realization aspects are ignored.

Stability and Dead Time

Closed-loop control loops can become unstable if not properly tuned. To ensure closed-loop stability is the most important goal. In general, feedback may lead to unstable closed-loop behavior due to delays, dead time, and high gains in the controlled process. The system is on the boundary of stability and instability if steady oscillations occur. Stability must be ensured for a feedback control system by all means.

Stability can be defined in various ways. Bounded input–bounded output (BIBO) stability means that all bounded inputs result in bounded outputs. Asymptotic stability means that when changing the reference signal or when disturbances occur, all the transient responses in the system will asymptotically approach zero.

To illustrate the problem of stability, consider the control system shown in Figure 2.5h. The controlled process is a dead time process, where the dead time can be caused by transportation lag.

It is assumed that the controller is proportional; its gain is K. Figure 2.5i shows the output and error signals that result from a step change in the set point (reference signal), if $K =$ 0.5, 1, and 2, respectively.

If the proportional gain is $K = 0.5$, the system is stable, but the steady-state value of the controlled variable (y, the output

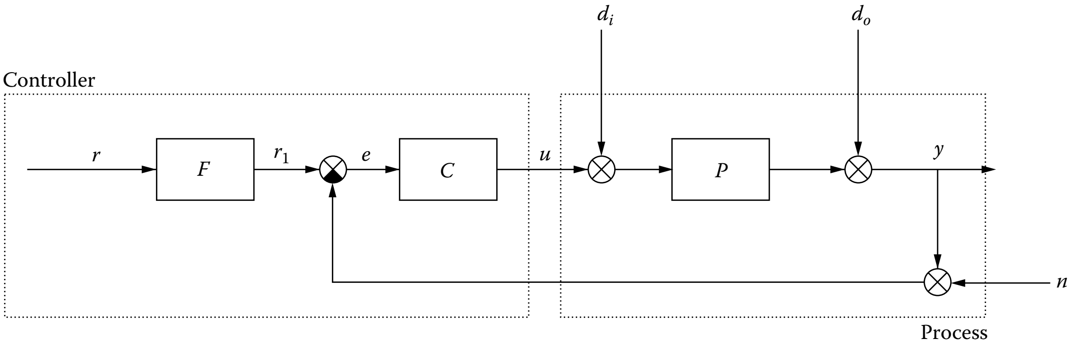

FIG. 2.5g
Simplified block diagram of a closed-loop control system. $P = P_1P_2P_3$.

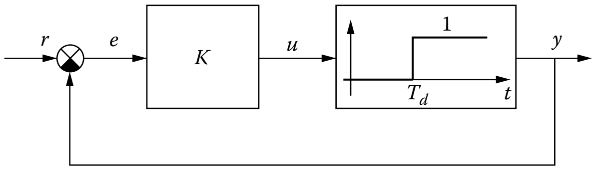

FIG. 2.5h
Proportional control of a dead-time process.

signal) is approaching 1/3 instead of 1. For $K = 1$ the system is on the boundary of stability, and with $K = 2$ the system becomes unstable. The controller has to be modified, such as replaced by a sample-and-hold controller (Section 2.2) in order to ensure both stability and acceptable steady-state response.

Advantages of Closed-Loop Control

One advantage of closed-loop control is that in the steady state, if the loop is properly tuned, the controlled variable is kept on set point within the accuracy of the system. This property is usually referred to as the *servo property.*

Another advantage of closed-loop control is the ability of a properly tuned controller to correct for process disturbances. As an example consider a controlled process that has two time lags, and review its response to a process disturbance under PI and under PID control. The process transfer function is:

$$P(s) = \frac{1}{(1+5s)(1+10s)} \qquad \textbf{2.5(5)}$$

The PI and PID controller transfer functions are:

$$C_1(s) = \frac{1+10s}{10s} \quad \text{and} \quad C_2(s) = 5\frac{1+10s}{10s}\frac{1+5s}{1+s} \qquad \textbf{2.5(6)}$$

Figure 2.5j shows the controlled variable (y, the output) and the manipulated variables (u, the input) control signals for both controllers as a function of time. At time $t = 80$ sec the same disturbance is introduced (a unit step). Both control loops return to set point, but with the PID controller the response is superior because it is faster.

Yet another advantage of feedback-based closed-loop controls is their ability to maintain control even when the process dynamics change. This is illustrated in Figure 2.5k, which shows the response of the previously discussed PID controller to changes in process dynamics. The line noted by "s" describes the loop's response when the gain and the time constants of the process drop by 20%, and the line identified by "h" shows the performance when the process gain and the time constants increase by 20%. It can be noted that the control system compensates for the by upsets in the process dynamics.

Closed-loop control can also be used to stabilize unstable open-loop control systems. To illustrate the stabilizing effect of feedback, consider the unstable process described by the transfer function $1/(s - 2)$. As the transfer function contains a pole on the right side of the complex plane, its step response goes to infinity.

If a plain proportional feedback controller with a gain of K is applied (Figure 2.5l), a proportional setting of $K > 2$

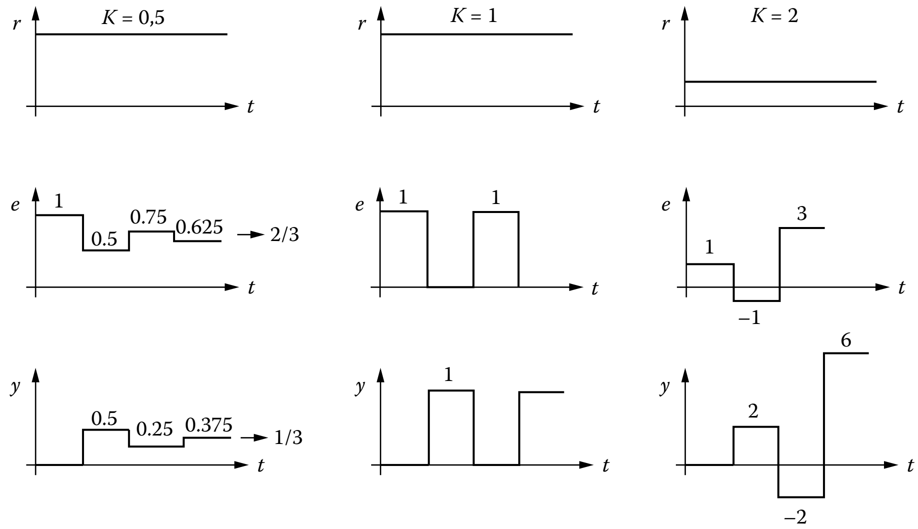

FIG. 2.5i
The response to a step change in set point (r) is shown when controlling a pure dead-time process with a plain proportional controller. The amounts of error (e) and the values of the controlled variable (y) are both shown in each dead-time period. It can be seen that the process becomes unstable when the gain setting exceeds K = 1.

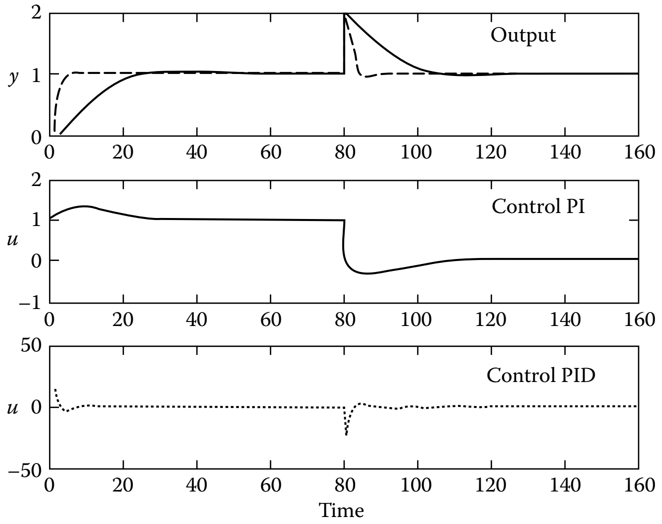

FIG. 2.5j
The controlled variable (y) recovers faster from the upset caused by a process disturbance if under PID control than with PI control.

will stabilize the loop. Figure 2.5m illustrates that with proportional gains of both $K = 5$ and $K = 10$, the response of the loop to a step change will be stable. Naturally, it also shows that proportional control cannot return the process to set point; a substantial offset remains.

CLOSED-LOOP TRANSFER FUNCTIONS

The relationships between external signals and response signals produced by the closed-loop control system with linear elements can be described by a set of transfer functions, called *overall transfer functions.*

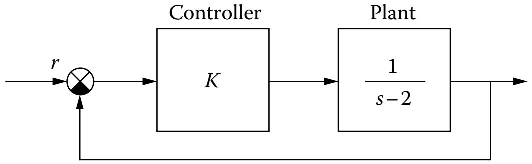

FIG. 2.5l
A high gain proportional controller can stabilize an otherwise unstable process loop but only if the gain is high (PB narrow).

When evaluating or designing a closed-loop control system, the response of the system to changes in the external signals is of interest. In the following paragraphs we will determine the overall transfer functions between the output signal (controlled variable — y) and the reference signal (set point — r), disturbances d_i and d_o and measurement noise n in Figure 2.2g. We will also derive the overall transfer functions related to the error signal e and the manipulated variable (control signal — u).

Block Diagram Algebra

Before calculating the transfer functions, let us consider some algorithms to handle the overall transfer functions of serial and parallel blocks (Figure 2.5n). For series connection the overall transfer function is obtained by multiplying the individual transfer functions, and for parallel connection the transfer functions are added.

Figure 2.5o shows the block diagram of a feedback control loop.

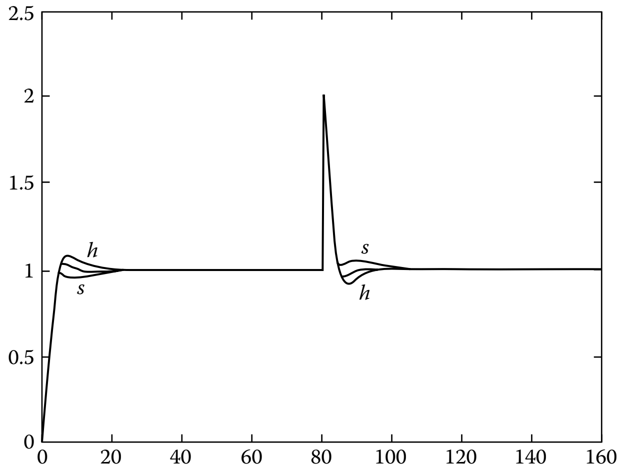

FIG. 2.5k
A closed-loop controller can correct for disturbances caused by changes in process dynamics. The process returns to set point both when the process gain and time constants drop (curve s) or when they rise (curve h).

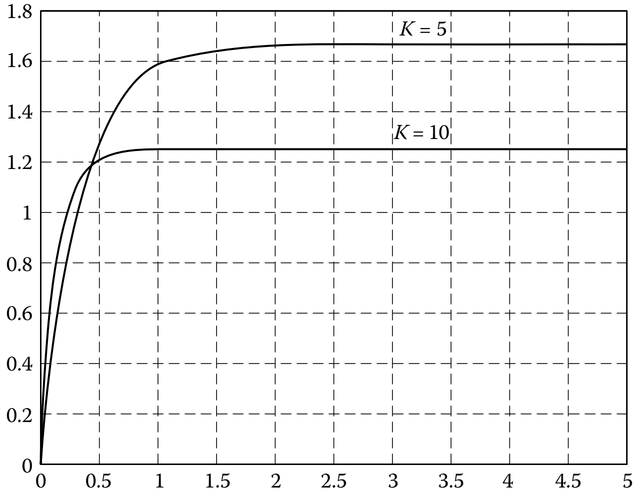

FIG. 2.5m
While the control loop in Figure 2.5l is stabilized, the plain proportional controller cannot return the controlled variable to set point.

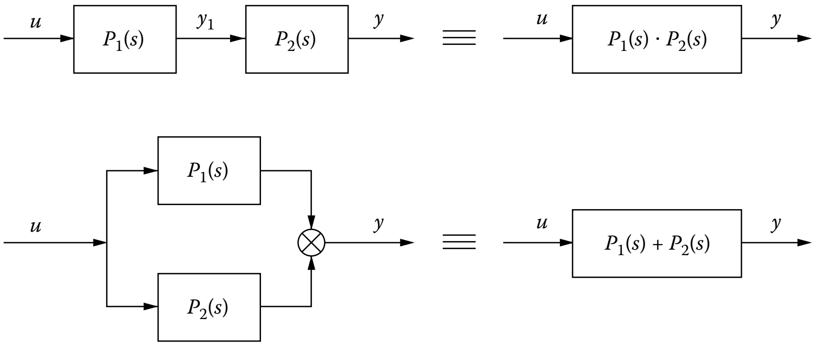

FIG. 2.5n
Overall transfer functions of serially and parallel connected blocks.

The transfer function that is obtained by walking around the loop is called the *loop transfer function L*(*s*)*:*

$$L(s) = C(s)P(s) \tag{2.5(7)}$$

The output signal, if for sake of simplicity the Laplace operator (*s*) is dropped, is calculated as

$$y = CPe = CP(Fr - y) \tag{2.5(8)}$$

The overall transfer function is

$$\frac{y}{r} = F\frac{CP}{1+CP} \tag{2.5(9)}$$

The numerator contains the transfer function along the forward path from a selected external input signal to the output signal of interest, while the denominator is simply (1 + *L*(*s*)). It is seen that the term 1 + *L*(*s*) is a rather important quantity. It is also called the *return difference*, a fictitious transfer function describing the difference between the signal entering the summation point (*F*(*s*)*r*(*s*)) and the signal returned by the control loop (−*L*(*s*)*e*(*s*)) , where *r*(*s*) is the Laplace transform of the reference signal and *e*(*s*) is the Laplace transform of the error signal.

Overall Transfer Functions

The overall transfer functions of the closed-loop control system described in Figure 2.5g are

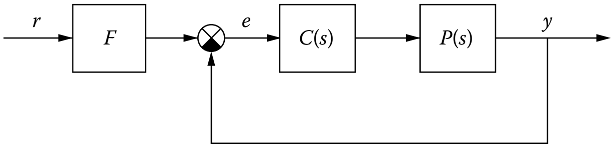

FIG. 2.5o
Overall transfer function of a feedback loop.

$$y(s) = \frac{F(s)C(s)P(s)}{1+C(s)P(s)}r(s) + \frac{P(s)}{1+C(s)P(s)}d_i(s) + \frac{1}{1+C(s)P(s)}d_o(s) - \frac{C(s)P(s)}{1+C(s)P(s)}n(s) \tag{2.5(10)}$$

$$e(s) = \frac{F(s)}{1+C(s)P(s)}r(s) - \frac{P(s)}{1+C(s)P(s)}d_i(s) - \frac{1}{1+C(s)P(s)}d_o(s) - \frac{1}{1+C(s)P(s)}n(s) \tag{2.5(11)}$$

$$u(s) = \frac{F(s)C(s)}{1+C(s)P(s)}r(s) - \frac{C(s)P(s)}{1+C(s)P(s)}d_i(s) - \frac{C(s)}{1+C(s)P(s)}d_o(s) - \frac{C(s)}{1+C(s)P(s)}n(s) \tag{2.5(12)}$$

Each component in the control loop can significantly contribute to the overall performance of the system. The denominators in all the transfer functions above are identical (return difference), and this denominator determines both the transient performance and the stability of the control loop.

The poles (the roots of the denominator polynomial) have to be at the left-hand side of the complex plain to ensure stability. Their location is essential as far as the properties of the transient response are concerned, too. Reference signal tracking in addition is influenced by the choice of the reference signal filter *F*. The numerators of the corresponding overall transfer functions also influence the set-point tracking, disturbance, and noise rejection properties.

One of the most important transfer functions among the above equations is the overall transfer function characterizing the servo property (set-point tracking), i.e., the way that the output of the closed-loop system follows the reference signal:

$$W(s) = \frac{y(s)}{r(s)} = \frac{F(s)C(s)P(s)}{1+C(s)P(s)} \tag{2.5(13)}$$

Bode introduced the term *sensitivity,* which describes the relative sensitivity of the overall transfer function (W) to the relative process model error:

$$S(s) = \frac{dW/W}{dP/P} = \frac{1}{1+C(s)P(s)} = \frac{1}{1+L(s)} \qquad \textbf{2.5(14)}$$

The ability of the closed-loop system to reject disturbances is also related to sensitivity. The sensitivity to the output disturbance is defined as

$$S_o(s) = \frac{e(s)}{d_o(s)} = \frac{-1}{1+C(s)P(s)} = \frac{-1}{1+L(s)} = -S(s) \qquad \textbf{2.5(15)}$$

Similarly, the sensitivity to the input disturbance is defined as

$$S_i(s) = \frac{e(s)}{d_i(s)} = \frac{-P(s)}{1+C(s)P(s)} = \frac{-P(s)}{1+L(s)} = -P(s)S(s) \qquad \textbf{2.5(16)}$$

and the sensitivity to the measurement noise is defined as

$$S_n(s) = \frac{e(s)}{n(s)} = \frac{-1}{1+C(s)P(s)} = \frac{-1}{1+L(s)} = -S(s) \qquad \textbf{2.5(17)}$$

Finally, the complementary sensitivity function has been introduced according to

$$T(s) = 1 - S(s) = \frac{L(s)}{1+L(s)} \qquad \textbf{2.5(18)}$$

Observe the straightforward relation

$$W(s) = F(s)T(s) \qquad \textbf{2.5(19)}$$

The complete set of the transfer function relations can be repeated as

$$y(s) = F(s)T(s)r(s) + P(s)S(s)d_i(s) + S(s)d_o(s) - T(s)n(s) \qquad \textbf{2.5(20)}$$

$$e(s) = F(s)S(r)r(s) - P(s)S(s)d_i(s) - S(s)d_o(s) - S(s)n(s) \qquad \textbf{2.5(21)}$$

$$u(s) = F(s)C(s)S(s)r(s) - T(s)d_i(s) - C(s)S(s)d_o(s) - C(s)S(s)n(s) \qquad \textbf{2.5(22)}$$

It is quite clear that the sensitivity function $S(s)$ plays a key role in the design procedure. For a one-degree-of-freedom system ($F(s) = 1$, when tracking and disturbance rejection properties are complementary), $C(s)$ is to be designed to fulfill the following closed-loop requirements: stability, good servo property, effective disturbance rejection, noise attenuation, and low sensitivity with respect to the process model uncertainties.

For two-degrees-of-freedom control systems ($F(s) \neq 1$) the servo property can be separated from the rest of the design goals by adding a filter to preprocess the reference signal. Some fundamental design aspects of this will be discussed in the next section, but first consider an introductory example.

EXAMPLE

The transfer function of the control system in Figure 2.5g is

$$P(s) = \frac{A}{(1+sT_1)^3}; \quad A = 1, \quad T_1 = 1; \quad C(s) = 0.3\frac{1+s}{s};$$

$$F(s) = \frac{1}{1+0.2s} \qquad \textbf{2.5(23)}$$

The step response and the magnitude curves for the overall transfer functions determining the output and control performance are shown in Figures 2.5p and 2.5q, respectively.

Figure 2.5r shows the controlled variable (y, the output) and the manipulated variable (u, the control response) to a unit-step change in the controller's set point (r, the reference signal). In this case, the disturbance is also a unit step, which occurs at $t = 30$ sec, and the measurement noise is a sinusoidal signal with a huge, unity amplitude and a frequency of 3 rad/sec.

The control system tracks the reference signal (returns to set point) without any steady-state error and also effectively corrects for the input disturbances. The effect of the measurement noise is significantly attenuated, as at this frequency the amplitude of the overall transfer function T is much below 1. The control effort to attenuate the effect of the noise therefore is considerable. Figure 2.5r also shows that at lower frequencies (below 1 rad/sec) the measurement noise is not filtered out effectively.

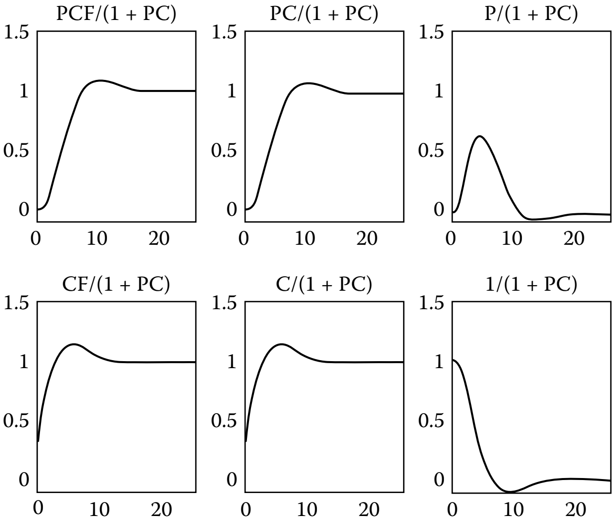

FIG. 2.5p
Step responses of the significant overall transfer functions in the control example.

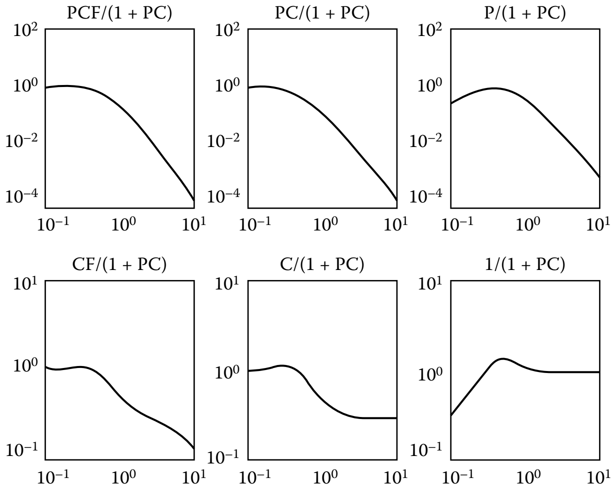

FIG. 2.5q
Gain curves of frequency responses of the significant overall transfer functions in the control example.

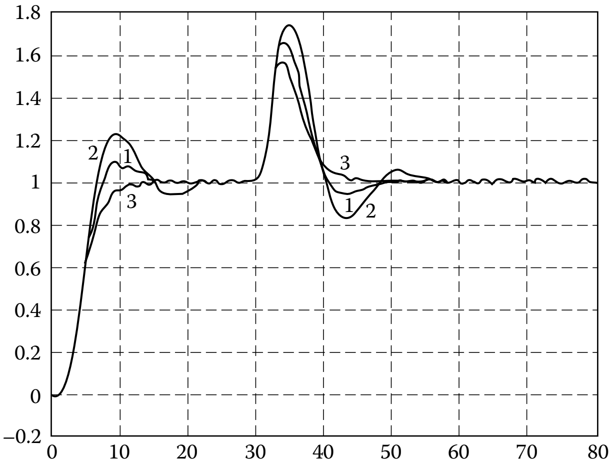

FIG. 2.5s
The response of the controlled variable (y, the process output) in response to variations in the gain and time constants of the process.

To evaluate the performance of a closed-loop control system, it is not enough to watch the controlled and manipulated variables (process output and control signals) of the model. The nominal design procedure assumes that the process model exactly matches the real process. It is also important to analyze how the system behaves if the plant parameters differ from their assumed nominal values.

When the model is inaccurate (has assumed a set of process dynamics, such as dead times and time constants, that are not accurate), Figure. 2.5s illustrates the effects of this inaccuracy on the controlled variable response to a disturbance.

Response curve 1 describes the situation where the transfer function $P(s)$ for the model was assumed to have a gain of $A = 1$ and time constant of $T_1 = 1$ sec and this was a correct assumption, i.e., it corresponds to the dynamics of the controlled process.

Response curve 2 describes the situation where the transfer function $P(s)$ for the model was assumed to have a gain of $A = 1$ and time constant of $T_1 = 1$ sec, while the real process had a gain of $A = 1.2$ and time constant of $T_1 = 1.2$ sec. Curve 3 describes the situation where the transfer function $P(s)$ for the model was as before, while the real process had a gain of $A = 0.8$ and time constant $T_1 = 0.8$ sec, respectively.

The response illustrated in Figure 2.5s shows that a 20% dynamic parameter uncertainty can be corrected for by the closed-loop controller.

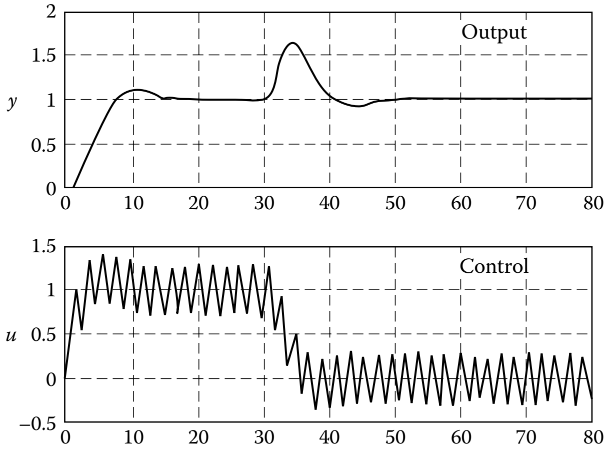

FIG. 2.5r
Controlled and manipulated variables (y and u, the output and input signals, respectively) of the controlled process with a measurement noise of 3 rad/sec frequency.

STABILITY AND DYNAMIC PERFORMANCE

The most important goal of control system design is to ensure *stability,* but some other goals are also important. These include steady-state accuracy (good set-point tracking), effective disturbance rejection along with noise attenuation, good transient performance (short settling time with no oscillations), and robustness with respect to modeling errors. In the paragraphs below, the goal of steady-state accuracy will be discussed first.

Following the Set Point

Let us first consider the set point (reference signal) tracking properties in steady state. In modeling set-point changes, one can consider the control system response to step changes and ramp and parabolic set-point adjustments.

Once a controller has been designed, the control loop can be described by the loop-transfer function $L(s) = C(s)P(s)$. The *type number* (number of pure integrators) of the control loop reflects the number of integrators in the loop transfer function. If no integrators are involved the type number is 0.

Assume that the loop-transfer function is given in the following form:

$$L(s) = \frac{K}{s^i} Q(s) \qquad \textbf{2.5(24)}$$

where i denotes the type number, $Q(s)$ is a rational transfer function with $\lim_{s \to 0} Q(s) = 1$, and K is the static loop gain.

Supposing a filter for the reference signal with unity steady-state gain ($F(0) = 1$), the error signal can be expressed as

$$e(s) = \frac{F(s)}{1 + L(s)} r(s) = \frac{F(s)s^i}{s^i + KQ(s)} r(s) \qquad \textbf{2.5(25)}$$

where $r(s) = \frac{1}{s^j}$, $j = 1$ for step, $j = 2$ for ramp, and $j = 3$ for parabolic reference input.

The steady-state value can be calculated by the final value theorem:

$$\lim_{t \to \infty} e(t) = \lim_{s \to 0} se(s) \qquad \textbf{2.5(26)}$$

Evaluating the above expression for j =1, 2, and 3, the results concerning the steady-state errors can be summarized in Table 2.5t.

According to the table, the Type 0 proportional control systems can track the set point (step reference signal) only with nonzero steady-state error, which error decreases as the proportional gain rises.

Controllers containing one integrator (Type 1) can track the step change in the set point accurately, without steady-state error, because an integrator keeps the output (controlled variable) constant only if its input (actually, the error signal) reaches zero.

TABLE 2.5t

Steady-State Errors Resulting from Different Types of Set Point Changes and for Different (Types 0, 1, 2) Processes

	Type 0	*Type 1*	*Type 2*
Step input $j = 1$	$\frac{1}{1+K}$	0	0
Ramp input $j = 2$	∞	$\frac{1}{K}$	0
Parabolic input $j = 3$	∞	∞	$\frac{1}{K}$

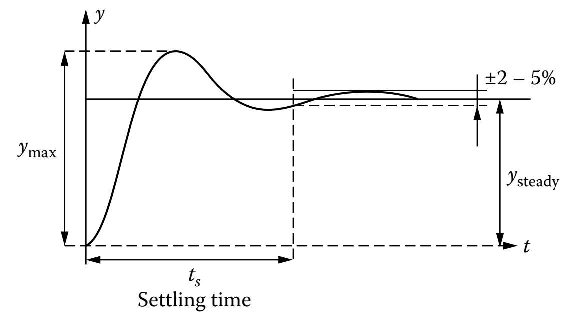

FIG. 2.5u

Dynamic response: overshoot and settling time.

With two integrators (Type 2), static accuracy is even better. Therefore, one may conclude that static accuracy is improved by increasing the number of integrators and/or the loop gain. This relation certainly holds; however, static accuracy and stability are conflicting requirements, in that too many integrators or high gains may cause instability. The goal of control system optimization is to find the best compromise.

Load Disturbance

A similar analysis can be performed to determine the impacts of load disturbances and measurement noise on the steady-state error. In the example discussed earlier in connection with Figure 2.5r, it was shown that a Type 1 control system accurately follows a step change in set point and completely eliminates the effect of a step disturbance.

Dynamic Response

The dynamic response of a closed-loop control system can be evaluated on the basis of the response of the controlled variable to a unit-step change in the set point (reference signal). Figure 2.5u describes such a response. The overshoot σ is defined by

$$\sigma = \frac{y_{\max} - y_{\text{steady}}}{y_{\text{steady}}} 100\% \qquad \textbf{2.5(27)}$$

The settling time t_s can be defined as time it takes to bring the controlled variable to within 2 to 5% of its steady-state value. Such dynamic properties as stability, overshoot, and settling time can also be evaluated from frequency domain analysis.

Frequency-Function-Based Evaluation

Figure 2.5v depicts a Bode amplitude–frequency diagram of an open-loop system $L(j\omega)$. The curve can be approximated

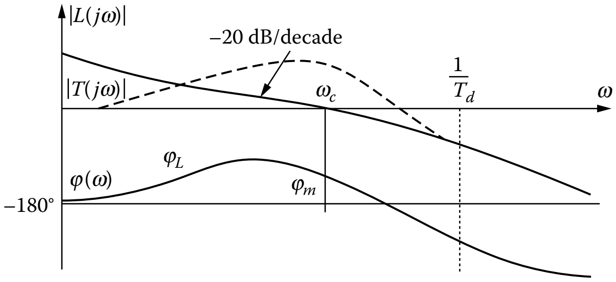

FIG. 2.5v
Typical open-loop Bode diagram of a stable system.

by its asymptotes. An important point on the curve is the cutoff frequency ω_c, where the absolute value is 1.

Stability properties can be obtained from the middle frequency performance of the open-loop frequency function. The system is stable if ω_c is at slope –20 dB/decade and is to the left of $1/T_d$, where T_d denotes the dead time of the plant. ω_c is also related to the settling time, which can be approximated as

$$3/\omega_c < t_s < 10/\omega_c \qquad \textbf{2.5(28)}$$

The shape of $|T(j\omega)|$ characterizing the relationship between the controlled variable (output) and the set point (reference signal) is also given in Figure 2.5v. Its magnification above 1 around ω_c indicates overshoot in the time response. This magnification must therefore be avoided.

The overshoot can be also estimated from the phase margin φ_m, which is calculated from the phase angle of the open-loop frequency function considered at frequency ω_c.

$$\varphi_m = 180° + \varphi_L(\omega_c) \qquad \textbf{2.5(29)}$$

The overshoot is expected to occur below 10% if $\varphi_c > 60°$.

Loop Shaping

When setting up a strategy to design a closed-loop control system to satisfy various control objectives one should consider Equations 2.5(20) to 2.5(22). Based on those, the fundamental design expectations can be summarized as follows:

- For good servo property $|L(j\omega)|$ has to be large.
- For good disturbance rejection $|L(j\omega)|$ has to be large.
- For good noise attenuation $|L(j\omega)|$ has to be small.
- To see moderate control $|L(j\omega)|$ has to be small.
- To compensate for the uncertainty in the process model $|L(j\omega)|$ has to be large.

Taking $S(s) = \frac{1}{1+L(s)}$ into account it is seen that requirements elaborated for $L(j\omega)$ can be transformed to a requirement for $S(j\omega)$. The sensitivity function $S(s)$ also plays a key role in the design. However, the challenge faced by the control engineers is that the above objectives are in conflict. To obtain a good design, the above listed control objectives should be carefully specified and a frequency region should be attached to each control objective.

In practice, the sinusoidal components of the reference signals and of the disturbances are in the low frequency region, while measurement noise is typically of high frequency. Consequently, most of the control objectives can be met by applying a high gain ($|L(j\omega)| > 1$) for low frequencies and a low gain ($|L(j\omega)| < 1$) at high frequencies. In addition, steady-state accuracy is also improved by high DC gain.

As far as the effect of the unmodeled process dynamics is concerned, uncertainty is usually reduced at the lower frequencies. If the model uncertainty exceeds a certain level even at low frequencies, there are two options to select from:

1. Conduct experiments to improve the process model by gaining more information about the process.
2. Lower the cutoff frequency and thereby decrease the demand for improved dynamic response.

The classical design technique performed in the frequency domain starts with the magnitude function of $P(j\omega)$ and evolves by gradually adding appropriate $C(j\omega)$ components to the loop of $L(j\omega) = C(j\omega)P(j\omega)$. This procedure is called *loop shaping*. When using this approach, special care should be taken when the controlled process is a nonminimum phase process or has substantial time delay.

Figure 2.5w shows the loop-shaping considerations related to the Bode amplitude diagram of the loop transfer function. A dotted line shows the complementary sensitivity function in the figure. At low frequencies it is approximately 1, while at high frequencies it is the same as $|L(j\omega)|$.

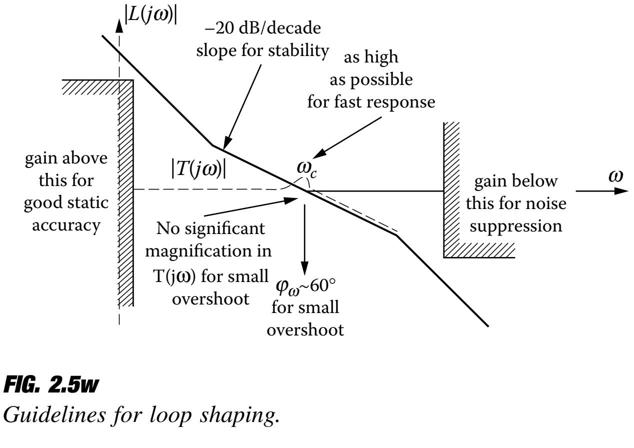

FIG. 2.5w
Guidelines for loop shaping.

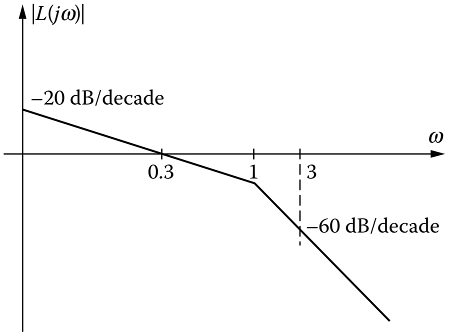

FIG. 2.5x
Bode amplitude–frequency diagram of the loop transfer function in the considered example.

Consider the third-order example analyzed previously. Assume that the process has three time lags and it is to be controlled by a PI controller. Figure 2.5x shows the Bode amplitude–frequency diagram of the loop's transfer function. The system is stable, as the Bode amplitude diagram crosses the zero dB axis with slope of –20 dB/decade (no dead time in the system).

The integrating effect in the PI controller ensures high gain at low frequencies. Therefore, as was shown in Figure 2.5s, steady-state error results from step changes in either set point or process load disturbances. Noise attenuation is very good, as at the noise frequency (3 rad/sec) the gain of the loop frequency function is very low. The phase margin is 58.8°, ensuring small overshoot. The settling time is about 15 sec.

CONCLUSIONS

The total performance of a control system depends on the overall response of the control loop and process acting together. The dynamic behavior of the total control system after an upset, which can be caused by a process disturbance, load change, or set point adjustment, is also a function of the type of controller used (Figure 2.5y).

The response is evaluated by the speed with which the controlled variable returns to the set point, by the amount of overcorrection or overshoot that occurs, and by the effects on the stability of the system during the upset condition. Depending on the nature of the process, different control modes may be required for optimum performance.

The system response utilizing transfer functions describing the controller and the process it controls has been analyzed. In case of uncertainties, sensitivity functions can be used to characterize the control system. To obtain guidelines for controller selection, loop-shaping considerations can be evaluated.

2.6 Control Systems — Cascade Loops

F. G. SHINSKEY (1970, 1985) **B. G. LIPTÁK** (1995) **R. BARS, J. HETTHÉSSY** (2005)

INTRODUCTION

Cascade control has a multi-loop structure, where the output of the controller in the outer loop (the "primary" or "master") is the set point of a controller in the inner loop (the "secondary" or "slave").

The slave measurement is an intermediate process variable that can be used to achieve more effective control of the primary process variable. In the cascade configuration the process is divided into two parts and therefore two controllers are used, but only one process variable (*m*) is manipulated.

In Figure 2.6a the primary controller maintains the primary variable y_1 at its set point by adjusting the set point r_2 of the secondary controller. The secondary controller, in turn, responds both to set point r_2 and to the secondary controlled variable y_2. This secondary controlled variable also affects the primary process and therefore the primary controlled variable (y_1), hence the loop is closed.

This cascade loop can also be shown in a more detailed block diagram form (Figure 2.6b). Here, the primary controller (C_1) generates the set point for the secondary controller (C_2), while the secondary controlled variable (y_2) also affects the primary process (P_1) and therefore it also affects the primary controlled variable (y_1).

Cascade control is advantageous on applications where the P_1 process has a large dead time or time lag and the time delays in the P_2 part of the process are smaller. Cascade control is also desirable when the main disturbance is in the secondary loop. This is because with the cascade configuration, the correction of the inner disturbance d_i occurs as soon as the secondary sensor (y_2) detects that upset.

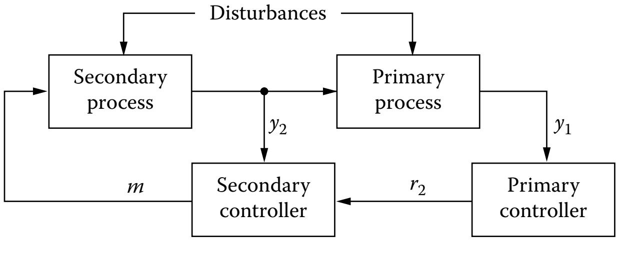

FIG. 2.6a
The cascade control system divides the process into two parts.

Cascade System Advantages

There are two main advantages gained by the use of cascade control:

1. Disturbances that are affecting the secondary variable can be corrected by the secondary controller before their influence is felt by the primary variable.
2. Closing the control loop around the secondary part of the process reduces the phase lag seen by the primary controller, resulting in increased speed of response. This can be seen in Figure 2.6c. Here, the response of the open loop curve shows the slow response of the secondary controlled variable when there is no secondary controller. The much faster closed loop curve describes the response of the secondary controlled variable when the cascade configuration adds a secondary inner control loop.

Other advantages of using cascade control include the ability to limit the set point of the secondary controller. In addition, by speeding up the loop response, the sensitivity of the primary process variable to process upsets is also reduced. Finally, the use of the secondary loop can reduce the effect of control valve sticking or actuator nonlinearity.

COMPONENTS OF THE CASCADE LOOP

The primary or outer control loop of a cascade system is usually provided with PI or PID control modes and is designed only *after* the secondary loop has already been designed. This is because the characteristics of the slave loop have an effect on the master loop.

For example, if the secondary measurement is nonlinear, such as the square root signal of an orifice-type flow sensor, it would produce a variable gain in the primary loop if the square root was not extracted.

For these reasons, the secondary loop requirements will be discussed first.

The Secondary Loop

Ideally, the secondary variable should be so selected as to split the process time delays approximately in half. This

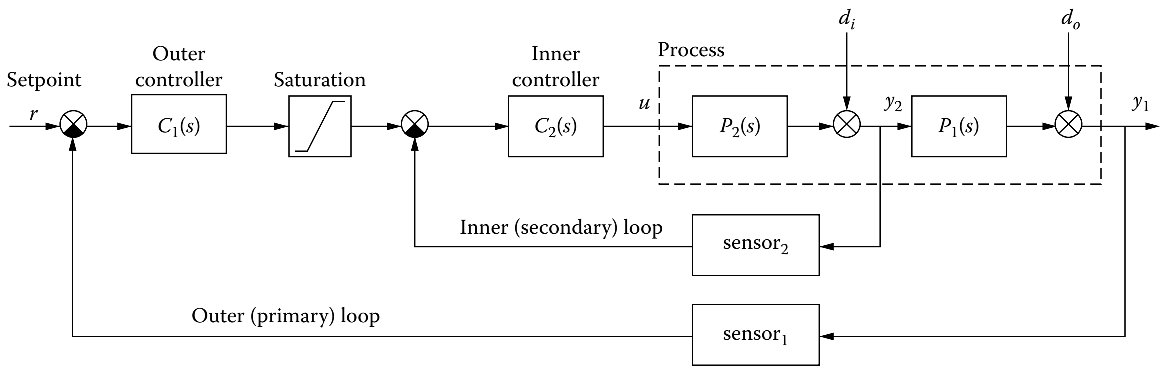

FIG. 2.6b
Block diagram of a cascade control system.

means that the secondary loop should be closed around half of the total time lags in the process. To demonstrate this need, consider two extreme cases:

1. If the secondary variable responded instantly to the manipulated variable (no time delay in the secondary loop), the secondary controller would accomplish nothing.
2. If the secondary loop was closed around the entire process, the primary controller would have no function.

Therefore, the dynamic elements of the process should be distributed as equitably as possible between the two controllers. When most of the process dynamics are enclosed in the secondary loop, that can cause problems. Although the response of the secondary loop is faster than the open loop configuration, in which a secondary controller does not even exist (Figure 2.6c), its dynamic gain is also higher, as indicated by the damped oscillation. This means that if stability is to be retained in a cascade configuration, the proportional band of the primary controller must be wider than it would be without a secondary loop; such de-tuning reduces responsiveness.

The right choice of the secondary variable will allow a reduction in the proportional band of the primary controller when the secondary loop is added because the high-gain region of the secondary loop lies beyond the natural frequency of the primary loop. In essence, reducing the response time of the secondary loop moves it out of resonance with the primary loop.

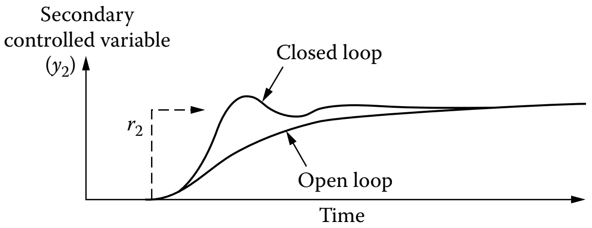

FIG. 2.6c
The response of the secondary variable is much improved when cascade control is used.

Secondary Control Variables

The most common types of secondary control variables are discussed next, discussed in the order of their frequency of application.

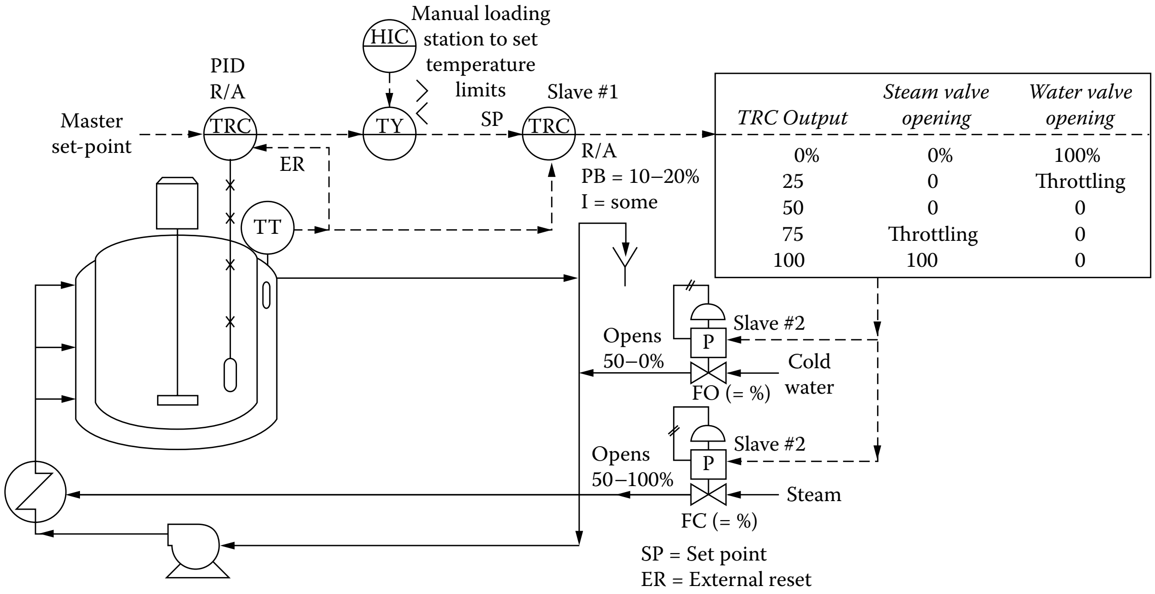
Valve Position Control (Positioner) The position assumed by the plug of a control valve is affected by forces other than the control signal, principally friction and line pressure. A change in line pressure can cause a change in the inner valve position and thereby upset a primary variable, and stem friction has an even more pronounced effect.

Friction produces hysteresis between the action of the control signal and its effect on the valve position. Hysteresis is a nonlinear dynamic element whose phase and gain vary with the amplitude of the control signal. Hysteresis always degrades performance, particularly where liquid level or gas pressure is being controlled with integral action in the controller.

The combination of the natural integration of the process, reset integration in the controller, and hysteresis can cause a "limit cycle" that is a constant-amplitude oscillation. Adjusting the controller settings will not dampen this limit cycle but will just change its amplitude and period. The only way of overcoming a limit cycle is to close the loop around the valve motor. This is what a positioner (a valve position controller) does; and this action can be considered to be the secondary loop in a cascade system.

Flow Control A cascade flow loop can overcome the effects of valve hysteresis as well as a positioner can. It also ensures that line pressure variations or undesirable valve characteristics will not affect the primary loop. For these reasons, in composition control systems, flow is usually set in cascade.

Cascade flow loops are also used where accurate manipulation of flow is mandatory, as in the feedforward systems shown in Section 2.8.



TRC Output	*Steam valve opening*	*Water valve opening*
0%	0%	100%
25	0	Throttling
50	0	0
75	Throttling	0
100	100	0

FIG. 2.6d

When cascade control is provided for a stirred reactor, it is recommended to provide the cascade master with a PID algorithm and with external reset from the measurement of the secondary controller. In this case, there are two inner loops; both can be plain proportional. The gain of the temperature controller is usually 5 to 10, while that of the valve positioner is about 20.

Temperature Control Chemical reactions are so sensitive to temperature that special consideration must be given to controlling the rate of heat transfer. The most commonly accepted configuration has the reactor temperature controlled by manipulating the coolant temperature in cascade. A typical cascade system for a stirred tank reactor is shown in Figure 2.6d.

Cascade control of coolant temperature at the exit of the jacket is much more effective than at the inlet because the dynamics of the jacket are thereby transferred from the primary to the secondary loop. Adding cascade control to this system can lower both the proportional band and reset time of the primary controller by a factor of two or more.

Since exothermic reactors require heating for startup as well as cooling during the reaction, heating and cooling valves must be operated in split range. The sequencing of the valves is ordinarily done with positioners, resulting in a second layer of inner control loops or cascade sub-loops in the system.

In Figure 2.6d, the secondary variable is the jacket temperature and the manipulated variables are the steam and cold water flows. Under control, the secondary variable will always come to rest sooner than the primary variable because initially the controller will demand a greater quantity of the manipulated variable than what is represented by the "equivalent" step change in the manipulated variable.

This is particularly true when the secondary part of the process contains a dominant lag (as opposed to dead time). Because with a dominant lag the gain of the secondary controller can be high, closing the loop is particularly effective. The dominant lag in the secondary loop of Figure 2.6d is the time lag associated with heat transfer across the jacket.

Secondary Control Modes Valve positioners are proportional controllers and are usually provided with a fixed band of about 5% (gain of 20). Flow controllers invariably have both proportional and integral modes. In temperature-on-temperature cascade systems, such as shown in Figure 2.6d, the secondary controller should have little or no integral. This is because reset is used to eliminate proportional offset, and in this situation a small amount of offset between the coolant temperature and its set point is inconsequential. Furthermore, integral adds the penalty of slowing the response of the secondary loop. The proportional band of the secondary temperature controller is usually as narrow as 10 to 15%. A secondary flow controller, however, with its proportional band exceeding 100%, does definitely require an integral mode.

Derivative action cannot be used in the secondary controller if it acts on set-point changes. Derivative action is designed to overcome some of the lag inside the control loop and if applied to the set-point changes, it results in excessive valve motion and overshoot. If the derivative mode acts only on the measurement input, such controllers can be used effectively in secondary loops if the measurement is sufficiently free of noise.

Cascade Primary Loop

Adding cascade control to a system can destabilize the primary loop if most of the process dynamics (time lags) are within the secondary loop. The most common example of this is using a valve positioner in a flow-control loop.

Closing the loop around the valve increases its dynamic gain so much that the proportional band of the flow controller may have to be increased by a factor of four to maintain

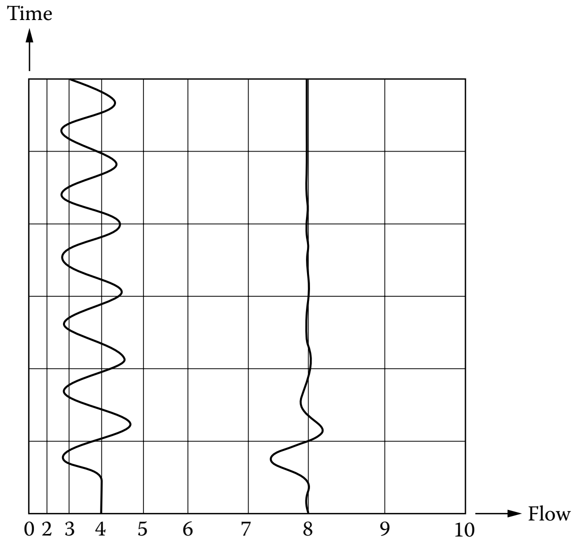


FIG. 2.6e
If cascade flow with a nonlinear orifice sensor is tuned at 80% of range, it will become unstable when the flow drops below 40%.

stability. The resulting wide proportional band means slower set-point response and deficient recovery from upsets. Therefore, in flow control loops, the existence of a large valve motor or long pneumatic transmission lines causes problems, and a volume booster rather than a positioner should be used to load the valve motor.

Instability Instability can also appear in a composition- or temperature-control system where flow is set in cascade. These variables ordinarily respond linearly to flow, but the nonlinear characteristic of a head flow meter can produce a variable gain in the primary loop.

Figure 2.6e compares the manipulated flow record following a load change that has occurred at 40% flow with a similar upset that took place at 80% flow. Differential pressure h is proportional to flow squared:

$$h = kF^2 \qquad \textbf{2.6(1)}$$

If the process is linear with flow, the loop gain will vary with flow, but when h is the manipulated variable, because flow is not linear with h:

$$\frac{dF}{dh} = \frac{1}{2kF} \qquad \textbf{2.6(2)}$$

Thus, if the primary controller is adjusted for 1/4-amplitude damping at 80% flow, the primary loop will be undamped at 40% flow and entirely unstable at lower rates.

Whenever a head-type flow meter provides the secondary measurement in a cascade system, a square-root extractor should be used to linearize the flow signal. The only exception to that rule is if flow will always be above 50% of full scale.

Saturation When both the primary and secondary controllers have automatic reset, a saturation problem can develop. Should the primary controller saturate, limits can be placed on its integral mode, or logic can be provided to inhibit automatic reset as is done for controllers on batch processes.

Saturation of the secondary controller poses another problem, however, because once the secondary loop is opened due to saturation, the primary controller will also saturate. A method for inhibiting reset action in the primary controller when the secondary loop is open (switched to manual) for any reason is shown in Figure 2.6f.

If the secondary controller has integral, its set point and measurement will be equal in the steady state, so the primary controller can be effectively reset by feeding back its own output or the secondary measurement signal. But if the secondary loop is open (in manual), so that its measurement no longer responds to its set point, the positive feedback loop to the primary controller will also open, inhibiting reset action.

Placing the dynamics of the secondary loop in the primary reset circuit is no detriment to control. In fact it tends to stabilize the primary loop by retarding the integral action. Figure 2.6f shows an application of this technique where the primary measurement is at the outlet of a secondary steam superheater, whereas the secondary measurement is at its inlet, downstream of the valve delivering water.

At low loads, no water is necessary to keep the secondary temperature at its set point, but the controllers must be prepared to act should the load suddenly increase. In this example the proportional band of the secondary controller is generally wide enough to require integral action.

When putting a cascade system into automatic operation, the secondary controller must first be transferred to automatic. The same is true in adjusting the control modes, insofar as the secondary should always be adjusted first, with the primary in manual.

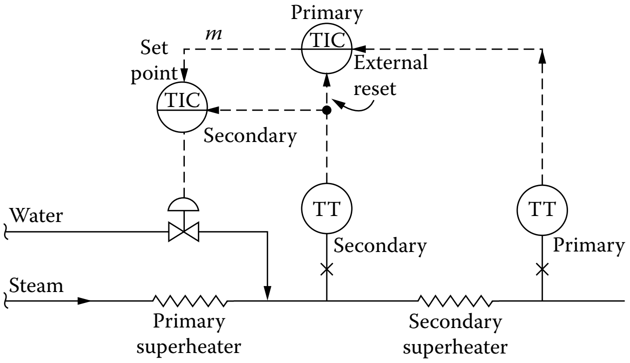

FIG. 2.6f
External reset is provided for the primary controller to prevent integral windup when the secondary controller is in manual.

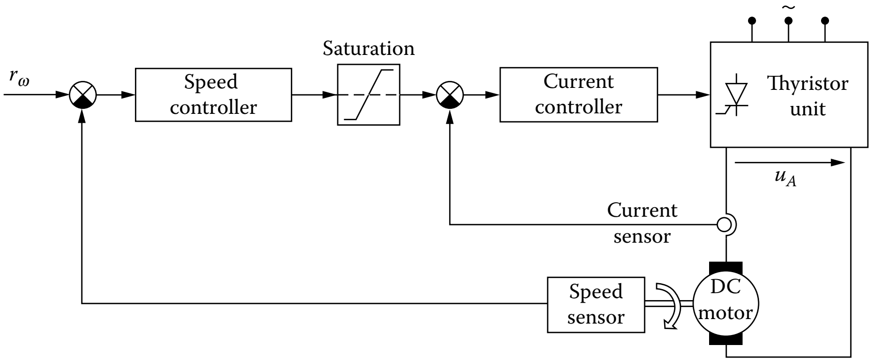

FIG. 2.6g
Cascade control of a DC motor.

Cascade Application Examples

Speed Control of a DC Motor When controlling the speed of a DC motor, the current can reach high peaks during the start-up and shut-down phases or when loading or breaking the motors. Therefore it is usual to apply cascade control with the armature current as the secondary variable. Saturation applied at the current set point (reference value) limits the maximum value of the current. The control system is shown in Figure 2.6g.

Another cascade control example is the control of electrical drives in controlling the position of servomechanisms with velocity feedback. Here the primary measured variable is the position, and the secondary measured variable is the velocity. The manipulated variable is the voltage applied to the servomotor.

Room Temperature Control A possible room temperature control configuration is shown in Figure 2.6h. The room is heated by a steam-heated heat exchanger, which warms the air supply to the room. The manipulated variable is the opening of the steam valve, which determines the steam flow through the heat exchanger. The primary variable is the room temperature. The variation in steam pressure can be the main source of upsets. The secondary variable is the inlet air temperature measured immediately after the heat exchanger, as the disturbances in the steam pressure affect it much sooner than they affect the room temperature.

Adding Valve Positioner to Tank Level Control When the liquid level in a tank is controlled by an outlet valve, placing a positioner on that valve forms a secondary cascade loop. This is desirable because the position of the valve's inner valve is affected by other factors besides the control signal, such as friction and inlet pressure. Variations in the line pressure can cause a change in position and thereby upset a primary variable. Stem friction can have an even more pronounced effect.

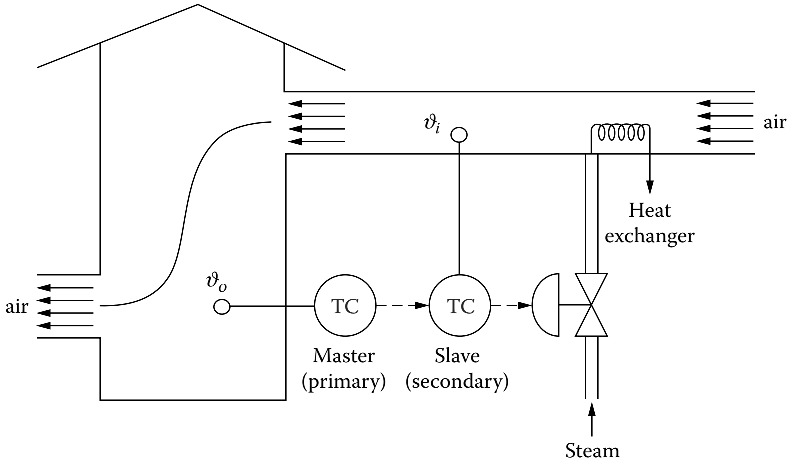

FIG. 2.6h
Cascade control of room temperature.

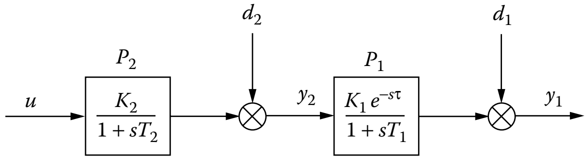

FIG. 2.6i
The process controlled by a cascade control system consists of two segments (P_1 and P_2) and has a measurable inner variable (y_2).

Inner valve sticking due to friction produces a square-loop hysteresis between the action of the control signal and its effect on the valve position. Hysteresis always degrades performance, particularly where liquid level is being controlled with integral action in the controller. The combination of the integrating nature of the process and the integral action in the controller with hysteresis causes a "limit cycle" that results in a constant-amplitude oscillation.

Adjusting the controller's tuning settings will not dampen this limit cycle but will only change its amplitude and period of oscillation. The only way of overcoming this limit cycle is to add a positioner and close the position-controlling slave loop around the valve motor.

Composition Control In composition control systems, flow is usually set in cascade. A cascade flow loop can overcome the effects of valve hysteresis. It also ensures that line pressure variations or undesirable valve characteristics will not affect the primary loop.

Cascade Controller Design and Simulation

The process controlled by a cascade system is shown in Figure 2.6i. The nominal values of the parameters and the uncertainties in their values are as follows:

$$K_{1n}=1,\quad 0.8<K_1<1.2 \quad K_{2n}=1,\quad 0.8<K_2<1.2$$
$$\tau_n=20,\quad 18<\tau<22 \quad T_{2n}=4,\quad 3<T_2<5$$
$$T_{1n}=10,\quad 8<T_1<12$$

The dual design objectives are:

1. First design a single-series PID controller, with feedback taken from the output signal y_1. Design objectives are stability and good reference signal (set point) tracking properties characterized by zero steady-state error and about 60° of the phase margin to keep the overshoot below 10%, when a step change is introduced in the set point.
2. Design a cascade control system with feedback taken from the primary and secondary (outer and inner) controlled variables (process outputs) y_1 and y_2, respectively. Both control loops have to be stable. The design objectives for tracking the set point (reference signal) are the same as before. Fast response is also required to any upsets in the secondary loop or measurement.

The design should consider the theoretical process model, and the effects of the possible errors or uncertainties in the model should be checked.

Single-Series Primary Controller The block diagram of the single control loop is shown in Figure 2.6j. To ensure accurate tracking of the set point (step reference signal), the controller must have an integral mode. The addition of rate action can accelerate the system response. A PID controller combines these two effects. With pole-cancellation technique the suggested PID controller transfer function is

$$C(s)=A\frac{(1+10s)(1+4s)}{10s(1+s)} \qquad \textbf{2.6(3)}$$

The ratio of the time constants of the PD part was chosen to be four.

The loop transfer function is

$$L(s)=\frac{A}{10s(1+s)}e^{-20s} \qquad \textbf{2.6(4)}$$

Gain A of the controller has to be chosen to ensure the required phase margin. In case of systems with dead time τ, a phase margin of about 60° is obtained if the cut-off frequency ω_c in the loop's Bode amplitude-frequency diagram is at slope of –20 dB/decade and is located at about $1/2\tau$.

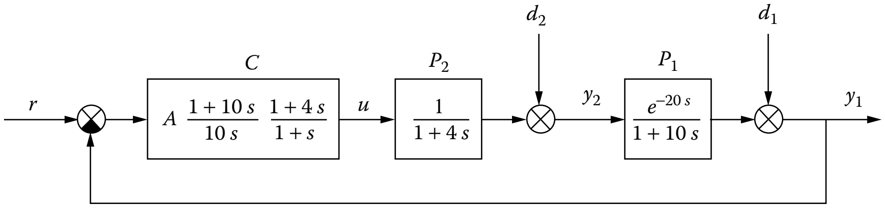

FIG. 2.6j
Series compensation.

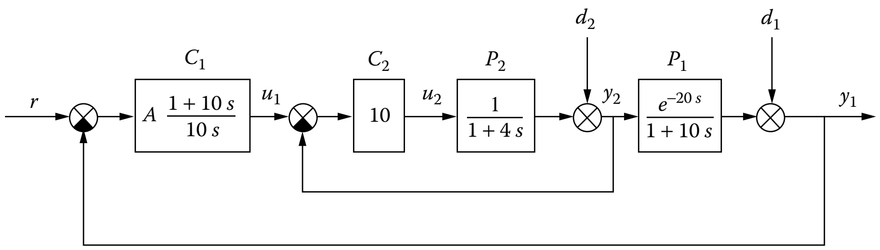

FIG. 2.6k
Cascade compensation.

In our case $\omega_c \sim 1/40$. At the cut-off frequency the absolute value of the frequency function is 1, thus $A/10\omega_c = 1$. Hence $A = 0.25$.

Cascade Controller System Design The block diagram of the control system is shown in Figure 2.6k. First the inner or secondary control loop is designed for fast correction of upsets that might occur in the secondary loop. The inner (secondary) controller can be proportional only. Its gain can be 10 and the cut-off frequency of the secondary loop can be 2.5. In that case the settling time is expected around $3/\omega_c$.

The resulting transfer function of the inner closed loop between signals y_2 and u_1 is

$$\frac{0.909}{1+0.36s} \qquad \mathbf{2.6(5)}$$

In the primary (outer) loop a PI controller is used, which will be responsible for accurate steady-state tracking of a step change in the set point (reference signal). Again, pole-cancellation technique is applied. The transfer function of the controller is

$$C_1(s) = A\frac{1+10s}{10s} \qquad \mathbf{2.6(6)}$$

The loop transfer function of the outer loop is

$$L(s) = A\frac{0.909}{10s(1+0.36s)}e^{-20s} \qquad \mathbf{2.6(7)}$$

The cut-off frequency is chosen again to be $\omega_c = 1/40$. At this frequency the absolute value of the frequency function is 1.

$$\frac{0.909A}{10\omega_c} = 1, \quad \text{hence } A = 0.275 \qquad \mathbf{2.6(8)}$$

Simulation Results The set-point (reference signal) change is a unit step that occurs at a time point of 10 sec. A unit step inner disturbance is added at a time point of 250 sec. The simulation ends at $t = 500$ sec.

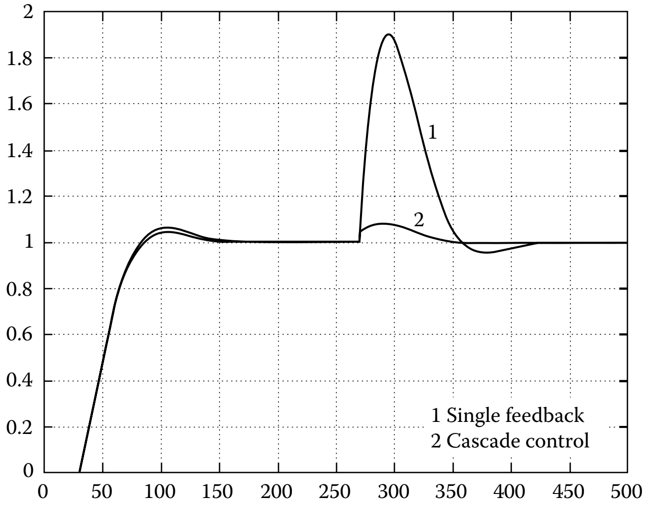

FIG. 2.6l
Tracking a unit change in set point that occurred at t = 10 sec and correcting for an upset of unit step size that occurred at t = 250 sec. Response 1 is that of a single feedback controller and 2 is that of a cascade system.

With the assumed nominal process model described earlier, the controlled variable responses (output signals) are shown in Figure 2.6l. It is seen that the set-point (reference signal) tracking is practically the same for both control configurations. On the other hand, the response to upsets (disturbance rejection) is much better with cascade control.

Figure 2.6m, in its upper part, shows the manipulated variable (u_2, controller output signal) and in the lower part, the controlled variable (y_2, inner variable) response of the secondary loop in the cascade configuration. The peak in the manipulated variable (secondary control signal) ensures the fast disturbance compensation. If the slave controlled variable (inner process variable) maximum value has to be under a given limit, this can be achieved by artificially saturating the output of the primary controller.

Figure 2.6n shows the effect of model parameter uncertainties in cases of the single loop and the cascade system. The controllers are designed based on the same nominal process model, and their responses to upsets are compared when the real process dynamics differ from the assumed

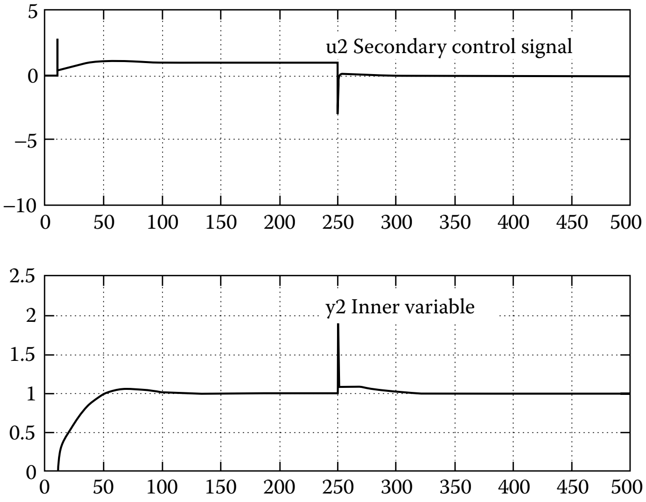

FIG. 2.6m
The response of the manipulated variable (u_2, controller output signal) and the controlled variable (y_2, inner variable) of the secondary loop in the cascade configuration.

nominal one that was used during tuning of the controllers (dynamics slower or faster) by various degrees.

Cascade control is more tolerant of model parameter uncertainties or errors in the model than a single controller and it gives particularly better performance when process upsets occur, as its disturbance rejection capability is superior to that of a single-loop controller.

Figure 2.6o describes the controlled variable responses of the single-loop and cascade control systems, assuming all dynamic parameters (time constants) of the process and its gain are both at their highest values.

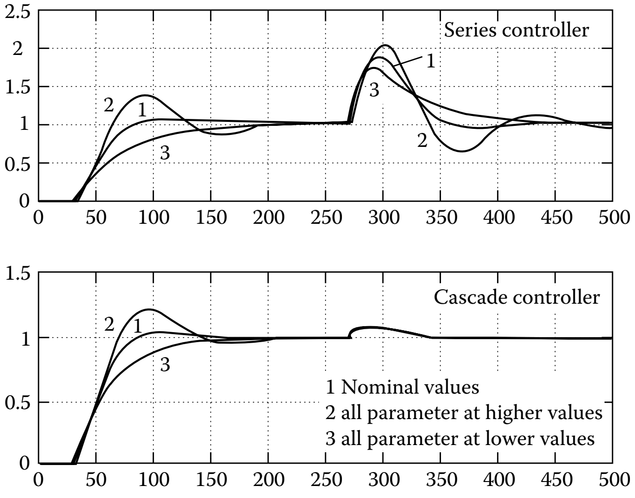

FIG. 2.6n
The response to both a set point step and a process upset of a single-loop controller (top) and a cascade system (bottom) to changes in the process dynamics. (1, correctly tuned; 2, process faster than at time of tuning; 3, process slower).

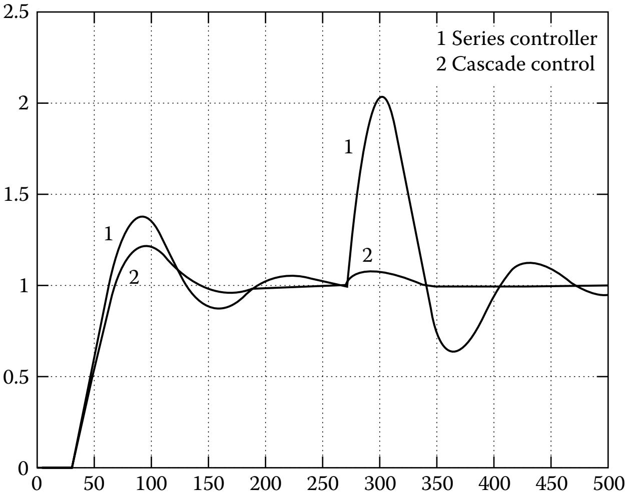

FIG. 2.6o
The controlled variable responses (output signals) of the single loop (series controller) and the cascade control system, when the time constants and the gain of the process are at their highest values.

SUMMARY

Cascade loops consist of two or more controllers in series and have only a single, independently adjustable set point, that of the primary (master) controller. The main value of having secondary (slave) controllers is that they act as the first line of defense against disturbances, preventing these upsets from entering and upsetting the primary process.

For example, in Figure 2.6d, if there were no slave controller, an upset due to a change in steam pressure or water temperature would not be detected until it had upset the master measurement. In this configuration, the cascade slave detects the occurrence of such upsets and immediately counteracts them, so that the master measurement is not upset and the primary loop is not even aware that an upset occurred in the properties of the utilities.

In order for the cascade loop to be effective, it should be more responsive (faster) than the master. Some rules of thumb suggest that the slave's time constant should be under 1/4 to 1/10 that of the master loop and the slave's period of oscillation should be under 1/2 to 1/3 that of the master loop.

The goal is to distribute the time constants more-or-less evenly between the inner (slave or secondary) and outer (master or primary) loops, while making sure that the largest time constant is *not* placed within the inner loop. When that occurs, such as in the case where a valve positioner is the slave and a very fast loop such as a flow or liquid pressure controller is the master, stability will be sacrificed because the valve has the largest time constant in the loop. In such configurations, stability can be regained only at the cost of reduced control quality (sluggish response to load or set-point changes).

Therefore, in such cases one would try to either speed up the valve or avoid the use of cascade loops. If the reason for using a positioner is to increase the air flow to the actuator, one can replace the positioner with a booster relay.

Providing external reset (Figures 2.6d and 2.6f) for the cascade master from the slave measurement is always recommended. This guarantees bumpless transfer when the operator switches the loop from automatic control by the slave to full cascade control. The internal logic of the master controller algorithm is such that as long as its output signal (m) does not equal its external reset (ER), the value of m is set to be the sum of the external reset (ER) and the proportional correction ($K_c e$) only. When m = ER, the integral mode is activated, and in case of a PI controller, the output is:

$$m = K_c(e + 1/T_i e\,dt) + b \qquad \textbf{2.6(9)}$$

2.7 Empirical Process Optimization

D. W. HOYTE (1995) **B. G. LIPTÁK** (2005)

Suppliers of Optimization Software: DMC; Gensym; Setpoint; Statistical Programs; Ultramax ($1000 to $20,000)

The optimization of control loops is discussed in Section 2.20, and the optimization of such unit operations as chemical reaction or distillation is covered in Chapter 8. Here the subject is the optimization of empirical processes, but before that discussion, it is appropriate to say a few words about optimization in general.

LEVELS OF OPTIMIZATION

The highest level of optimization is business- or enterprise-wide optimization, which includes not only the manufacturing process, but also the optimization of the raw material supply chain and of the packaging and product distribution chain. This is a higher and more important level of optimization than process optimization alone because it requires the simultaneous consideration of all three areas of optimization and requires the finding of enterprise-wide operation strategies that will keep all three areas within their optimum areas of operation (Figure 2.7a).

Plant-wide optimization also involves more than the optimization of the unit processes because it must also consider documentation, maintenance, scheduling, and quality management considerations. Plant-wide optimization involves the resolution of the sometimes conflicting objectives of the many unit operations and the envelope strategies required to optimize the entire plant.

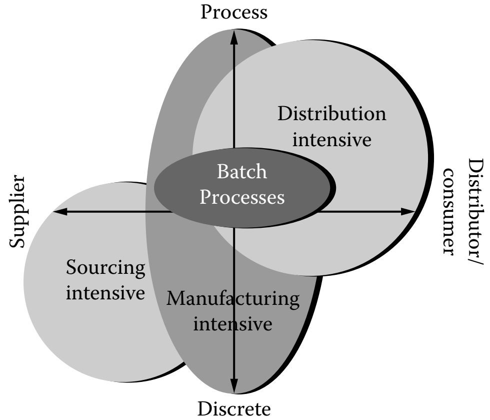

FIG. 2.7a
Enterprise-wide optimization requires the optimization of not only the manufacturing plant but also the raw material supply chain and the product distribution chain.

At the unit operations level, it goes without saying that multivariable optimization cannot be achieved when individual processing equipment is defective or when control loops are not properly tuned. In addition, it is important that measurements be sampled fast enough and that loops be tuned for sufficiently fast rates of recovery. Loop cycling must also be eliminated, which usually requires the elimination or correction for interactions between loops. When no mathematical model can describe a process and therefore the process can only be optimized experimentally, empirical optimization is required. This is the subject of this section.

EMPIRICAL OPTIMIZATION

The performance of some processes can be described by theoretical mathematical models. In these cases, mathematical techniques are available to determine the best operating conditions to satisfy selected performance criteria and thereby optimize the process.[1] There are, however, many processes for which no adequate mathematical model exists. These are known as *empirical* processes, and they can only be optimized experimentally. This section discusses approaches to finding the optimum process settings by experiment. The discussion concentrates on the Ultramax method, which is appropriate to a wide variety of processes and for which excellent user-friendly computer tools are available.

Optimization

The term "optimize" is used here as it refers to a measurable criterion or quality of the process (Q) that the user wishes to maximize or minimize. For example:

1. Plant production rate is to be maximized.
2. Cost-per-ton of output, calculated from many measurements, is to be minimized.

3. Flavor of a product, rated 1 to 10 by a group of tasters, is to be maximized.
4. Height/width ratio of a chromatograph peak is to be maximized.

Q is sometimes referred to as the target variable or the objective function. Several contending criteria may be given weights to produce a single measurement of process performance.[2] To simplify the discussion, the examples here will be limited to maximizing the value of Q.

Optimizing the process may include maximizing Q while other measured results of the process (R, S, etc.) remain within specified limits (e.g., maximizing plant production rate in making butter, paper, or sulfuric acid must be subject to a specified limit on water content in each product).

Information Cycle Times Some processes have inherently long information cycle times; resistance to weathering of different paint formulations or increase in farmland productivity from different mixtures of synthetic fertilizers are examples. In both cases, the search for an optimum would take an unacceptably long time if the results from one test were awaited before deciding the conditions for the next test. Therefore, multiple formulations of paints and fertilizers must be planned and then tested in parallel at the same time. This type of planning, and the subsequent analysis of the results, is often called parallel design of experiments.

Parallel Design Taking a specific example: A material is baked for time duration (D), at an oven temperature (T), to result in a quality (Q), which is to be maximized. This process could be, for example, the case-hardening of steel, the polymerization of resin, or the diffusion of ions in silicon chips. Only D and T are manipulated to affect Q.

Processing is performed with a selected array of D and T values, and the corresponding values of Q are measured. The optimum can be found graphically by drawing contours of Q on a graph showing the points ($D1$, $T1$), ($D2$, $T2$), and so on. Optimum operating conditions for the process are the values of D and T at the top of the "hill."

The contours of Q are sometimes called the response surface of the process and can be fitted to the data points mathematically, instead of sketching contours by eye.[3] This has clear advantages when there are many manipulated variables in the process. The math is simplified by selecting the array of experimental points to suit it. Also, the analysis is simplified by limiting the equation for the response surface to the second order.

Note that while statistical texts often refer to D and T as the *controlled* variables, an engineer will usually refer to D and T as *manipulated* variables and to Q as the *controlled* variable.[4]

Some commercially available computer programs for parallel designs of experiments are in the nature of a collection of routines that are useful to an experienced industrial statistician. The practicing engineer is likely to work faster with a user-friendly, menu-driven package such as Catalyst or Discover.[5]

Sequential Design Many processes have short information cycle times. In such cases, the results from using particular process settings become available in time to help in deciding the settings for the next test. This method is often called sequential design of experiments, or hill climbing.

Using the previous example, three different values for the settings D and T are evaluated in this process. The slope of the response surface defined by the values of $Q1$, $Q2$, and $Q3$ shows the direction "up the hill" to increase Q. The next values of D and T are selected to proceed in this direction. Repeating this procedure, the experimenter can "hill-climb" step by step, toward the maximum value for Q.

If the process has many independent variables and also has some noise that is affecting the results, it can be difficult to determine how each variable is affecting the quality of the product (Q). The Simplex search procedure works (finds the maximum value of Q) all the time, with one more process result than the number of independent variables. In the example used here, it would require three process results.

Figure 2.7b illustrates the method. To find the next settings for the process, a line is drawn from the settings with the lowest result, through the midpoint of the opposite face, to an equal distance beyond. In this example, the search reaches optimum with 20 data points.

The Simplex search was invented by William Spendley at ICI Billingham, England to automate the evolutionary operation (EVOP) procedures of G. P. Box and others, and the methods are amenable to implementation using paper and pencil or a desk calculator.[6,7] Reference 8 provides a practical treatment of the subject in which the authors review related computer programs.

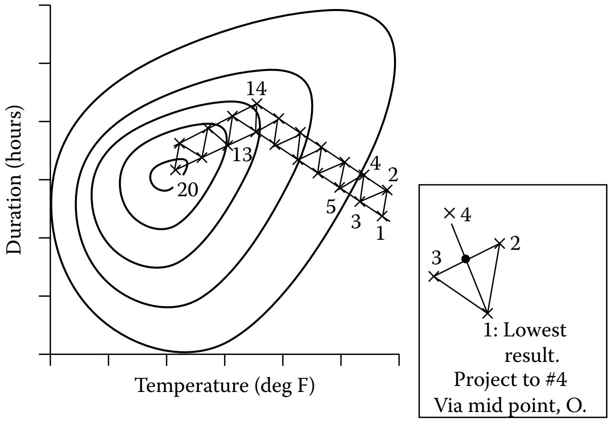

FIG. 2.7b

SIMPLEX search for a maximum of quality, Q. Contours of Q are shown, though usually unknown. Inset shows how the next process settings are found. Direction changes where #14 has lower Q than #13.

FIG. 2.7c

Main menu and a Problem Formulation for the Ultramax program. In the formulation, "Type" designates treatment of the variable. Note that all Ultramax reports have been simplified here to highlight concepts. (Courtesy of Ultramax Corp., Cincinnati, OH.)

Bayesian Methods Bayesian statistics are designed to match the human decision-making process in situations where few data are available. They are used to help in selecting the next process settings in a sequential hill-climbing program, Ultramax,[9] designed for the PC or mainframe computers. Ultramax is a menu-driven, engineer-oriented package.

The following illustration uses the baking process mentioned earlier, but with the addition of a constraint: volume (V) per unit of product. Here, volume and quality are both affected by duration and temperature of baking; the goal is to find settings of D and T to give maximum Q while holding V between specified limits.

Figure 2.7c shows the Main Menu of Ultramax. Keying F prompts the user to specify the "Problem Formulation" shown there. (Note that all examples shown have been simplified to clarify the concepts.) Salient points of this formulation are as follows:

1. Q is only acceptable when V is ranged from 30 to 31 cu. in.
2. TYPE code specifies how the program is to treat each variable, as follows:
   Types 0 and 4 are for data-recording only. (Types 0, 2, and 4 are not used in this example.)
   Type 1 is an independent (manipulated) variable.
   Type 2 is an independent variable that affects the target but cannot be manipulated (e.g., the time of day, the price of crude oil, a process disturbance).
   Type 5 is a dependent (*results*) variable with constraints.
   Type 6 is the target variable.
3. One Type 6 target variable must be specified in the formulation; several variables of other types may be specified. The standard version of Ultramax can deal with ten Type 1 variables, and *all* can be changed at will in each step of the search.
4. The "Prior Region" specifies the range where the user expects the optimum to lie and wishes the search to start. Note: A *parallel* design of experiments for two independent variables requires a dozen data points in this region and in every further region selected for exploration.

Providing Process Data

After the formulation of the problem, the menu function E (Enter Data) is used next. The user can enter, at one time, one or many data points: for example, sets of measurements of D, T, V, and Q from the process.

Process data can be keyed in or can be read in from a file. Although users often have extensive data to enter from prior process runs, they may wish to obtain and enter data points one at a time after the initial loading in order to obtain advice from Ultramax on the recommended process settings to use next. This way the optimum will be reached with the fewest runs of the process.

The search up through run #14, following the advice of Ultramax, is shown in Figure 2.7d. This starts with the same three data points used in Figure 2.7b and explores the contours

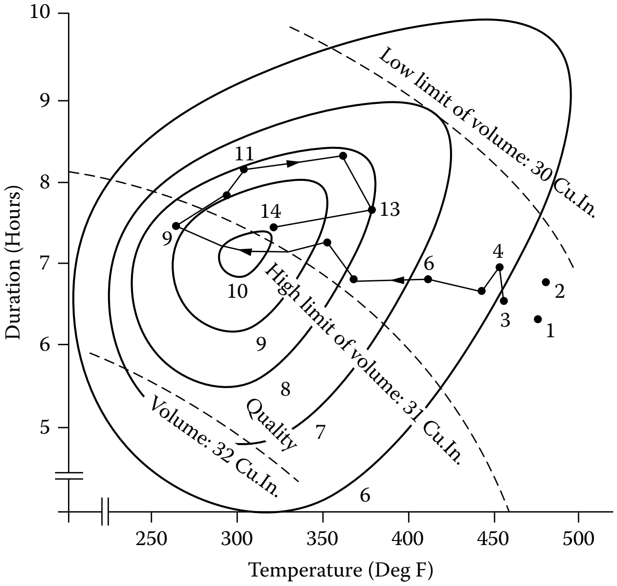

FIG. 2.7d

Ultramax search for process settings to give maximum quality (Q) without violating limits on volume (V). The contours are not known before the search.

of Q as it seeks the maximum. At the same time, the search is recognizing the contours of V and locating the barrier of $V = 31$ cu. in. By run #14, the search is close to the optimum settings for duration and temperature in this process. (The contours are shown for illustration only; they are not, of course, known while the search is being made.)

Search Procedure

After process data have been entered, menu function L (Build Model), is used to fit a second-order model to the data points. This is illustrated in the "Coefficients Report for Quality," which appears after the data for run #13 have been entered (see Figure 2.7e). (A similar report obtained for the model of V is not shown here.)

The user seeks process settings that give the largest value of Q and is only interested in fitting the model in that region. The data points used earlier in the search may detract from that fit; if they do, Ultramax automatically discards them. The actual points used in the model are listed at the bottom of Figure 2.7e together with their errors. "Minimum Prediction Error" at the top of Figure 2.7e gives a single value for goodness-of-fit.

Model coefficients for variable #4: quality.
problem: maximum quality subject to limits on volume

Model type: local fixed-point-centered quadratic

Minimum prediction error = 0.26 score

Model Equation:

$$F(x) = +12.28 - 0.0392 \ {}^*X(1) + 1.139 \ {}^*X(2) - 0.00006016 \ {}^*X(1)^{**}2 + 0.009428 \ {}^*X(2)^*X(1) - 0.289 \ {}^*X(2)^{**}2$$

Key	Variable	Units	Type
F(x)	Quality	Score	6
X(1)	Temperature	Deg F	1
X(2)	Duration	Hours	1

Datapoints Used and the Errors of the Model:

Run #	Actual quality	Model quality	Error
13	8.00	7.97	−0.03
12	8.10	8.06	−0.04
11	8.00	8.19	0.19
10	8.76	8.43	−0.33
9	8.62	8.70	0.08
8	8.09	8.16	0.07
7	7.78	7.70	−0.08
6	6.71	6.74	0.03

FIG. 2.7e
Example of a Model Coefficients Report: Run #13. Goodness-of-fit is shown by minimum prediction error and list of model errors. Ultramax fits the model in the region of the maximum quality, as desired by the user. It has discarded outlying data points numbers 1 to 5. (Courtesy of Ultramax Corp., Cincinnati, OH.)

Advice Report: Seeking Maximum Quality Subject to Limits on Volume

	Optimum	Advice	Advice	Advice
Advice #	14	15	16	17
Process Settings				
1 Temperature Deg. F	303	321	324	359
2 Duration Hours	7.44	7.52	7.86	9.27
Expected Results				
3 Volume Cu.In.	31.00	30.91	30.81	30.33
Expected Error	0.19	0.19	0.19	0.39
4 Quality Score	8.6	8.5	8.4	7.6
Expected Error	0.6	0.6	0.6	1.2
Standard distance ("Boldness")	1.1	1.0	1.0	2.8

FIG. 2.7f
Example of an "Advice Report" showing Advices for the next settings to run the process after run #13. "Optimum" gives the best process settings based on present data. "Standard Distance" is the estimated risk in the results from each Advice (similar to confidence limits). Maximum Standard Distance has been set by the user at 3.0. (Courtesy of Ultramax Corp., Cincinnati, OH.)

After the model-building step, the menu function A (Generate Advice) gives a report for a selected number of "Advices," as shown in Figure 2.7f. The column headed "Optimum" gives the best calculated settings for the process, based on the data at that stage. The user can then follow Advices for the next process settings to explore further for the optimum, in the priority order that Ultramax sees as the need for information. The user may choose to select several or only one of the Advices for the next process settings, or the user can use settings to explore the process based solely on the user's own knowledge and intuition about the process. Ultramax will use any data points it is given.

Finding the Optimum Sequential cycles consist of:

Data Entry
Build Model
Get Advices
Run Process
Data Entry

and will initially lead to data points in the general region of the process maximum. In this phase of the search, the size of steps made in changing the process settings is limited by a "Boldness-of-Search" parameter that the user specifies. Thus the user can choose either to search quickly or to make smaller and more cautious changes. This is somewhat similar to tuning one of the process control loops. The "boldness" of each Advice is ranged from 0 to 3 and is shown as "Standard Distance" in Figure 2.7f.

The search continues until the distinction between the best process settings is limited only by the repeatability (*noise*) of the process. At this point, changes in the "Optimum" value from one process-run to another for each manipulated variable (Figure 2.7f) will bottom out.

Process Sensitivity The model can be explored with menu function W (What-If Analysis). This evaluates Q and V from the models for any desired settings of D and T, showing the sensitivities of Q and V to changes in each independent variable.

Ultramax may be called periodically by a process control program such as The Fix or Onspec (see References 10 and 11) to calculate new values for the setpoints of manipulated variables. The program will perform a reasonableness check, then transmit these setpoints to its own process-control algorithm or to hardware controller setpoints.

Process Repeatability Where the repeatability of the process is not adequate for analyzing for optimum, the following steps can be considered:

1. Average many measurements of a variable to reduce "noise."
2. Improve repeatability of the measuring devices through recalibration and other means.
3. Seek further variables that affect the process and are not yet in the model.
4. Do a time-series analysis to investigate interactions and delayed actions.[12]

Programs are available to make this analysis.[13] A user-friendly interface was written for them, but it is not now available in the United States.[14] However, some control-system contractors, such as the ACCORD system, offer time-series analysis.[15,16]

CONCLUSIONS

The techniques of optimizing an empirical process owe much to the insights and work of the late James M. Brown.[17] These methods were once the sole preserve of the specialist statisticians but are now available in forms that are suitable for use by the practicing engineer.

Industrial user companies seldom advertise the successes they are achieving by the use of these tools, but information and assistance are readily available from the suppliers of optimization software.

2.8 Expert Systems

B. A. JENSEN (1995) **B. JOSEPH** (1995) **B. G. LIPTÁK** (2005)

Artificial intelligence is the field in which computers model or make available nonnumeric human-like intelligence. Neural networks, like expert systems, fuzzy logic, robotics, natural language processing, and machine vision, are parts of an overall technology umbrella known as artificial intelligence (AI). Most of these techniques are discussed in this section, while model based control (MBC), model free control (MFC), multivariable (MIMO) control, and statistical process control are also covered in other sections of this chapter.

ARTIFICIAL INTELLIGENCE

Artificial intelligence (AI) is a field of computer science concerned with the development and deployment of machines that mimic human behavior. Broadly speaking, AI can be divided into five major categories: expert systems, robotics, vision, natural language processing, and artificial neural networks (ANN). Of these five, the expert systems and ANNs have had the greatest impact on process control.

Expert Systems

Expert systems are computer software systems that mimic the tasks routinely carried out by experts. Usually, the domain of expertise of these systems is restricted to a well-defined area. Unlike humans, these systems lack common sense and hence cannot extrapolate their knowledge much beyond their narrow domain of expertise. Expert systems can be thought of as a storehouse of knowledge with efficient ways of retrieving this knowledge to solve the problem at hand.

Expert systems are valuable because they can serve as a permanent storehouse of knowledge that is widely accessible. Expert systems have been applied in process control in such areas as fault diagnosis, quality control, control system synthesis, statistical process control, alarm management, and process troubleshooting. Some companies specialize in the application of AI technology to process control.

Structure of Expert Systems Expert systems mimic the tasks carried out by experts. They encode the relevant knowledge that relates to a problem in a form that is suitable for manipulation. The structure of the expert system separates the knowledge from the mechanism for manipulating that knowledge. This has significant advantages because it makes the system easier to maintain and update. It is this separation of the knowledge base from the reasoning process that makes expert systems different from other software packages. Figure 2.8a shows the typical structure of an expert system.

The type of knowledge in the knowledge base depends on the problem domain. Knowledge is stored in the form of *facts* (e.g., as temperature goes up reaction rate increases), *rules* (e.g., if temperature in the reactor is high, then the cooling system is faulty), and *data frames* (frames are data structures for storing information in a hierarchical format). Knowledge may be also contained in *objects* that can perform specific tasks (e.g., do an energy balance). Objects may be coded in other programming languages. Both the knowledge and the data can be either qualitative or quantitative. This is another distinguishing feature of expert systems: ability to deal with qualitative data and knowledge.

The general problem-solving strategy of the expert system is contained in the inference engine. Common strategy here is to apply the rules in the knowledge base in a certain sequence until a conclusion is reached. This is called rule chaining. The user interface provides a mechanism for the expert to enter knowledge and the user to enter data for a specific problem.

Most expert systems are programmed using expert system shells. An expert system shell contains all of the structure shown in Figure 2.8a, but its knowledge base is empty. By programming the shell to contain knowledge about a domain, an expert system can be built.

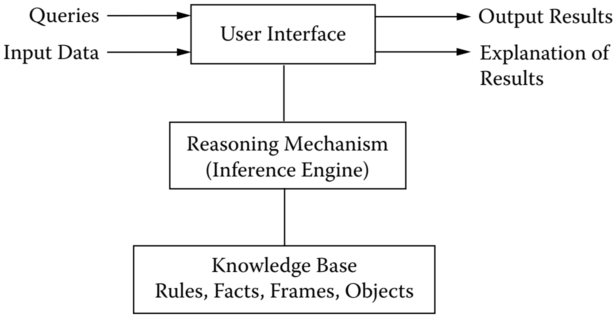

FIG. 2.8a
Structure of an expert system.

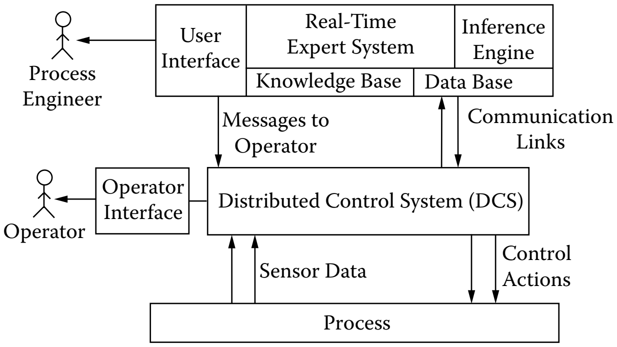

FIG. 2.8b
Structure of a real-time expert system.

Real-Time Expert Systems Real-time expert systems require additional features: e.g., the ability to include the time element in the reasoning process. Software vendors have recognized the unique requirements of real-time expert systems, and expert system shells are currently available on the market tailored to meet the requirements of process control applications. Naturally, it requires close integration with the underlying distributed control system (DCS) for exchange of sensor data and communication with the operator.

Figure 2.8b shows the structure of a real-time expert system. Examples of real-time expert system shells include G2 (from Gensym Corporation; see Reference 1) and Expert 90 (from ABB Process Automation, formerly Bailey Controls; see Reference 2).

Knowledge acquisition is widely recognized as the bottleneck in the implementation of expert systems. It had been thought that personnel trained in the technology of expert systems (called knowledge engineers) would interview the process control experts to elicit the knowledge and then incorporate these into an expert system. However, it has been found that it is easier for the expert to directly enter the knowledge into the expert system shell. The current shells on the market are built so that knowledge-base construction is highly automated.

Some shells can also generate the knowledge base from examples. At least one large chemical company (DuPont) espouses the philosophy that experts themselves are the best candidates for constructing the expert systems. Table 2.8c compares the advantages and disadvantages of using human experts vs. expert systems.

TABLE 2.8c
Expert Systems vs. Human Experts

Human Expert	*Expert System*
Knowledge is difficult to transfer	Knowledge is easily reproduced
Difficult to document	Self-documenting
Sometimes inconsistent	Consistent
Expensive	Affordable
Volatile	Permanent
Creative	Uninspired
Adaptive	Rigid
Broad focus	Narrow focus
Common-sense knowledge	Knowledge is limited to a narrow domain

Expert Systems in Control System Design Expert system applications to process control can be divided into two areas: control system design and real-time process control. The goal of an expert system for design is to capture the expertise of the design engineers and thereby reduce the design time that is required to produce an optional design strategy. For example, consider a control system engineer who is an expert on distillation control. He or she knows precisely what questions to ask and knows which control system configuration is appropriate for a given situation. For a typical design problem, the expert gathers all the necessary information on the particular problem at hand and uses experience to suggest a control system.

An expert system for distillation control would be built by first gathering the knowledge used by the expert, organizing this knowledge, and finally encoding it into a computer program. The user will interact with the program in an interview mode, supplying relevant data as needed for the specific problem. The expert system will suggest an appropriate control configuration. This was one of the early applications reported by Shinskey.[3]

The advantage of such an expert system is that it can be easily reproduced and distributed; hence, the expertise of one or a few experts becomes widely available. Many people view the expert system as a way of permanently capturing the knowledge of expert(s) that was gathered by years of experience while working in a specialized area.

This does not mean that experts can be replaced by expert systems. The knowledge contained in an expert system is never complete. The output of an expert system must still be validated by the design engineer to make sure that it conforms to the engineer's original design specifications.

Batch Process Control In the area of real-time control, expert systems have been applied in many areas, including batch process control, fault diagnosis, and statistical process control. Joseph et al.[4] discuss an application of expert systems to quality control of a batch process for making oil additives. The problem was to control the quality and production rate of a set of batch reactors.

The processing chemistry is not well understood and involves gas, liquid, and solid phases. Normally a team consisting of a process chemist, engineer, and operators is assembled to troubleshoot production problems. The objective is to capture the knowledge of these experts and encode that knowledge in a software package that could then be used by the operators to diagnose routine problems.

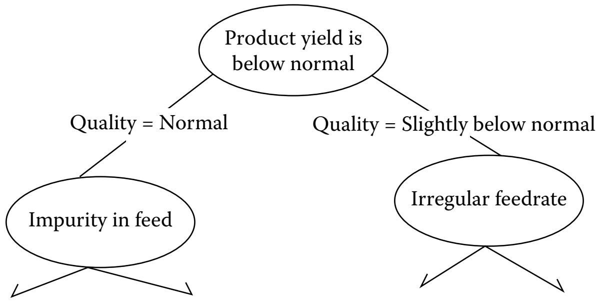

FIG. 2.8d
An example of a decision tree structure used for representing knowledge.

In such cases, the most convenient way to represent the knowledge is in the form of a decision tree with each node in the tree representing a decision to be made regarding the possible cause of the problem. Consider for example the following rules used by the experts:

Rule 1. "If production yield is low and the quality is within spec, then the problem is due to impurities in raw material A."

Rule 2. "If production yield is low and quality is slightly below target, then the problem is due to irregularity in the feed rate of raw material A."

These two rules can be represented in the decision tree shown in Figure 2.8d. The decision tree structure is a convenient way to extract and validate knowledge from experts.

The decision tree can consist of several levels and can provide for the exchange of business- and control-related data. The integration of business and control functions requires the definition of interfaces and the development of standards on nomenclature. ISA-SP95 Committee is working to develop an integration standard for enterprise-wide control (Figure 2.8e).

Fault Diagnosis In a process plant, fault diagnosis requires experts who are familiar with the operation. Although some failures can be diagnosed by a novice using an operations manual, often this is not the case, and experienced operators must be called in. Expert systems can serve as an additional tool for the inexperienced operator in diagnosis of faults.

Rich et al.[5] describe an application of expert systems to diagnose of faults in a whipped toppings process. The objective of the expert system was twofold: first, to diagnose the cause of the fault, and second, to suggest remedial actions to correct the situation and bring the process back to normal. The knowledge was acquired from two experts familiar with the day-to-day operations of the plant.

When multiple experts are involved, it is possible that their opinions may conflict. Care must be exercised to resolve such conflicts in a mutually agreeable fashion before the knowledge base is completed. It is preferable to first gather the knowledge from each expert using one-on-one interviews and then to bring them together as a group to resolve the conflicts. Completeness of the expert system (defined as the ability to resolve potential faults) may have to be sacrificed in favor of efficiency and speed of response.

Careful attention must be paid to the user interfaces provided. This includes the type of queries made by the expert system during the diagnostic session, the language and terminology used (explanation of terms should be incorporated), the effective use of graphics, and the response time of the system to entries made by the user.

Statistical Process Control (SPC)

Statistical process control (SPC) is discussed in more detail in a later section of this chapter. Online SPC is a very good tool for monitoring if the process is operating normally or if something unusual is going on. Many DCS systems have the ability to automatically generate quality control charts. The operator has to decide what action to take if some abnormality is detected. This can be done using some type of Pareto analysis.

Online expert systems (or DCS-embedded expert systems, as they are sometimes called) offer the capability of doing this diagnosis automatically. The DCS can feed the current state of the process to the expert system at prespecified time intervals. Using the knowledge contained in the expert system, further analysis of the data can be performed to provide advice and guidance to the operator so that the operator can take appropriate action. This advice can be in the form of messages that appear on the operator's CRT console or can be printed out on a printer. This can be thought of as an intelligent alarm device that not only points to the abnormality in the system but also provides advice on possible causes and remedies.

Unfortunately, problems still exist in the implementation of such online expert systems. Plant characteristics change from time to time, which often requires an updating of the knowledge base in the expert system. Often, the knowledge needed for diagnosis is not available. Research is underway to overcome these deficiencies. One approach is to build systems that can acquire the needed knowledge automatically.

This falls under the domain of machine learning. There are two major issues here. The first issue is the large amount of data that is usually generated on a process from online sensors; the second is the ability to assimilate these numbers and reduce them to a form that can be used by an expert system. Some progress has been reported in solving both of these issues, but it may be awhile before such products appear on the market.

Artificial Neural Networks

Artificial neural networks (ANNs) represent an important information abstraction in modeling intelligence in process control. In a simplistic sense, neural networks may be thought of as a functional mapping of inputs connected to outputs through an interconnected network of nodes. The weights given to the node interconnections are varied to achieve the desired mapping.

The advantages of neural networks lie in their ability to learn arbitrary function mapping with little or no prior knowledge about the function itself. Thus, they provide the capability to do "blackbox modeling" of a process for which only input/output data are given. In addition, these networks have been shown to be robust, resilient, and capable of adaptive learning. The disadvantage of this model is that the knowledge is implicit in the network connection weights.

Neural networks are excellent at doing pattern classification. Recent applications in industry involve the use of neural networks as "virtual" or soft sensors to infer quality from readily available sensor data on a process. Pivoso and Owens at DuPont have reported two applications of ANNs in this category.[6] The first is in the area of predicting the composition of a two-polymer mixture from the mixture's infrared spectrum. The inputs to the network are 39 measurements of the mixture spectrum at different wavelengths, and the output is the concentration of the primary component in the mixture.

To train the network (i.e., to determine the network connection weights), training data are generated from spectra of mixtures whose composition is known. Various numerical algorithms are available to train the network, and commercial software packages that implement these schemes are available.[7,8]

Another application reported in Reference 6 is the use of ANN as a virtual sensor to predict periodically measured concentrations. In many processes a critical quality variable to be controlled can only be measured intermittently. At DuPont, historical data on temperature, pressure, and concentration were used to train a network to predict the concentration from temperature and pressure measurements. This trained network could then be used to provide continuous, online prediction of concentration for process control purposes. The error in prediction was reduced to 1/1000 of a linear regression estimator. This may be attributed to the ability of ANNs to map nonlinear functions.

Future Trends

Expert systems open a new dimension in the way computers can be used for process control. Expert systems technology is being integrated into the architecture of distributed control systems and networked programmable controller systems. In some instances, such as in the self-tuning PID controllers, this technology is already incorporated.

Current and future applications include sensor testing and validation, control system design validation, performance evaluation, diagnostics, online tuning of multivariable control systems, and statistical process control and analysis. Many manufacturers are incorporating expert systems as part of the packaged machinery that they manufacture. For example, a boiler maker may incorporate a troubleshooting and diagnostic expert system as part of the control system for the boiler. Such enhancements could give the manufacturer a competitive edge.

Fuzzy Logic and Neural Networks

The common characteristics of fuzzy logic and neural networks is that one does not need to know anything about the mathematical model of the process in order to utilize them. In a way it is like the tennis player who can hit the ball without an in-depth knowledge of Newton's laws of motion and how these laws apply to the tennis process. A fuzzy logic controller just mimics the operator (the tennis player) in its responses.

Neural networks are similar to fuzzy logic insofar that the mathematical model which relates the inputs to the outputs of the process need not be known. It is sufficient to know the process response (as in tennis). The major difference between fuzzy logic and neural networks is that neural networks can only be trained by data, not with reasoning. In fuzzy logic each controller parameter can be modified both in terms of its gain (its importance) and also in terms of its functions.

Neural Networks

Artificial neural networks (ANN) can be looked upon as tools for examining data and building relationships. AAN has found applications in the process industry for capturing relationships among measurements and modeling. Compared to the technology of expert systems, the technology of ANN is immature and still evolving.

Neural networks attempt to mimic the structures and processes of biological neural systems. They provide powerful analysis properties such as complex processing of large input/output information arrays, representing complicated nonlinear associations among data and the ability to generalize or form concepts/theory.

Neural networks are a tool to solve many complex problems. Although they are often deployed as stand-alone applications, they can also be integrated into overall solutions. They may be embedded within databases or expert system applications, act as preprocessors or postprocessors to other systems, or be linked in a distributed architecture.

Advantages of neural networks include:

- Their good fit for nonlinear models
- Ability to adapt, generalize, and extrapolate results
- Speed of execution in recall mode
- Ease of maintenance

However, neural nets have the following inherent disadvantages:

- Cannot alone handle constraints
- Cannot optimize
- Need lots of data
- Need lots of horsepower (CPU) in training (learning) session
- Are unpredictable for utilization in "untrained" areas
- Are not well understood and therefore are not yet widely accepted

Terminology A definition for artificial neural networks (ANN) is "A cognitive information processing structure model based upon models of brain function. It is a highly parallel dynamic system that can carry out information processing by means of state response to inputs."[9,10] A cynical definition may refer to neural networks as the ultimate "fudge factor" algorithm, as the feedforward neural network has the potential to approximate any nonlinear function.[11]

Neural networks obtain their name and some of their associated terminology through the analogy to the biological system. For example, neural networks are built of "neurons." They are also called "nodes" or "processing elements." "Nodes" are usually arranged in layers or slabs and are often connected to many nodes in other layers.

A "layer" is a set of nodes whose weights are actively manipulated, serving as a buffer between input or output or other layers. A "slab" is a set of nodes that may be different in terms of internal specifications or connectivity but that share the same layer. A single layer may consist of multiple slabs. The comparison of a basic unit of a neural network model (processing element) is shown alongside a biological representation of a neuron[12] in Figure 2.8f.

Each node processes the input it receives via these connections and provides a continuous analog value to other

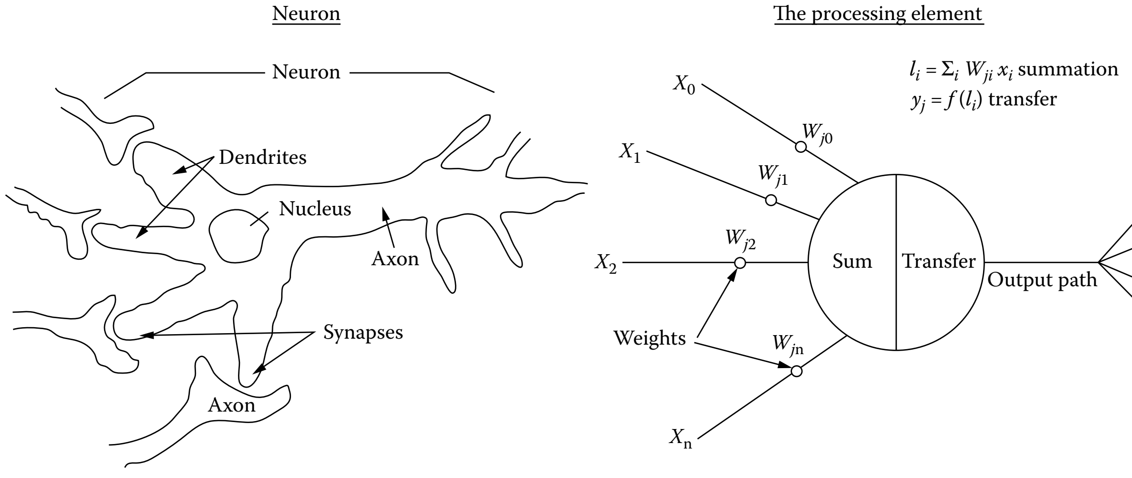

FIG. 2.8f
Neural net analogy with the brain.[12]

processing elements via its outgoing connections. As in biological systems, the strengths of these connections can change. Deciding how the processing elements in a network are connected, how the processing elements process their information, and how the connection strengths are modified all go into creating a neural network. Owing to the rapid progress of neural technology, today hundreds of different types of neural networks exist,[13] with more being added.

Traditional programming techniques, used for linear programs (LP) and other models, require that an algorithm be written to describe how the system should proceed. Data are fetched when needed for execution of the instructions, and the results are stored. All of these operations are performed in a deterministic and sequential manner. In contrast, neural networks consist of heavily interconnected processing elements that do not store information. The knowledge is stored by the way the processing elements are connected and by the importance of each connection, known as its weight. In contrast to being programmed, neural networks are trained. This means that examples are presented to the network, and the network adjusts itself by a specified learning rule (based on how correct the response is to the desired response). Therefore, many representative samples must be presented to a neural network in order for it to learn its rules for processing knowledge.

History The fundamental concepts of neural networks have existed since the 1940s,[14] with theoretical foundations laid down in the 1960s[15,16] and 1970s.[17] Research from the 1980s[18–22] and the early 1990s provides the basis of most neural network applications, (Section 2.1B discusses the most recent developments), as many groups are performing research into neural networks. These groups, each providing a different emphasis, insight, and motivation, include neuroscientists, cognitive psychologists, physicists, computer scientists, mathematicians, and engineers. The increasing power and inexpensive cost of computing has allowed development and deployment of systems for industrial applications.

Characteristics of Neural Networks A neural network processing element has many input paths. These inputs are individually multiplied by a weight and then summed. A nonlinear transfer function (also known as a squashing function) is applied to the result to calculate each processing element's output. The transfer function adds nonlinearity and stability to the network. It is supposed that the network has some global error function, E, associated with it, which is a differentiable function of all the connection weights. Common differentiable transfer functions include:

The sigmoid: where $f(z) = 1/(1 + e^{-z})$ **2.8(1)**

The hyperbolic tangent (tanh): where $f(z) = (1 - e^{-z})/(1 + e^{-z})$ **2.8(2)**

The linear: where $f(z) = z$ **2.8(3)**

The sine: where $f(z) = \sin(z)$ **2.8(4)**

Transfer functions used in other network types include:

The signum: where $$f(z) = 1 \quad \text{if } z > 0$$ $$= -1 \quad \text{if } z < 0 \qquad \textbf{2.8(5)}$$

The perceptron: where $$f(z) = z \quad \text{if } z > 0$$ $$= 0 \quad \text{if } z < 0 \qquad \textbf{2.8(6)}$$

Variations in how these transfer functions are fired determines the uniqueness of other types of networks. The sigmoid is the transfer function most often used in back-propagation networks. TanH is just a bipolar version of the sigmoid.

The output value of the transfer function is generally passed directly to the output path of the processing element (although exceptions to this exist). The output path is then connected to input paths of other processing elements through connection weights. These weights and connections form the "memory" or knowledge of the neural net. Since each connection has a corresponding weight, the signals on the input lines to a processing element are modified by these weights prior to being summed. Thus, the summation function is a weighted summation.

A neural network consists of many processing elements joined together. A typical network consists of a sequence of layers with full or random connections between successive layers. A minimum of two layers is required: the input buffer where data are presented, and the output layer where the results are held. However, most networks also include intermediate layers called hidden layers. Figure 2.8g shows a three-layer fully connected neural network.

Developing and Building Neural Networks The phases of a neural network life cycle[23,24] are concept, design, implementation, and maintenance.

Concept Phase The concept phase plans the approach to building the application. A strong emphasis is placed on experimentation. The user experiments under a multiple development environment in order to refine, redesign, and reformulate network parameters to achieve the best outcome. Successful applications for neural networks have several common characteristics. They include:

- Richness in historical data or examples
- Intensiveness of data and dependence upon several interacting parameters
- Incompleteness of data set, or a data set that contains errors or describes specific examples
- Unknown functions or expensive-to-discover solutions

The first step in implementing a neural network is to select a neural paradigm. Selection is based upon the traits of:

- Size (number of layers/number of slabs/number of nodes)
- Required output type (prediction/classification/association/conceptualization/filtering/optimization)

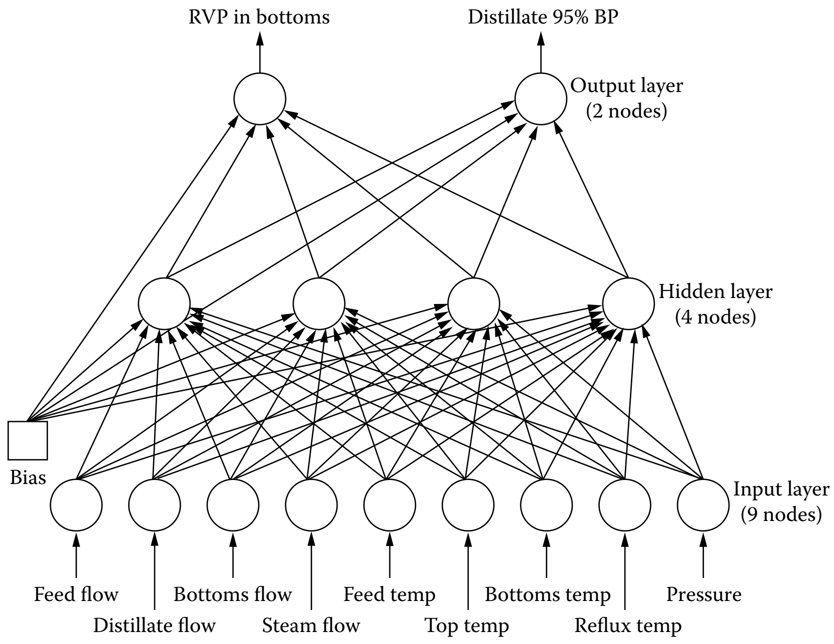

FIG. 2.8g
Example of a three-layer back-propagation network describing the application of physical property prediction.

- Associative memory classification (auto-/hetero-associative)
- Method of training (supervised/unsupervised)
- Time constraints (learning threshold limit)

Back-propagation neural networks have proven their applicability in chemical process control and have shown the ability to learn plant dynamics very well.[25] Two classic examples of a nonlinear relationship are the prediction of pH values in a stirred tank[26] and the predictions of physical properties (boiling points) of products from fractionators.[27] Other good applications include the use of neural networks to control systems,[28] including controller modeling[29] and process modeling.[30] Applications, therefore, should be based upon the following considerations:

- Conventional computing technology is inadequate.
- The problem requires qualitative or complex quantitative reasoning.
- The solution is derived from highly interdependent parameters that have no precise quantification.
- Data are readily available but multivariate and intrinsically noisy or error-prone.
- Project development time is short, but sufficient neural network training time is available.

Conversely, applications that are not suited for neural net solutions include:

- Mathematically accurate and precise applications (i.e., accounts receivable and inventory)
- Applications that require temporary data load, analysis, and reporting (i.e., sales data analysis and resource management)
- Applications that require deduction and stepwise logic

Design Phase The design phase specifies initial values and conditions for the selected neural paradigm. The type and number of processing elements, the number of slabs, the number of layers, the connectivity of the layers, the transfer function, the learning algorithm or rule, and other parameters such as momentum factor, learning threshold, learning coefficients, and learning schedules are design decisions that must be made.

The learning schedule is a breakpoint table that allows the learning coefficient to decay after a number of learning passes. The higher the value of the learning coefficient, the faster the learning. However, the higher the learning coefficient, the slower the convergence. Therefore, if the learning coefficient can be reduced as training proceeds, high learning and fast convergence can take place. The momentum factor acts as a low-pass filter on the weight differences that allows faster learning on low learning coefficients.

Other features to expedite convergence include algorithms for random weight generation, introduction of noise as the network learns, and algorithms to jog the weights randomly. Some neural paradigms constrain the choices or provide defaults, while other paradigms are very flexible and require numerous decisions.

Hidden layers act as layers of abstraction and help the network generalize and even memorize. Increasing the number of hidden layers augments the processing power of the neural network but also significantly increases and complicates training by requiring more training examples. Generally, most process control applications require only one hidden layer. Multiple parallel slabs within a layer may help to increase a network's processing power. This architecture forces the extraction of different features simultaneously. A common method of determining whether multiple layers or multiple slabs improve the performance of a network is experimentation.

Determining the number of nodes in a hidden layer is another experimental exercise. Rules of thumb give a starting point. One suggestion[23] is that if one hidden layer is chosen, the number of processing elements may be equal to 75% of the size of the input layer. Another suggestion is that the number of hidden nodes equals twice the square root of the sum of the number of input and output characteristics, rounded down to the nearest integer.[31] Using the amount of training data to set an upper bound for number of processing elements in the hidden layer has been promoted[12] according to the following equation:

$$h = \frac{\text{number of data sets}}{X(m+n)} \tag{2.8(7)}$$

where

h = number of processing elements in the hidden layer
m = number of processing elements in the output layer
n = number of processing elements in the input layer
X = noise factor—usually 2 to 10, where 10 is relatively noisy and 2 is very clean (extremely noisy data could require a number as high as 50 or 100)

In general, the more complex the relationship, the more processing elements are required in the hidden layer. Too few nodes in the hidden layer prevent the network from properly mapping inputs to outputs. On the other hand, too many nodes promote memorization and inhibit generalization. Memorization occurs when the patterns presented to the network are reproduced exactly without extracting the salient features. The network is then unable to process new patterns correctly because it has not discovered the proper relationships.

Depending upon the number of total nodes in a network, a sufficient number of training sets must be provided in order to train the system adequately. Otherwise, the situation is the same as trying to fit a third-order polynomial with two data points, where an infinite number of sets of polynomial constants can satisfy the equation. The situation of underspecification due to a lack of sufficient training examples is probably the single most common cause of problems for deployed networks.

Implementation Phase As many training data as possible need to be collected. Instead of volume, the quality and representativeness is important. A good training set will contain routine, unusual, and boundary condition cases. Preparing the data is an important consideration.[32] It includes:

- Transforming inputs into the proper form (ratios, classes) and data types (binary, bipolar, continuous)
- Preprocessing
- Converting the data to ASCII or binary vectors
- Normalizing (Euclidean, logarithmic) the data
- Scaling

The data may need to be converted into another form to be meaningful to the neural network. Likewise, how the data are represented and translated plays an important role in the network's ability to understand during training. Data may be continuous or binary, time-oriented or static. Data can be naturally grouped, may be represented as actual amounts or changes in amounts, or may be evenly or unevenly distributed over the entire range. When naturally occurring groups appear, binary categories are often the best method for making correlations.

Continuous data should not be used to represent unique concepts, however. When values are very continuous, artificially grouping them may hinder the network from distinguishing values on or near the border between two groups. At any rate, all data need to be normalized in order for the transform function to operate. Data may be scaled between minimum and maximum ranges or be set within a predefined range.

Implementing the neural network involves applying the design criteria using customized or commercial environments. Experimentation is carried out with learning coefficients, momentum factors, noise injection, etc., in order to train the network most efficiently. Because of the nature of some learning algorithms, the method of presenting the training data can also affect the training results.

Testing the neural network is required to verify the training process. Often the network is trained on one set of data (training data) and verified with a different set of data (recall data). Many statistical tools can help determine the degree to which the network produces the correct outputs. It can then be determined whether the sizes of the layers need to be changed and whether the learning parameters need to be adjusted.

Training three or four neural networks using the same paradigm is one common approach to verify training.

Another form of testing involves analyzing the actual weights of the network. Very small weights indicate that the processing elements are not influencing the outcome of the network. These nodes could then be eliminated and the network retrained in order to simplify the overall network configuration. Large weights may indicate too much dependence upon a particular input, indicating some degree of memorization.

Maintenance Phase Once a network is trained on a set of data, it is deployed to predict results based upon new sets of gathered data. Maintenance involves modifying the deployed neural network application because of decreasing accuracy due to conditions encountered for which the network was not trained. In such cases, the training set must either be modified or replaced. Next, the network must undergo retraining and reevaluation in an iteration of the implementation phase. If reevaluation shows that the network performance is not to specification with the new data set, the design phase must be repeated.

Back-Propagation Example The back-propagation network is the most popular feedforward predictive network deployed in the process industries. The back-propagation network assumes that all processing elements and connections are somewhat responsible for the difference between the expected output and the actual output. It uses the chain rule of derivative calculus to allocate the prediction error to every node in the feedforward network.[9] This error is propagated from the output layer back to the input layer through the connections to the previous layer. The process is repeated until the input layer is reached. The training algorithm is an iterative gradient descent algorithm designed to minimize the root mean square error (RMS) between the actual output and the desired output. It requires a continuous differentiable nonlinear search space.

Consider a fractionation example, where the product specifications are based on the Reid vapor pressure in the bottom product and on the 95% boiling point of the distillate. Process analyzers have inherent dead time in producing these measurements, or analyzers are not available to provide these measurements. Process models can be used to predict these properties, or other measurements can be used to infer them.

However, if data exist regarding the measurements around the fractionator based on collected laboratory or analyzer results, as commonly recorded on log sheets, a nonlinear neural network model can be built. Shown in Figure 2.8g is a back-propagation model with nine input nodes, four hidden nodes, and two output nodes with bias. Training a back-propagation network that uses the methodology represented in Figure 2.8h can be summarized as follows:

Step 1: All weights and processing element offsets are set to small random values.

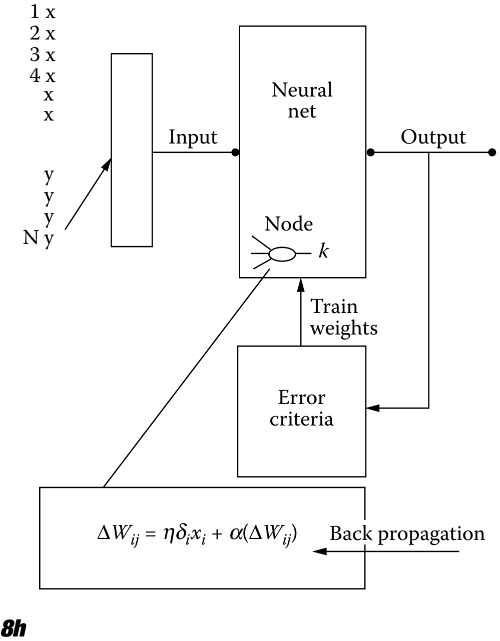

FIG. 2.8h
Back-propagation training.

Step 2: All inputs and outputs are normalized and presented to the network. Normalization is generally based upon expected minimum and maximum values.

Step 3: A transfer function (also known as a squashing function) is applied to the weighed sum of the normalized inputs at each processing element to calculate each processing element's output. The sigmoid is an often-used transfer function. TanH is a bipolar version of the sigmoid and is used when the output tends to saturate ("saturation" is when many transformed values congregate toward the upper or lower limit).

Step 4: A recursive algorithm starting at the output processing elements is used and repeated until the input processing elements are reached. The weights are adjusted by the equation below:

$$W_{ij}(t+1) = W_{ij}(t) + hd_j x_i \qquad \textbf{2.8(8)}$$

where

$W_{ij}(t)$ = the weight from hidden node i or from an input to node j at time t
x_i = either the output of node i or an input
h = a gain term
d_j = an error term for node j

Since the error term is

$$d_j = dE/dx_j \qquad \textbf{2.8(9)}$$

where E is the difference between the desired output and the actual output, using the sigmoid function gives

$$f(x) = 1/(1+e^{-x})^{-1} \qquad \textbf{2.8(10)}$$

which gives

$$dE/dx_j = x_j(1 - x_j) \qquad \textbf{2.8(11)}$$

If node j is an output node, then

$$d_j = y_i(1 - y_i)(d_j - y_i) \qquad \textbf{2.8(12)}$$

where d_j is the desired output of node j and y_i is the actual output.

If node j is a hidden node, then

$$d_j = x_j(1 - x_j)\sum d_k w_{jk} \qquad \textbf{2.8(13)}$$

where k is over all nodes in the layers before node j.

Internal node thresholds are adapted in a similar manner by assuming they are connection weights on links from auxiliary constant-valued inputs. Convergence is sometimes faster if a momentum term is added and weight changes are smoothed by the following equation:

$$W_{ij}(t+1) = W_{ij}(t) + hd_j x_i + a(W_{ij}(t) - W_{ij}(t-1)) \qquad \textbf{2.8(14)}$$

where $0 < a < 1$.

As with any gradient descent method, back-propagation could find a local minimum instead of the global minimum. The momentum term is designed to help the training algorithm overcome the small valleys of local minimums. The learning procedure requires that the change in weights be proportional to rate of change of error, with respect to changes in weights. The constant of proportionality is called the learning rate, h (or learning coefficient). The larger the value of h, the faster the learning rate.

Step 5: Repeat by going to step 2 until convergence is reached. Convergence will be when the RMS error reaches a user-set threshold value.

The initial choice of weights is very important to convergence. Small random numbers should be used and equal weights should be avoided. It is possible for the system to require many iterations before convergence: 10,000 to 100,000 iterations are not uncommon.

SUMMARY

As with expert systems, several good neural shells have come onto the market.[33] These shells offer a very good method of organizing and implementing an application. Neural networks are a tool for solving many complex problems. They can be deployed as stand-alone applications or integrated into overall solutions. They may be embedded within databases or expert system applications,[34,35] act as preprocessors or postprocessors to other systems, or be linked in a distributed architecture.

As a preprocessor, networks have been used to identify objects within an image and pass that information to an expert system. As a postprocessor, neural networks can remove noise, classify patterns, and make predictions from a database. Neural networks, combined with statistical validation, have also been introduced as viable solutions for the control of manufacturing facilities.[36]

2.9 Feedback and Feedforward Control

M. F. HORDESKI (1985) **B. G. LIPTÁK** (1995) **F. G. SHINSKEY** (1970, 2005)

Feedback control is the action of moving a manipulated variable *m* in response to a deviation or error *e* between the controlled variable *c* and its set point *r* in such a way as to reduce, or if possible, to eliminate the error. Feedback control cannot anticipate and thereby prevent errors, because it can only initiate its corrective action *after* an error has already developed. Because of dynamic lags and delays in the response of the controlled variable to manipulation, some time will elapse before the correction will take effect. During this interval, the deviation will tend to grow, before eventually diminishing. Feedback control cannot therefore achieve perfect results; its effectiveness is limited by the responsiveness of the process to manipulation. By contrast, feedforward correction can be initiated as soon as any change is detected in a load variable as it enters the process; if the feedforward model is accurate and the load dynamics are favorable, the upset caused by the load change is canceled before it affects the controlled variable. Because feedforward models and sensors are both imperfect, feedforward loops are usually corrected by feedback trimming.

FEEDBACK CONTROL

The purpose of any process control system is to maintain the controlled variable at a desired value, the set point, in the face of disturbances. The control system regulates the process by balancing the variable load(s) with equivalent changes in one or more manipulated variables. For the controlled variable to remain stationary, the controlled process must be in a balanced state.

Regulation through feedback control is achieved by acting on the change in the controlled variable that was induced by a change in load. Deviations in the controlled variable are converted into changes in the manipulated variable and sent back to the process to restore the balance. Figure 2.9a shows the backward flow of information from the output of the process back to its manipulated input. The load *q* is a flow of mass or energy entering or leaving a process, which must be balanced by an equal flow leaving or entering. It may have more than one component—for example in a temperature loop, both the flow and temperature of a stream are components of its energy demand, but they may be balanced by a single manipulated variable such as steam flow. The steady-state gain *K* and dynamic gain vector **g** in the paths of the manipulated and load variables may differ, and therefore have been given different subscripts *m* and *q*.

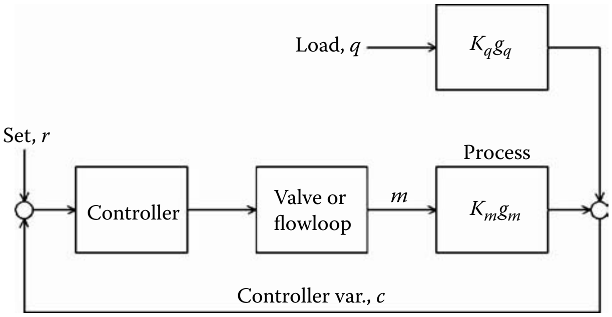

FIG. 2.9a
Load changes can enter through different gain and dynamics from the controller output.

Limitations of Feedback Control

Feedback, by its nature, is incapable of correcting a deviation in the controlled variable at the time of detection. In any process, a finite delay exists between a changing of the manipulated variable and the effect of the change on the controlled variable. Perfect control is not even theoretically attainable because a deviation in the controlled variable must appear before any corrective action can begin. In addition, the value of the manipulated variable needed to balance the load must be sought by trial and error, with the feedback controller observing the effect of its output on the controlled variable.

Best-Possible Feedback Control

An absolute limitation to the performance of a feedback control loop is imposed by any deadtime in the loop. Figure 2.9b describes the results of a step-load change applied to a process whose dynamics consist of deadtime and a single lag in both the load path $\mathbf{g}_q$ and the manipulated-variable path $\mathbf{g}_m$. The time scale is given in units of deadtime τ_d in the path of the manipulated variable. To simplify the illustration, the deadtimes in both paths are identical (this is not essential—*any*

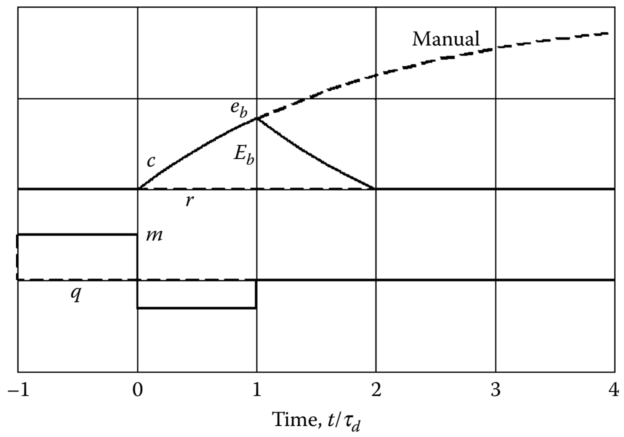

FIG. 2.9b
The best-possible load response for a process having deadtime and a single lag.

deadtime in the load path, or none, will produce the same response, simply shifting its location in time). Also for simplification, the steady-state gains in both paths are made equal.

At time –1, a step decrease in load q enters the process. After the deadtime in the load path expires, at time zero, the controlled variable c responds, beginning to rise along an exponential curve determined by the gain and lag in the load path. If the controller were left in Manual, it would continue to a new steady state. In this example, K_q is 2.0, leaving the final value of c in Manual having changed twice as much as load q; the time constant τ_q of the load lag in this example is $2.0\tau_d$.

Also shown is the possible return trajectory of c to set point r if the manipulated variable m were to step as soon as any deviation is detected, i.e., at time zero, by an amount

$$\Delta m = \Delta q(K_q/K_m)(1+\varepsilon^{-\tau_d/\tau_q}) \qquad \textbf{2.9(1)}$$

where ε is the exponential operator 2.718. This move turns out to be the best that is possible by a feedback controller,[1] as it causes the deviation to decay to zero during the next deadtime. The peak deviation reached during this excursion is

$$e_b = \Delta q K_q(1-\varepsilon^{-\tau_d/\tau_q}) \qquad \textbf{2.9(2)}$$

At the time the peak is reached, the controller output must be stepped to match the new steady-state load.

The leading edge of the curve, i.e., up to time 1.0, is determined completely by the load step and the gain and dynamics in its path; the trailing edge is determined by the controller and its tuning. The leading and trailing edges of the best response are complementary, so that the area that they enclose is

$$E_b = e_b\tau_d = \Delta q K_q \tau_d(1-\varepsilon^{-\tau_d/\tau_q}) \qquad \textbf{2.9(3)}$$

These values of e_b and E_b are the *best* that can be obtained for any feedback controller on a process whose dynamics consist of deadtime and a single lag. A real controller will yield a somewhat larger peak deviation and an area at least twice as great, depending on its modes and their tuning. If the process contains two or more lags, the value of E_b remains the same as estimated above but is more difficult to approach with a real controller.

Integrated Error

The actual effectiveness of feedback control depends on the dynamic gain of the controller, which is a function of its control modes and their tuning. Although a high controller gain is desirable, the dynamic gain of the closed loop at its period of oscillation must be less than unity if the loop is to remain stable. In effect, then, the dynamic gain of the process dictates the allowable dynamic gain of the controller.

For each process and controller, optimum settings exist that minimize some objective function such as Integrated Absolute Error (IAE). However, most controllers are not tuned optimally, for various reasons, such as process nonlinearities. Therefore, controller performance needs to be stated in terms of the actual settings being used. As an example, the integrated error produced by a load change to a process under ideal Proportional-Integral-Derivative (PID) control will be evaluated based only on its mode settings. The controller output m_1 at time t_1 is related to the deviation e_1 between the controlled variable and its set point by

$$m_1 = \frac{100}{P}\left(e_1 + \frac{1}{I}\int_{t_0}^{t_1} e\,dt + D\frac{de_1}{dt}\right) + C \qquad \textbf{2.9(4)}$$

where P, I, and D are the percent Proportional Band, Integral time and Derivative time, respectively, and C is the output of the controller at time, t_0 when it was first placed in Automatic. Let t_1 be a steady state, so that $e_1 = 0$ and its derivative is also zero.

Then a load change arises, causing the controller to change its output to return the deviation to zero. When a new steady state is reached, the controller will have an output m_2:

$$m_2 = \frac{100}{P}\left(e_2 + \frac{1}{I}\int_{t_0}^{t_2} e\,dt + D\frac{de_2}{dt}\right) + C \qquad \textbf{2.9(5)}$$

where e_2 and its derivative are again zero.

The difference in output values between the two steady states is

$$\Delta m = m_2 - m_1 = \frac{100}{PI}\int_{t_1}^{t_2} e\,dt \qquad \textbf{2.9(6)}$$

Solving for the integrated error:

$$E = \int_{t_1}^{t_2} e\,dt = \Delta m\frac{PI}{100} \qquad \textbf{2.9(7)}$$

For any sustained load change, there must be a corresponding change in the controller output, and in fact the current load is often reported as the steady-state controller output. The wider the proportional band and the longer the integral time, the greater will be the integrated error per unit load change. (While the derivative setting does not appear in the integrated-error function, its use allows a lower integral time than is optimum for a PI controller.) Therefore, loops with controllers having large PI products are candidates for feedforward control.

FEEDFORWARD CONTROL

Feedforward provides a more direct solution to the control problem than finding the correct value of the manipulated variable by trial and error, as occurs in feedback control. In the feedforward system, the major components of load are entered into a model to calculate the value of the manipulated variable required to maintain control at the set point. Figure 2.9c shows how information flows forward from the load to the manipulated variable input of the process. The set point is used to give the system a command. (If the controlled variable were used in the calculation instead of the set point, a positive feedback loop would be formed.)

A system, rather than a single control device, is normally used for feedforward loops because it is not always convenient to provide the computing functions required by the forward loop with a single device or function. Instead, the feedforward system consists of several devices if implemented in hardware or several blocks of software if implemented digitally. The function of these blocks is to implement a mathematical model of the process.

Load Balancing

A dynamic balance is required to keep the control variable at set point. It is achieved by solving the process material- and/or energy-balance equations continuously. When a change in load is sensed, the manipulated variable is automatically adjusted to the correct value at a rate that keeps the process continually in balance. Although it is theoretically possible to achieve such perfect control, in practice the system cannot be made to duplicate the process balance exactly.

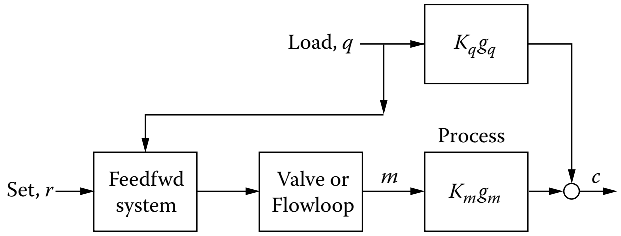

FIG. 2.9c
Feedforward calculates the value of the manipulated variable based on current load and set point.

The material- and energy-balance equations are not usually difficult to write for a given process. Variations in nonstationary parameters such as heat-transfer and mass-transfer coefficients do not ordinarily affect the performance of a feedforward system. The load components are usually inflow or outflow when level or pressure is to be controlled, feed flow and feed composition where product composition is to be controlled, and feed flow and temperature where product temperature is to be controlled. Flow is the primary component of load in almost every application because it can change widely and rapidly. Composition and temperature are less likely to exhibit such wide excursions, and their rate of change is usually limited by upstream capacity. In most feedforward systems these secondary load components are left out; their effects are accommodated by the feedback controller.

The output of a feedforward system should be an accurately controlled flow rate, if possible. This controlled flow rate cannot usually be obtained by manipulating the control valve directly, since valve characteristics are nonlinear and inconsistent, and the delivered flow is subject to such external influences as upstream and downstream pressure variations. Therefore, most feedforward systems depend on some measurement and feedback control of flow to obtain an accurate manipulation of the flow rate. Only when the range of the manipulated variable exceeds that which is available in flowmeters, or the required speed of response exceeds that of a flow loop, should one consider having the valves positioned directly, and in such cases care must be taken to obtain a reproducible response.

Steady-State Model

The first step in designing a feedforward control system is to form a steady-state mathematical model of the process. The model equations are solved for the manipulated variable, which is to be the output of the system. Then the set point is substituted for the controlled variable in the model.

This process will be demonstrated by using the example of temperature control in a heat exchanger (Figure 2.9d).[2] A liquid flowing at rate W is to be heated from temperature T_1 to controlled temperature T_2 by steam flowing at rate W_s. The energy balance, excluding any losses, is

$$WC_p(T_2 - T_1) = W_s\lambda \qquad \textbf{2.9(8)}$$

Coefficient C_p is the heat capacity of the liquid and λ is the latent heat given up by the steam in condensing. Solving for W_s yields

$$W_s = WK(T_{2\text{set}} - T_1) \qquad \textbf{2.9(9)}$$

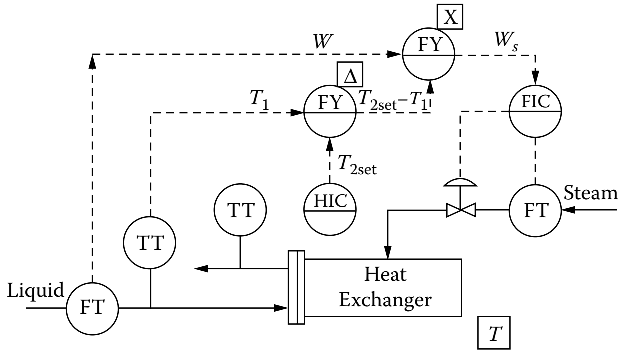

FIG. 2.9d
Steam flow is calculated here to satisfy the steady-state heat balance.

where $K = C_p/\lambda$, set point T_{2set} replaces T_2, and W and T_1 are load components to which the control system must respond.

Note that this energy balance is imperfect, because it disregards minor loads such as the heat losses to the environment and any variations in the enthalpy of the steam. Another factor is that even the two major loads cannot be measured perfectly, as there are no error-free sensors of flow and temperature. The net result is a model that is approximately an energy balance around this process.

An implementation of Equation 2.9(9) is given in Figure 2.9d. A control station introduces T_{2set} into the difference block [Δ] where input T_1 is subtracted. The gain of this block is adjusted to provide the constant K. Its output is then multiplied by the liquid flow signal W to produce the required set point for steam flow.

During startup, if the actual value of the controlled variable does not equal the set point, an adjustment is made to gain K. Then, after making this adjustment, if the controlled variable does not return to the set point following a change in load, the presence of an error in the system is indicated. The error may be in one of the calculations, a sensor, or some other factor affecting the heat balance that was not included in the system. Heat losses and variations in steam pressure are two possible sources of error in the model. Since any error can cause a proportional offset, the designer must weigh the various sources of error and compensate for the largest or most changeable components where practical. For example, if steam pressure variations were a source of error, the steam flowmeter could be pressure compensated. Because of all these errors, feedforward control as shown in Figure 2.9d is seldom used without feedback trim. Later in this section, a feedback controller will be added to automatically correct the loop for the errors in the model.

Dynamic Model

With the feedforward model as implemented in Figure 2.9d, a step decrease in liquid flow results in a simultaneous and proportional step decrease in steam flow. Transient errors following a change in load are to be expected in feedforward control systems. Two typical dynamic responses of the controlled variable are shown in Figure 2.9e; the offset in the dashed curve results from a 10% error in the static calculations.

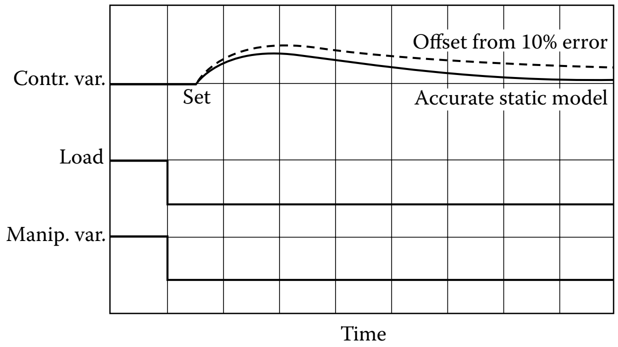

FIG. 2.9e
The dynamic response of the uncompensated feedforward system when the controlled variable responds faster to changes in load than to changes in manipulated flow.

If there is no static error, the temperature returns to set point eventually. However, the dynamic balance is missing. The decreased steam flow does not result in an instantaneous decrease in heat-transfer rate, because the temperature difference across the heat-transfer surface must first be decreased, and this requires a decrease in shell pressure. The lower shell pressure at lower loads means that the shell contains less steam as the load decreases. Since the static feedforward system does not overtly lower the steam inventory in the shell, it is lowered through a lagging heat-transfer rate, resulting in a transient rise in exit temperature on a falling load; conversely, a transient temperature drop follows a rising load. This transient error reveals a dynamic imbalance in the system—on a drop in load, the exchanger temporarily needs less heat than the steam flow controller is allowing. In order to correct the transient temperature error, a further cutback in the flow of energy must be applied to the exchanger beyond what is required for the steady-state balance.

A more general explanation is provided through the use of Figure 2.9f. This figure shows the load and the manipulated

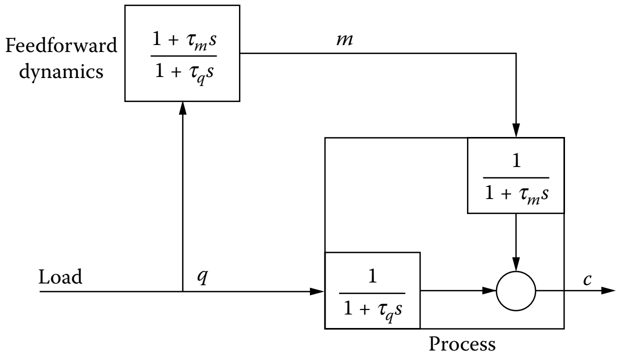

FIG. 2.9f
A feedforward dynamic model for a general process.

variable as entering the process at different points, where they encounter different dynamic elements. In the heat-exchanger example, the liquid enters the tubes while the steam enters the shell. The heat capacities of the two locations are different. As a result, the controlled variable (the liquid temperature) responds more rapidly to a change in liquid flow than to a change in steam flow. Thus, the lag time of the load input is less than that of the manipulated variable.

The objective of the feedforward system is to balance the manipulated variable against the load, providing the forward loop with compensating dynamic elements. Neglecting steady-state considerations, Figure 2.9f shows what the dynamic model must contain to balance a process having parallel first-order lags. The lag time τ_q of the load input must be duplicated in the forward loop, and the lag time τ_m in the manipulated input of the process must be cancelled. Thus the forward loop should contain a lag divided by a lag. Since the inverse of a lag is a lead, the dynamic compensating function is a *lead-lag*. The lead time constant should be equal to τ_m, and the lag time constant should equal τ_q. In the case of the heat exchanger, the fact that τ_m is longer than τ_q causes the temperature rise on a load decrease. This is the direction in which the load change would drive the process in the absence of control.

In transfer function form, the response of a lead-lag unit is

$$G(s) = \frac{1+\tau_1 s}{1+\tau_2 s} \qquad \textbf{2.9(10)}$$

where τ_1 is the lead time constant, τ_2 is the lag time constant, and s is the Laplace operator.

The frequency response of a feedforward loop is usually not significant, since forward loops cannot oscillate. The most severe test for a forward loop is a step change in load. The response of the lead-lag unit output y to a step in its input x is

$$y(t) = x(t)\left(1+\frac{\tau_1-\tau_2}{\tau_2}\varepsilon^{-t/\tau_2}\right) \qquad \textbf{2.9(11)}$$

Its maximum dynamic gain (at $t = 0$) is the lead/lag ratio τ_1/τ_2. The response curve then decays exponentially from this maximum at the rate of the lag time constant τ_2, with 63.2% recovery reached at $t = \tau_2$ as shown in Figure 2.9g. The figure shows some deadtime compensation added to the lead-lag function—however, it is not required for the heat exchanger.

When properly adjusted, the dynamic compensation afforded by the lead-lag unit can produce the controlled variable response having the form shown in Figure 2.9h. This is a signature curve of a feedforward-controlled process — since most processes do not consist of simple first-order lags, a first-order lead-lag unit cannot produce a perfect dynamic balance. Yet a major reduction in peak deviation is achieved over the uncompensated response, and the area can be equally distributed on both sides of the set point.

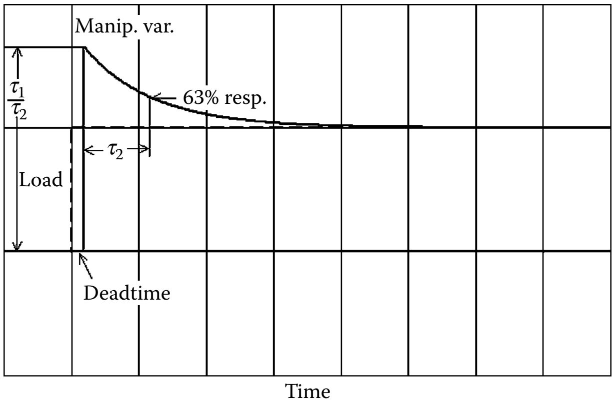

FIG. 2.9g
The step response of a lead-lag unit with deadtime compensation.

The lead-lag unit is applied to the flow signal as $[f(t)]$ in Figure 2.9i. Its settings are particular to that load input, and therefore it must be placed where it can modify that signal and no other. No dynamic compensator is included for T_1, as it is not expected to change quickly.

Tuning the Lead-Lag Unit First, a load change should be introduced without dynamic compensation by setting the lead and lag time constants at equal values or zero to observe the direction of the error. If the resulting response is in the direction that the load would drive it, the lead time should exceed the lag time; if not, the lag time should be greater. Next, measure the time required for the controlled variable to reach its maximum or minimum value. This time should be introduced into the lead-lag unit as the smaller time constant. Thus, if the lead dominates, this would be the lag setting. For example, in Figure 2.9e the temperature responds in the direction the load would drive it, and therefore the lead time setting should exceed the lag time setting. The time required for the temperature in Figure 2.9e to rise to its peak should be set equal to the smaller time constant, in this case equal to the lag time setting. Set the greater time constant at twice

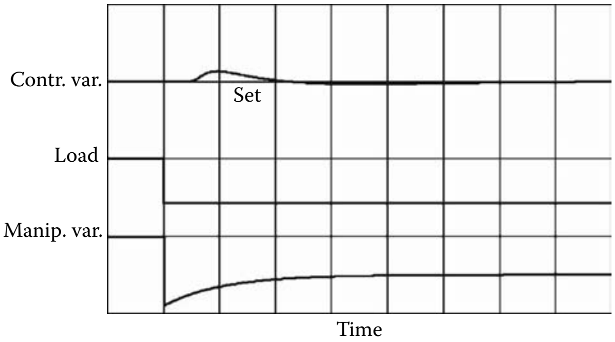

FIG. 2.9h
The typical step response of a dynamically compensated feedforward system.

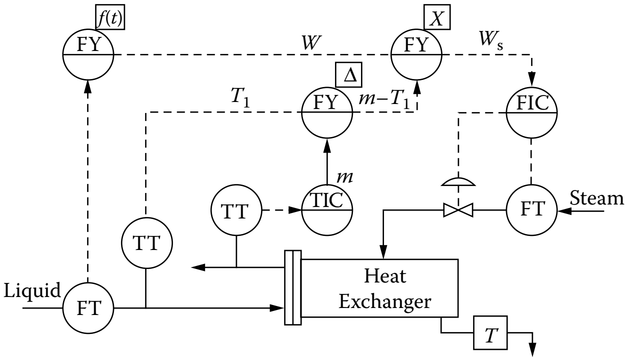

FIG. 2.9i
Feedforward–feedback control of the heat exchanger, with dynamic compensation.

this value and repeat the load change. If the peak deviation is reduced, but the curve is still not equally distributed around the set point, increase the greater time constant and repeat the load change.

The area (integrated error) of the response curve will be equally distributed about the set point if the difference between the lead and lag settings is correct. Once this equalization is obtained, both settings should be increased or decreased with their difference constant until a minimum error amplitude is achieved. When the controller is properly tuned, the steam energy equivalent of the transient (area between temperature and its set point) in Figure 2.9e should match the extra steam introduced (area above input step change) in Figure 2.9g.

If there is a significantly greater deadtime in the load path than in the manipulated-variable path, deadtime compensation may be added, which will reduce the peak deviation. However, if the deadtime in the manipulated-variable path is the longer of the two, exact compensation is impossible, and this is the case in the heat exchanger. Still, careful adjustment of the lead-lag compensator can result in zero integrated error.

Adding a Feedback Loop

Any offset resulting from steady-state errors can be eliminated by adding feedback. This can be done by replacing the feedforward set point with a controller, as shown in Figure 2.9i. The feedback controller adjusts the set point of the feedforward system in cascade, while the feedforward system adjusts the set point of the manipulated flow controller in cascade.

The feedback controller should have the same control modes as it would without feedforward control, but the settings need not be as tight. The feedback controller reacts to a disturbance by creating another disturbance in the opposite direction one-half cycle later. However, the feedforward system positions the manipulated variable so that the error in the controlled variable disappears. If acted upon by a tightly set feedback controller, the correct position calculated by feedforward will be altered, producing another disturbance that prolongs the settling time of the system.

The feedback controller must have the integral mode to eliminate any steady-state offset that might be caused by errors in the sensors, the model, or the calculations. However, the integrated error it sustains following a load change is markedly reduced compared to what it would be following a load change without feedforward. Now its output changes only an amount equal to the change in the *error* in the feedforward calculation. For small load changes, this change in error would approach zero, leading to an integrated error of zero, with or without dynamic compensation. In the presence of feedback, but without dynamic compensation, the transient in Figure 2.9e would be balanced by a following transient on the other side of set point, until the area is equalized. This usually prolongs the response without reducing the peak deviation. The dynamic compensator therefore needs to be tuned with the feedback controller in manual, to approach zero integrated error before adding feedback.

Linear and Bilinear Feedforward Systems

The relationship shown in the energy balance of Equation 2.9(8) is *bilinear*: steam flow is related to both liquid flow and to temperature rise in a linear manner, but as their product rather than their sum or difference. This distinction is crucial to the successful functioning of feedforward control because a bilinear system has variable gains. The feedforward gain—the ratio of steam flow to liquid flow—varies directly with the required temperature rise. This variable gain is accommodated in the system by the multiplier [×].

If inlet temperature were to vary so slowly that it did not require feedforward compensation or if it were not measured, then feedforward from flow alone would be required. Yet the required feedforward gain—the ratio W_s/W—would vary directly with $T_{2\text{set}} - T_1$. If either $T_{2\text{set}}$ or T_1 were to change, the feedforward gain should change with it. For a bilinear process, then, a linear feedforward system having a constant gain is a misfit—it is accurate at only one combination of secondary load and set point. To be sure, feedback control can trim any errors in the feedforward calculation and return the deviation to zero. But if the error is in the gain term, the feedback controller should adjust the feedforward gain, through a multiplier—otherwise the gain will be incorrect for all subsequent flow changes, resulting in only partial feedforward correction or even overcorrection.

Eliminating inlet temperature as a variable in Figure 2.9i also eliminates the difference block [Δ]. The controller output m then goes directly to the multiplier, and in reducing the temperature deviation to zero, m will assume a value representing $K(T_{2\text{set}} - T_1)$. If either $T_{2\text{set}}$ or T_1 were then to vary, the feedback controller would respond to the resulting deviation by changing its output until the deviation returns to zero. In so doing, it has changed the gain of the multiplier to the new value of $K(T_{2\text{set}} - T_1)$.

Control of composition is also a bilinear process. The required ratio of two flows entering a blender, for example, is a function of their individual compositions and that of the blend. Similarly, the ratio of product flow to feed rate or steam flow to feed rate in a distillation column or evaporator also varies with feed and product compositions. In general, temperature and composition loops are bilinear, and their flow ratios should always be adjusted through a multiplier. By contrast, pressure and level loops are linear, and their feedforward gain can be constant. An example of the latter is three-element drum-level control, where each unit of steam removed from the drum must be replaced by an equal unit of feedwater—the feedforward gain is constant at 1.0.

This distinction is crucial because many "advanced" multivariable control systems are based on a linear matrix with constant coefficients. The plant is tested to develop the coefficients that relate the variables, and the control matrix is built from these results. When the plant operating conditions move away from the original test conditions, the fixed coefficients in the control matrix may no longer represent the process relationships accurately, degrading the performance of the feedforward loops. This may require frequent retesting and recalibration of the matrix. Some multivariable systems contain multiple matrices, each corresponding to its own set of operating conditions and switched into service when those conditions develop.

Self-tuning feedforward control[3] is also available, applied either in a linear (additive) or bilinear (multiplicative) manner, as configured manually. The parameters that are tuned adaptively are the steady-state gain and a lag compensator. The steady-state gain is adjusted to minimize integrated error following a change in measured load, and the lag is adjusted to minimize integral-square error. Load changes must be sharp, clean steps, with settling time allowed between them, for tuning to proceed effectively. But once tuned, random disturbances can be accommodated. However, self-tuning is only recommended where precise modeling and flow control are unavailable.

Performance

The use of feedback in a feedforward system does not detract from the performance improvement that was gained by feedforward control. Without feedforward, the feedback controller was required to change its output to follow all changes in load. With feedforward, the feedback controller must only change its output by an amount equal to what the feedforward system fails to correct. If a feedforward system applied to a heat exchanger could control the steam flow to within 2% of that required by the load, the feedback controller would only be required to adjust its output to compensate for 2% of a load change, rather than the full amount. This reduction of Δm in Equation 2.9(7) by 50/1 results in the reduction of E by the same ratio. Reductions by 10/1 in errors resulting from load changes are relatively common, and improvements of 100/1 have been achieved in some systems.

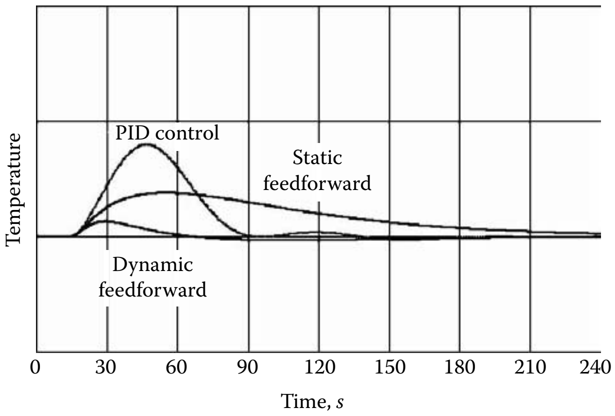

FIG. 2.9j
Comparison of feedforward control of a heat exchanger against optimally tuned PID feedback control.

Figure 2.9j illustrates the control performance of a steam-heated exchanger that has experienced a step decrease in process flow. The static feedforward model reduces the peak deviation substantially but extends settling time and does not improve on the integrated error. Dynamic compensation is seen to be essential in maximizing performance in this example. It is not perfect because the deadtime in the path of the manipulated variable is somewhat longer than that in the load path, and that lost time cannot be made up. Still, the lead-lag compensator has been tuned to eliminate any integrated error.

The feedforward system is more costly and requires more engineering effort than a feedback system does, so prior to design and installation, the control improvement it brings must be determined to be worthwhile. Most feedforward systems have been applied to processes that are very sensitive to disturbances and slow to respond to corrective action and to product streams that are relatively high in value. Distillation columns of 50 trays or more have been the principal systems controlled with this technology. Boilers, multiple-effect evaporators, direct-fired heaters, waste neutralization plants, solids dryers, compressors, and other hard-to-control processes have also benefited from feedforward control.

Variable Parameters

Heat exchangers are characterized by gain and dynamics that vary with flow. The settings of both the PID controller and the feedforward compensator that produced the results shown in Figure 2.9j were optimized for the final flow and would not be optimum for any other flow. Differentiation of the heat-balance equation, Equation 2.9(8), shows the process gain to vary inversely with process flow W:

$$\frac{dT_2}{dW_s} = \frac{\lambda}{WC_p} \qquad 2.9(12)$$

If PID control alone is applied, this gain variation can be compensated through the use of an equal-percentage steam valve, whose gain varies directly with steam flow. However, when the PID controller is combined with bilinear feedforward, its output passes through the multiplier shown in Figure 2.9i, where it is multiplied by process flow. This operation keeps the PID loop gain constant, while manipulating steam flow linearly.

Heat-exchanger dynamics—deadtime and lags—also vary inversely with process flow, as is typical of *once-through* processes, i.e., where no recirculation takes place. This problem is less easily solved. The PID controller must have its integral time set relative to the slowest response (lowest expected flow) and its derivative time set relative to its fastest response (highest expected flow), or ideally, programmed as a function of measured flow. Otherwise, instability may result at extreme flow rates. Ideally, lead and lag settings of the feedforward dynamic compensator should also be programmed as a function of measured flow. However, the penalty for not doing so is not severe. The lead-lag ratio is not subject to change because the lags on both sides of the process change in the same proportion with flow. The primary purpose of the dynamic compensator is to minimize the peak deviation following the load change, and this is accomplished by the dynamic gain of the compensator, which is its lead-lag ratio. Any subsequent variation in integrated error is eliminated by the PID controller.

Although parameter variations can also be accommodated by a self-tuning feedforward compensator and feedback controller, these methods are less accurate in arriving at optimum settings and are always late, having tuned for the last flow condition and not for the next one.

2.10 Genetic and Other Evolutionary Algorithms

J. MADÁR, J. ABONYI (2005)

INTRODUCTION

The evolutionary algorithm (EA) uses the computational model of natural selection for optimization. EA has proved particularly successful in applications that are difficult to formalize mathematically and that are therefore not easily handled by the engineering tools of classical analysis.

EA does not rely on domain-specific heuristics and therefore is attractive for applications that are highly nonlinear, stochastic, or poorly understood; very little *a priori* information is required, although it can be utilized if so desired. For problems that are well understood, approximately linear, and for which reliable solutions exist, the EA is unlikely to produce competitive results.

It is possible for an EA to provide several dissimilar but equally good solutions to a problem, due to its use of a population. Hence, the EA is a robust search-and-optimization method that is able to cope with multimodality, discontinuity, time-variance, randomness, and noise.

A single control engineering problem can contain a mixture of "decision variable" formats (numbers, symbols, and other structural parameters). Since the EA operates on a "genetic" encoding of the optimized variables, diverse types of variables can be simultaneously optimized.

Each of the previously mentioned properties can prove significantly problematic for conventional optimizers. Furthermore, an EA search is directed and, hence, represents potentially much greater efficiency than a totally random or enumerative search.[1]

Real-time performance of an optimization algorithm is of particular interest to engineers. Unfortunately, there is no guarantee that the EA results will be of sufficient quality for use online. This is because EAs are very computationally intensive, often requiring massively parallel implementations in order to produce results within an acceptable timeframe.

In real-time applications there is also the matter of how individuals will be evaluated if no process model is available. Furthermore, EAs should be tested many times due to the algorithms' stochastic nature. Hence, online control of real-time processes, especially applications for safety-critical processes, is in most cases not yet feasible.

Applications

Evolutionary algorithms have been most widely and successfully applied to offline design applications. In the field of control systems engineering, these applications include controller design, model identification, robust stability analysis, system reliability evaluation, and fault diagnosis.

The main benefit of the EA is that it can be applied to a wide range of problems without significant modification. However, it should be noted that EA has several implementations: evolutionary programming (EP), evolutionary strategy (ES), genetic algorithm (GA), and genetic programming (GP), and the selection of the proper technique and the tuning of the parameters of the selected technique require some knowledge about these techniques.

Hence, the aim of this section is to introduce the readers to the basic concept of EAs, describe some of the most important implementations, and provide an overview of the typical process engineering applications, especially in the area of process control.

THE CONCEPT OF EA

Fitness Function: Encoding the Problem

EAs work with a population of potential solutions to a problem. In this population, each individual represents a particular solution, which can be described by some form of genetic code. The fitness value of the individual solution expresses the effectiveness of the solution in solving the problem. Better solutions are assigned higher values of fitness than the less well performing solutions.

The key of EA is that the fitness determines the success of the individual in propagating its genes (its code) to subsequent generations.

In practical system identification, process optimization, or controller design it is often desirable to simultaneously meet several objectives and stay within several constraints. For the purposes of the EA, these factors must be combined to form a single fitness value. The weighted-sum approach has proved popular in the literature because it is amenable to a solution by conventional EA methods, but Pareto-based

TABLE 2.10a
A Typical Evolutionary Algorithm

```
procedure EA;

        Evaluate offspring;
        Replace some old individuals by some offspring;
    }
}
```

multi-objective techniques are likely to surpass this popularity in the future.

In some cases, the objectives and constraints of the problem may be noncommensurable and the objective functions explicitly/mathematically are not available. In these cases, interactive evolutionary computation (IEC) should be used to allow subjective human evaluation; IEC is an evolutionary algorithm whose fitness function is replaced by human users who directly evaluate the potential solutions.

Model of Natural Selection

The population has evolved over generations to produce better solutions to the task of survival. Evolution occurs by using a set of stochastic genetic operators that manipulate the genetic code used to represent the potential solutions. Most evolutionary algorithms include operators that select individuals for reproduction, produce new individuals based on the characteristics of those selected, and determine the composition of the population of the subsequent generation.

Table 2.10a outlines a typical EA. A population of individuals is randomly initialized and then evolved from generation to generation by repeated applications of *evaluation, selection, mutation* and *recombination.*

In the *selection* step, the algorithm selects the parents of the next generation. The population is subjected to “environmental pressure,” which means the selection of the fittest individuals. The most important automated selection methods are stochastic uniform sampling, tournament selection, fitness ranking selection, and fitness proportional selection:

- *Stochastic uniform sampling* (*SUS*) is the simplest selection method. In it, every individual has the same chance to be selected without considering individual fitness. This technique can be useful when the size of the population is small.
- The *tournament selection* method is similar to SUS, but the individuals that have higher fitness values have higher probabilities to be selected. The selection procedure is simple; in every tournament two individuals are picked randomly from the population, and the one with the higher fitness value is selected.
- *Fitness proportional selection* is the most often applied technique. In this selection strategy the probability of selection is proportional to the fitness of the individuals.[2]
- The *fitness ranking selection* method uses a rank-based mechanism. The population is sorted by fitness, and a linear ranking function allocates a rank value for every individual. The probability of selection is proportional to the normalized rank value of the individual.

After the selection of the individuals, the new individuals (offspring) of the next generation are created by recombination and mutation.

- *Recombination* (also called crossover) exchanges information between two selected individuals to create one or two new offspring.
- The *mutation* operator makes small, random changes to the genetic coding of the individual.

The final step in the evolutionary procedure is *replacement*, when the new individuals are inserted into the new population. Once the new generation has been constructed, the processes that resulted in the subsequent generation of the population are repeated once more.

GENETIC ALGORITHM

The GA, as originally defined by John Holland and his students in the 1960s,[3] uses bit-string representation of the individuals. Depending on the problem, the bit strings (chromosomes) can represent numbers or symbols (e.g., see Figure 2.10b).

Of course, this automatically raises the question as to what precision should be used, and what should be the mapping between bit strings and real values. Picking the right precision can be potentially important. Historically, genetic algorithms have typically been implemented using low precision, such as 10 bits per parameter.

Recombination means the swapping of string fragments between two selected parents (see Figure 2.10c), while mutation means the flip of a few bits in these strings.

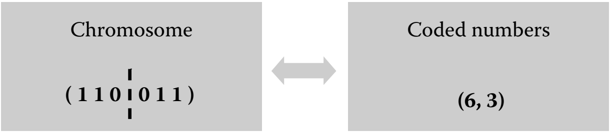

FIG. 2.10b
Example of binary representation of integer numbers.

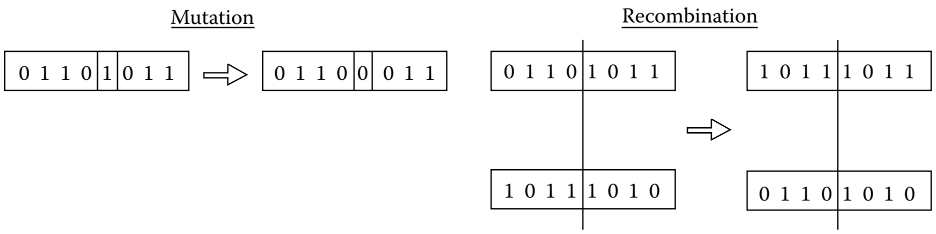

FIG. 2.10c
Mutation and recombination of binary strings.

Recombination has much higher probability than mutation, so recombination is often said to be the "primary searching operator."[3]

GA applies simple replacement technique: all the original individuals are replaced by the created offspring; except in case of the *elitist strategy* when some of the best individuals are also placed into the next generation.

GENETIC PROGRAMMING

GA is a powerful technique for numeric optimization, but because of the fixed length bit-string representation, it is not really suitable for solving structural and symbolic optimization problems. Genetic programming (GP), which has been developed by John Koza,[4] is based on tree representation. This representation is extremely flexible, since trees can represent computer programs, mathematical equations, or complete models of process systems.

A population member in GP is a hierarchically structured computer program consisting of functions and terminals. The functions and terminals are selected from a set of functions and a set of terminals. For example, function set F could contain the basic arithmetic operations: $F = \{*, -, +, /\}$. However, the function set may also include other mathematical functions, Boolean operators, conditional operators, or any user-defined operators.

The terminal set T contains the arguments for the functions, for example $T = \{y, x, p_i\}$ with x and y as two independent variables and p_i representing the parameters. The potential solution (program) can now be depicted as a rooted, labeled tree with ordered branches, using operations (internal points of the tree) from the function set and arguments (leaves of the tree) from the terminal set. An example of such a tree using the aforementioned function sets F and T is given in the top left corner of Figure 2.10d.

GP inherited the selection and replacement strategies from GA, but the mutation and crossover are adapted to the tree representation. The mutation exchanges a node in the tree, or deletes a sub-tree from the tree, or inserts a new sub-tree into the tree. Mutation can be implemented in two different ways:

- A random terminal or function is selected and replaced by another (randomly selected) terminal or function.

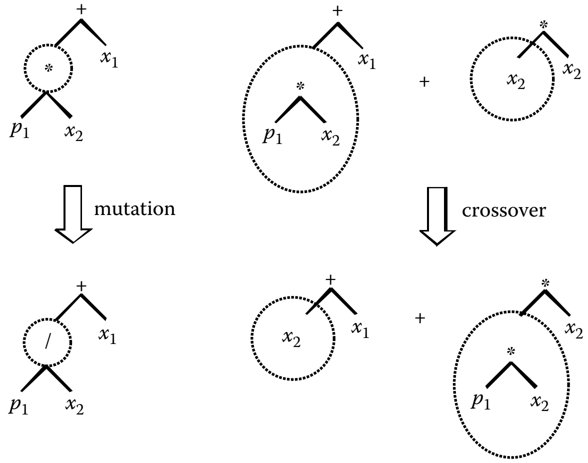

FIG. 2.10d
Mutation and crossover of trees in GP.

- A randomly selected sub-tree is replaced by a randomly generated sub-tree.

The crossover generates new children trees by jointing parental sub-trees. Crossover is determined by choosing two individuals based on fitness and generating for each tree the crossover point (node) at random.

For example: consider the trees shown at the top right of Figure 2.10d with crossover points 2 and 2. The sub-tree of the first solution (program) starting from crossover point 2 will be swapped with the sub-tree of the second program at crossover point 2, resulting in two new individuals shown at the bottom right of Figure 2.10d.

The size of tree can vary during mutation and crossover, which gives additional flexibility to GP. Hence, GP is more used for structure optimization than for parameter optimization. Koza[4.] has shown that GP can be applied to a great diversity of problems. He especially illustrated the use of GP with regard to optimal control problems, robotic planning, and symbolic regressions.

The key advantage of GP is the ability to incorporate domain-specific knowledge in a straightforward fashion. Another advantage is that the results can be readily understood and manipulated by the designer. However, GP structures can become complicated and may involve redundant pathways. Minimizing the complexity of a solution should be a specific objective, and the topic of “bloat” is a continuing area of study for GP researchers.[5]

Furthermore, GP can be quite processor intensive, especially for structural identification, where a parameter estimation procedure must be carried out for each individual structure at each generation. Due to the complexity of the structure, traditional (trusted and efficient) parameter estimation methods are often impossible to apply.

EVOLUTIONARY STRATEGY

Contrary to GP, ES searches in continuous space. The main distinction from GA is that ES uses real-valued representation of the individuals.

The individuals in ES are represented by n-dimensional vectors $(\mathbf{x} \in \Re^n)$, often referred to as object variables. To allow for a better adaptation to the particular optimization problem, the object variables are accompanied by a set of so-called strategy variables. Hence, an individual $\mathbf{a}_j = (\mathbf{x}_j, \boldsymbol{\sigma}_j)$ consists of two components, the object variables, $\mathbf{x}_j = [x_{j,1},\ldots,x_{j,i}]$, and strategy variables, $\boldsymbol{\sigma}_j = [\sigma_{j,1},\ldots,\sigma_{j,n}]$.

As in nature where small changes occur frequently but large ones only rarely, normally distributed random numbers are added as mutation operators to the individuals:

$$x_{j,i} = x_{j,i} + N(0, \sigma_{j,i}) \qquad \textbf{2.10(1)}$$

Before the update of the object variables, the strategy variables are also mutated using a multiplicative normally distributed process.

$$\sigma_{j,i}^{(t)} = \sigma_{j,i}^{(t-1)} \exp(\tau' N(0,1) + \tau N_i(0,1)) \qquad \textbf{2.10(2)}$$

with $\exp(\tau' N(0,1))$ as a global factor that allows an overall change of the mutability and $\exp(\tau N_i(0,1))$ allowing for individual changes of the mean step sizes $\sigma_{j,i}$. The parameters can be interpreted in the sense of global learning rates. Schwefel suggests to set them as

$$\tau' = \frac{1}{\sqrt{2n}} \qquad \tau = \frac{1}{\sqrt{2\sqrt{n}}} \qquad \textbf{2.10(3)}$$

Recombination in ES can be either sexual (local), where only two parents are involved in the creation of an offspring, or global, where up to the whole population contributes to a new offspring. Traditional recombination operators are discrete recombination, intermediate recombination, and geometric recombination, all existing in a sexual and global form. When *F* and *M* denote two randomly selected individuals from the μ parent population, the following operators can be defined:[6]

$$x_i' = \begin{cases} x_{F,i} & \text{no recombination} \\ x_{F,i} \quad \text{or} \quad x_{M,i} & \text{discrete} \\ (x_{F,i} + x_{M,i})/2 & \text{intermediate} \\ \sum_{k=1}^{\mu} \mathrm{x}_{k,i}/\mu & \text{global avarge} \end{cases} \qquad \textbf{2.10(4)}$$

$$\boldsymbol{\sigma}_i' = \begin{cases} \sigma_{F,i} & \text{no recombination} \\ \sigma_{F,i} \quad \text{or} \quad \sigma_{M,i} & \text{discrete} \\ (\sigma_{F,i} + \sigma_{M,i})/2 & \text{intermediate} \\ \sum_{k=1}^{\mu} \sigma_{k,i}/\mu & \text{global avarge} \end{cases} \qquad \textbf{2.10(5)}$$

The selection is stochastic in the ES. First we chose the best μ individuals to be parents, and then we select the parent-pairs uniformly randomly from these individuals.

The standard notations in this domain, $(\mu + \lambda)$ and (μ, λ), denote selection strategies in which the μ number of parents are selected to generate λ number of offspring. In case of (μ, λ) only the λ offspring are inserted into the subsequent generation (it means that λ is equal to the population size). In the case of $(\mu + \lambda)$ not only the λ offsprings but the μ parents are also inserted into the subsequent generation (it means that $\mu + \lambda$ is equal to the population size).

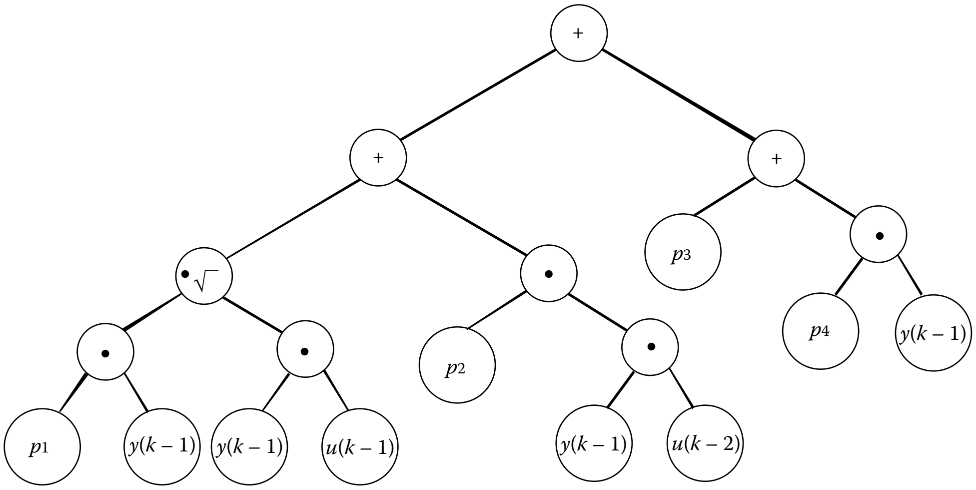
EVOLUTIONARY PROGRAMMING

Evolutionary programming (EP) was developed by Fogel et al.[7] independently from ES. Originally, it was used to achieve machine intelligence by simulated evolution. In the EP there are μ individuals in every generation. Every individual is selected and mutated (there is no recombination).

After the calculation of the fitness values of the new individuals, μ individuals are selected to form the next generation from the $\mu + \mu$ individuals, using a probabilistic function based on the fitness of the individuals.

SYSTEM IDENTIFICATION

System identification can be decomposed into two interrelated problems: selection of a suitable model structure and estimation of model parameters. Well-developed techniques exist for parameter estimation of linear models and linear-in-the-parameters nonlinear models. Techniques for nonlinear-in-the-parameters estimation and for the selection of the model structure are still the subject of ongoing research.



$$y(k) = -0.01568\, y(k-1)\sqrt{y(k-1)\, u(k-1)}$$
$$-6.404\, y(k-1)\, u(k-2) + 1.620\, y(k-1) + 9525$$

FIG. 2.10e
Tree representation of a solution.

The application of EAs to parameter identification of black-box and gray-box models has received considerable interest since the seminal papers by Kristinsson and Dumont[8] and Choi et al.[9]

One of the central problems in system identification is the choice of the input, output, and delay terms that are to contribute to the model. EAs provide a simple method for searching the structure space for terms that make the most significant contributions to process output.[10,11]

Multi-objective NARMAX (nonlinear autoregressive with exogenous input) polynomial model structure identification has been accomplished by the use of a multi-objective genetic programming (MOGP) strategy.[12] Here, seven objectives were optimized simultaneously: the number of model terms, model degree, model lag, residual variance, long-term prediction error, the auto-correlation function of the residuals, and the cross-correlation between the input and the residuals.

Polymerization Reactor Example

This example demonstrates how GP can be used for the development of a dynamic input–output model of a process from the input–output data of that process. The studied system is the dynamic model of a continuous polymerization reactor.[13]

The manipulated input variable in this process is the flow rate of the initiator, which influences the rate of the polymerization reaction. The controlled output is the mean molecular weight of the produced polymer (product quality).

The terminal set consists of the delayed process input and output terms. The function set simply consists of sum, product, and square root. The first two functions are sufficient to construct any NARMAX polynomial model, while the square root function is used on the basis of *a priori* knowledge about the reaction dynamics of the process.

In order to develop the model, input–output data were collected from the dynamic model of the process. Based on this process data, input–output models were identified. Figures 2.10e and 2.10f show the results.

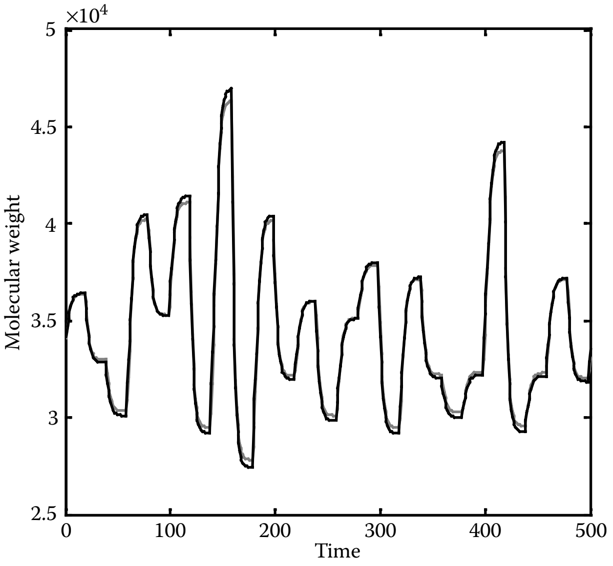


FIG. 2.10f
The results of model identification (GP). The solid line is the "real" output; the dotted line is the "estimated" output generated by the identified model.

Most of the resulting input-output models and estimates obtained by Rhodes and Morari[14] have identical input and output order. Hence, this result shows that GP is a useful tool for the data-driven identification of the model orders of unknown processes. In addition, the equations obtained by GP frequently had square-root terms, which were also in the original differential equations of the state-space model of the process.[13]

Hence, this example illustrates that the GP is not only good for the development of input–output models having good prediction capabilities, but because of the transparent model structure, these models are also useful tools to obtain additional knowledge about the process.

Complete Process Models

Gray et al.[15] performed nonlinear model structure identification using GP. They considered two representations: block diagrams (using Simulink) and equations (differential and integro-differential). A function library was constructed, which included basic linear and nonlinear functions and also specific *a priori* knowledge. The resulting scheme was applied to diverse systems of varying complexity, including simple transfer functions, a coupled water tank, and a helicopter rotor speed controller and engine.

In a paper by Marenbach et al., a general methodology for structure identification using GP with a block diagram library was developed.[16] Typical blocks included time delays, switches, loops, and domain-specific elements. Each block in the library was assigned a value, representing the subjective complexity of the block, and the method utilized an evaluation function that used this value. The developed methodology was applied to a biotechnological batch-type fermentation process, providing a transparent insight into the structure of the process.

PROCESS CONTROL APPLICATIONS

Controller Tuning

An early use of EAs was the tuning of proportional-integral-derivative (PID) controllers. Oliveira et al.[17] used a standard GA to determine initial estimates for the values of PID parameters. They applied their methodology to a variety of classes of linear time-invariant (LTI) systems, encompassing minimum phase, nonminimum phase, and unstable systems.

In an independent inquiry, Porter and Jones[18] proposed an EA-based technique as a simple, generic method of tuning digital PID controllers. Wang and Kwok[19] tailored an EA using inversion and preselection “micro-operators” to PID controller tuning. More recently, Vlachos et al.[20] applied an EA to the tuning of decentralized proportional-integral (PI) controllers for multivariable processes.

Onnen et al.[21] applied EAs to the determination of an optimal control sequence in model-based predictive control (MBPC), which is discussed in Section 2.17. Particular attention was paid to MBPC for nonlinear systems with input constraints. Specialized genetic coding and operators were developed with the aim of preventing the generation of infeasible solutions. The resulting scheme was applied to a simulated batch-type fermenter, with favorable results reported (compared to the traditional branch-and-bound method) for long control horizons.

The main problem of optimized controller tuning is the selection of the appropriate objective function. For this purpose classical cost functions based on the integral squared error (ISE) can be used. Usually, not only the control error is minimized but also the variation of the manipulated variable:

$$\min \sum_{k=1}^{n} e(k)^2 + \beta \cdot \sum_{k=1}^{n} \Delta u(k)^2 \qquad \textbf{2.10(6)}$$

The second term of this cost function is responsible for providing a smooth control signal, and in some control algorithms, such as model predictive control, stability.

The selection of the β weighting parameter, which balances the two objectives, is an extremely difficult design problem. Besides the selection of this weighting parameter, there are other freely selectable design parameters, e.g., the error can be weighted with the elapsed time after the setpoint change. As can be seen, the design of an appropriate cost function is not a straightforward task. The performance of the optimized controller does not always meet the expectations of the designer.

The following example will show that the application of IEC[22] is a promising approach to handle this problem; IEC is an evolutionary algorithm whose fitness function is replaced by human users who directly evaluate the potential solutions.

Application of IEC in Controller Tuning

The continuously stirred tank reactor (CSTR) control system model is taken from Sistu and Bequette.[23] The dynamic behavior of this system is interesting: it has multiple steady states as a function of the cooling water flow rate and reactor temperature. The reactor’s dynamic behavior is complex and nonlinear and as such, presents a challenging control problem.[24]

To control the reactor temperature, it is advantageous to use cascade-control, where the slave controls the jacket temperature, while the master controls the reactor temperature. According to the industrial practice, a PID controller in the master loop and a *P* (proportional) controller in the slave loop have usually been applied. If properly tuned, this selection of control modes should give good control performance.

This example demonstrates how ES can be used for the tuning of these controllers. The chromosomes consist of design and strategy variables. In this case study, the design variables ($\mathbf{x}_j$) are the three tuning settings of the master PID controller (gain, integral time and differential time) and the gain of the slave *P* controller.

Instead of using a fully automated ES optimization, interactive evolutionary strategy has been applied, where the user evaluates the performances of the controllers with the use of a process simulator incorporated into a graphical user interface tailored for this purpose. With this human–machine interface (HMI), the user can analyze the resulting plots and some numerical values, such as performance indices and parameters, and can select one or more individuals based on this information.

The prototype of this tool, which has been developed in MATLAB/Simulink, can be downloaded from www.fmt.vein.hu/softcomp/EAsy. The number of individuals is limited due to human fatigue; hence in this example the user can run, analyze, and evaluate eight independent tuning settings to provide feedback to the evolutionary process. Figure 2.10g shows the interactive figure that was used in this example.

The IEC converged quickly to good solutions; after only ten generations it resulted in well-tuned controllers (see Figure 2.10h).

For comparison, the direct optimization of the tuning settings by sequential quadratic programming (SQP) is considered. First, the cost function is based on the squared controller error and the variance of manipulated variable (Equation 2.10[6]). Although several β weighting parameters have been used, the SQP-technique led to badly tuned controllers.

Finally, the term that in the cost function contained the sum of the squared errors was replaced by a term based on the absolute value of the control errors. With the use of this new cost function, the SQP resulted in better controllers after a few experiments with different β weighting parameters. This example demonstrated that with the use of Interactive Evolutionary Computing we obtained the same controller performance as with a cost function–based controller tuning approach, but with much less effort and time.

Control Structure Design

Many EA applications simply optimize the parameters of existing controller structures. In order to harvest the full potential of EA, some researchers have experimented with the manipulation of controller structures themselves.

GP has been utilized for the automatic synthesis of the parameter values and the topology of controllers.[25] The system has reportedly duplicated existing patents (for PI and PID controllers) and rediscovered old ones (a controller making use of the second derivative of the error, which is the difference between the set point and the controlled variable, or in simulation language, the reference signal and the output signal).

Multi-objective evolutionary algorithms (MOEAs) have been utilized in controller structure optimization. For example, MOEAs have been used to select controller structure and suitable parameters for a multivariable control system for a gas turbine engine.[26]

Online Applications

Online applications present a particular challenge to the EA. The number of successful applications have been limited to date.

In online applications, it is important that at each sample instant, the controller must generate a signal to set the

manipulated variable(s). The actions of the "best" current individual of the EA may inflict severe consequences on the process. This is unacceptable in most applications, especially in the case of a safety- or mission-critical control system.

Given that it may not be possible to apply the values represented by any individual in an EA population to the system, it is clear that evaluation of the complete, evolving population cannot be performed on the actual process. The population may be evaluated using a process model, assuming that such a model exists, or performance may be inferred from system response to actual input signals.

Inference may also be used as a mechanism for reducing processing requirements by making a number of full evaluations and then computing estimates for the remainder of the population based on these results.

In a real-time application, there is only a limited amount of time available for an optimizer between decision points. Given current computing power, it is unlikely that an EA will execute to convergence within the sampling time limit of a typical control application. Hence, only a certain number of generations may be evolved. For systems with long sample times, an acceptable level of convergence may well be achieved.

In the case of a controller, an acceptable control signal must be provided at each control point. If during that period the EA evolved for only a few generations, then population performance may still be poor. A further complication is that the system, seen from the perspective of the optimizer, is changing over time. Thus, the evolved control signal at one instant can become totally inappropriate at the next.

EAs can cope with time-varying landscapes to a certain extent, but a fresh run of the algorithm may be required. In this instance, the initial population can be seeded with previous "good" solutions. Note that this does not guarantee fast convergence and may even lead to premature convergence.

There are three broad approaches to the use of EAs for online control:[27]

- Utilize a process model.
- Utilize the process directly.
- Permit restricted tuning of an existing controller.

The last approach can be used to ensure stability when combined with some form of robust stability analysis, while permitting limited exploration.

SOFTWARE TOOLS

Here an overview is provided of the EA implementation environments, based on the taxonomy of Filho,[28] which utilizes three major classes: application-oriented systems, algorithm-oriented systems, and tool kits (see Tables 2.10i and 2.10j).

Application-Oriented Systems

Most potential users of a novel computing technique, such as genetic algorithms, are not interested in the details of that

TABLE 2.10i
Programming Environments and Their Categories

	Algorithm-Oriented		*Tool Kits*	
Application-Oriented	*Algorithm-Specific*	*Algorithm Libraries*	*Educational*	*General Purpose*
EVOLVER	ESCAPADE			EnGENEer
OMEGA	GAGA	EM	GA Workbench	GAME
PC/BEAGLE	GAUCSD			MicroGA
XpertRule GenAsys	GENESIS	OOGA		PeGAsusS
	GENITOR			Splicer

technique, only in the contribution it can make to their applications. By using an application-oriented programming environment, it is possible to configure a particular application without having to know the encoding technique or the genetic operators involved.

Application-oriented systems follow many innovative strategies. Systems such as PC/BEAGLE and XpertRule GenAsys are expert systems using GAs to generate new rules to expand their knowledge base of the application domain. EVOLVER is a companion utility for spreadsheets, and systems such as OMEGA are targeted at financial applications.

EVOLVER is an add-on utility that works within the Excel, WingZ, and Resolve spreadsheets on Macintosh and PC computers. It is being marketed by Axcélis, Inc., which describes it as "an optimization program that extends mechanisms of natural evolution to the world of business and science applications."

The user starts with a model of a system in the spreadsheet and calls the EVOLVER program from a menu. After filling a dialogue box with the information required (e.g., cell to minimize/maximize) the program starts working, evaluating thousands of scenarios automatically until it is sure it has found an optimal answer.

The program runs in the background, freeing the user to work in the foreground. When the program finds the best result, it notifies the user and places the values into the spreadsheet for analysis. This is an excellent design strategy given the importance of interfacing with spreadsheets in business.

The OMEGA Predictive Modeling System, marketed by KiQ Limited, is a powerful approach to developing predictive models. It exploits advanced genetic algorithm techniques to create a tool that is “flexible, powerful, informative, and straightforward to use.” OMEGA is geared to the financial domain.

The environment offers facilities for automatic handling of data; business, statistical, or custom measures of performance; simple and complex profit modeling; validation sample tests; advanced confidence tests; real-time graphics, and optional control over the internal genetic algorithm.

PC/BEAGLE, produced by Pathway Research Ltd., is a rule-finder program that applies machine-learning techniques to create a set of decision rules for classifying examples previously extracted from a database.

XpertRule GenAsys is an expert system shell with embedded genetic algorithms, marketed by Attar Software. This GA expert system is targeted to solve scheduling and design applications. The system combines the power of genetic algorithms in evolving solutions with the power of rule-base programming in analyzing the effectiveness of solutions.

Some examples of design and scheduling problems that can be solved by this system include: optimization of design parameters in electronic and avionics industries, route optimization in the distribution sector, and production scheduling in manufacturing.

Algorithm-Oriented Systems

Algorithm-oriented systems are programming systems that support specific genetic algorithms. They subdivide into:

- Algorithm-specific systems—which contain a single EA; the classic example is GENESIS.
- Algorithm libraries—where a variety of EAs and operators are grouped in a library, as in Lawrence Davis’s OOGA.

Algorithm-oriented systems are often supplied in source code and can be easily incorporated into user applications.

Algorithm-Specific Systems Algorithm-specific environments embody a single powerful genetic algorithm. These systems typically have two groups of users: system developers requiring a general-purpose GA for their applications and researchers interested in the development and testing of a specific algorithm and genetic operators. The code has been developed in universities and research centers and is available free over worldwide computer research networks.

The best-known programming system in this category is the pioneering GENESIS system, which has been used to implement and test a variety of new genetic operators. In Europe, probably the earliest algorithm-specific system was GAGA. For scheduling problems, GENITOR is another influential system that has been successfully used.

GAUCSD allows parallel execution by distributing several copies of a GENESIS-based GA into UNIX machines in a network. Finally, ESCAPADE employs a somewhat different approach, as it is based on an evolutionary strategy.

Algorithm Libraries These systems are modular, allowing the user to select a variety of algorithms, operators, and parameters to solve a particular problem. Their parameterized libraries provide the ability to use different models (algorithms, operators, and parameter settings) to compare the results for the same problem.

New algorithms coded in high level languages, such as “C” or Lisp, can be easily incorporated into the libraries. The user interface is designed to facilitate the configuration and manipulation of the models as well as to present the results in different shapes (tables, graphics, etc.).

The two leading algorithm libraries are EM and OOGA. Both systems provide a comprehensive library for genetic algorithms, and EM also supports strategies for evolution simulation. In addition, OOGA can be easily tailored for specific problems. It runs in Common Lisp and CLOS (Common Lisp Object System), an object-oriented extension of Common Lisp.

Tool Kits

Tool kits are programming systems that provide many programming utilities, algorithms, and genetic operators, which can be used for a wide range of application domains. These programming systems can be subdivided into:

- Educational systems—to help the novice user obtain a hands-on introduction to GA concepts. Typically, these systems support a small set of options for configuring an algorithm.
- General-purpose systems—to provide a comprehensive set of tools for programming any GA and application. These systems may even allow the expert user to customize any part of the software, as in Splicer.

Educational Systems Educational programming systems are designed for the novice user to obtain a hands-on introduction to genetic algorithms concepts. They typically provide a rudimentary graphic interface and a simple configuration menu. Educational systems are typically implemented on PCs for reasons of portability and low cost. For ease of use, they have a nice graphical interface and are fully menu-driven. GA Workbench is one of the best examples of this class of programming environments.

General-Purpose Programming Systems General-purpose systems are the ultimate in flexible GA programming systems. Not only do they allow users to develop their own GA applications and algorithms, but they also provide users with the opportunity to customize the system to suit their own purposes.

These programming systems provide a comprehensive tool kit, including:

- A sophisticated graphic interface
- A parameterized algorithm library
- A high-level language for programming GAs
- An open architecture

Access to the system components is via a menu-driven graphic interface and a graphic display/monitor. The algorithm library is normally "open," allowing the user to modify or enhance any module. A high-level language—often object-oriented—may be provided to support the programming of GA applications, algorithms, and operators through specialized data structures and functions. Lastly, due to the growing importance of parallel GAs, systems provide translators to parallel machines and distributed systems, such as networks of workstations.

The number of general-purpose systems is increasing, stimulated by growing interest in the application of GAs in many domains. Examples of systems in this category include Splicer, which presents interchangeable libraries for developing applications, *Micro*GA, an easy-to-use object oriented environment for PCs and Macintoshes, and parallel environments such as EnGENEer, GAME, and PeGAsusS.

2.11 Hierarchical Control

J. W. BERNARD (1970) **T. J. WILLIAMS** (1985, 1995) **B. G. LIPTÁK** (2005)

In modern, computer-controlled control systems (Figure 2.11a), several layers of control can be superimposed onto the basic controls, which are physically connected to the process. Such hierarchical control uses several levels of computer systems in an extended master–slave relationship to carry out not only the process control but also the supervisory, management and business functions in controlling industrial plants. This section describes the historical evolution of hierarchical control and some typical forms of such control systems, including the distribution of the potential duties among the several levels of computers involved.

HIERARCHICAL LEVELS

There are basically four levels in the hierarchy:

1. All direct connections to the process are uniformly referred to as Level 1. These basic controls include all sensors, final control elements, continuous PID controls, sequential interlocks, alarms, and monitoring devices. In some systems, where several levels of basic controls exist, they are referred to as Levels 1A and 1B.
2. Supervisory control is universally called Level 2. The control functions of this level are targeted to increased production, improved environmental protection, energy conservation, optimization, predictive maintenance, and plant-wide safety. The means used to achieve these goals include envelope control, model-based controls, fuzzy logic, statistical process control, and other types of expert systems, which are all described in this section.
3. In some plants the area controls or inter-area coordination is called Level 3, while in other plants it is included in Level 2. From this example it can be seen that not even the language has yet been standardized; this whole field is still in a process of evolution.

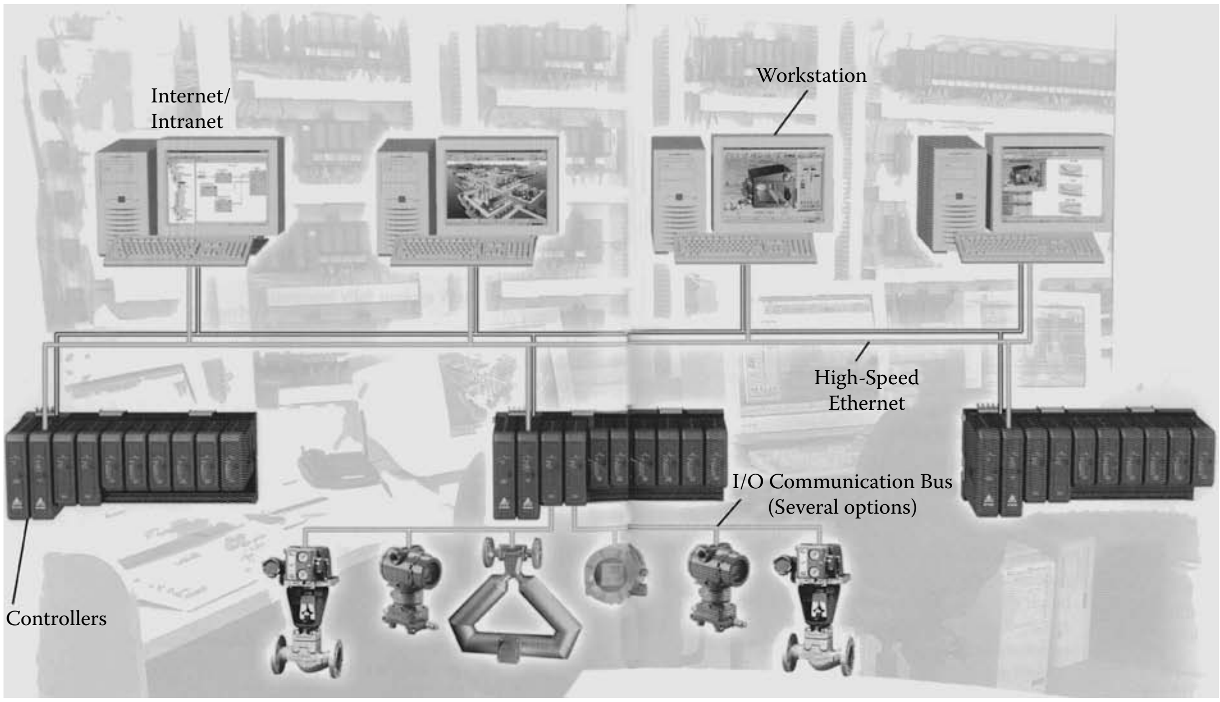

FIG. 2.11a
Modern control systems are well suited for hierarchical control because Level 1 controls, which consist of devices with direct connections to the process, can be cascaded to supervisory and management levels of control. (Courtesy of Control Associates, Inc.)

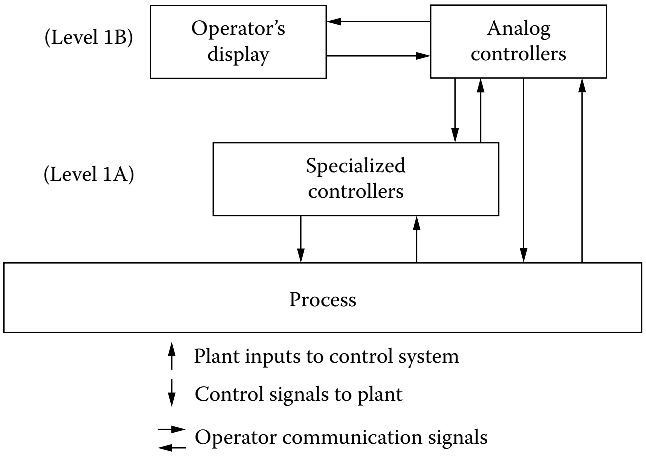

FIG. 2.11b
The basic old analog control system operated at Level 1 only.

4. In some plants the management functions are referred to as Level 3, while in others the scheduling and management information functions are called Level 4. Often this level is split into Levels 4A and 4B, where 4A covers contact with the plant (scheduling, etc.) and 4B covers contact with upper management. Management functions include marketing, financing, human resources, production scheduling, and inventory tasks. Some generalized software packages already exist for enterprise resource planning (ERP) and material requirement planning (MRP).

HISTORY

Prior to the introduction of the use of computers for industrial control applications, the standard industrial control system consisted of a large number of single-loop analog controllers, either pneumatic or electronic, as diagrammed in Figure 2.11b. Note in the figure that Level 1A refers to those instruments that have no signal readouts that are readily available to the operator (e.g., some field-mounted controllers, ratio instruments, etc.). Level 1B devices have transmitters and provide indication to the operator by a pointer or on a strip chart, etc. These latter devices include the standard PID (proportional, integral, and derivative control mode) controllers.

Computers were first used in industrial plants not as controllers but as monitors or data loggers (see Figure 2.11c). However, these installations were quickly followed by the first supervisory controllers (early 1960s), which used the computer to change the set points of the analog controllers (Figure 2.11d).

It was the desire of most control engineers who were working with early computer control systems to completely bypass the analog controllers of Figure 2.11d and have the computer directly control the valves. This resulted in direct digital control (DDC), as illustrated in Figure 2.11e and Figure 2.11f. Figure 2.11f includes specialized dedicated digital controllers to illustrate the relationship to Figure 2.11b. Although common today, these devices were not available in the earliest DDC systems. In these early systems, all computational work was carried out in the digital computer of Level 2 (Figure 2.11d).

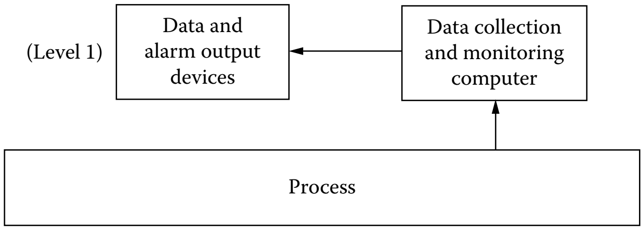

FIG. 2.11c
The early computers served only for data collection and monitoring.

Although direct digital control always had the potential for assuming an unlimited variety of complex automatic control functions, most early DDC systems were implemented as digital approximations of conventional three-mode analog controllers. Thus the computer system of Figure 2.11f is considered most often as a direct substitution for the analog control system of Figure 2.11b.

The Central Computer

The early digital control systems suffered from many drawbacks. Among these were:

1. The computers were all drum machines, i.e., the memory was located on a magnetic drum. As a result, they were very slow. A typical addition time for such machines was 4 milliseconds.
2. The memories were very small, usually 4000 to 8000 words of 12 to 16 bits each.
3. All programming had to be done in machine language.

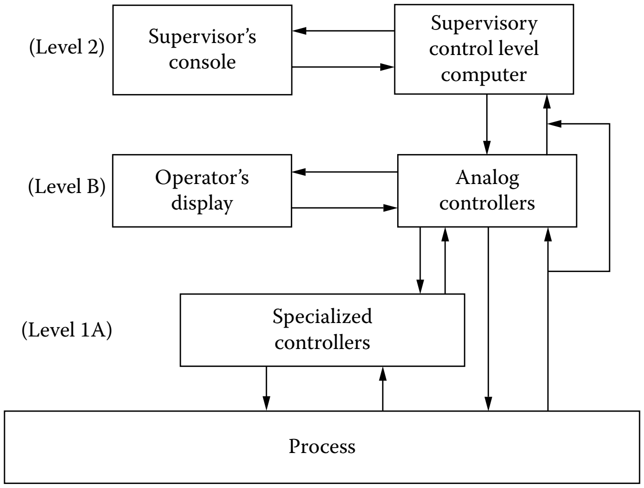

FIG. 2.11d
Level 2 supervisory computer used to adjust the set-points at Level 1.

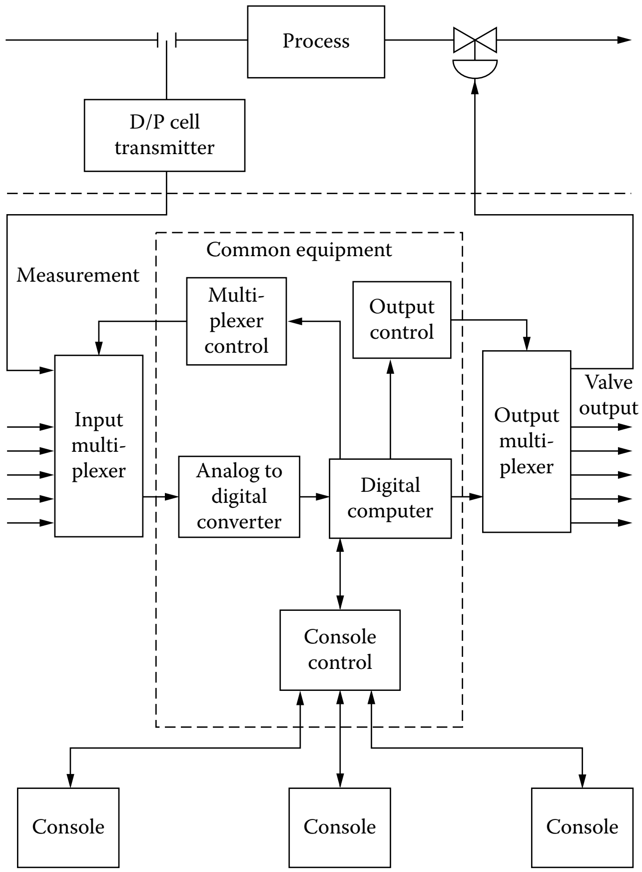

FIG. 2.11e
Block diagram of a direct control system.

4. Neither vendors nor users had any experience in computer applications. Thus, it was very difficult to size the project properly within computer capabilities. Most projects had to be reduced in size to fit the available machines.
5. Many of the early computer systems were very unreliable, particularly if they used temperature-sensitive germanium rather than silicon circuitry, as many did. In addition, these computers depended on unreliable mechanical devices, such as air conditioners, for their successful operation.

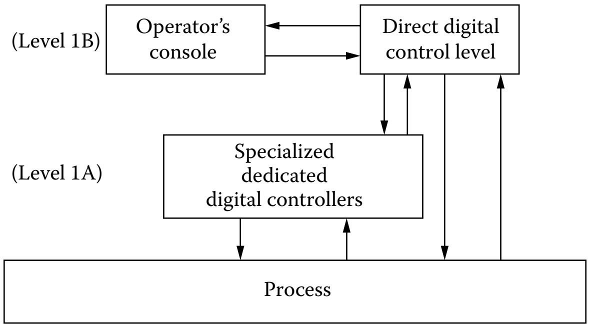

FIG. 2.11f
Digital substitution for the analog system in Figure 2.11b.

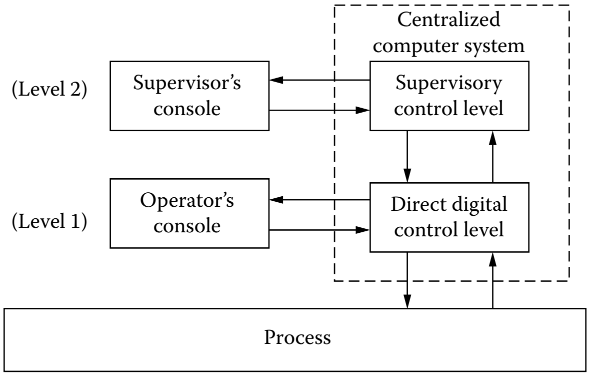

FIG. 2.11g
Two-level hierarchical control with supervisory control (Level 2) and direct digital control (Level 1).

In response to these problems, the computer manufacturers came out with a second-generation computer, which was much larger and had a magnetic core memory, wired-in arithmetic functions, etc., which made it much faster. But the high cost of core memories and the additional electronic circuitry made the system much more expensive. To help justify the cost, vendors advocated the incorporation of all types of computer functions, including both supervisory and DDC, into a single computer or mainframe in the central control room (Figures 2.11g and 2.11h.)

Although these computers had much greater speed and memory size compared to earlier systems, their use led to still further problems:

1. Most were marketed before their designs were thoroughly proven or their programming aids (compilers, higher-level languages, etc.) were fully developed. Thus there were many frustrating delays in getting them installed and running.
2. The vast amount of wiring and communication system required to bring the plant signals to the centralized computer location and return the control signals to the field was very expensive, and unless it was very carefully designed and installed, it was prone to electrical noise problems.
3. Because all of the control functions were located in one computer, the possibility that the computer might fail resulted in demands for a complete analog backup system. The resulting system, illustrated in Figure 2.11i, was a combination of the systems shown in Figures 2.11d and 2.11g, and it greatly increased the cost.
4. To compensate for these high costs, users and vendors alike attempted to squeeze as many tasks as possible into the computer system, thus drastically complicating the programming and aggravating the difficulties described in item 1 above.

As a result of these difficulties, management in many companies reacted disapprovingly to computer control, and there was a hiatus in computer system installations until the 1970s.

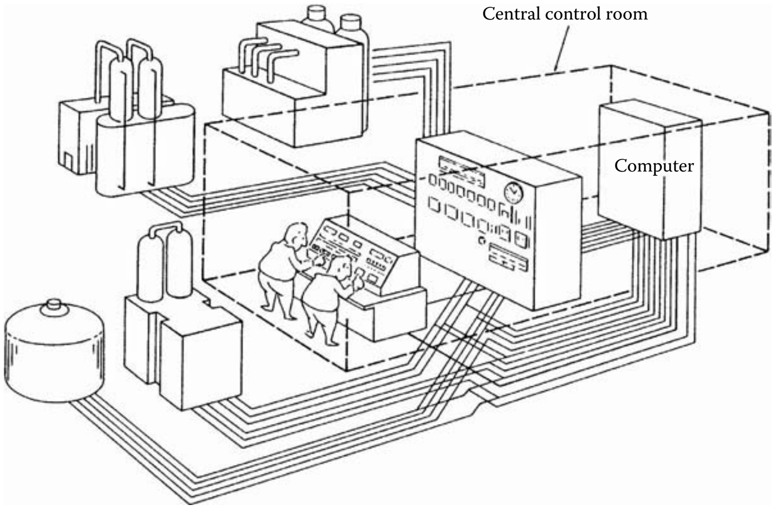

FIG. 2.11h
The use of centralized computer in a supervisory mode over analog controls located on an analog panel board and on a backup board (circa 1965–1975).

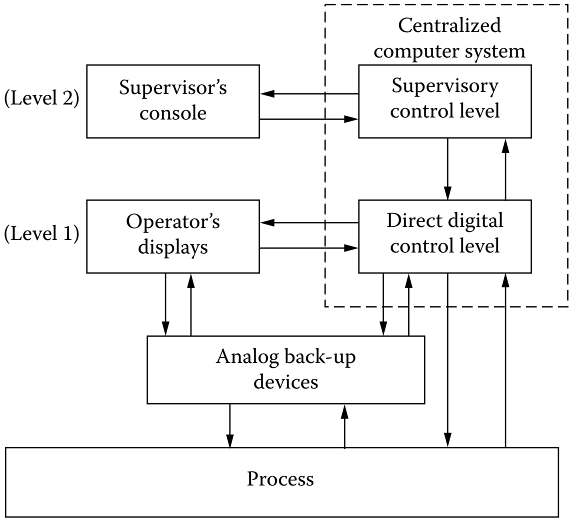

FIG. 2.11i
Complete secondary digital control: supervisory plus direct digital control with associated analog control backup.

Distributed Control

Because of the problems experienced with the centralized computer systems of the late 1960s, most of the new computer projects of the early 1970s were relatively small, specialized projects that took advantage of the capabilities of the newly arrived minicomputer. Many such projects flourished. They generally followed the lines of Figures 2.11d or 2.11i and differed from earlier undertakings mainly in their smaller size.

However, at this time, two other developments were under way that would forever change digital computer–based control and indeed all process control. The first of these was the rapid development of the integrated circuit and the resulting production of the all-important microprocessor or microcomputer. The second development was the courageous effort begun by the Honeywell Company in 1969 to design an alternative to the unwieldy and unreliable centralized computer control system. This alternative was the distributed computer system.

The idea behind the distributed computer system was to have a set of small, widely distributed computer "boxes" containing one or more microprocessors. Each of the boxes controlled one or a very few loops. All of them were connected by a single high-speed data link that permitted communication between each of the microprocessor-based "boxes" and with a centralized operator station or console.

This became the TDC 2000 system, the principles of which were widely followed by other process control system vendors. These systems solved reliability problems in two ways. First, these units controlled only a few process loops; thus any single failure involved only those few loops. Second, a digital backup capability was developed, that is, backup computer systems were included to take over the duties of any failed components.

Figure 2.11j illustrates this concept. Comparing this figure with Figure 2.11h shows what was accomplished with this new concept. Almost universally, the distributed computer systems offered the following features and capabilities, which greatly fostered their acceptance over electronic analog or centralized computer-based control systems:

1. A modular system development capability that is easy to use, particularly with the configuration aids available from the vendor.
2. A color-CRT–based, largely preprogrammed operator interface system that is easy to adapt to the individual plant situation.

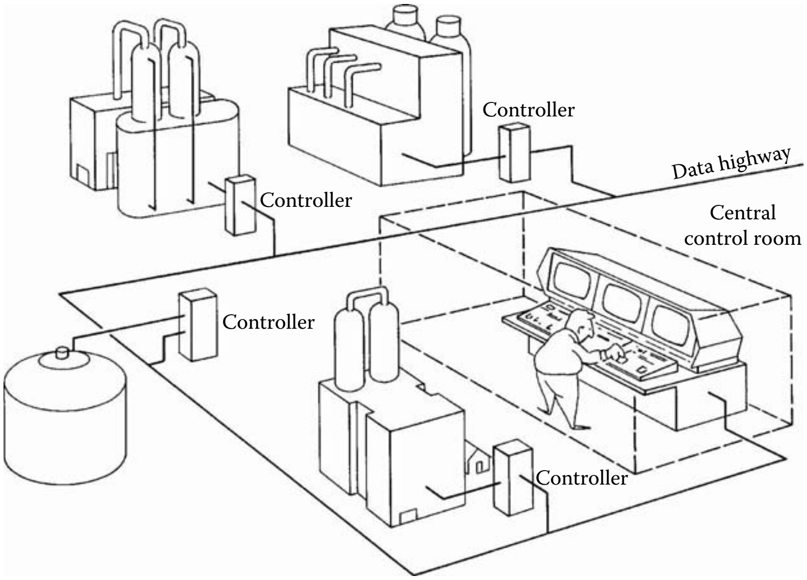

FIG. 2.11j
Microprocessor-based distributed direct digital computer control system (circa 1975).

3. A preprogrammed menu type of instruction system for the microcomputers of the controller box. This permits the final programming (configuration) of the total system to be done by pushing a few buttons on the keyboard.
4. A very wide selection of control algorithms or computational schemes within the preprogrammed menu, which permits easy selection and testing of alternate control schemes for a process.
5. Data highway based data transmission and communications capabilities between separate units of the system. Data highways provide very-wide-band communications and the possibility of redundancy for extra safety.
6. Relatively easy communications with mainframe computer systems for supervisory control or other higher-level process control or hierarchy control functions. However, these new control systems themselves are generally restricted to supplying the needs of the 1A and 1B level or dynamic control. Supervisory control is externally supplied.
7. Extensive diagnostic schemes and devices for easy and rapid maintenance through replacement of entire circuit boards.
8. Redundancy and other fail-safe techniques to help promote high system reliability. These features are often standard, but may be optional.

What was achieved with these systems is illustrated by Figures 2.11h and 2.11j, as noted above. These particular sketches are adapted from Honeywell drawings, but they are just as applicable to almost any other vendor's process control system.

HIERARCHICAL CONTROL

The development of the distributed digital control system greatly simplified the connection of the computer to the process. (Compare Figure 2.11k to Figure 2.11d.) Also, since redundancy or other backup devices could be incorporated directly into the digital system, the need for analog safety backup systems was minimized.

As illustrated in Figure 2.11k, there are three levels of control devices. Each has its distinct duties, as they form a hierarchical computer system in which upper-level computers depend on lower-level devices for process data, and the lower-level systems depend upon the higher ones for direction that serves more sophisticated control functions such as overall plant optimization. This configuration makes it possible to design a computer control system — one that combines the company's production scheduling and management information functions with the process control functions to form a total plant hierarchical control system, as illustrated in Figure 2.11l. This figure outlines most of the probable functions of such a hierarchical computer control system, but the magnitude of the tasks to be accomplished in the upper levels of the system is better indicated by the expanded version shown in Figure 2.11m. Such a system represents the ultimate dream of many process control system engineers. While what has already been achieved in the field of computer control fits easily within the framework shown in this diagram, this framework is only one of several possible structures for such a system and is not necessarily the optimal one for the task. Nevertheless, it is an excellent vehicle for our purpose here since it allows us to treat all the possible benefits of the computer system with one example.

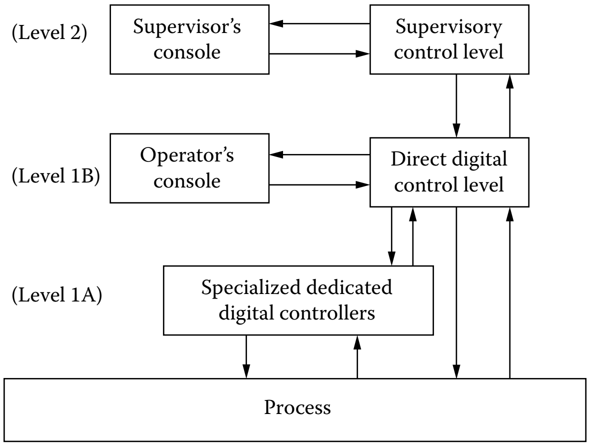

FIG. 2.11k
Complete secondary digital control: supervisory plus direct digital control.

It should be noted that the several levels shown in Figure 2.11m are operational levels and do not necessarily represent separate and distinct computer or hardware components. Although in large systems each level is likely to be handled by a separate computer, in small systems two or more operational levels might be combined into a single computer. The dedicated digital controllers at Level 1A require no human intervention since their functional tasks are completely fixed by systems design and are not altered online by the operator. All other levels have human interfaces as indicated in the figure. It should also be noted that each element of the hierarchy can exist as an individual element. Indeed, all of the earlier forms of industrial digital computer systems (Figures 2.11c, 2.11d, 2.11f, and 2.11i) still exist and will no doubt continue to be applied where their particular capabilities appear to best fit the application at hand.

The paragraphs below explain the basis for the organization of the six-level hierarchical system depicted in Figure 2.11m.

Overall Tasks of Digital Control Systems

Automatic control of any modern industrial plant, whether it is by a computer-based system or by conventional means, involves an extensive system for the automatic monitoring of a large number of variables, each having its own dynamics. The generation of control output signals requires the development of a large number of functions, some of which might be quite complex. These control corrections must be transmitted to a large number of widely scattered final control elements of various types. Because of the nature of the manufacturing processes involved, these control corrections often require the expenditure of very large amounts of material and energy.

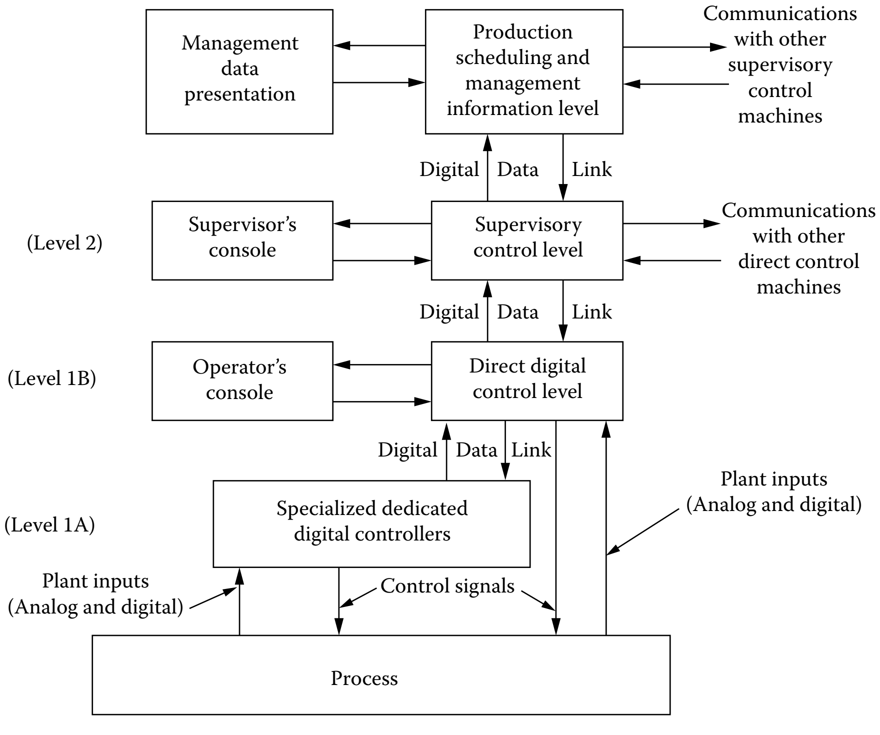

FIG. 2.11l
Hierarchical organization for a complete process computer control system.

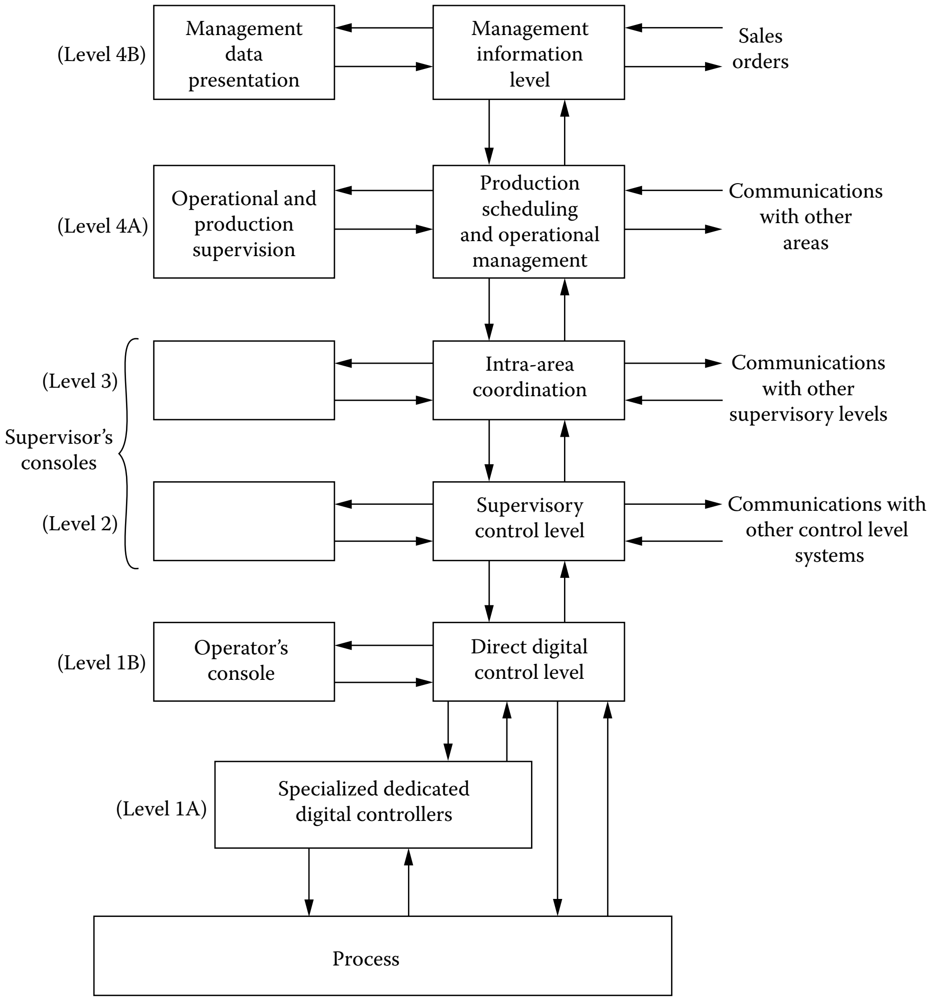

FIG. 2.11m
Hierarchical computer system structure for a large manufacturing complex.

Also, both operators and managers must be kept aware of the current status of the plant and of each of its processes.

In addition, an industrial plant is faced with the continual problem of adjusting its production schedule to match its customers' needs, as expressed by the order stream being continually received, while maintaining high plant productivity and the lowest practical production costs. Production scheduling today is usually handled through a manual, computer-aided production control system in conjunction with an in-process and finished goods inventory judged adequate by plant personnel.

Another role of digital computer control systems in industrial plants is as a "control systems enforcer." In this mode, the main task of the lower-level computers is continually to ensure that the control system equipment is actually carrying out the job that it was designed to do in keeping the units of the plant production system operating at some optimal level—that is, to be sure that the controllers have not been set on manual, that the optimal setpoints are being maintained, etc.

Often the tasks carried out by these control systems are ones that a skilled and attentive operator could readily do. But the automatic control systems offer a much greater degree of attentiveness over much longer periods of time.

All of these requirements must be factored into the design and operation of the control system that will operate the plant, including the requirements for maximum productivity and minimum energy use. As the overall requirements become more complex, more sophisticated and capable control systems are necessary. Thus we enter the realm of the digital computer-based control system.

System Capabilities To obtain the above described control responses, an overall system is needed that offers the following capabilities:

1. Tight control of each operating unit of the plant to ensure that it is using raw materials and energy at maximum efficiency and/or is operating at the most

efficient production level, based upon the production level set by the scheduling and supervisory functions of the control system. This control reacts directly to any emergencies that occur in its own unit. (These control functions are executed by Levels 1A and 1B in Figure 2.11m)
2. A supervisory and coordinating system that determines and sets the local production level of all units working together between inventory locations and optimizes their operation. This system ensures that no unit exceeds the general area level and thus ensures that no unit uses unnecessary amounts of energy or raw materials. This system responds to emergencies or upsets in any of the units under its control to shut down or systematically reduce the output in these and related units. (These control functions are executed by Levels 2 and 3 of Figure 2.11m.)
3. An overall production control system capable of carrying out the scheduling function for the plant based on customer orders or management decisions so as to produce the required products at the optimum combination of time, energy, and raw materials, suitably expressed as cost functions. (This is the specific task of Level 4A of the hierarchy.)
4. A method of assuring the overall reliability and availability of the total control system through fault detection, fault tolerance, redundancy, and other applicable techniques built into the system's specification and operation. (This task is performed at all levels of the control system.)

Because of their ever-widening scope of authority, control tasks 1, 2, and 3 above can effectively become the distinct and separate levels of a hierarchical control structure. Also, in view of the amount of information that must be passed back and forth among these three control tasks, it appears that some sort of distributed computational capability, organized in a hierarchical fashion, could be a logical structure for the required control system.

In Figure 2.11m, we can see that the right-hand elements of Levels 2 to 4A are all handled by computers of increasing capability as one goes up the hierarchy. Level 4B also contains a computer, but it is used mainly for communications and database management tasks. These elements are best handled by data processing or scientific computers since the noncontrol tasks at these levels far outnumber the process control tasks. These noncontrol computational tasks will thus determine the design and cost of these computers. As long as they are satisfactory for the purposes of process control, these established computer models should be used so that the economy gained from large-scale production can be capitalized on. This leaves Levels 1 and 2 as candidates for the application of digital process control hardware — the distributed, microprocessor-based systems discussed earlier.

TABLE 2.11n
Duties of Control Computer Systems

IV. Reliability assurance

Detailed Task Listings

In the context of a large industrial plant, the tasks carried out at each level of the hierarchy are as described in Tables 2.11n to 2.11t. Note that in each table the tasks are subdivided into ones that are related to production scheduling, control enforcement coordination/reporting, and reliability assurance. This was described in items 1 through 4 previously. Note also that the duties listed in Table 2.11o for Levels 1 and 2 begin with Item II, Control Enforcement, since the lower-level machines do not do any production scheduling. Likewise, the upper-level machines do no control enforcement since they have no direct connection to the process actuators.

Finally, Level 4B does neither since its main task is management and staff function communications, with a production data file maintained by Level 4A, Production Scheduling. These tables outline the tasks that must be carried out in any industrial plant, particularly at the upper levels of the hierarchy. Details of how the operations are actually carried out will vary drastically, particularly at the lowest levels, because of the nature of the actual processes being controlled, but this does not change the basic definition of these tasks.

The general duties of the different levels in the hierarchical computer system are summarized in Figure 2.11t.

TABLE 2.11o
Duties of the Control Levels (Levels 1A and 1B)

II. Control enforcement
  1. Maintain direct control of the plant units under their cognizance.
  2. Detect and respond to any emergency condition in these plant units
III. System coordination and reporting
  3. Collect information on unit production raw material and energy use and transmit to higher levels.
  4. Service the operator's man/machine interface.
IV. Reliability assurance
  5. Perform diagnostics on themselves.
  6. Update and standby systems.

TABLE 2.11p
Duties of the Supervisory Level (Level 2)

II. Control enforcement
  1. Respond to any emergency condition in its region of plant cognizance.
  2. Locally optimize the operation of units under its control within limits of established production schedule; carry out all established process operational schemes or operating practices in connection with these processes.

III. Plant coordination and operational data reporting
  3. Collect and maintain data queues of production, inventory, and raw material and energy usage for the units under its control.
  4. Maintain communications with higher and lower levels.
  5. Service the man/machine interfaces for the units involved.

IV. System reliability assurance
  6. Perform diagnostics on itself and lower-level machines.
  7. Update all standby systems.

Lower-Level Computer Tasks

In the hierarchy shown in Figure 2.11m, all contact with the controlled process is maintained through the computers of Levels 1 and 2. The distributed, microprocessor-based systems, are all effectively stand-alone Level 1 and 2 systems.

TABLE 2.11q
Duties of the Area Level (Level 3)

I. Production scheduling
  1. Establish the immediate production schedule for its own area, including transportation needs.
  2. Locally optimize the costs for its individual production area as a basis for modifying the production schedule established by the production control computer system (Level 4A) (e.g., minimize energy usage or maximize production).

III. Plant coordination and operational data reporting
  3. Make area production reports.
  4. Use and maintain area practice files.
  5. Collect and maintain area data queues for production, inventory, raw materials usage, and energy usage.
  6. Maintain communications with higher and lower levels of the hierarchy.
  7. Collect operations data and off-line analysis as required by engineering functions.
  8. Service the man/machine interface for the area.
  9. Carry out needed personnel functions (such as vacation schedule, work force schedules, and union line of progression).

IV. System reliability assurance
  10. Diagnostics of self and lower-level functions.

TABLE 2.11r
Duties of the Production Scheduling and Operational Management Level (Level A)

I. Production scheduling
  1. Establish basic production schedule.
  2. Modify the production schedule for all units per order stream received, energy constraints, and power demand levels.
  3. Determine the optimum inventory level of goods in process at each storage point. The criteria to be used will be the trade-off between customer service (e.g., short delivery time) versus the capital cost of the inventory itself, as well as the trade-offs in operating costs versus costs of carrying the inventory level. (This is an offline function.)
  4. Modify production schedule as necessary whenever major production interruptions occur in downstream units, where such interruptions will affect prior or succeeding units.

III. Plant coordination and operational data reporting
  5. Collect and maintain raw material use and availability inventory and provide data for purchasing for raw material order entry.
  6. Collect and maintain overall energy use data for transfer to accounting.
  7. Collect and maintain overall goods in process and production inventory files.
  8. Collect and maintain the quality control file.
  9. Maintain interfaces with management interface level function and with area level systems.

IV. System reliability assurance
  10. Run self check and diagnostic routines on self and lower-level machines.

According to Table 2.11o, the tasks of these systems are to maintain direct control of the process; to detect and respond to timing signals, emergencies, and other events in the process; to collect process data for the plant operators or

TABLE 2.11s
Required Tasks of the Intracompany Communications Control System (Level 4B)

III. Plant coordination and operational data reporting
  1. Maintain interfaces with plant and company management, sales personnel, accounting and purchasing departments, and the production scheduling level (Level 4A).
  2. Supply production and status information as needed to plant and company management, sales personnel, and the accounting and purchasing departments. This information will be supplied in the form of regular production and status reports and in response to online inquiries.
  3. Supply order status information as needed to sales personnel.

IV. System reliability assurance
  4. Perform self check and diagnostic checks on itself.

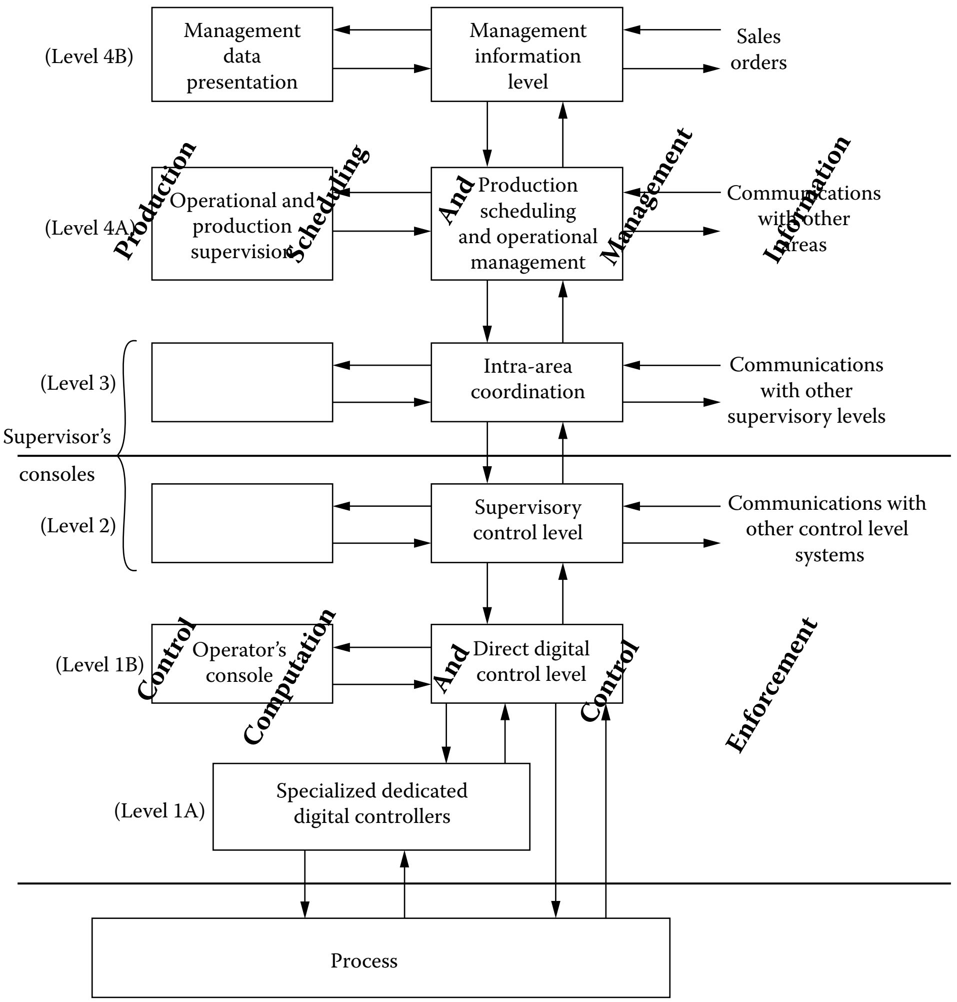

FIG. 2.11t
Summary of the tasks of the hierarchical computer.

for higher-level functions; and to ensure reliability by monitoring their own operation.

To do this, the system must monitor each important plant or process variable on a regular basis. That is, it must read the current value of the variable and, first, compare it with a set of alarm limits to detect the presence of any emergency situation and, second, compare it with the current operating set point to determine whether any correction to the current control output is necessary. Close check is also kept of the passage of time on the system real-time clock since most systems are time coordinated. That is, the monitoring program is reinitiated at fixed time intervals based upon the required sampling interval for the process variables.

As just indicated, plant variables are normally monitored either on a fixed time schedule, so that every variable is tested each second or fraction of a second (common in microprocessor-based distributed systems) or on a variable schedule depending upon the detected variable type. Table 2.11u lists the frequencies at which the various process variables are sensed. This second system has been popular for minicomputer-based digital control systems that commonly do not have the speed capability of the distributed systems. It is based on the dynamics or speed of response of the process being monitored and controlled.

TABLE 2.11u
Sampling Frequency for Process Variables

Variable	*Frequency*
1. Flow	Once each second
2. Level and pressure	Once each 5 seconds
3. Temperature	Once each 10 seconds
4. Queries from the operator's console	Once each second

Note: In some systems, process variables are sampled much more frequently than this. These are minimum rate values established from plant experience.

The timing of the process variable sampling is normally based upon a real-time clock included in the computer system.

If an emergency is detected, the computer's program contains routines for correcting the emergency or calling the operator's attention to it. The routines are selected according to a priority interrupt scheme. Control correction computations are carried out by means of a set of control algorithms or computational routines also stored in the computer's memory.

In addition to being used for emergency detection and control corrections, the values of the process variables are stored in the computer's memory in a process data base. These data are then available for readouts on the operators' consoles, for data logging, for historical records, for process efficiency calculations, and for readout to higher-level computers for optimization calculations, inventory monitoring, overall plant production status, historical file updates, and other necessary calculations. These calculations thus fulfill the systems coordination and reporting functions listed in Table 2.11o.

The computer uses any spare computational time to run test computations to check the validity of its own operation and of any companion computers in the system. These and other related tests fulfill the need for the reliability assurance functions listed in Table 2.11o.

Higher-Level Computer Tasks

As noted in the previous section, all contact with the controlled process is maintained through the input/output interfaces of Levels 1A and 1B. These interfaces may be part of a microprocessor-based distributed control system or of a minicomputer-based direct digital controller. Any other layout would require a reversion to the schemes of Figures 2.11d, 2.11g, or 2.11i, all of which have distinct drawbacks compared to Figures 2.11k or 2.11m.

The upper-level machines are connected to the lower-level systems and to each other through the communications system. Their major tasks, as outlined in Tables 2.11p to 2.11t, are to carry out the extensive computations involved in (1) the optimization of productivity and of raw material and energy use in each process; (2) the development of the best production schedule for the overall plant; and (3) the minimization of the plant's inventory.

An equally important task is the processing of the plant's production data as collected by the lower-level machines in order to supply the proper information to plant supervisory and management personnel and in order to maintain the plant's production database for the company's production, financial, and personnel reports.

2.12 Interaction and Decoupling

S. OCHIAI (1995, 2005)

INTRODUCTION

In this section, the interaction between loops, the measurement of interaction, and the design of the algorithms used are illustrated through a case study of level control on a chemical reactor and flasher system. The achievement of noninteracting control, or decoupling, is one of the goals of multivariable control. The decoupling algorithm is simple, and the physical meaning of the individual decoupling elements is clear to the designer and the plant operator.

During the last decade, advanced process control methods have been extensively used in processing industries. However, these methods have usually been applied to large processing systems because the cost of software and process model development is rather high.

In applications where the process is small or is only a small part of a larger process, the use of advanced process control may not be economically justified. When this is the case, process control engineers can develop and implement multivariable control on their own. Decoupling control is a tool that can be used to reach this goal.

INTERACTING PROCESS EXAMPLE

Figure 2.12a illustrates the conventional level controls of a process consisting of a chemical reactor and a flasher. Such systems are typical subprocesses in many petrochemical plants.

As shown in Figure 2.12a, feeds 1 and 2 enter the reactor, and the product from the reactor is sent to the flasher. The pressure in the flasher is much lower than that in the reactor, and therefore the low boilers contained in the product are vaporized and are sent from the flasher to a downstream distillation column for recovery.

The liquid from the flasher is returned to the reactor under level control (m_2). The product flow from the reactor to the flasher is manipulated to control the level in the reactor. Therefore, when the reactor level rises, the level controller increases the product flow, which in turn causes the flasher level to rise. Inversely, when the flasher level rises, the level controller on the flasher increases the recycle flow, which in turn raises the reactor level.

The left side of Figure 2.12b illustrates the oscillation, which is caused by the interaction between the two level control loops. On the right side of the figure, the response obtained by "partial decoupling" is shown. This technique will be described later, after developing some general equations and comments about noninteracting control.

Decoupling the Process

Figure 2.12c illustrates a noninteracting or decoupled version of the previously described process, in which the interaction between the level loops has been eliminated.

The reactor product flow is set as the sum of signals m_1 and m_2, which are the output signals of the level controllers on the reactor and the flasher. The recycle flow is set as $am_1 + m_2$, where "a" is the fraction of the product flow that stays in the flasher base as a liquid.

When the reactor level increases, causing the direct acting LC-1 controller output to also rise by Δm_1, the liquid flow to the flasher base will increase by $a\Delta m_1$. However, the recycle flow also increases by $a\Delta m_1$ if the adder #2 is correctly adjusted.

Therefore, the flasher level remains unchanged and the interaction has been "decoupled." A similar sequence of events occurs when the flasher controller output changes by Δm_2.

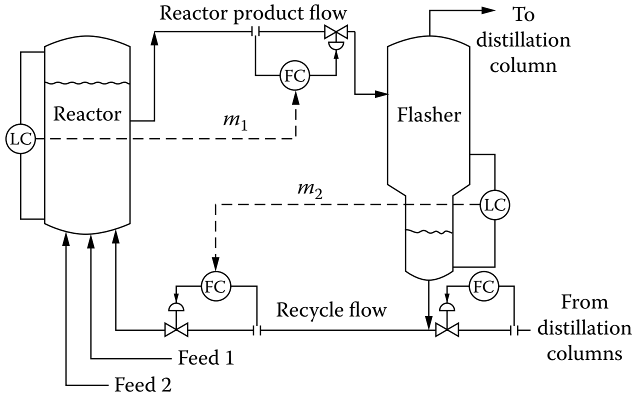

FIG. 2.12a
Level controls for reactor and flasher process without decoupling the interaction of the loops.

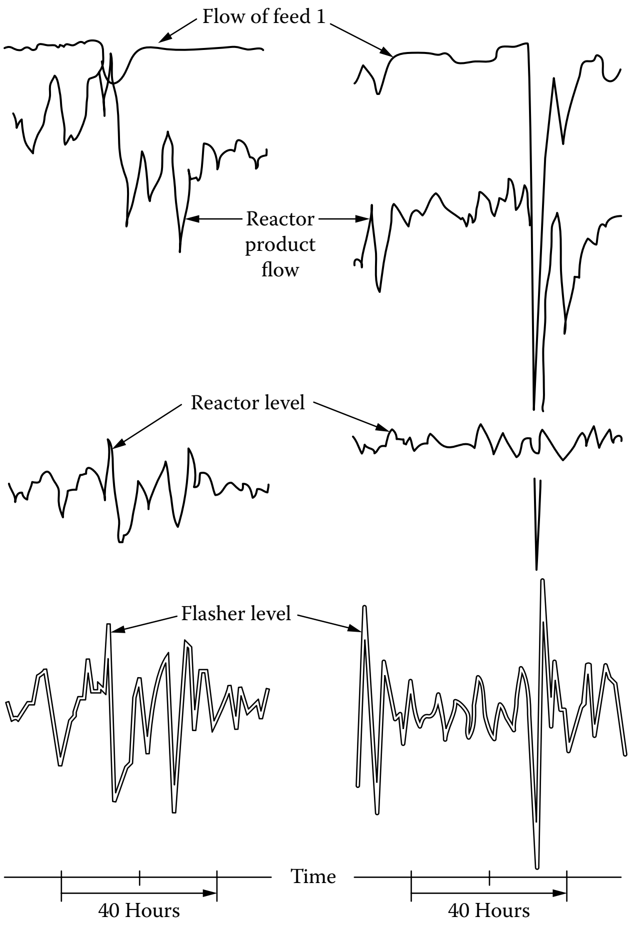

FIG. 2.12b
Response of the reactor–flasher system to upsets in feed flow under conventional (left) and partially decoupled controls.

In this example, the process dynamics were very simple, and a noninteracting control system could be configured by direct physical interpretation of the process. In the following discussion a generalized approach will be described.

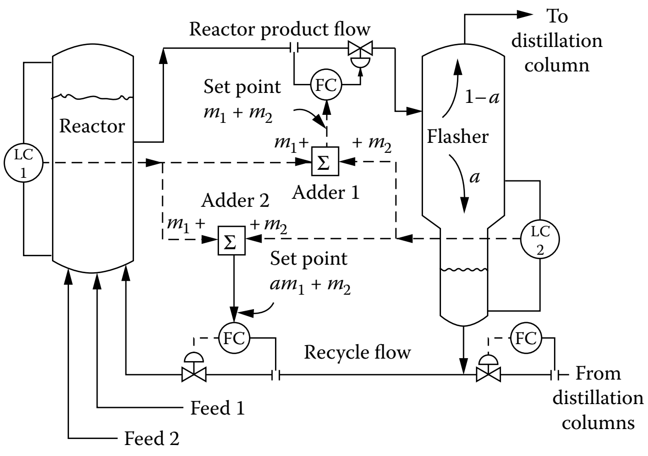

FIG. 2.12c
Noninteracting (decoupled) level control system for the reactor–flasher process.

Generalizing the Solution

Figure 2.12d represents a control system[1] having two controlled variables (such as levels of the reactor and the flasher in the previous example), $c_1(s)$ and $c_2(s)$, where s is a complex variable.

The transfer functions[1–3] of the processes are represented by $G(s)$ symbols, and the transfer functions[2,3] of the two controllers are denoted by $F_{11}(s)$ and $F_{22}(s)$. The controller outputs are respectively $m_1(s)$ and $m_2(s)$. The set points of the controllers are designated by $r_1(s)$ and $r_2(s)$.

In a noninteracting control system, the decoupler elements $F_{21}(s)$ and $F_{12}(s)$ are added so that they will compensate for and thereby eliminate the process interactions designated as $G_{21}(s)$ and $G_{12}(s)$.

In order to build a decoupled control system, one would first obtain F_{21}. The effect of m_1 to c_2 is transmitted from point "P" to "Q" via two (heavily drawn) paths, one through G_{21}, the other through F_{21} and G_{22}, and the sum of the two should be zero:

$$G_{21}m_1 + F_{21}G_{22}m_1 = 0 \qquad \textbf{2.12(1)}$$

Therefore,

$$F_{21} = -G_{21}/G_{22} \qquad \textbf{2.12(2)}$$

Similarly, considering the influence of m_2 on c_1,

$$F_{12} = -G_{12}/G_{11} \qquad \textbf{2.12(3)}$$

For a general case with n controlled variables and n manipulated variables, see Reference 4.

For the reactor and flasher system:

$$\begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22} \end{bmatrix} = \begin{bmatrix} -1/(A_1 s) & 1/(A_1 s) \\ a/(A_2 s) & -1/(A_2 s) \end{bmatrix} \qquad \textbf{2.12(4)}$$

where A_1 and A_2 are, respectively, the cross-sectional areas of the reactor and the flasher. Consequently, the decoupler settings are

$$F_{21}(s) = -\frac{G_{21}}{G_{22}} = -\left(\frac{a}{A_2 s}\right)(-A_2 s) = a \qquad \textbf{2.12(5)}$$

$$F_{12}(s) = -\frac{G_{12}}{G_{11}} = -\left(\frac{1}{A_1 s}\right)(-A_1 s) = 1 \qquad \textbf{2.12(6)}$$

Note that the values of A_1 and A_2 in Equation 2.12(4) do not appear in Equations 2.12(5) and 2.12(6) because they

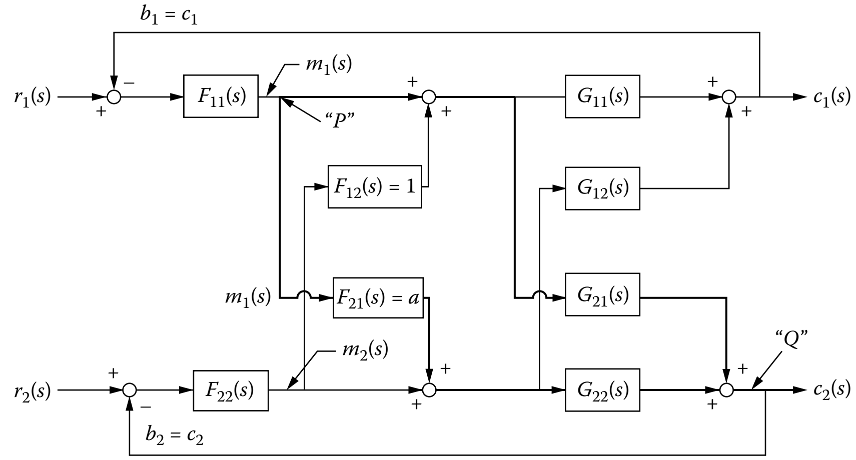

FIG. 2.12d
Generalized block diagram representation of a two-variable noninteracting control system.

cancel out. In general, it is easier to estimate the ratios than to estimate the individual transfer functions. This is particularly so when only crude estimates are available.

Measuring the Interactions

Before an effort is made to design a noninteracting control system, it is desirable to have an idea of the amount of interaction that is present. A relative gain calculation, described in Section 2.25, serves this purpose.

Relative gain is defined as the open-loop gain when all the other loops are in manual, divided by the open-loop gain when all the other loops are in automatic.

$$\lambda_{11} = \frac{\left.\dfrac{\partial c_1}{\partial m_1}\right|_{m_2}}{\left.\dfrac{\partial c_1}{\partial m_1}\right|_{c_2}} \qquad \mathbf{2.12(7)}$$

It can be seen from the block diagram in Figure 2.12d that if both $F_{12}(s)$ and $F_{21}(s)$ were nonexistent (i.e., if the single-variable control system of Figure 2.12a were implemented), the numerator in the relative gain calculation would be $G_{11}(s)$ and the denominator would be

$$(G_{11}G_{22} - G_{12}G_{21})/G_{22} \qquad \mathbf{2.12(8)}$$

because the control loop for c_2 would force m_2 to take on the value which would cause

$$G_{21}m_1 + G_{22}m_2 = 0 \qquad \mathbf{2.12(9)}$$

If the value of a is 0.5, then from Equations 2.12(5) to 2.12(8):

$$\lambda_{11} = 1/(1 - a) = 2.0 \qquad \mathbf{2.12(10)}$$

This means that when the recycle flow m_2 is manually fixed at a constant value (which is the numerator in Equation 2.12[7]), the effect of manipulating the reactor product flow m_1 to control the reactor level is twice as much as it is in the case when m_2 is automatically manipulated (the denominator in Equation 2.12[7]).

When the decoupler of Equation 2.12(5) is inserted into the loop (Figure 2.12d), c_2 does not vary when m_1 is changed. Therefore, output m_2 of controller F_{22} does not vary either, i.e., the denominator in Equation 2.12(7) is equal to the numerator and therefore the relative gain is 1.0. (As is shown in Section 2.25, $\lambda_{22} = \lambda_{11}$.)

Therefore, the effect of manipulating the recycle flow m_2 can be treated similarly. Interaction between the two loops is significant.

MERITS, DRAWBACKS, AND COMPROMISES

Decoupling algorithms such as Equations 2.12(5) and 2.12(6) can be simple, and therefore their physical meanings can be easily understood by the designer and by the plant operators. After noninteracting control is implemented, the control loops can be easily tuned based on single-variable control theory (Section 2.35).

Drawbacks

When noninteracting control is implemented, a set point change applied to one controlled variable will have no effect on the other controlled variable(s).

In some other industrial process control systems interaction between control loops can be exploited to achieve overall control. In other words, a noninteracting control system can be slower in recovery from an upset than an interacting one.

A more obvious drawback of decoupling can occur in the case when one of the G_{ij}'s in Figure 2.12d has a positive zero, that is, for example,

$$G_{11} = (s - b)/(s + c) \qquad \textbf{2.12(11)}$$

where b and c are positive constants. Such a process characteristic is called inverse response.[1] In this case decoupler $F_{12}(s)$ in Equation 2.12(3) will have a term $(s - b)$ in the denominator, and the control system will provide poor performance and could become unstable.

Partial and Static Decoupling

Because of these potential drawbacks, it is recommended to give consideration to partial decoupling, i.e., to implement only some of the available decouplers. Likewise, it may be an advantage to use a smaller gain than complete decoupling would allow. Partial decoupling can be more robust and less sensitive to modeling errors,[5] and in some cases it can achieve better control than complete decoupling does.

Another method of obtaining noninteracting control is through static decoupling.[6] Here the objective is to eliminate only the steady-state interactions between loops. The static decouplers are obtained by $\lim_{s\to 0} F_{21}(s)$ and $\lim_{s\to 0} F_{12}(s)$ in Equations 2.12(2) and 2.12(3). In case of the reactor and flasher systems, the decouplers used are static decouplers.

The Reactor–Flasher Example

The right half of Figure 2.12b was obtained by setting the decoupler F_{12} to 0.5 instead of using the 1.0 setting, which Equation 2.12(6) would have called for. The gain in the decoupler was halved to reduce the flow variation in the flasher overhead to the subsequent distillation column.

In addition, decoupler $F_{21}(s)$ was not implemented at all. It was left out because the response of the flasher level is much faster (the cross-sectional area of the tank is smaller) than that of the reactor, and therefore variation in the flasher level, within reasonable limits, is not detrimental to the operation, while changes in the reactor level are.

As can be seen in Figure 2.12b, even with only partial decoupling, the variation in the reactor level is much reduced in comparison to the case without decoupling. It should be noted that this improvement occurred even though a drastic change in reactor feed #1 did substantially upset the flasher level.

2.13 Model-Based Control

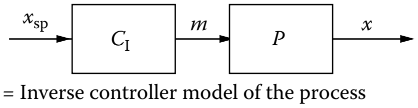
R. R. RHINEHART (1995, 2005)

In model-based control (MBC), computers use a process model to make control decisions. By comparison to PID-type approaches, the MBC action is "intelligent" and has shown benefits in uniformity, disturbance rejection, and setpoint tracking, all of which translate into better process safety and economics. On the other hand, MBC requires higher skill by the operator and engineer, and computational power. On the other hand, higher level of understanding of process models means better process understanding, better personnel training, diagnosis ability, and process management. There are many successful commercial controllers, and some distributed control system (DCS) suppliers offer MBC software packages with their equipment.

THE STRUCTURE OF MBC

The basic concept of MBC is illustrated in Figure 2.13a, where the "controller," C_I, uses a model of the process to calculate a value for the manipulated variable that should make the controlled variable (x) behave in a desired way. If it does, then that calculated value of m is then implemented. The controller does not have PID components and, in general, there is only one tuning parameter per controlled variable—the choice of how fast the controlled variable (x) should move to the setpoint (x_{sp}). The symbol C_I represents the model inverse. The "inverse" nomenclature arises from how the model is used. In a normal modeling approach, one specifies the process input, and the model predicts the process output response. By contrast, MBC determines the process input that causes a desired process output response; this is the model inverse.

If the model is perfect and no constraints exist, the open loop structure of Figure 2.13a will work. However, nearly all controller models are not perfect; therefore, they require some form of feedback correction. The conventional feedback approach is illustrated in Figure 2.13b, where the difference (d) between the model (C_M) and the process output (x) is monitored and used to adjust a controller feedback (c), which usually is either a bias to the setpoint (x_{sp}) or a model coefficient. The controller consists of the three functions C_I, C_M, and C_A, enclosed by the dashed line.



C_I = Inverse controller model of the process
P = Process

FIG. 2.13a
Model-based control (MBC) concept.

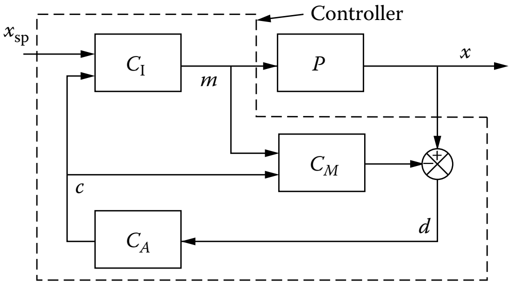


FIG. 2.13b
The three MBC functions: inverse, model, and adjustment.

Although the common aim of this strategy is to make intelligent control decisions, the choices of model structure, control objective, adjusting mechanism, and adjustable parameters have led to many variations in model-based controllers. The choice of model structure affects implementation, limits choices of other controller functions, and sets the accuracy of control decisions. Model structure, therefore, is of primary importance. Choices for control objective, adjustment mechanisms, and adjustable parameters, and methods for other features such as constraint handling, optimization, and data reconciliation are influential but secondary. Accordingly, MBCs are generally classified by model type.

MODELING APPROACHES

The three dominant modeling approaches of commercially offered MBC products—linear transfer function, linear time series, and nonlinear time series—are all empirical. However, phenomenological or fundamental, mechanistic models are used on a custom basis. Transfer function models are mostly based on open-loop Laplace transform descriptions of the process response to a step input and have been the traditional control modeling approach. Their familiarity and the simplicity of the resulting MBC are advantages which offset their limitations of linear and simplistic dynamic modeling. In addition, a controller based on a Laguerre polynomial model has demonstrated sustained commercial success.

Time series models represent the open-loop response of the process with a vector of impulses that are empirically determined and consist of 30 to 180, or so, elements. The precision of the performance of the modeled dynamic process is an advantage that offsets the limiting assumption that the process is linear, as well as the need for using matrix/vector algebra. This is the most common modeling approach in the industrial use of MBC today.

Some vendors offer nonlinear MPC versions that extend the valid operating range otherwise limited by the linear models. These include transitioning between multiple linear models when transitioning between operating regions, neural network–based models, or gain scaling of the linear model by any number of methods (fuzzy logic, expert rules, neural networks, process properties, etc.).

Nonlinear phenomenological models are design-type simulators. For markedly nonlinear or nonstationary process applications, their control intelligence can offset the disadvantage of their modeling and computational complexity.

In all cases, control is only as good as the model is a true representation of the process. Initializing the controller with a model that has been validated by process testing is the first and most critical implementation step.

INTERNAL MODEL CONTROL (IMC)

IMC uses open-loop step-response Laplace transfer function models. The model, C_M, may be the simple first-order-plus-deadtime (FOPDT) representation of a single-input–single-output (SISO) process:

$$\frac{\hat{x}}{\hat{m}} = C_M(s) = \frac{K_p}{\tau_p s + 1} e^{-\Theta_p s} \qquad \textbf{2.13(1)}$$

Ideally, the inverse is the reciprocal of the model, and if one wants the process to track the setpoint ($x = x_{\text{sp}}$) then

$$\hat{m} = C_I(s)\hat{x}_{\text{sp}} = C_m^{-1}(s)\hat{x}_{\text{sp}} = \left[\left(\frac{\tau_p}{K_p}s + \frac{1}{K_p}\right)e^{+\Theta_p s}\right]\hat{x}_{\text{sp}} \qquad \textbf{2.13(2)}$$

Equation 2.13(2) specifies how to calculate m, given x_{sp}, but its use presents some problems. First, the exp($+\Theta_p s$) term specifies that m must change before a change in x_{sp} has occurred. Since the future cannot be predicted, that action term is unrealizable. Second, the $(\tau_p/K_p)s$ term specifies taking the derivative of x_{sp}, and therefore, it responds to step changes in x_{sp} with the generation of an infinite spike in m. Third, if either the value of K_p is not exactly correct or if calibration errors have occurred, Equation 2.13(2) will result in a steady-state offset.

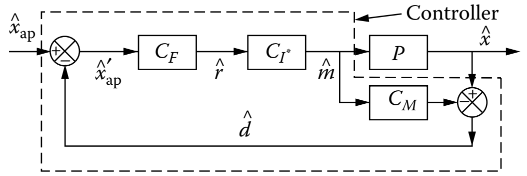

FIG. 2.13c
The basic IMC structure.

These problems are remedied in the IMC structure shown in Figure 2.13c. Here C_{I^*} is the realizable and stable part of the model inverse. For the SISO FOPDT example:

$$C_{I^*}(s) = \left(\frac{\tau_p}{K_p}s + \frac{1}{K_p}\right) \qquad \textbf{2.13(3)}$$

In Figure 2.13c, the variable d represents the model-to-process difference, a modeling error, regardless of error cause. If the model is in error, then steady-state offset can be removed by biasing the setpoint by that error, as shown. Setpoint biasing is the IMC feedback adjustment method. To eliminate spikes in m due to both measurement noise and setpoint changes, the biased setpoint is filtered (C_F) to obtain a reference trajectory, r. The inverse (C_I) calculates m, which would make the idealized process output (x) track r.

After some block diagram rearrangement, Figure 2.13d presents the SISO IMC function blocks for a process that can be modeled as FOPDT. Note that the functions are leads, lags, delays, summations, and gains, and they can be configured in almost any distributed control system (DCS), single-loop controller (SLC), or programmable logic controller (PLC). The single tuning parameter is τ_f, the filter time-constant. Lower values of τ_f make the controller more aggressive; higher values make it gentler.

One technical drawback to IMC is that the model is linear and stationary. If either the process gain or the time-constants change, the model-based calculations become either too aggressive or sluggish, and therefore, retuning is required.

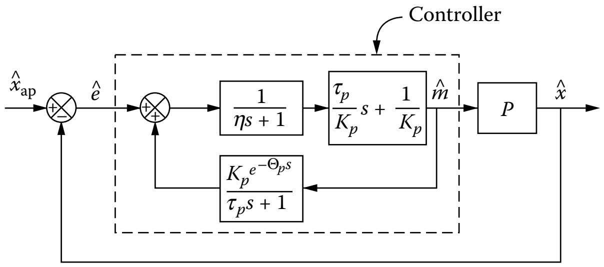

FIG. 2.13d
IMC for a FOPDT process. The C_F, C_{I^*}, and C_M blocks have been rearranged to show implementation.

This is not different from PID control, in which changes in process gain or dynamics also require retuning. If the process gain or dynamics change substantially, the model parameter values should be renewed. The other technical disadvantage of IMC is that for multi-input–multi-output (MIMO) processes the coupling causes the number of models to increase as the square of the number of manipulated variables, which makes finding the realizable inverse somewhat complicated, and there is no useful approach to solving for the MIMO control action in the case of constraints of an excess number of manipulated variables.

An advantage is that SISO IMC can be implemented with the skill of most control engineers using standard DCS or PLC functions. As a note, lambda tuning of PID controllers is based on the IMC approach.

MODEL PREDICTIVE CONTROL (MPC)

The MPC models, often called time series or convolution models, represent the open-loop process response as a vector. Figure 2.13e illustrates this. At i time increments after the single, unity input step change in the manipulated variable (m), the output (x) has changed by an amount h_i. A list of the values of the h_i elements in the vector $\underline{h}$ is the process model.

Any input behavior can be represented as a sequence of steps, and the output of a linear process as the cumulative effects of those steps. Figure 2.13f illustrates this for an input modeled as three steps after an extended period of steady conditions. Mathematically, this SISO time series process model is

$$\begin{aligned} x_1 &= x_0 + h_1 \cdot \Delta m_1 \\ x_2 &= x_0 + h_2 \cdot \Delta m_1 + h_1 \cdot \Delta m_2 \\ x_3 &= x_0 + h_3 \cdot \Delta m_1 + h_2 \cdot \Delta m_2 + h_1 \cdot \Delta m_3 \\ &\cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \quad \cdot \end{aligned} \qquad \textbf{2.13(4)}$$

where x_i is the ith value of x due to all preceding Δm's.

In compact vector/matrix notation,

$$\underline{\Delta x} = \underline{\underline{H}} \cdot \underline{\Delta m} \qquad \textbf{2.13(5)}$$

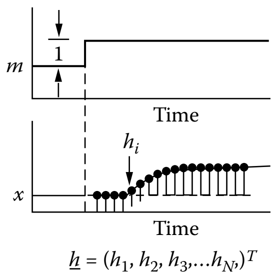

FIG. 2.13e
Dynamic vector, $\underline{h}$, describes an ideal unit step response.

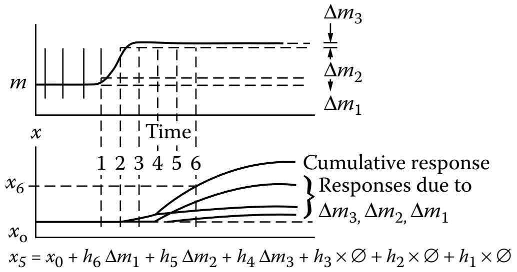

FIG. 2.13f
Illustration of time series modeling.

where $\underline{\Delta x} = \underline{x} - x_0 \cdot \underline{1}$ and $\underline{\underline{H}}$ is the lower diagonal matrix composed of staggered $\underline{h}$'s. $\underline{\underline{H}}$ is termed the dynamic matrix. $\underline{\Delta m}$ is the vector of past input steps.

If a desired behavior for x is specified (for instance, a path of return to setpoint), it can be expressed as a vector of Δr's and the necessary sequence of Δm's can be idealistically calculated from the SISO model inverse.

$$\underline{\Delta m}_f = \underline{\underline{H}}^{-1} \cdot \underline{\Delta r}_f \qquad \textbf{2.13(6)}$$

Here $\underline{\Delta m}_f$ is the required future sequence of m's. There are several problems, however, with this primitive concept. If the process has deadtime, leading elements of $\underline{\underline{H}}$ are zero and Equation 2.13(6) will result in a division by zero. Another problem is that Equation 2.13(6) ignores the residual influence of past Δm's that will affect x. If $\underline{h}$ is not a true model, it will result in steady-state offset. The methods for handling such issues vary but are conceptually expressed in Figure 2.13b. The function C_M is the model of Equation 2.13(5). The function C_A may simply be a filter to remove measurement noise from the model mismatch signal, d. For a SISO controller the function C_I would be

$$\underline{\Delta m}_f = \underline{\underline{H}}^{*-1} \cdot (\underline{\Delta r}_f + d \cdot \underline{1} - \underline{\underline{H}} \cdot \underline{\Delta m}_p) \qquad \textbf{2.13(7)}$$

where the subscripts f and p mean future and past, and d is the filtered value of the model mismatch, which is assumed to be constant into the future and is used to bias the reference trajectory. $\underline{\underline{H}}^*$ is the realizable model inverse, and the division-by-zero problem has been eliminated.

Exact tracking of $\underline{\Delta r}$ by Equation 2.13(7) may define extreme manipulated variable (MV) moves for high-order or inverse-acting processes. Accordingly, in practice, the MPC law, Equation 2.13(7), is usually restructured so as to determine the $\underline{\Delta m}_f$ values that minimize the sum of squared deviations of the model prediction from the desired path plus a weighted sum of squared changes in m, a least-squares optimization. There exist a variety of single-line equations that specify the linear algebra operations that would be used to calculate values for MVs for selected MIMO processes. However, there is one additional complication to be handled.

The preceding discussion was for a SISO process. The development is similar for MIMO processes. If the process is a "square system," in which the number of unconstrained manipulated variables (MV) equals the number of unconstrained controlled variables (CV), then the vector terms in Equations 2.13(5 to 7) become matrices of vectors, and the matrices in those equations become matrices of matrices. However, MIMO systems are rarely square. Manufacturing optimization usually places the operating point on a process constraint — either a maximum MV value or an uncontrolled process variable (PV) related to safety (pressure) or to proper operations (flooding). If not, there are often excess numbers of MVs. In either case, the square concept that leads to the closed form analytical expression of Equation 2.13(7) will not work. For nonsquare systems, we use numerical optimizers to minimize the sum of squared deviations from the setpoint, with a penalty for excessive manipulated variable changes, penalty for utilities cost, and subject to a variety of process constraints. An example is

$$\begin{aligned} &\frac{\min J}{\{m_{k,l}\}} = \sum_{i}^{n\mathrm{CV}} \left[\lambda_i \sum_{j}^{t} (e_{i,j})^2 \right] + \sum_{k}^{n\mathrm{MV}} \left[f_k \sum_{l}^{t} (\Delta m_{i,j})^2 \right] \\ &\mathrm{S.T} \left| \Delta m_{k,l} \right| < \Delta m_{\max k} \qquad \textbf{2.13(8)} \\ &\quad \mathrm{PV}_{\min i} \le \mathrm{PV}_{i,j} \le \mathrm{PV}_{\max i} \end{aligned}$$

where *n*CV and *n*MV represent the number of CVs and MVs, and subscripts *j* and *l* represent discrete future samplings.

MPC is used in standard industrial practice and is marketed by many control consulting and DCS vendor companies. Optimizing algorithms include linear programming and successive quadratic programming, and there are a variety of refinements to the objective function and constraints. Several major process companies have used teams of engineers to develop in-house controllers, but most users prefer to buy a tested externally developed package.

The common limitation of MPC is that $\underline{h}$ is a linear and stationary model; and therefore, substantial changes in operating conditions may require the development of a new model. To extend the range of linear MPC algorithms, some vendors are offering a range of improvements, which include transitioning between models, gain scheduling, or nonlinear time series models.

PROCESS-MODEL-BASED CONTROL (PMBC)

Process models can be developed from a mechanistic (or first-principles, or phenomenological) point of view, based on material and energy balances and thermodynamic relations. Design-type simulators and supervisory optimizers use the steady state form of these sorts of models. However, for control, full design rigor is not required. Simple, reduced, or tendency models are usually sufficient for control, but the model needs to include dynamic response. A dynamic model for a SISO process may be represented as

$$\frac{dx}{dt} = f(x, m, p) \qquad \textbf{2.13(9)}$$

where p is an adjustable process parameter.

A simple control objective would be to have the process start moving from x to x_{sp} at a rate such that it would reach x_{sp} within some time τ. This specifies the local derivative, and the control law becomes the model inverse which determines m from the desired control action. For the SISO process,

$$f(x, m, p) - \frac{x_{\mathrm{sp}} - x}{\tau} = 0 \qquad \textbf{2.13(10)}$$

Since x is measured, p is set, and x_{sp} and τ are user-defined, Equation 2.13(10) can be solved for m. τ is the single tuning parameter. Such equations are often nonlinear, and the solution may require iterative techniques such as Newton's or bisection. However, for nonlinear processes there is an advantage over linear model controllers. The PMBC model accounts for changes in process gain and dynamics; and, once tuned, the controller does not need to be returned when the process conditions change.

Expectedly, Equation 2.13(10) will result in steady-state offset if the model is not perfect. A variety of feedback adjustment approaches have been demonstrated; some bias the setpoint, some adjust a process parameter. SISO Generic Model Control (GMC) can be implemented relatively easily by the control engineer. It biases the setpoint with an integral of the past errors to yield the control law:

$$f(x, m, p) - \frac{x_{\mathrm{sp}} - x}{\tau_1} - \tau_2 \int (x_{\mathrm{sp}} - x)\,dt = 0 \qquad \textbf{2.13(11)}$$

This functional form is comfortable for many. It is like a PI controller with a nonlinear function on the controller output. And, comfortably, it is easily tuned by adjusting τ_1 like a proportional band to determine the aggressiveness of the initial response, then adjusting τ_2 to remove the offset at a comfortable rate.

A variety of other nonlinear model-based controllers result from a variety of choices about the feedback procedure. For instance, external reset feedback can be used to eliminate integral windup. Model parameter values can be adjusted to track process changes. Criteria for selecting the adjustable parameters are:

1. Choose a parameter that represents a real process mechanism (not a hypothetical disturbance).

2. Choose a mechanism that changes.
3. Choose a mechanism that has a substantial influence on the process output.

Choices for adjustable parameters might include heat exchanger fouling factors, ambient heat losses, catalyst activity, or tray efficiency. A secondary benefit of this feedback approach is that the adjustable parameter value can be used for process diagnosis and to trigger maintenance.

The PMBC approach extends to MIMO processes; but to accommodate nonsquare systems, the control law would be the same as Equation 2.13(8).

The same PMBC model can be used for supervisory economic process optimization throughout the process operating range. For nonlinear or nonstationary processes, the self-tuning, diagnostic, and economic optimization advantages of PMBC can offset the engineering effort required to develop an appropriate phenomenological model.

SUMMARY

Model-based controllers have demonstrated economic advantages over classical PID approaches, but they also have disadvantages. In order to develop a front-end model one must initiate substantial process disruptions (step tests) or initiate expensive engineering efforts. Often, additional or improved sensors are also required. Although SISO model-based controllers can be implemented in existing DCS or PLC microprocessors, often an additional microcomputer is also required for model-based controllers. The technology of the modeling, controller, tuning, and optimization approaches requires operator and process engineer training.

Accordingly, MPC methods are recommended for difficult-to-control, multivariable, constrained, and/or economically critical processes.

INTRODUCTION

From optics to distillation to financial derivatives trading to navigation, the applications of model-based predictive control seem practically endless. Likewise, mathematical techniques vary from Model Algorithmic Control to Dynamic Matrix Control to Inferential Control to Internal Model Control. Diverse applications or functions, and techniques or forms, make model-based predictive control popular in the patent literature.

Patent Basics

For a patent to be granted, one has to "tell all," or as put forth by the U.S. Code of Federal Regulations:

> (a) The [Patent] specification must include a written description of the invention or discovery and of the manner and process of making and using the same, and is required to be in such full, clear, concise, and exact terms as to enable any person skilled in the art or science to which the invention or discovery appertains, or with which it is most nearly connected, to make and use the same.
>
> (b) The specification must set forth the precise invention for which a patent is solicited, in such manner as to distinguish it from other inventions and from what is old. It must describe completely a specific embodiment of the process, machine, manufacture, composition of matter, or improvement invented, and must explain the mode of operation or principle whenever applicable. The best mode contemplated by the inventor of carrying out his invention must be set forth.

Thus, the freely available patent databases of the world are a natural place to play out one's interest in any technical field. Whether one is interested in a particular application or the fundamental basics of the calculations involved, ample material exists to satisfy that interest.

The U.S. Patent Office (USPTO) describes a patent as a grant of property right to exclude others from making, using, offering for sale, selling, or importing the invention. Once a patent is issued, the patentee must enforce the patent on his or her own. Any person who "invents or discovers any new and useful process, machine, manufacture, or composition of matter, or any new and useful improvement thereof, may obtain a patent," subject to the conditions and requirements of the law. The word "process" is defined by law as a process, act, or method, and primarily includes industrial or technical processes. Three general types of patents exist worldwide. In the U.S., they are described as follows:

> *Utility patents* may be granted to anyone who invents or discovers any new and useful process, machine, article of manufacture, or compositions of matters, or any new useful improvement thereof.

Design patents may be granted to anyone who invents a new, original, and ornamental design for an article of manufacture.

Plant patents may be granted to anyone who invents or discovers and asexually reproduces any distinct and new variety of plants.

All of the patents discussed here fall under the Utility patent classification.

Basic Patent History

Recent events on the global stage have made the patent process anything but "basic." Thus, a brief recap of the history of industrial intellectual property rights and a summary of recent developments is in order.

The United Kingdom claims to have the longest tradition of granting patents, beginning in 1449 with a "Letters Patent" issued by Henry VI to the manufacturer of stained-glass windows at Eton College. Elizabeth I granted around 50 open-ended term patents between 1561 and 1590 for the manufacture and sale of commodities such as soap, saltpeter, alum, leather, salt, glass, knives, sailcloth, starch, iron, and paper. She rejected the application for a water closet patent, however.

By 1610, concerns about the effect of monopolies led James I to revoke all patents. In 1624, the doctrine of the public interest was incorporated into the Statute of Monopolies. This statute banned monopolies except those "for the term of 14 years or under hereafter to be made of the sole working or making of any manner of new manufactures within this Realm to the true and first inventor." Such monopolies should not be "contrary to the law nor mischievous to the State by raising prices of commodities at home or hurt of trade."

The first U.S. patent law was enacted in 1790. The first U.S. utility patent was issued in 1836 to the inventor of a special type of wheel. Whether this is the source of the phrase "reinventing the wheel" is uncertain. As of this writing, there are over 6.6 million U.S. utility patents.

The first attempt to globalize industrial intellectual property rights was the 1883 Paris Convention. Further efforts led to the creation of the World Intellectual Property Office (WIPO) in 1967. WIPO is a specialized agency of the United Nations system of organizations with 179 member states. It administers 16 industrial property rights and 6 copyright treaties. Globalization efforts culminated with the Patent Cooperation Treaty (PCT). The PCT was concluded in 1970, amended in 1979, and modified in 1984 and 2001. There are well over 100 PCT contracting states at this time.

The PCT consolidates and streamlines the international patent application process for inventors. Although the patent offices of the individual states are still ultimately responsible for granting patents and collecting grant fees, inventors who use international applications under PCT only have to apply once.

They also pay a single application fee in the 1000 to 3000 USD range with the fee variation largely depending on the size of the application, the number of designated jurisdictions, whether they exercise a demand for preliminary examination, and the choice of authority (USPTO or EPO for example). In any event, the costs of multiple foreign filings dwarf the PCT fees. Moreover, while buying time for further commercial assessments, the PCT filing fees are often less than the time value of money incurred with multiple domestic and foreign filings. The process allows an inventor to establish global priority with one application.

WIPO promotes the value of the international patent search they sell. The results are set out in an "international search report." This report is generally made available to the inventor by the fourth or fifth month after the international patent application is filed. The international search report contains no comments on the value of an invention but lists prior art documents from the 30 million-plus universe of international patents (some of which are duplicates). Thus it comments on the possible relevance of the citations to the questions of novelty and inventive step (nonobviousness). This enables one to evaluate the chances of obtaining patents in the countries designated.

The most immediate effect the patent researcher will notice is the WO patent applications—the designation given to those applications filed under the PCT process. When a patent is finally granted by an individual state, the standard numbering for that state will be employed, prefixed by the state's two-letter code.

Online Patent Databases

Currently, several online patent databases that anyone can search are available. The approaches taken vary greatly. For example, some databases have global reach while others are restricted to the country that administers them. The USPTO is an example of the latter and the German database of the former. Whichever database you choose to search, you can retrieve four basic types of records:

Bibliographical—Information such as Title, Patent Number, Publication Date, Inventor(s), Applicant(s), Application Number, Priority Number(s), Classification, Literature References, and Prior Patents Cited. What you obtain depends on the country of origin and the date, as newer patents tend to be filed under the PCT.

Abstracts—Brief descriptions of the invention, usually available in English. The Japanese patent office has a "just in time" Japanese-to-English converter that is quite accurate.

Full Text—Text-only form of a patent, usually in HTML format. Full text formats differ from country to country. Some, such as the Canadian and the European Patent Offices, include drawings. There are some drawbacks to full text. For example, the U.S. full text patent database attempts to convey mathematical formulae using a plain English code page.

The USPTO provides full text records for patents back to 1976. Full text records often provide hyperlinks to other information, such as prior patents that were cited by the inventor. This is the type of information that allows for automated research.

Scanned Image — Practically all patents are now available or will be in the future in scanned form. PDF or TIFF file formats are usually employed. While not convenient for automated research, one often will ultimately need to obtain the original image in order to obtain diagrams and mathematical formulae in their original form. Patents in this form are usually in the language preferred in the country of origin. Unfortunately, at today's bandwidth, one can only download one page at a time.

Several countries and private organizations provide online patent databases that anyone can search. Some, such as Germany's DEPATISNet and the European Patent Office's esp@cenet, cover multiple foreign databases with their search engines. Others, such as the United Kingdom, rely on third parties, the European Patent Office (EPO), to provide such services. Currently the EPO's esp@cenet has the following coverage:

1. Abstracts, bibliographic data and full text:
   EPO, France, Germany, Switzerland, United Kingdom, United States, and WIPO
2. Abstracts and bibliographic data:
   China and Japan
3. Bibliographic data only:
   Argentina, ARIPO, Australia, Austria, Belgium, Brazil, Bulgaria, Canada, Croatia, Cuba, Cyprus, Czechoslovakia, Czech Republic, Denmark, Egypt, Ellas, Eurasian Patent Office, Finland, GDR, Hong Kong, India, Ireland, Israel, Italy, Kenya, Korea, Latvia, Lithuania, Luxembourg, Malawi, Mexico, Moldova, Monaco, Mongolia, The Netherlands, New Zealand, Norway, OAPI, Philippines, Poland, Portugal, Romania, Russia, Slovakia, Slovenia, South Africa, Soviet Union, Spain, Turkey, Vietnam, Yugoslavia, Zambia, Zimbabwe

Most online databases are accessible via an epacenet.com link that is a combination of the country's two-letter abbreviation and "espacenet.com." Whenever a county also maintains its own freely searchable database, the link for that database is given. In the case of Germany, the German database itself is linked to other databases—much like espacenet—but in German.

Patent Contents

Besides the basic types of information noted above, patents contain a wealth of useful information for a researcher. At the beginning of U.S. patents in full text form, one first sees an abstract. This is followed by the bibliographic information. Next come links to patents cited by the inventor as prior art. Both patents that are useful to the present invention and those that will be improved upon by it are cited. Often what follows is a list of references to other, nonpatent resources that either aid in the understanding of the current patent, are to be incorporated by reference, or further describe the prior art to be improved upon.

Following the bibliographical and claims information usually comes a brief summary followed by a description of the prior art. Prior art descriptions often contain references to previous patents and the like, making it easy for one to quickly grasp an understanding of the field of invention and to understand what is to be improved upon. Next, the inventor will typically give a brief description of how the prior art is to be improved upon followed by a description of any drawings accompanying the patent. What then follows is a detailed description of the invention, its preferred embodiments, and any examples. Examples often include sample data and even source code in order to facilitate duplication of the work by anyone skilled in the art.

GUIDE

Patent literature concerning model-based control is rich in both form and function. Form represents the various core technologies that may or may not have developed into specific functions. Function represents specific implementations that may or may not have developed from established forms. The following attempt to produce a guide that characterizes patents according to their perceived form and/or function is based on a survey of over 280 U.S. patents pertaining directly to either the form and/or function of model-based control. These patents in turn cite over 1000 other patents and over 750 other references.

Such supporting citations either deal directly with the form of model-based control or some superseding technological function. The U.S. patent database Web site provides a very convenient means of surfing to both the patents that a given patent cites as well as those patents that cite a given patent. It also makes its own attempt at classification. Other references can be obtained online from sources such as the Linda Hall Library in Kansas City, Missouri, or in some other fashion via your own local university library system.

Forms

Prediction and adaptation are the business of Model-Based Predictive Control (MBPC). To those ends, a wide variety of approaches exist that fit fairly well into two major classes.

The first class involves predictors based on rigorous mathematical models of specific processes.

Generic controllers that can be used on any process form the other major class of MBPC patents. Early implementations focused on making controllers "adaptive." Over time and with the decrease in memory costs, multivariable predictive controllers gained in importance. One subclass of such controllers is known as extended horizon predictive and predictive adaptive controllers. This subclass is further divided according to the method used to supply the "extra" inputs that extend beyond the process horizon or delay time.

These controllers include the Extended Horizon Adaptive Controller (EHC), the Receding Horizon Adaptive Controller (RHC), the Control Advance Moving Average Controller (CAMAC), the Extended Prediction Self-Adaptive Controller (EPSAC), the Generalized Predictive Controller (GPC), the Model Predictive Heuristic Controller (MPHC), and the Dynamic Matrix Controller (DMC).

Neural net-based predictors, often called "model-free predictors" because very little understanding of the process is required, are also popular members of this class. Monte Carlo simulation, Kalman filters, hill climbing, constraint control, least squares, linear programming, quadratic programming, fuzzy logic, and partial differential equation-based approaches round out the generic predictor universe. Many of these known methods are represented in the U.S. patent literature.

U.S. Patents 4,349,869 and 4,616,308 and PCT patent WO03060614 all deal with the well-known Dynamic Matrix Control, or DMC, form of Model-Based Predictive Control (MBPC). The PCT version, published July 24, 2003, provides step-by-step guidance through an actual distillation unit example (Figure 2.14a), with actual input and output data. The U.S. patent versions, also highly detailed with respect to the calculation procedures, suggest methods for coupling DMC with an offline economic optimizer applied to a typical FCC.

U.S. Patent 4,358,822, "Adaptive-Predictive Control System," also provides detailed calculation procedures, two examples, and source code. The first example is a binary distillation unit. The second is for a single-input–single-output (SISO) process. The well-documented source code is for an adaptive control program capable of controlling SISO processes with time delays.

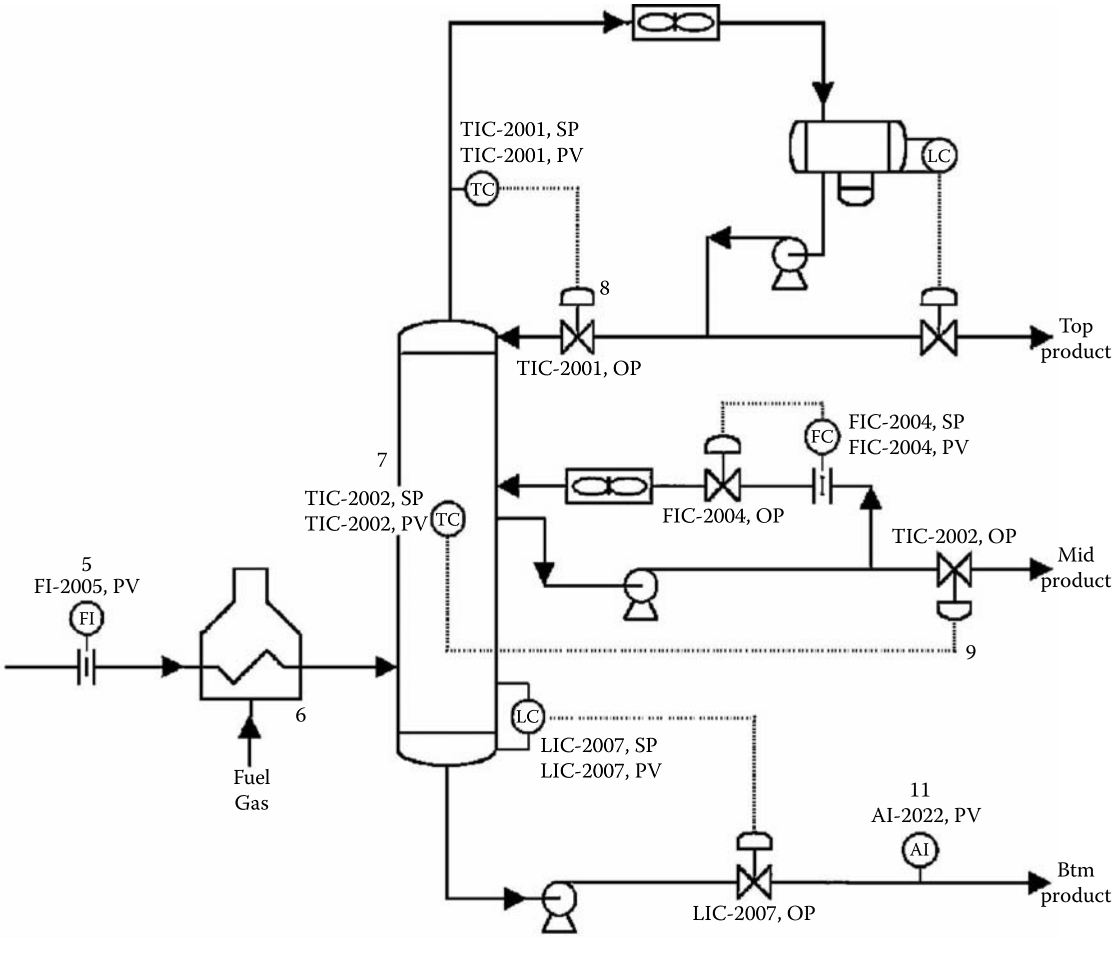

FIG. 2.14a

The Dynamic Matrix Control (DMC) form of Model-Based Predictive Control (MBPC), provides step-by-step guidance through an actual distillation unit example with actual input and output data.

Functions

As mentioned above, the applications for model-based control are practically limitless. As one would suspect, over time the range of applications has grown exponentially. While we tend to equate model-based predictive control with advanced digital control systems, inventors were applying analog systems well before the dawn of the digital age. The prime advantage that digital computing holds over analog systems is not that it is somehow easier for the inventor to perfect. Rather, it has more to do with the way in which computers facilitate dissemination of the art to those who actually apply it.

Auto-piloting aircraft were an early impetus for the art, and automation of advanced military craft remains a significant driving force. Recently, interest in automotive applications has grown. The art is actually applied in order to facilitate its application via computers. The literature on the use of MBPC in disk-drive tracking is extensive, for example. That the art itself is useful in bettering itself is rather unique.

Patents that are specific in form usually target a single process. However, those intended for generic use will often provide details, references, and examples of their use in specific processes. What follows is a guide to patents that are either specifically intended for a given field or those that cite a given field as an example.

Aircraft Aircraft experience large variations in the gains and time constants of the external disturbances they encounter, making them strong candidates for the application of model-based control. As time is compressed more and more for fighter pilots, model-based control is finding a niche in target identification and weapons targeting. One can even find patents related to missile flight path control. Today's stealth aircraft, such as the F-117A "Wobblin Gobblin," in which function is often sacrificed for form, would not be flyable save for MBPC.[1,2]

Computing MBPC finds application in two specific areas of computing—wafer fab and disk-drive positioning. In wafer fab, the goal is the reduction in run-by-run variability of the CVD, spin coating, and etching processes. CVD temperature control garners particular attention. Disk-drive accuracy and hence speed can be enhanced via MBPC, just as with any other servo process.[3,4]

Utility Power MBPC patents relating to power generation and distribution attack problems at both the system and equipment levels. For example, there are MBPC patents for better control of boiler chemicals as well as patents for optimal dispatching of multi-unit cogeneration facilities.

More and more plants designed for base load service are being used to meet peaking power demand. Steam turbines designed to operate in a continuous range of steady-state conditions are being cycled to meet peaking load. This can induce large thermal stresses in both the turbine and the boiler as a result of steep steam-to-metal temperature gradients that develop during rapid loading or unloading of the turbine. Thus, much attention is given to predicting loads based on extended load profiles. Figure 2.14b gives an example of a MBPC design

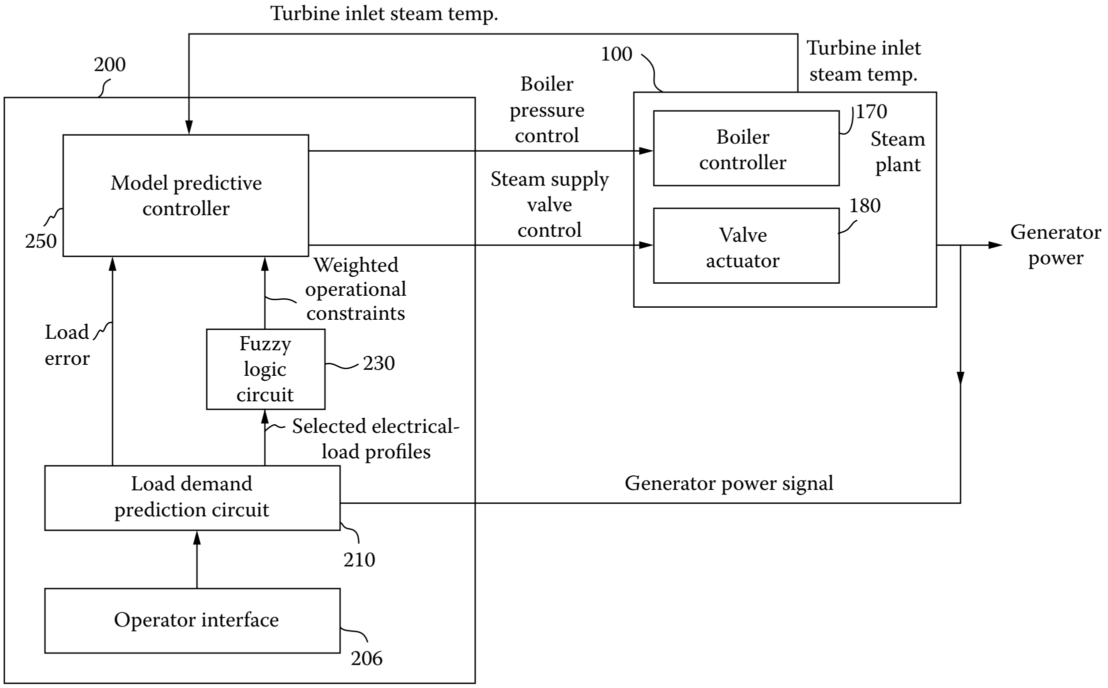

FIG. 2.14b
Patent for MBPC design used in peak-shedding applications to predict loads based on extended load profiles.

TABLE 2.14c
Steam Utility Patents and Their Areas of Application

Steam Power Patents

Patent No.	*Title*	*Year*	*Application*	*Approach*
3,758,762	Decoupled feedforward-feedback control system	9/11/1973	STEAM TURBINE	MODEL
3,939,328	Control system with adaptive process controllers especially adapted for electric power plant operation	2/17/1976	TURBINE	SELF ADAPTIVE
4,027,145	Advanced control system for power generation	5/31/1977	COGENERATION	ROM
4,110,825	Control method for optimizing the power demand of an industrial plant	8/29/1978	COGENERATION	ROM
4,258,424	System and method for operating a steam turbine and an electric power generating plant	3/24/1981	STEAM TURBINE	ROM
4,297,848	Method of optimizing the efficiency of a steam turbine power plant	11/3/1981	STEAM TURBINE	ROM
4,403,293	Control apparatus for use in multiple steam generator or multiple hot water generator installations	9/6/1983	COGENRATION	LP
4,628,462	Multiplane optimization method and apparatus for cogeneration of steam and power	12/9/1986	COGENRATION	MULTIPLANE
4,630,189	System for determining abnormal plant operation based on whiteness	12/16/1986	POWER PLANT	AR WHITENESS
4,768,143	Apparatus and method using adaptive gain scheduling algorithm	8/30/1988	WATER HEATER	LEAST SQUARES
4,802,100	Advanced cogeneration control system	1/31/1989	COGENRATION	ROM
4,805,114	Economical dispatching arrangement for a boiler system	2/14/1989	COGENRATION	ROM
4,922,412	Apparatus and method using adaptive gain scheduling	5/1/1990	WATER HEATER	LEAST SQUARES
4,969,408	System for optimizing total air flow in coal-fired boilers	11/13/1990	COAL FURNACE	ROM
5,040,725	Adaptive controller for forced hot water heating systems	8/20/1991	WATER HEATING	ADAPTIVE
5,159,562	Optimization of a plurality of multiple-fuel fired boilers using iterated linear programming	10/27/1992	BOILER	LP
5,268,835	Process controller for controlling a process to a target state	12/7/1993	STEAM GEN	ROM
5,305,230	Process control system and power plant process control system	4/19/1994	STEAM TURBINE	NEURAL NET
5,311,421	Process control method and system for performing control of a controlled system by use of a neural network	5/10/1994	STEAM TURBINE	NEURAL NET
5,347,466	Method and apparatus for power plant simulation and optimization	9/13/1994	STEAM TURBINE	ROM
5,442,544	Single input single output rate optimal controller	8/15/1995	ELECTRIC UTILITY	ROC
5,517,424	Steam turbine fuzzy logic cyclic control method and apparatus therefore	5/14/1996	STEAM TURBINE	FUZZY LOGIC
5,619,433	Real-time analysis of power plant thermohydraulic phenomena	4/8/1997	POWER PLANT	RELAP5/MOD3
5,696,696	Apparatus and method for automatically achieving and maintaining congruent control in an industrial boiler	12/9/1997	BOILER CHEMS	MACC
5,923,571	Apparatus and method for automatic congruent control of multiple boilers sharing a common feedwater line and chemical feed point	7/13/1999	BOILER CHEMS	ROM

from U.S. Patent 5,517,424, which is intended to address this issue. Table 2.14c provides a sample of steam utility patents and their application forms.[5–7]

Nuclear Energy Although regulatory issues tend to discourage the application of MBPC to direct control of nuclear power systems, MBPC still finds use in the industry. For example, motor operator valve (MOV) reliability is a subject of great concern. Hundreds of MOV failures have been investigated in different studies. In one study, electromechanical torque switches and limit switches were identified as the components at the root of approximately 32% of the documented MOV failures.

Mechanical failures (failure to operate, bent stems, damage to valve seats, gear binding and damage) accounted for 22% of the MOV failures. U.S. Patent 4,694,390 seeks to address this problem by instrumenting MOVs with a valve stem position sensor, a stem load sensor, and motor load sensor. Then, an MBPC-based monitor periodically tests the status of the motor-operated valve and turns off the power to the valve's motor if certain predefined criteria for the valve stem position and the valve load are not satisfied.

Pressurized and boiling water reactor core monitoring is an important area for MBPC. For example, U.S. Patent 4,770,843 discloses a MBPC application "for controlling the stability of a boiling water reactor using a digital computer to calculate online, from distributed steady-state values of only power, flow, enthalpy, and pressure; a stability index for selected fuel assemblies taking into account nuclear feedback as well as detailed hydrodynamic effects." U.S. Patent 4,234,925 applies linear programming (LP) to the problem of generating the optimum excitation waveform for excitation of the plasma in fusion reactors. U.S. Patent 4,982,320 discloses a self-adaptive controller for particle beam accelerator control.[8,9]

Motor Fuel Production Patents on processes ranging from gas lift oil production to hydrogen fluoride (HF) alkylation target the motor fuel production industry, where small optimizations can mean large returns. Hydrocracking and Fluid Catalytic Cracking (FCC) are especially well represented. U.S. Patent 4,349,869 provides a detailed example of the application of Dynamic Matrix Control coupled with offline optimization to FCC.[10,11]

Pulp and Paper MBPC patents target practically every aspect of pulp and paper production. Digestion, delignification, additive control, and final webbing all gain attention.[12,13]

Distillation Distillation is difficult to optimize because of its numerous degrees of freedom both controllable, such as reboiler and heat input, and uncontrollable, such as feed composition. Making matters worse are the strong couplings between variables and the nonlinearity encountered in high-purity towers. For example, as stated in U.S. Patent 5,343,407, "a 10% increase in boilup rate will result in only a moderate increase in the purity of the bottoms product, while a 10% decrease would cause a drastic decrease in the purity of the bottoms product. In addition, a 10% increase in boilup by itself will cause a drastic reduction in the purity of the overhead product."

Despite the inherent difficulties, high-purity distillation is a very common process. As noted again in U.S. Patent 5,343,407, "ethylene, propylene and styrene monomers of nearly 100% purity are required for their respective polymerization processes in order to produce polymers with the desired characteristics. Also, for the production of industrial grade acetic acid, levels of less than 200 ppm propanoic acid impurity must be maintained. In addition, chemical intermediate xylene products are typically produced as high purity products. Ethylene oxide and propylene oxide are separated industrially to produce products, each with about 200 ppm impurities."

Distillation's prominence coupled with its tricky nature makes it an ideal candidate for MBPC solutions. Table 2.14d

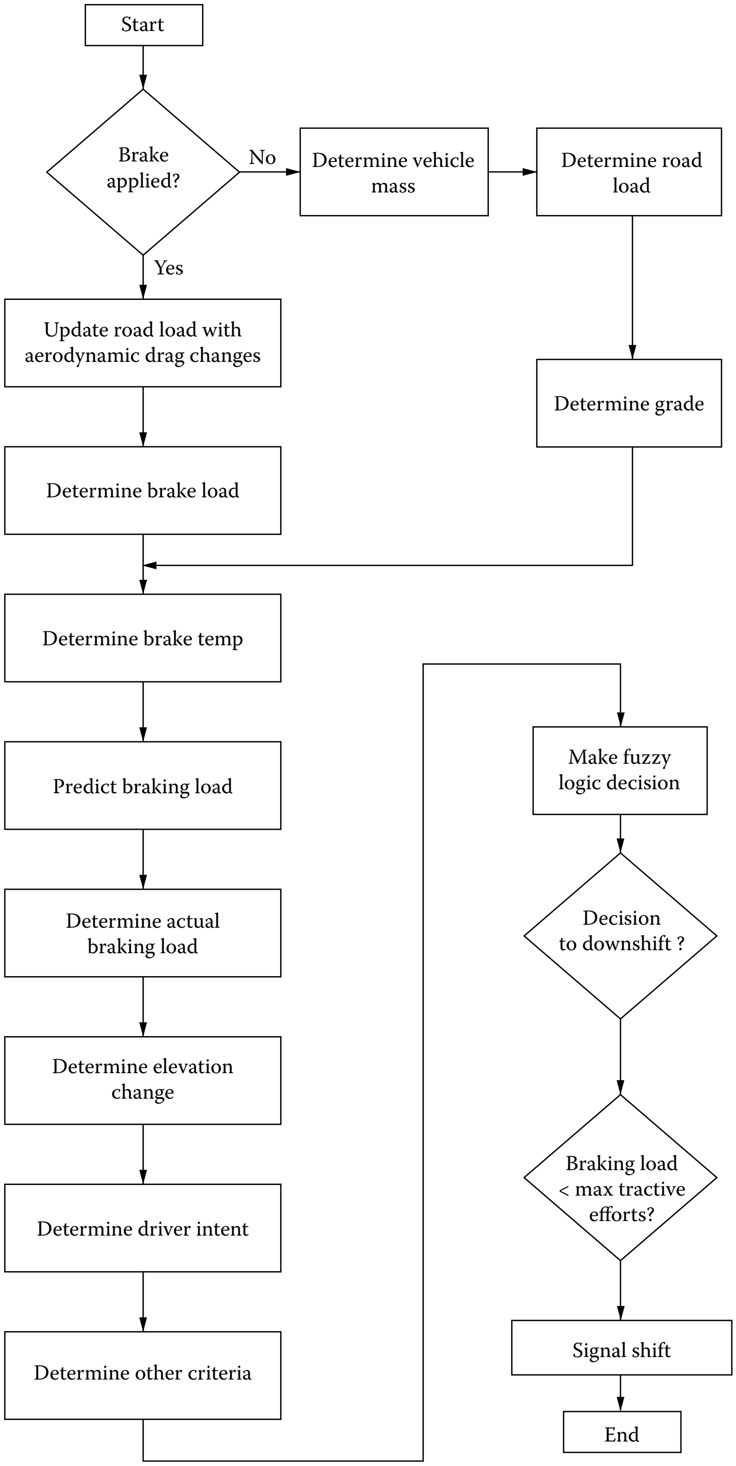

FIG. 2.14e
Patent describing a control strategy for braking.

provides a sample of distillation-related patents and their forms.[14,15]

Robotics It is unfortunate that something once labeled an "autonom"—which would imply independent action—has been more recently labeled a "robot," when that implies something that performs the same task in the same way, over and over again. The patent literature alone would beg to differ as it reflects a movement to make robots more adaptive and autonomous.

Today, hybrid robotic control incorporates adaptive force and position controllers based on highly rigorous models.

Automatic targeting systems can recognize moving targets and predict where they will be once fired upon. Unmanned aerial vehicles are able to perform missions unattended.[16,17]

Optics, Photography, and Astronomy Many of the technologies for the Keck telescope on the Mauna Kea volcano in Hawaii are fairly well represented in the patent literature, including relatives of its MBPC-based adaptive optics. Looking back at Earth, U.S. Patent 4,748,448 discloses a MBPC approach to gauging wind speed and direction from oceanic wave action observed from a satellite. Optimization and quality control of photographic emulsion products are also represented.[18,19]

Automotive The automotive field is one of the latest to which MBPC has been applied. Fuel-to-air ratio (lambda), braking, and cylinder disablement are some examples of areas where both rigorous and generic models are just some of the applications where inventions have been disclosed. U.S. Patent 6,625,535 discloses a control scheme for braking, whose logic is shown in Figure 2.14e.[20,21]

Polymers The patent literature describes MBPC-based inventions related to monomer production (for example, ethylene), polymerization reactions, and the production of polymer suspensions.

An area of particular interest is predicting polymer melt index from process data rather than having to rely on samples taken to the lab. As U.S. Patent 5,504,166 states,

> The desired control of the polymerization process is extremely difficult to attain because of the holdup time of polymerization reactors and the time involved in obtaining polymer samples and measuring the properties of those samples. Because of this time period, the polymerization conditions employed in the reactor at the time at which a property of a polymer sample withdrawn from the reactor is measured are not necessarily the same as the polymerization conditions employed in the reactor at the time at which such polymer sample was produced in the reactor and/or withdrawn from the reactor.
>
> This is especially the case when the attempted control of the polymerization process is based on the measurement of the melt flow rate — or in other words, the melt index — of the polymer product as determined according to the ASTM Test D-1238-62T. Although the melt flow rate or the melt index is a satisfactory control property for most solid polymers prepared from alpha-olefins, the time consumed in obtaining a polymer sample for measurement and in measuring the melt index of the sample combines with the aforesaid holdup time of the reactor to seriously hamper accurate control of the polymerization process.[22,23]

Financial Derivatives Trading Underlying the price of a commodity is a market process that can be modeled just like any other process. A trader makes a series of inputs to a continuous process based on analysis of feedback from a market.

"Financial engineering" was born in 1973 when a mathematician, Fischer Black, and an economist, Myron Scholes, devised one of the first mathematically accepted approaches for pricing options that can only be exercised at their expiration date ("European options"). Today there are well over a thousand "systems trading" applications on the market that can be used by anyone to "control" portfolios.

According to U.S. Patent 6,546,375: "What has become known as the Black–Scholes option formula was described first in 'The pricing of options and corporate liabilities,' *Journal of Political Economy* 81 (1973). The Black–Scholes option formula is presently of widespread use in financial markets all over the world. The price of such an option can be found by solving the Black–Scholes equation with the initial condition at expiration (i.e., the payoff of the option). The Black–Scholes equation is a reverse diffusion equation with parameters determined by the statistical characteristics of involved stocks and currencies such as risk-free interest rate, holding cost or expected dividends, and volatility."

Determining the forward pricing of "American options," which can be exercised before expiration, is difficult because it leads to an infinite-dimensional free boundary problem that cannot be solved explicitly nor finitely. In order to approximate a solution, U.S. Patent 6,546,375 employs a "discretized partial differential linear complementary problem (PDLCP)-based system." An "optimization problem in the form of a mathematical program with equilibrium constraints (MPEC)" is also used to derive implied volatilities of the assets underlying the subject derivatives.

Other patents integrate the MBPC side of the overall process with the requisite feedback information systems, much as a DCS workstation works with an operator and a process. Orders can be placed, real-time data can be analyzed, margins can be calculated, and buy and sell signals can be generated automatically via one's Internet-ready PC.[24,25]

2.15 Model-Free Adaptive (MFA) Control

G. S. CHENG (2005)

Model-free adaptive (MFA) control, as its name suggests, is an adaptive control method that does not require process models. An MFA control system is defined to have the following properties:

1. No precise quantitative knowledge of the process is available.
2. No process identification mechanism or identifier is included in the system.
3. No controller design for a specific process is needed.
4. No manual tuning of controller parameters is required.
5. Closed-loop system stability analysis and criteria are available to guarantee the system stability.[1–3]

Derivations of the core MFA control technology address specific control problems as described here:[4–14]

- SISO MFA to replace PID so that manual controller tuning is eliminated
- Nonlinear MFA to control nonlinear processes
- MFA pH controller to control pH processes
- Feedforward MFA controller to deal with measurable disturbances
- Antidelay MFA to control processes with large time delays
- Robust MFA to protect the process variable from running outside a bound
- Time-varying MFA controller to control time varying processes
- Antidelay MFA pH controller for pH processes with varying time delays
- MIMO MFA to control multivariable processes

MFA controllers can be readily embedded into various control equipment and are becoming available on more and more platforms offered by multi-vendors including building controllers, single-loop controllers, programmable logic controllers (PLC), hybrid controllers, process automation controllers (PAC), control software, and distributed control systems (DCS).

SINGLE-LOOP MFA CONTROL SYSTEM

Figure 2.15a illustrates a single-loop MFA control system that includes a single-input single-output (SISO) process, a SISO MFA controller, and a feedback loop. The control objective is for the controller to produce an output $u(t)$ to force the process variable $y(t)$ to track the given trajectory of its setpoint $r(t)$ under variations of setpoint, disturbance, and process dynamics. In other words, the task of the MFA controller is to minimize the error $e(t)$ in an online fashion, where $e(t)$ is the difference between the setpoint $r(t)$ and the process variable $y(t)$. The minimization of error $e(t)$ is achieved by (i) the regulatory control capability of the MFA controller, and (ii) the adjustment of the MFA controller weighting factors that allow the controller to deal with the dynamic changes, disturbances, and other uncertainties of the control system.

MFA Controller Architecture

Figure 2.15b illustrates the core architecture of a single-input single-output MFA controller. A multilayer perceptron (MLP) artificial neural network (ANN) is used in the design of the controller. The ANN has one input layer, one hidden layer with N neurons, and one output layer with one neuron.

Within the neural network there is a group of weighting factors (w_{ij} and h_i) that can be updated as needed to vary the behavior of the dynamic block. The algorithm for updating the weighting factors is based on the goal of minimizing the error between the setpoint and process variable. Since this effort is the same as the control objective, the adaptation of the weighting factors can assist the controller in minimizing the error while process dynamics are changing. From another point of view, the artificial neural network–based MFA controller "remembers" a portion of the process data providing valuable information for the process dynamics. In comparison, a digital version of the PID controller remembers only the current and previous two samples. In this regard, PID has

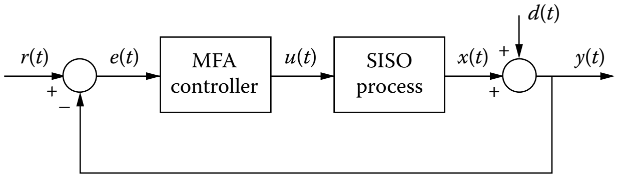

FIG. 2.15a
Single-loop MFA control system.

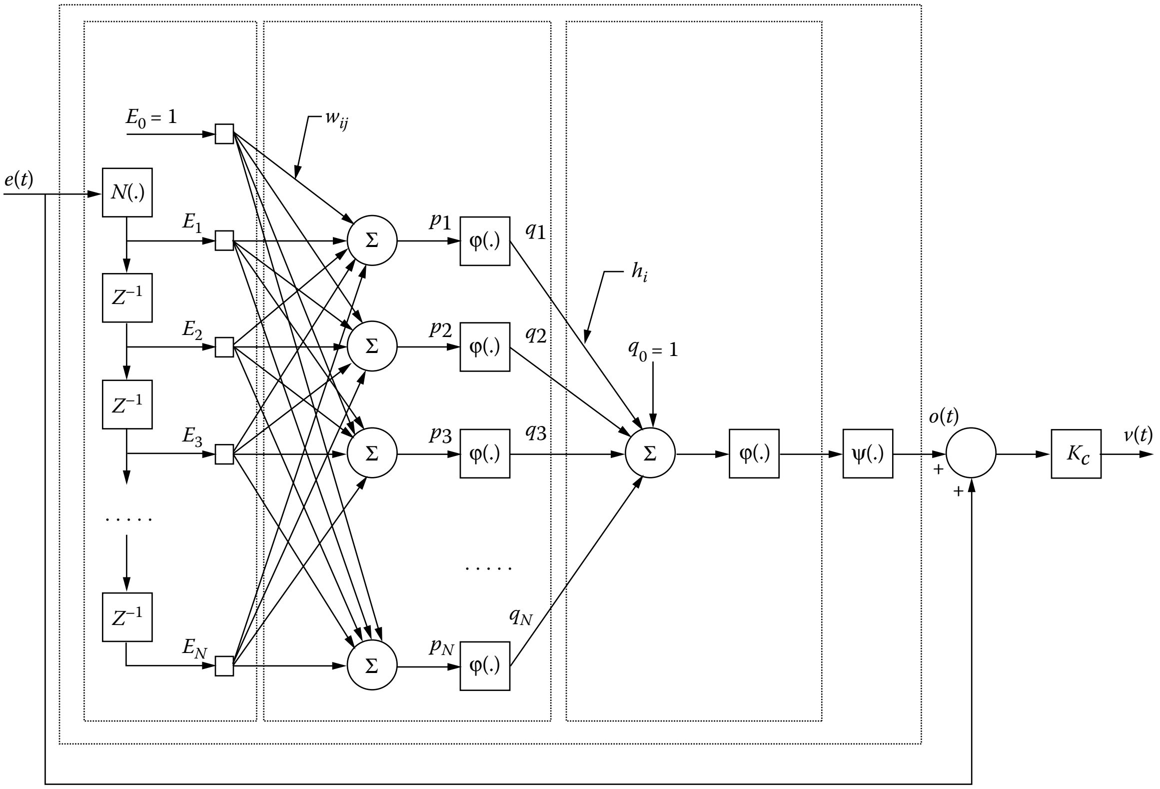

FIG. 2.15b
Architecture of a SISO MFA controller.

almost no memory, and MFA possesses the memory that is essential to a "smart" controller.

SISO MFA Control Algorithm

The core MFA control algorithm comprises the following difference equations:

$$p_j(n) = \sum_{i=1}^{N} w_{ij}(n)E_i(n) + 1, \qquad \textbf{2.15(1)}$$

$$q_j(n) = \varphi(p_j(n)), \qquad \textbf{2.15(2)}$$

$$\begin{aligned} o(n) &= \psi\left[\varphi\left(\sum_{j=1}^{N} h_j(n)q_j(n) + 1\right)\right], \\ &= \sum_{j=1}^{N} h_j(n)q_j(n) + 1, \end{aligned} \qquad \textbf{2.15(3)}$$

$$v(t) = K_c[o(t) + e(t)], \qquad \textbf{2.15(4)}$$

where n denotes the nth iteration, $o(t)$ is the continuous function of $o(n)$, $v(t)$ is the output of the MFA controller, $K_c > 0$ and is the MFA controller gain, and w_{ij} and h_j are weighting factors.

The weighting factors can be updated online at every sample interval using the following formulas:

$$\Delta w_{ij}(n) = \eta K_c e(n) q_j(n)(1 - q_j(n)) E_i(n) \sum_{k=1}^{N} h_k(n), \qquad \textbf{2.15(5)}$$

$$\Delta h_j(n) = \eta K_c e(n) q_j(n). \qquad \textbf{2.15(6)}$$

A more detailed MFA control algorithm and discussions can be found in references 1 and 2.

MFA and PID

Most industrial processes are still being controlled by PID (proportional–integral-derivative) controllers. PID is a simple general-purpose automatic controller that is useful for controlling simple processes. However, PID has major problems in controlling complex systems and also requires frequent manual tuning of its parameters when the process dynamics change. The performance of MFA (top) and PID (bottom) controllers is compared in Figure 2.15c to show how MFA adapts when process dynamics change.

Starting from the same oscillating control condition, the system will continue to oscillate under PID control, while the MFA system will quickly adapt to an excellent control

Comparison of MFA and PID.

condition. If both controllers start from a sluggish situation, MFA will control the process faster and better.

MFA Control System Requirements

As a feedback control system, MFA requires the process to have the following behavior:

1. The process is controllable.
2. The process is open-loop stable.
3. The process is either direct or reverse acting (process does not change its sign).

If the process is not controllable, improvement of the process structure or its variable pairing is required. If the process is not open-loop stable, it is always a good practice to stabilize it first. However, for certain simple open-loop unstable processes such as a non-self-regulating level loop, no special treatment is required when using MFA. If a process changes its sign within its operating range, special MFA controllers are required.[1]

SISO MFA Configuration

A SISO MFA controller has only a few parameters to configure:

1. Sample interval—the interval between two samples or calculations in seconds. A high-speed MFA controller can run at a 1 millisecond rate.
2. Controller gain—use of a default value is recommended.
3. Time constant—a rough estimate of the process time constant in seconds.
4. Acting type—direct or reverse action of the process. If the process input increases and then its output increases, it is direct acting, and vice versa. However, MFA controllers embedded in various platforms always use the vendor's definition. Sometimes, controller acting type is used, which is different than the process acting type.

According to the principles in the information theory, it is required that sample interval be less than or equal to one third of the time constant. That is,

$$T_s \leq \frac{1}{3} T_c, \qquad 2.15(7)$$

where T_s is the sample interval, and T_c is the time constant.

Once the configuration is done, MFA can be launched at any time and will control the process immediately. MFA does not require process identification and is not a dynamic modeling-based controller; there is no need to first collect data to train the model. MFA controllers can be switched between automatic and manual at any time. No specific bumpless transfer procedure is required.

NONLINEAR MFA CONTROLLER

Nonlinear control is one of the most challenging topics in modern control theory. Although linear control system theory has been well developed, it is the nonlinear control problems that present the most headaches. The main reason that a nonlinear process is difficult to control is because there could be so many variations in process nonlinear behavior. Therefore, it is difficult to develop a single controller to deal with the various nonlinear processes. Traditionally, a nonlinear process has to be linearized first before an automatic controller can be effectively applied. This is typically achieved by adding a reverse nonlinear function to compensate for the nonlinear behavior so that the overall process input–output relationship becomes somewhat linear. It is usually a tedious job to match the nonlinear curve, and process uncertainties can easily ruin the effort.

The nonlinear MFA controller is a general-purpose controller that provides a more uniform solution to nonlinear control problems. The nonlinear MFA controller is well suited for nonlinear processes or processes with nonlinear sensors, actuators, and other elements.

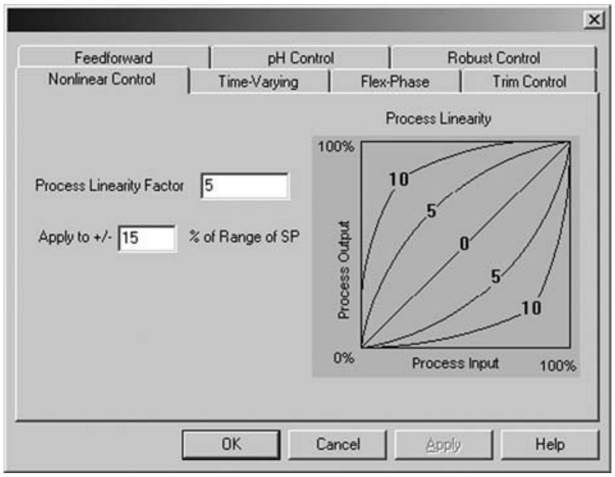
A flow or high-pressure loop is a typical nonlinear process that can cause the actuator to lose its authority in different operating conditions. Inevitable wear and tear on a valve typically makes a linear valve nonlinear. The dissolved oxygen in a bio-tech micro reactor to cultivate cells is another nonlinear process example. As cells grow, they suddenly start to consume much more oxygen. Since the number of bio-tech experiments is huge and the types of cells to grow can vary significantly, it is difficult and costly to deal with nonlinear characterization problems. The general-purpose nonlinear MFA controller is well suited for this application.

Nonlinear MFA Configuration

In addition to the parameters used in SISO MFA including sample interval, time constant, controller gain, and acting type, the nonlinear MFA has an extra parameter to enter: the process nonlinearity factor. As shown in Figure 2.15d, the graph on the menu shows how severe the nonlinear behavior is between the process input and process output.

The process linearity factor is a number between 0 and 10. A 10 represents an extremely nonlinear process while a 0 represents a linear process. Notice that the graph shows a nonlinear curve marked with 10 on both upper and lower positions. This means that a nonlinear MFA controller does not care what the nonlinear characteristics are for this process. For instance, the valve can be either "fast open" or "fast close," as represented by these two convex and concave curves.

When using nonlinear MFA, there is no need to worry about how the nonlinear curve is laid out. The curve can be concave, convex, or S-shaped. Simply advise the controller whether the process is extremely nonlinear (enter a 9 or 10), quite nonlinear (enter a 5 or 6), or somewhat nonlinear (enter a 1 or 2). The nonlinear MFA controller will be smart enough to handle the rest.



Process Linearity Factor 5

Apply to +/- 15 % of Range of SP

FIG. 2.15d
Configuration menu of nonlinear MFA.

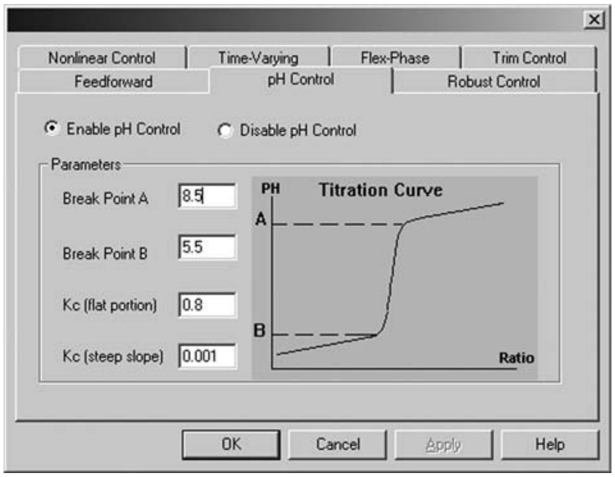
Simulations and real applications show that the nonlinear MFA controller can easily deal with a nonlinear process even if its gain changes hundreds of times. In a nonlinear MFA, there is no linearization calculation or process model. The MFA controller gain K_c is simply set at its nominal point and not retuned.

MFA pH CONTROLLER

Most process plants generate a wastewater effluent that must be neutralized prior to discharge or reuse. Consequently, pH control is needed in just about every process plant, yet a large percentage of pH loops perform poorly. The results are inferior product quality, environmental pollution, and material waste. With ever-increasing pressure to improve plant efficiency and tighter regulations in environmental protection, effective continuous pH control is highly desirable.

A strong-acid-strong-base pH process is highly nonlinear. The pH value vs. the reagent flow has a logarithmic relationship. Away from its neutrality, the process gain is relatively small. Near the neutrality where pH = 7, its process gain can be a few thousand times higher. There is no way for a fixed controller such as PID to effectively control this process. In practice, most pH loops are in a "bang-bang" type of control, with pumps turning on and off, resulting in large oscillations. Since acid and caustic neutralize each other, over-dosing acid and caustic is like continuously burning money. Statistics show that a poorly controlled pH process can cost tens of thousands of dollars in chemical usage each month, not counting the penalties imposed by violating Environmental Protection Agency (EPA) or local government discharge codes.

The MFA pH controller is able to control a wide range of pH loops because its adaptive capability allows it to compensate



● Enable pH Control ○ Disable pH Control

Parameters

Break Point A 8.5

Break Point B 5.5

FIG. 2.15e
Configuration menu of MFA pH controller.

for the large nonlinear gain changes. In addition, it can control the full pH range with high precision and enables automatic control of acid or alkaline concentration, both of which are critical quality variables for the chemical process industry.

MFA pH Controller Configuration

As shown in Figure 2.15e, one can easily enter Break Points A and B to define the estimated shape of the titration curve of the pH process. Then the MFA controller gain K_c for the flat portion and steep slope can be entered. For a strong-acid-strong-base pH process, if the controller gain for the flat portion is one, then the gain for the steep slope can be estimated as 0.001, which is 1000 times smaller. Due to the adaptive capability of the MFA controller, the titration curve does not have to be accurate and, in fact, its shape can vary in real applications. In addition, the flow rate and the pH value of the inflows may vary significantly. The MFA pH controller can effectively deal with these large disturbances.

The MFA pH controller has helped many users effectively control their tough pH loops. Return-on-investment in weeks or even days has been reported with savings on chemical reagents, no violation of discharge code, and smoother production operation.

FEEDFORWARD MFA CONTROLLER

Feedforward is a control scheme to take advantage of disturbance signals. If a process has a significant measurable disturbance, a feedforward controller can be used to reduce its effect before the feedback loop takes corrective action. A good feedforward controller can improve the control system performance economically.

Feedforward compensation can be as simple as a ratio between two signals. It could also involve complicated energy or material balance calculations. The feedforward MFA is a general-purpose feedforward controller. It does not attempt a perfect cancellation of the disturbances, which is very difficult to implement in industrial applications due to changing process dynamics and operating conditions. A feedback/feedforward MFA control system diagram is illustrated in Figure 2.15f, where G_{p1} is the main process and G_{p2} is the process with disturbance input and the process variable as output.

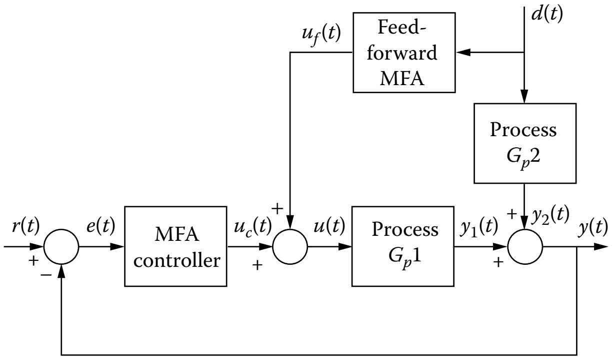

FIG. 2.15f
Feedback and feedforward MFA control system.

Feedforward MFA Controller Configuration

Since the feedback MFA controller has strong adaptive capabilities, the feedforward MFA can be designed in a simple form. There are two parameters to configure, the feedforward controller gain and time constant. The controller gain can be estimated based on the following formula:

$$K_{fc} = -\frac{K_{p2}}{K_{p1}}, \qquad 2.15(8)$$

where K_{p1} and K_{p2} are the estimated static gain for processes G_{p1} and G_{p2}, respectively. The rules for selecting the sign in order to ensure that the feedforward action rejects the disturbance can be summarized as follows:

- If processes G_{p1} and G_{p2} have the same sign, the feedforward gain should be negative.
- If processes G_{p1} and G_{p2} have different signs, the feedforward gain should be positive.

The feedforward MFA time constant can be an estimate of the time constant of G_{p2}. This is related to how fast the disturbance will affect the process variable (PV).

ANTIDELAY MFA CONTROLLER

Many processes have large time delays due to the delay in the transformation of heat, materials, and signals. No matter what control action is taken, its effect is not measurable during a period of time delay. This is equivalent to disabling

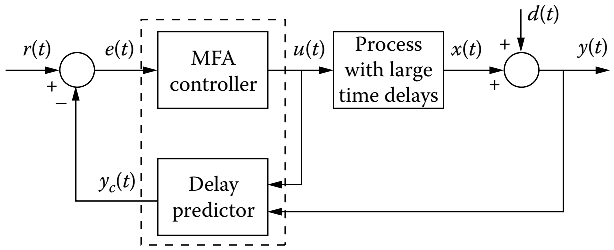

FIG. 2.15g
Antidelay MFA control system.

the feedback for a period of time, where feedback information is essential to automatic control.

If a PID is used to control a process with significant time delays, the controller output will keep growing during the delay time and cause a large overshoot in system responses or even make the system unstable. Typically, a PID has to be detuned significantly in order to stay in automatic but will sacrifice control performance. Generally speaking, a PID controller usually works for the process if its τ-T ratio (delay time/time constant) is smaller than one, unless it is detuned. When a controller is detuned, it loses the sharpness of its control capability, so the process cannot be tightly controlled. The Smith predictor is a useful control scheme to deal with processes with large time delays. However, a precise process model is usually required to construct a Smith predictor. Otherwise, its performance may not be satisfactory.

Figure 2.15g shows a block diagram for a SISO antidelay MFA control system with an antidelay MFA controller and a process with large time delays.

A special delay predictor is designed to produce a dynamic signal $y_c(t)$ to replace the process variable $y(t)$ as the feedback signal. The idea here is to produce an $e(t)$ signal for the controller and let it "feel" its control action without much delay so that it will keep producing proper control signals. In other words, the artificial dynamic signal $y_c(t)$ is able to keep the feedback loop working even when there is a large time delay. Since the MFA controller in the system has adaptive capability, the delay predictor can be designed in a simple form without knowing the quantitative information of the process.[1,2]

Compared to the traditional Smith predictor, the antidelay MFA controller does not need a precise process model. It only needs an estimated delay time as the basic information for its delay predictor. If the delay time used in the MFA delay predictor has a mismatch with the actual process delay time, the controller is robust enough to deal with the difference. Typically, it can deal with the situation where the delay time is two to five times larger or smaller than the actual delay time with satisfactory control performance. In addition, there is no real limitation on how large the τ-T ratio is, as long as an estimated delay time is provided.

The antidelay MFA controller is especially useful in controlling process quality variables since a quality variable is typically measured after the product or process material travels to a certain point, cools off, forms its shape, etc. Antidelay MFA makes it possible for process industries to achieve six sigma or zero defects quality control objectives.

In a semicontinuous production environment, the process line speed may change as many as 100 times or more, which will cause the delay time to change on a similar scale. Since the line speed is measurable, the delay time can be easily calculated and provided to the antidelay MFA controller in real time. In this way, the control performance will not sacrifice much even during large line speed changes.

On the other hand, if the delay time of a process changes on a scale of more than five times, and the delay time information cannot be provided to the controller, the time-varying MFA controller will be more suitable for this application.

ROBUST MFA CONTROLLER

In complex control applications, the following challenges may occur:

1. A large change in the system dynamics occurs, so that a prompt control action is required to meet the control performance criteria.
2. The dominant disturbance to the system cannot be economically measured, and therefore feedforward compensation cannot be easily implemented.
3. A controller purposely detuned to minimize the variations in its manipulated variable may lose control when a large disturbance or significant dynamic behavior change occurs.
4. The system dynamic behavior or load change does not provide triggering information to allow the control system to switch operating modes.

For instance, controlling the reaction temperature for a batch reactor is always a challenge due to the complex nature of the process, large potential disturbances, interactions between key variables, and multiple operating conditions. A large percentage of batch reactors running today cannot keep the reactor temperature in automatic control throughout the entire operating period, thus resulting in lower efficiency, wasted manpower and materials, and inconsistent product quality.

An exothermal batch reactor process typically has four operating stages:

1. Startup stage: ramps up the reactor temperature by use of steam to a predefined reaction temperature.
2. Reaction and holding stage: holds the temperature by use of cooling water while chemical reaction is taking place and heat is being generated.
3. No-reaction and holding stage: holds the temperature by use of steam after the main chemical reaction is complete and heat is not being generated.
4. Ending stage: ramps down the reactor temperature for discharging the products.

During the transition period from Stage 2 to Stage 3, the reactor can change its nature rapidly from a heat-generation process to a heat-consumption process. This change happens without any triggering signal because the chemical reaction can end at any time depending on the types of chemicals, their concentration, the catalyst, and the reaction temperature. Within a very short period of time, the reactor temperature can drop significantly. The control system must react quickly to cut off the cooling water and send in a proper amount of steam to drive the reactor temperature back to normal. A regular feedback controller is not able to automatically control a batch reactor during this transition. In practice, batch reactors are usually switched to manual control and rely on well-trained operators during critical transitions. It is a tedious and nerve-wracking job that can result in low product quality and yield.

The robust MFA controller is able to control the problematic processes described. Without the need to redesign a controller, using feedforward compensation, or retune the controller parameters, the robust MFA controller is able to keep the system in automatic control through normal and extreme operating conditions when there are significant disturbances or system dynamic changes.

Robust MFA Controller Configuration

As shown in Figure 2.15h, the robust MFA controller can be easily configured with these parameters:

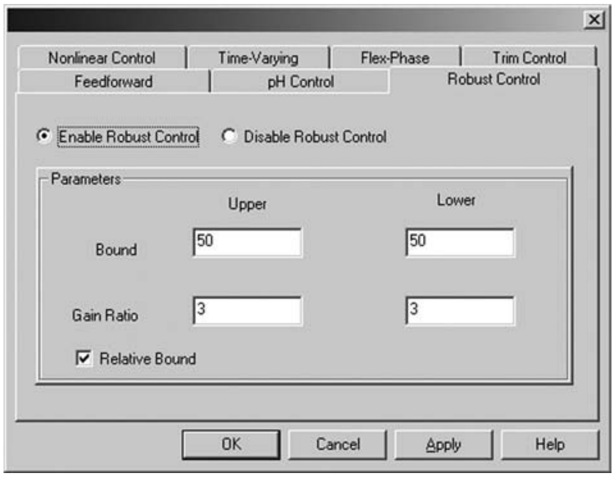
1. *Upper and lower bound*—the bounds for the process variable (PV) being controlled. They provide "intelligent" upper and lower boundaries for the PV. These bounds are typically the marginal values that the PV should not go beyond. PV is unlike the controller output (OP), where a hard limit or constraint can be set. PV is a process variable that can only be controlled by manipulating the OP. Therefore, the upper and lower bounds for PV are very different from the OP constraints.
2. *Gain ratio*—The coefficient to increase or decrease the MFA control action. Typically, you want to enter gain ratio = 3, which implies that the MFA gain working in abnormal situations is three times higher than the regular MFA gain setting. It is important to understand that this is not a gain scheduling approach, although it appears to be this way. Gain scheduling will not be able to resolve the complex problems described.

TIME-VARYING MFA CONTROLLER

The time-varying MFA controller is used to control a process with large time constant and/or delay variations. For instance, a temperature control loop usually has a shorter time constant when it heats up and a much longer time constant when it cools down because adding heat to the process is much faster than taking it away. Also, a line speed or flow rate change will cause the process delay time to vary significantly.

Time-Varying MFA Controller Configuration

As shown in Figure 2.15i, the time-varying MFA controller can be easily configured with an estimated minimum and maximum process time constant plus delay time. The controller is able to deal with the large time constant and/or delay time changes without having to retune any parameters.



● Enable Robust Control ○ Disable Robust Control

For Time-Varying MFA, enter Min and Max process time constant plus its delay time.

FIG. 2.15i
Time-varying MFA controller configuration menu.

ANTIDELAY MFA pH CONTROLLER

When combining the time-varying MFA and MFA pH control functions, an antidelay MFA pH controller is generated that can control a pH process with large and varying time delays.

When a pH process has large varying time delays as well as large inflow rates and pH changes, the difficulty for this control loop quadruples. The extremely large gain changes with varying time delays make an already bad situation worse, causing the process to become almost "uncontrollable." Traditionally, a "bang-bang" type of control or batch-based pH neutralization would be the only solution.

The antidelay MFA type pH controller has the combined power of being predictive, adaptive, and robust. It is adaptive to compensate for the large gain changes, predictive to deal with large time delays, and robust enough to handle inflow changes, titration curve moves, and other uncertainties.

MULTIVARIABLE MFA CONTROL SYSTEM

Figure 2.15j illustrates a multivariable feedback control system with a model-free adaptive controller. The system includes a multi-input multi-output (MIMO) process, a set of controllers, and a set of signal adders, respectively, for each control loop.

Similar to a SISO system, the MIMO system has controller setpoints **r(t)**, error signals **e(t)**, controller outputs **u(t)**, process variables **y(t)**, and disturbance signals **d(t)**. Since it is a multivariable system, all the signals here are vectors represented in bold type.

TWO-INPUT TWO-OUTPUT MFA CONTROL SYSTEM

Without losing generality, we will show how a multivariable model-free adaptive control system works with a two-input two-output (2 × 2) system as illustrated in Figure 2.15k, which is the 2 × 2 arrangement of Figure 2.15j. In the 2 × 2 MFA control system, the MFA controller set consists of two controllers—C_{11} and C_{22}—and two compensators—C_{21} and C_{12}. The process has four subprocesses—G_{11}, G_{21}, G_{12}, and G_{22}.

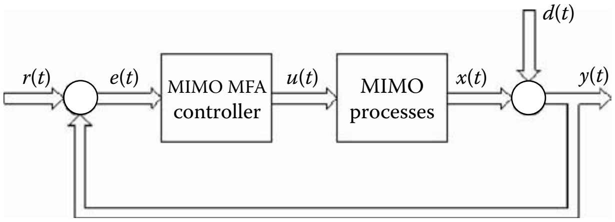

FIG. 2.15j
Multivariable MFA control system.

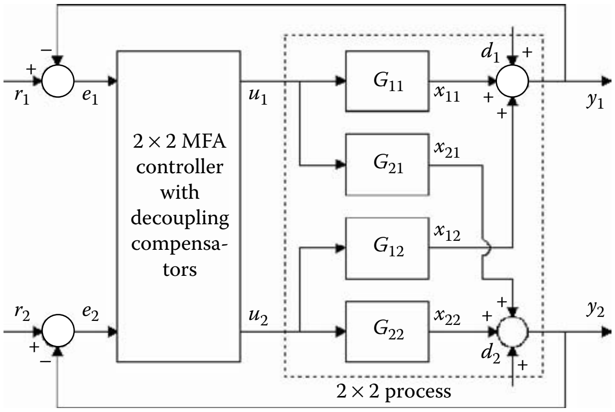

FIG. 2.15k
Two-input two-output MFA control system.

The measured process variables y_1 and y_2 are used as the feedback signals of the main control loops. They are compared with the setpoints r_1 and r_2 to produce errors e_1 and e_2. The output of each controller associated with one of the inputs, e_1 or e_2, is combined with the output of the compensator associated with the other input to produce control signals u_1 and u_2. The output of each subprocess is cross-added to produce measured process variables y_1 and y_2. Notice that in real applications the outputs from the subprocesses are not measurable and only their combined signals y_1 and y_2 can be measured. Thus, by the nature of the 2 × 2 process, the inputs u_1 and u_2 to the process are interconnected with outputs y_1 and y_2. The change in one input will cause both outputs to change.

The control objective for this 2 × 2 MFA control system is to produce control outputs $u_1(t)$ and $u_2(t)$ to force the process variables $y_1(t)$ and $y_2(t)$ to track their setpoints $r_1(t)$ and $r_2(t)$, respectively. The minimization of $e_1(t)$ and $e_2(t)$ is achieved by:

1. The regulatory control capability of the MFA controllers
2. The decoupling capability of the MFA compensators
3. The adjustment of the MFA weighting factors, which allow the controllers to deal with the dynamic changes, large disturbances, and other uncertainties

2 x 2 MFA Controller Configuration

A 2 × 2 MFA controller can be considered to have two main controllers, C_{11} and C_{22}. For each main controller, the parameters to configure are:

1. Sample interval—the interval between two samples or calculations in seconds. A high-speed MFA controller can run at a 1 millisecond rate.
2. Controller gain—use of a default value is recommended.

3. Time constant—a rough estimate of the process time constant in seconds.
4. Acting type—direct or reverse acting of the process.
5. Compensator gain—to deal with the interaction from the other loop.

MIMO MFA CONTROLLER APPLICATION GUIDE

A MIMO system can be much more complex than a SISO system; precautious have to be taken when applying a MIMO MFA controller. When designing a multivariable control system, the first step is to decide which process variable is paired with a manipulated variable. A MIMO MFA control system should follow these pairing rules:

1. Each process of the main loops has to be controllable, open-loop stable, and either reverse or direct acting.
2. A process with a large static gain should be included in the main loop as the main process (G_{11}, G_{22}), and a process with a small static gain should be treated as a subprocess (G_{21}, G_{12}).
3. A faster process should be paired as the main process and a slower process, and processes with time delays should be treated as subprocesses.
4. If pairing rules 2 and 3 should result in a conflict, a tradeoff is the only option.

In addition, an MFA control system should be designed based on the degree of interactions between the loops. Table 2.15l lists the control system design strategy based on the degree of interaction of a MIMO process.

TABLE 2.15l
MIMO System Design Strategy

Interaction Measure	Control Strategy
Small to no interaction	Tighten both loops with SISO MFA
Moderate interaction	Tighten important loops with SISO MFA and detune less important loops or use MIMO MFA for better overall control
Severe interaction	Use MIMO MFA to control the process; may need to de-tune less important loops

MFA CONTROL METHODOLOGY

"All roads lead to Rome." A problem usually has multiple possible solutions, and a process can usually be controlled using different controllers based on different control methods. Almost every control method has its merits and weakness. What is important is to use the right controller to fit the application at a minimum cost.

In natural science, the combination of physics, mathematics, and philosophy plays an integral part in developing a theory that is practically useful. Physics is the foundation for the study of the physical process or environment, mathematics provides the tools to precisely describe the physical process or phenomenon, and equally important is the philosophy that provides directions.

The development of model-free adaptive control technology started from a simple desire to develop a new controller that could easily and effectively solve various industrial control problems. The actual development process has evolved from a prolonged interest in the study of combined intelligence methodology. Since model-free adaptive control does not follow the traditional path of model-based adaptive control, the philosophy behind the combined intelligence has led the way up this long and rocky road.

SUMMARY

To see how the MFA control method is developed based on the combined intelligence methodology, we will relate MFA to each of four key points.

Simple Solution

PID control is simple since it is a general-purpose controller and its algorithm is easy to understand. However, PID is almost too simple to control complex systems. In this regard, PID cannot be considered an effective solution to the more difficult control problems. On the other hand, model-based advanced control methods have proven themselves too complex to launch and maintain since they depend on either a first principle or an identification-based process model. A dream controller has to be powerful enough to control various complex processes yet simple enough to use, launch, and maintain. MFA is a solution that fits these requirements.

Use All Information Available

Model-free adaptive control, as its name suggests, is a control method that does not depend on either first principle or identification-based process models. However, we do try to use all the process information available. For this reason, it can be considered an information-based controller.

For instance, process time constant defines how fast a dynamic system responds to its input. A slow process might have a 10-hour time constant and a fast process might have a 10-millisecond time constant. It would be unwise not to use this information for the controller. In addition, it is relatively easy to estimate the time constant by reading a trend chart. Other important yet easily obtained information about a process includes its acting type (either direct or reverse), static gain, and delay time if any. An MFA controller is designed to use the process parameters that can be easily estimated.

Information's Accuracy

A process can be classified as a white, gray, or black box. If its input–output relationship is clear, the process is a white box. We can easily use existing well-established control methods and tools to design a controller for this process.

When we are not sure if the process input–output relationship is accurate, or if the process has potential disturbances, dynamic changes, and uncertainties, the process is a gray box. In this case, MFA's adaptive capability is able to handle such changes and uncertainties. PID or model-based control methods will have a much tougher time or higher cost addressing these uncertainties.

Technique That Fits the Application

MFA is neither model based nor rule based. We might say that it is an information-based control method. If the argument is made that the process information used is equivalent to a process model, that is perfectly acceptable. The key to this approach is that we focus on delivering a simple, adaptive, and effective solution.

To extend this idea, a series of MFA controllers, many of which are described here, has been developed to address different difficult control problems. Users can simply select the appropriate MFA, configure its parameters, launch the controller, and reap the benefits.

2.16 Modeling and Simulation of Processes

G. K. MCMILLAN (1995, 2005)

Presented below are a variety of simulation and modeling software categories and a partial list of their suppliers.

Steady State to Design Complex Chemical Processes:	ASPEN plus (Aspen Technology, Inc. /www.aspentech.com/) CHEMCAD (Chemstations, Inc. /www.chemstations.net/) Design II (WinSim Inc. /www.winsim.com/) gPROMS (Process Systems Enterprise Ltd. /www.psenterprise.com/) HYSYS (Hyprotech, Ltd. /www.hyprotech.com/) PEGS (CADcentre Ltd. /www.energyweb.net/OSO/) Pro II (SIMSCI-ESSCO division of Invensys /www.simsci.com/) ProChem (OLI Systems, Inc. /www.olisystems.com/) SIMSMART (Simsmart Inc. /www.ahtcopr.com/) VisualModeler (Omega Simulation Co, Ltd. /www.omegasim.co.jp/)
Steady State for Real Time Optimization of Chemical Processes:	DMO-PML and RTOpt (Aspen Technology, Inc. /www.aspentech.com/) HYSYS RTO$^+$ (Hyprotech, Ltd. /www.hyprotech.com/)
Dynamic to Design Complex Chemical Process Control Systems:	ASPEN Dynamics (Aspen Technology, Inc. /www.aspentech.com/) cc-Dynamics (Chemstations, Inc. /www.chemstations.net/) DynaChem (OLI Systems, Inc. /www.olisystems.com/) DYNSIM (SIMSCI-ESSCO division of Invensys /www.simsci.com/) gPROMS (Process Systems Enterprise Ltd. /www.psenterprise.com/) HYSYS Dynamics (Hyprotech, Ltd. /www.hyprotech.com/) VisualModeler (Omega Simulation Co, Ltd. /www.omegasim.co.jp/)
Dynamic to Design Specific Unit Operations in Batch Processes:	cc-Batch (Chemstations, Inc. /www.chemstations.net/) BatchCAD (Hyprotech, Ltd. /www.hyprotech.com/) Batchfrac and Batch plus (Aspen Technology, Inc. /www.aspentech.com/)
Dynamic for Custom Simulation:	acslXtreme (AEgis Technologies Group Inc. /www.acslxtreme.com/) ANSYS Multiphysics (ANSYS Inc. /www.ansys.com/) Custom Modeler (Aspen Technology, Inc. /www.aspentech.com/) MatLab-SimuLink (MathWorks Inc. /www.mathworks.com/)
Real Time for DCS Configuration Checkout and Operator Training Systems:	Autodynamics (Trident Computer Resources Inc. /www.tridentusa.com/) DYNSIM (SIMSCI-ESSCO division of Invensys /www.simsci.com/) HYSYS OTS$^+$ (Hyprotech, Ltd. /www.hyprotech.com/) MIMIC (MYNAH Technologies division of Experitec, Inc. /www.mynah.com/) XANALOG NL-SIM (Xanalog Corporation /www.xanalog.com/)
Dynamic to Optimize and Estimate Parameters for Continuous Systems:	ACSL optimize (AEgis Technologies Group Inc. /www.acslxtreme.com/) SIMUSOLVE (Dow Chemical Co.)
Dynamic to Optimize and Estimate Schedules for Discrete Systems:	GPSS/H (Wolverine Software Corp. /www.wolverinesoftware.com/) SLAM (Advanced Planning & Scheduling division of Frontstep /www.pritsker.com/)

Dynamic Evaluation of Business Decisions on Manufacturing and Inventory Control:
Arena (Rockwell Automation /www.software.rockwell.com/arenasimulation/)
WITNESS (Lanner Group /www.lanner.com/)

Real Time to Tune Controllers:
ExperTune (ExperTune /www.expertune.com/)
ProTuner (Techmation /www.protuner.com/)

Some of the benefits of simulation are listed in Table 2.16a. Simulation has an expanding role in many aspects of industrial production, including research, design, operations, maintenance, and regulatory compliance.

TYPES OF SIMULATIONS

Dynamic simulations are employed to obtain test results more rapidly, less expensively, and in a more controlled environment than through laboratory experimentation. Simulations can model both chemical and biological systems. They can be used to significantly narrow the range and detail of the types of experiments needed in chemical and biochemical research.[1] Custom simulations typically numerically integrate the differential equations that were set by the user.

Steady-State Simulation

Steady-state simulations are extensively used for process design and optimization and provide data for process flow sheets in terms of material and energy balances. They are also used to design process equipment such as heat exchangers, reactors, and distillation columns. These simulations usually consist of blocks of unit operations interconnected by the user and of physical property data for the chemical components of input streams specified by the user.

TABLE 2.16a
Simulation Functions, Types, and Benefits

Function	*Type*	*Benefits*
Experiment design	Dynamic iterative	Better, fewer experiments and faster research
Process design	Steady state	Faster design and better process performance
Equipment design	Steady state	Faster design and better equipment performance
Event optimization	Dynamic discrete	Better utilization, less equipment, more capacity
Controls design	Dynamic continuous	Faster design and better control-loop performance
Controls test	Dynamic real time	Safer and faster startup and greater onstream time
Sequence test	Dynamic real time	Safer and faster startup and greater onstream time
Interlock test	Dynamic real time plus verification	Safer and faster startup and greater onstream time
Operator training	Dynamic real time, custom or generic	Safer and faster startup and greater onstream time

Dynamic Simulations

Dynamic discrete simulations are run to optimize schedules to maximize throughput and minimize equipment requirements for batch processes, inventory management, and parts manufacturing and assembly. These simulations sequence an event list detailed by the user, provide random numbers for stochastic models, and accumulate statistics.

Dynamic continuous simulations enable users to improve control system design strategies to reduce control-loop errors, reduce startup time, and improve on-stream time. These simulations are similar in construction to those used for experimental design except that they provide a library of functional blocks or subroutines to model the more common types of process equipment and instrumentation. Consequently, iteration of the dynamic solution is usually unnecessary.

Real-Time Simulations

Real-time simulations are run to debug configurations and train personnel in the use of distributed control systems (DCS) and programmable logic controllers (PLC). These simulations are essential to smooth commissioning, continuing operation, and maintenance of the systems. They were first extensively used in utility power plants.[2,3] Their benefits are realized not only in improved process and control system performance but also in greater safety.

Operations, maintenance, and control system responses to various scenarios of disturbances or to equipment and instrument failures can be examined quickly and repetitively. Simulation can be used to reduce safety interlock trips through human factors engineering.[4] Simple or small-scale simulations have been configured into various DCS software packages to eliminate the need for an external computer, its associated interface, and wiring or serial communication.[5–8]

Expansion of simulations to develop the detailed response of large complex processes demanded the use of dedicated external computers and either the emulation of the controls or the development of serial communication with them. The increased power of personal computers and workstations has

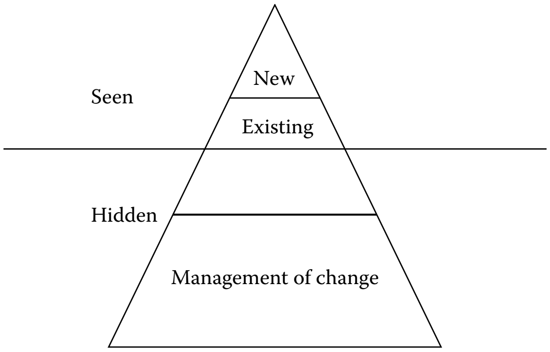

FIG. 2.16b
The iceberg of documentation and training.

facilitated the migration of simulation applications to PCs from general-purpose computers. Whatever computing hardware is used, the benefits are significant. It has been found that it is 20 times faster to correct a program error on a simulator than to correct an error in the field.[9]

New packages are emerging to systematically screen all possible discrete input and output combinations for valid patterns or exceptions and search for common mode failures in safety shutdown systems, as well as to provide dynamic simulation of plant operation. These packages detect both supplier and user software errors to provide a comprehensive verification of software integrity and reliability.

Although software cannot be proven to be bug-free, simulations can go a long way toward reducing software errors to a safe level and ensuring compliance with environmental and safety regulations.

The implications of the management of change dictated by the Occupational Safety Health Act's (OSHA) Process Safety Management Center are greater than realized by most participants in the process industry. The documentation requirements of the initial design are just the tip of the iceberg, as illustrated by Figure 2.16b. The identification and incorporation of changes in existing and new plants require a very large effort that will demand new tools, such as the integration of simulation and computer-aided design with DCS or PLC configurations.

Part of the attractiveness of DCS and PLC is their ability to readily accommodate changes to improve plant operations. Although heaviest during the test and commissioning of the system, the ongoing effort to improve the configuration increases as we proceed with more and more automation. The number of configuration parameters, which can be adjusted manually and automatically, rises exponentially as systems move toward the "Horizon" plant concept. In this system, routine operator actions have been eliminated and the operator's role is elevated to the higher technical role of process optimization.[10] The motivation for the "Horizon" plant is not manpower reduction but a step improvement in product quality, on-stream time, yield, and safety. Simulation is a key prerequisite for such a plant.

Generic Real-Time Simulations Generic real-time simulations are used to train operators for processes such as ammonia production. Packages have been developed for many of the more common hydrocarbon processes. The packages can be modified to include the user's instrument tag numbers, scales, and control system. For those systems that emulate the control system, the user's interface is also mimicked by the package. The emphasis is not on addressing the peculiarities of the plant or control system for an individual application but is more on the familiarization of operators with general process behavior.

These models represent years of process knowledge, simulation development, and improvement. The benefits are significant and have led to such statements as, "Two days on a simulation is worth several years of training in a control room."[11] Such models usually provide more realistic process interactions and simulation control options than do custom-built simulations.[12–14] An effective plant training center uses a variety of generic and project-specific simulations.[15]

STEADY-STATE SIMULATIONS

Steady-state simulations for process design are much more rigorous in the employment of chemistry and chemical engineering principles than are dynamic custom simulations written in software such as ACSL and MatLab, which are based on setting up and numerically integrating differential equations. Most of the newer steady-state simulation software packages now allow the user to graphically configure the model as a process flow diagram (PFD).

A new class of PFD-based dynamic simulation software, such as Aspen Dynamics, DYNSIM, CC-Dynamics, gPROMS, HYSYS Dynamics, and Visual Modeler, has also emerged that has a process fidelity as good as that of the steady-state models used to design processes. However, real-time simulations for configuration checkout and operator training and to optimize business decisions and scheduling generally lack the sophistication of physical property database integration found in the PFD simulators. Some exceptions are HYSYS OTS$^+$ and RTO$^+$, which are extensions of HYSYS Dynamics.

Steady-state simulators, while primarily for process design, can accurately estimate the steady-state process gain, which is important for control-loop analysis and tuning. Multiple runs are made to show changes in the controlled variable in response to changes in the manipulated variable. Since most processes exhibit nonlinearities in their operating points and direction, the simulation runs are made for changes in both directions around the projected set point.

For distillation column control, these runs are used to select the best location of the control tray for temperature control. The selected tray is the one that shows the largest and most symmetrical change in temperature for a change in distillate-to-feed ratio. For pH control, these runs are used to generate a titration curve (a plot of pH versus the ratio of reagent to influent flow). The titration curve is critical for assessment of system difficulty, control valve selection, signal linearization, set point selection, and controller tuning (for further discussion of pH control, see Chapter 8).

For column temperature control, the point with the highest process gain (sensitivity) is sought because the measurement sensitivity is normally low, and the temperature measurement error can translate to a significant composition error. For pH control, the point with the lowest process gain is sought because near neutrality the measurement sensitivity is normally extremely high, and large oscillations in pH can result from imperceptible fluctuations in reagent or influent flow or composition. The process gains are computed by taking the change in temperature and pH at set point and dividing these by the change in distillate and reagent flow, respectively.

Software Packages

The steady-state process flow diagram (PFD) simulators have integrated extensive physical property packages and/or provided links to the American Institute of Chemical Engineering (AIChE) DIPPR, the British PPDS, and the German DECHEMA data compilations. Some also provide the ability to model polymer and electrolyte systems.

Design II is a software package directed toward the hydrocarbon and petrochemical industries. It has essentially no rigorous electrolyte modeling capability to date. It runs conceptually in a batch mode.

Pro-II is widely distributed, has generic capabilities, and has more breadth than but not as much depth as other steady-state simulators. It has a connection with OLI, Inc., a firm specializing in the simulation of electrolyte systems.

ProChem extensively and rigorously models the equilibrium of ionic species in aqueous solutions (electrolyte systems). It is useful for accurately modeling the compositions and pH of waste streams to meet environmental regulations for surface discharges and deep wells. It is not well known that dissociation constants significantly change with temperature and are expressed in terms of activities and not concentrations.

ProChem can compute the change in dissociation constants with temperature and the change in activity from ionic interaction (data that is usually not available). Thus, ProChem can generate titration curves that include the effects of temperature and ionic strength for complex mixtures and are extremely useful for pH control system design.

ProChem is actually a package of programs such as *ElectroChem* (single-stage electrolyte model), *DynaChem* (dynamic model), *FraChem* (multistage electrolyte and reaction model), *ReaChem* (single-stage nonelectrolyte continuous stirred reactor model), *ScaleChem* (scale formation tendency model), *TransChem* (chemical upsets to natural geological formation model), and *DataChem* (data bank manager). Environmental Protection Agency (EPA) and international lists of chemicals of environmental concern and a process analysis section have been added to create an *Environmental Simulation Program* (ESP).

DYNAMIC SIMULATIONS

Dynamic simulations are used to model systems that are in transition to or from a steady state or that are in a state of flux and consequently never reach a steady state. Thus, they are used to investigate biological systems, upsets, failures, and startup/shutdown conditions for continuous processes, batch process conditions and scheduling, discrete manufacturing, fiber-spinning viscoelastic effects, and control system behavior.

The art of dynamic simulation is related to the need for economy. Since custom dynamic simulations numerically integrate and normally require significant original effort, the process detail must be less than that used in steady-state simulations. Similarly, the details of instrumentation and control system dynamics also need to be reduced.

The new class of PFD-based dynamic simulations and the virtual plant have as much or more process detail than do the steady-state simulations used to design the process and can be interfaced to the actual control system configuration. However, these are generally lumped models with perfectly mixed volumes, which means that transportation and mixing delays must be added.

The art is to know, *a priori*, what is and is not important to include. Since loop performance heavily depends on total loop dead time, it is critical to seek out all the major dead-time contributors.[16] The tendency is to concentrate on the dead-time contributions from process equipment and neglect the potentially larger sources of dead time shown in the block diagram for a pH loop in Figure 2.16c. For example, the dead time from reagent piping transportation delay and control valve dead band and stick-slip are significantly larger than the dead time from mixer turnover time for well-designed neutralizers (see the section on pH control in Chapter 8).

Differential equations set up for dynamic simulations are based on the principle of conservation of mass, energy, momentum, spin, and charge (the conversion of mass to energy for nuclear reactions will not be addressed). The net accumulation of these quantities at any point in the process is the integral of the net difference between the input and output, as shown in Figure 2.16d. For steady-state simulations, the output equals the input, so the accumulation and hence the process variable is constant.

There may be multiple inputs and outputs in various forms or phases. These need to be converted to common dimensions and summed. For example, inputs and outputs for a mass balance would be mass flow (e.g., pounds per hour) and would include vaporization, condensing, reaction, precipitation, and crystal growth rates besides stream flows.

Inputs and outputs for an energy balance would consider the energy flow (e.g., BTUs per hour), and the simulation model would include heat transfers, heats of reaction multiplied by reaction rates, heats of dilution and neutralization multiplied by reagent flows, heats of vaporization multiplied by vapor flows, and heats of condensation multiplied by condensing rates, plus the sensible heats of streams multiplied by flow rates. The various heat terms are functions of temperature.

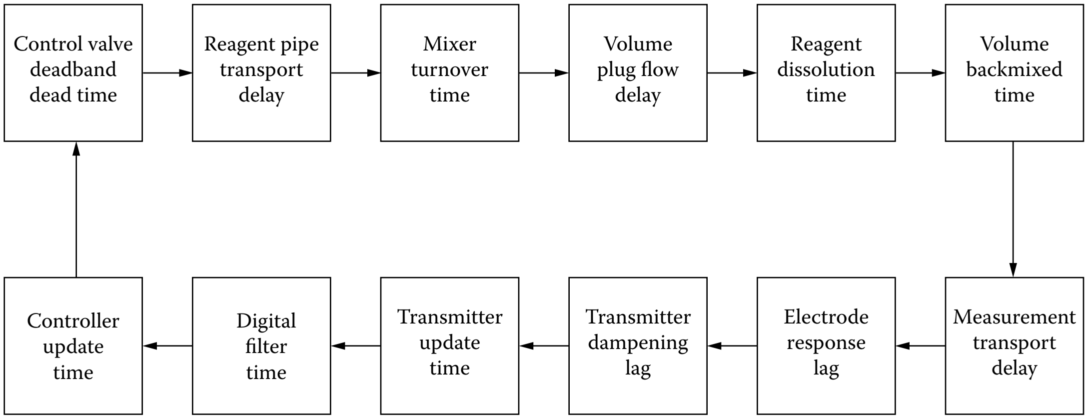

FIG. 2.16c
Block diagram of pH loop dynamics.

Temperature and Vaporization

Temperature processes are simulated by the segmentation of the equipment into volumes, each described by an individual differential equation for an energy balance. The temperature is the energy accumulation divided by the product of the mass and heat capacity of the contents. The smaller the volume, the greater the accuracy. The division into volumes should be greatest where the temperature changes are the largest.

For example, a heat exchanger would be split into volumes for the tube side fluid, the tube wall metal, and the shell side fluid. For counter flow exchangers, either the initial coolant temperature profile must be known or an iterative search should be done for the exit coolant temperature that gives the right inlet coolant temperature. For boiling mixtures, the boiling point as a function of pressure and composition is computed. When the temperature rises to the boiling point, vaporization starts in proportion to the net heat input (BTUs per hour) from streams and heat transfer surface areas divided by heat of vaporization (BTUs per pound).

Vaporization also occurs due to humidification. For scrubbers and textile air washers, the outlet air can be assumed to be saturated. The mole fraction water content of the exiting air can be estimated by dividing the partial pressure of water as a function of temperature by the total pressure of the air.[17] For the inlet air, the same calculation multiplied by the fractional relative humidity gives its moisture content. The mole fractions are converted to weight fractions and multiplied by the inlet and outlet air flows to get the net water loss out of the volume.

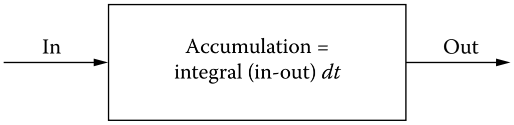

FIG. 2.16d
Accumulation for dynamic simulation.

Pressure and Water Hammer

Gas pressure processes are simulated by segmentation of the system into volumes, each with an individual differential equation for a mass balance. The pressure is computed from the mass accumulation via the ideal gas law and hence depends on the compressibility factor, molecular weight, temperature, and volume of the gas. For vapor spaces above solids and liquids, the gas volume changes with level. For furnace pressures of a few inches of water column, a temperature change can cause the measurement to go off scale, because the interaction between the energy and material balances is significant.

Liquid pressure processes are simulated by the use of pump curves and profiles of pressure drops through the system. The pump discharge pressure is computed from the curve for changes in speed or control valve position. The new pressure drops are proportional to the new flow rate squared, divided by the initial flow rate squared, and that ratio multiplied by the initial pressure drop. The new pressure drop determines a new intersection point of the system drop with the pump curve for variable speed pumps or a new pressure drop for a throttling control valve.

An algebraic loop is created, which is typically broken by the addition of a filter to simulate the gradual response due to impeller inertia, fluid inertia, and/or control valve actuator characteristics. Algebraic loops occur in a model when differential equations are omitted, and they create numerical instability unless a filter is added.

The simulation of water hammer, shock waves (i.e., pressure waves that travel at the speed of sound through the fluid), compressor surge, and the viscoelastic effect of fiber spinning requires the use of a momentum balance. The dynamics are extremely fast and require small integration step sizes. Momentum balances often create stiff systems (i.e., systems with relatively fast and slow dynamics) that require special variable order and step size integration methods to prevent excessively long run times.

pH and Solubility

The simulation of pH requires a component mass balance for each ionic species and for the solvent. The solvent and component concentrations and dissociation constants are substituted into an equation for a charge balance, and interval halving is used to search for the pH value that gives a net charge of zero for the volume. For greater accuracy, activities instead of concentrations should be used, the dissociation constants should be made a function of temperature, and electrode alkalinity and acid error should be included in the measurement response.

Precipitation processes require a solubility calculation based on temperature and concentrations in the liquid phase. Thus, they necessitate energy and component balances. When the solute concentration goes above or below the solubility limit, the precipitation and dissolution rate, respectively, proceed as fast as permitted for numerical stability.

Sensors, Transmitters, and Final Control Elements

The response of a variable speed drive or the stroke of a control valve is simulated by a velocity-limited filter. For the control valve there is also a prestroke dead time associated with the filling and exhausting of air from the actuator, and a dead time caused by dead band. The prestroke dead time is usually negligible, except for large actuators with accessories (e.g., air sets, solenoid valves, current-to-pneumatic transducers, or positioners) with small flow coefficients.

The dead time from dead band is often significant and is calculated by dividing the dead band by the rate of change of controller output. It is simulated by the use of a backlash functional block. Control valves with excessive friction, breakaway torque, or dynamic unbalance can exhibit stick-and-slip action. This is simulated by use of a stroke quantitizer block.

The dead times of chromatographs and digital transmitters and the dead times caused by the scan, cycle, and update times of digital controllers are simulated by delay blocks. The dead times from transportation delays for plug flow, conveyors, pipelines, and sampling lines are also simulated by use of delay blocks, but their delay times are a function of the throughput. A decrease in time delay can be handled bumplessly, but an increase does pose some computational difficulties. Most users pick a conservative fixed delay time.

The damping settings of sensors and transmitters are simulated by the addition of filters. For temperature and pH sensors, the time constant is variable. It depends upon such operating conditions as fluid velocity and process coatings, and the direction and magnitude of the change. Filter time constants can be bumplessly updated.

Simulation Languages

The *Advanced Continuous Simulation Language (ACSL)* will sort the equations in the dynamic section for integration and will identify any algebraic loops. It has many different integration methods and functional blocks. There are no blocks for unit operations, so users must develop their own library of macros and FORTRAN subroutines for process models. Also, the user must construct an extensive steady-state section for a starting point.

REAL-TIME SIMULATION

Real-time simulation connects a simulation of the process to the actual control system. Consequently, the control strategies, proportional–integral–derivative (PID) algorithms, filter time constants, and update, cycle, and scan times do not need to be simulated. It would be difficult to get enough information on proprietary PID algorithms with antireset windup protection and integral tracking options to do a good job of simulating their action. Thus, the use of the actual control system considerably reduces the simulation burden.

The wiring (documentation and installation) of a large simulation system to a control system can take as much time as the construction of the simulation. Most new systems use a high-speed serial communication link from the computer, which directs the simulation and the controller. Here the computer functionally replaces the input and output (I/O) wiring to the field, as shown in Figure 2.16e.

In other words, the same I/O channel assignments are used and the configurations are unaltered so that it is transparent to the controller whether it is connected to the actual plant or to a simulation. This setup as depicted for a combined DCS and PLC system is best from a standpoint of checking the entire control system as it will be used in actual operation.

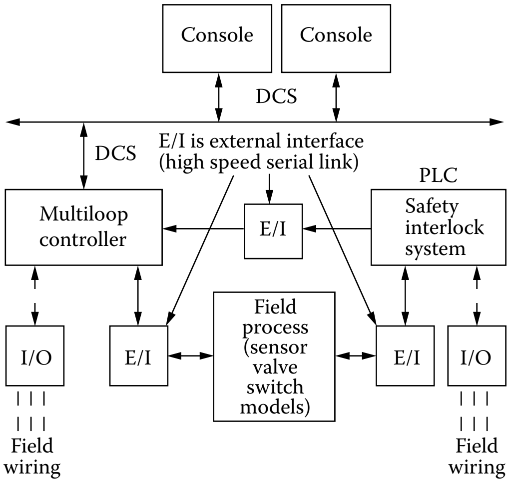

FIG. 2.16e
Real-time simulation system setup.

The use of the DCS data highway for the serial link is not advised because the data flow rate for fast loops will bog down the highway.

When the purpose of real-time simulations is to train operators, the emphasis is more on process rather than on familiarity with the control system. One can then emulate the control system to eliminate the need for communication links and control system hardware.

Real-time integration uses a fixed step size equal to the cycle time of the simulation. Consequently, the step size is too large to simulate fast pressure dynamics or use momentum balances. The gas volumes are increased or calculations similar to those for liquid pressure dynamics are used to achieve numerical stability. Compressor surge is simulated by following the negative slope and jumping over the positive slope portions of the characteristic curve and by the use of a filter to break the algebraic loop between compressor flow and discharge pressure.

The simulation is speeded up or slowed down by the multiplication of the derivative by a gain factor adjustable by the user. The filling and emptying of tanks are often speeded up to test batch operations. Also, the subroutine for integration can be set up to detect a change between the present and last accumulation that is larger than what is possible, and will substitute this as the new desired operating point. This gives the user the ability to make step changes in the operating point. This is particularly useful for batch operations where it is desired to change tank levels to start or retry sequences.

The running of a simulation connected to a control system other than real time will not show the true response of a control loop unless the PID algorithm speed is adjusted and the same ratio is maintained between loop dead time and time constant. This means that all delay times and time constants need to be scaled to simulation speed.

FUTURE TRENDS

The management of change and the desire for increased automation and design efficiency will be the impetus for integration of simulation, computer-aided design (CAD), and DCS or PLC configurations. The goal will be to enter a minimal amount of data (eventually this will be done graphically) and have an integrated system generate the documentation, simulations, control strategy, and interlock configurations required for implementation.

For example, a CAD drawing of the process flow diagram (PFD) with input streams might generate a steady-state simulation of the process that would fill in missing operating conditions and output stream compositions on the PFD. The PFD would in turn generate the skeleton for the piping and instrument diagrams (P&ID). The steady-state simulation would initialize a dynamic simulation whose controlled and manipulated variables would be set by instrumentation added to the P&ID.

The dynamic simulation would consist of two parts, the field and the control strategy. The field data source would be the P&ID, and the control strategy and the safety interlock system data source would be a graphical representation of the DCS or PLC configurations. The dynamic simulation of the strategy and interlocks would migrate to the actual configuration of the DCS or PLC used for real-time control. The dynamic simulation of the field would be designed to prove that the DCS or PLC configuration is wrong rather than to prove that it is right.

Specifically, the control system configuration would not generate the field portion of the dynamic simulation. Toward this end and to reduce common mode failures and to prevent frequent changes to the configuration from affecting the field simulation, the sources of the two parts of the simulations would be kept separate. Similarly, the interlock and control strategy configurations would be separated. These separations would be done by software rather than hardware because the continual increase in reliability and power of computers and the need for fast coordination will push the trend toward integration within a single computer for an operating unit.[18]

Thus, the control strategy and interlock documentation, dynamic simulation, and configuration before and after commissioning would be generated by graphical entry of the configuration. The dynamic simulation would be run faster than real time for control system studies and for accelerated control system testing or operator training. The flow of information for integration is shown in Figure 2.16f.

It is possible that neural networks (Section 2.18) will be used in conjunction with first-principle dynamic models to efficiently predict complex nonlinear effects and that rules and fuzzy logic will be used for more qualitative relationships. Equations from chaos theory may generate data that are not possible to obtain from a deterministic approach.[19] These simulations would run online faster than real time to project future failures and violations of operating

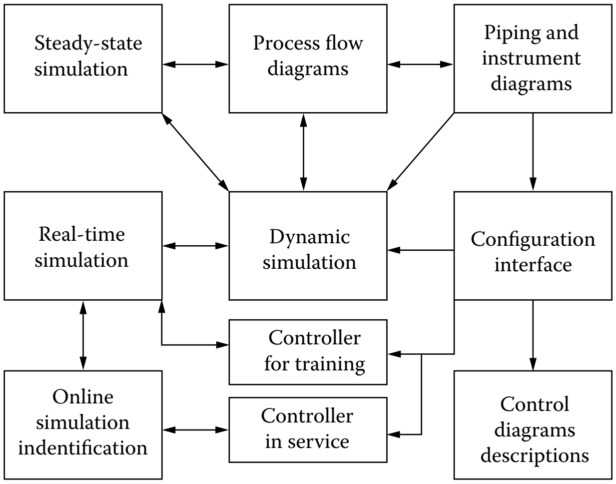

FIG. 2.16f
Future integration.

constraints that will facilitate global online optimization of processes.[20]

VIRTUAL PLANT

Virtual plants are the models and the seamless extension of the actual process and control system design. The dynamic process model must be the steady-state model used to design the process with just volumes and valves added, and the control system must be the actual configuration running in the DCS. The configuration from the DCS can be downloaded into the virtual plant and vice versa. This concept ensures maximum fidelity and eliminates errors from duplication, emulation, and simplification.

The virtual plant becomes a dynamic warehouse of process and control system knowledge. This knowledge can be used for fast prototyping and opportunity assessment in addition to the conventional uses of configuration checkout and operator training.[21] The virtual plant can be operated under conditions that might be considered hazardous for the actual plant. This provides an opportunity to explore new operating regions and methods for model predictive control and real-time optimization.[22]

Costs:

The price for MPC usually based on: 1) Controller size, defined by the number of process inputs and outputs a given controller is capable of handling; 2) Number of controllers purchased; 3) Site wide or corporate licensing; 4) Run-time licenses vs. configuration licenses. In some cases the configuration tools are available at little or no cost; run-time licenses are always required; 5) Some DCS include embedded limited-size MPC software with no extra cost.

Model predictive control (MPC) was developed in the 1970s and 1980s to meet control challenges of refineries. Since then it has become the most effective advanced control technique for a wide range of industries. The advantages of MPC are most evident when it is used as a multivariable controller integrated with an optimizer.

The greatest MPC benefits are realized in applications with dead time dominance, interactions, constraints, and the need for optimization. Model predictive control takes into account the effect of past actions of manipulated and disturbance variables on the future profile of controlled and constraint variables and computes a sequence of controller moves to achieve the desired future profile of controlled variables.

The majority of MPC applications assume linear process models and apply linear programming (LP) for optimization. Techniques have been developed to also include nonlinear modeling and optimization.

The refining and petrochemical industries lead in MPC applications. MPC is also widely used in other industries including pulp and paper, chemicals, cement, power, food processing, automotive, metallurgy, and pharmaceuticals.

This section provides the basics of MPC operation and its theoretical background. It outlines also the following steps required for MPC implementation: process analysis and MPC configuration, process testing and model development, MPC simulation, and commissioning.

MODEL PREDICTIVE CONTROL PRINCIPLES

One way to understand MPC is to develop an analogy with a traditional feedback control loop (Figure 2.17a). As opposed to a traditional control loop, where the controller applies the difference (error) between the set point and the recent values of the measurement as its input, the predictive controller uses the difference between the future trajectory of the set point and the predicted trajectory of the controlled variable as its input. The difference is expressed not by a single value as in a traditional feedback loop, but as a vector of error values from target for a time period from the present to some set time in the future, usually defined to cover the settling time of the process.

Figure 2.17a shows an MPC controller for a process with two inputs and one output that allows one to see the analogy to a typical feedback control loop. The process has a manipulated variable (MV) and a disturbance variable (DV) on the input and a controlled variable (CV) on the output. A simple MPC controller used in this configuration has three basic components:

- A process model that predicts the process output in the future up to the *prediction horizon* (typically, 120 or more scans)
- A future trajectory of the set point for the same number of scans as the trajectory of the predicted process output
- A control algorithm for computing a control action based on the error vector as the difference between the future trajectories of the set point and the predicted process output

The controller output is an MV that is applied to the inputs of the process and the process model, which is a part of every MPC controller. A measured load upset to the process input is also applied as a DV to the model input. The process model computes a predicted trajectory of the CV that is the process output. After correction of this trajectory for any mismatch between the predicted and an actual measured value of the controlled variable, the predicted trajectory is subtracted from the future trajectory of the set point to form an error vector (Figure 2.17b) applied on the predictive controller input. The predictive control algorithm develops outputs to minimize the sum of squared errors over the prediction horizon, taking into account several future MV moves in its calculations.

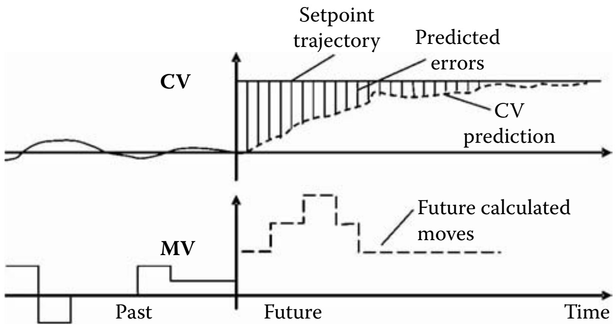

FIG. 2.17b

Illustration of the operation of an MPC controller. (Copyright © 2002, ISA—The Instrumentation, Systems, and Automation Society. All rights reserved. Used with permission of ISA—The Instrumentation, Systems, and Automation Society.)

MPC vs. Feedback Control Summary

The major differences between the operation of an MPC controller and a feedback controller are:

- A predicted error vector is applied to the MPC controller algorithm instead of the scalar values of recent errors that are used in a feedback controller.
- The error vector for an MPC controller is computed as the corrected model prediction subtracted from the future set-point values; whereas the error in a feedback

controller is the measurement subtracted from the set-point value.
- The increments in the MPC controller output required to bring the process output trajectory as close as possible to the set point trajectory are spread over several moves into the future over the *control horizon.* However, only the first move is implemented, and the computation procedure is corrected and repeated for the next scan.
- An MPC controller includes disturbances with the proper dynamics based on identified models from process step responses in the prediction of the process output.

The operation of an MPC controller relies on a good process model. If the model is accurate, the MPC controller can demonstrate superior performance for processes with long dead times, inverse responses, and higher order dynamics that are difficult to control with a classical PID feedback controller. For multivariable processes, the MPC controller takes into account process interactions. Additionally, the MPC controller handles constraints on the process output and the manipulated variables. Finally, MPC controllers are set up to integrate and manage optimization. Taken together, these capabilities make MPC the right choice for incorporating process knowledge and solving complex control and optimization problems on the unit operation control level.

PROCESS MODELING

A generic multivariable process controlled by MPC is presented as a black box in Figure 2.17c. In MPC, the process inputs are MVs and measured DVs. The process outputs are CVs and auxiliary or constraint variables (AVs).

Manipulated variables are managed by MPC controller outputs, predominantly by the manipulation of set points of the fast loops that stabilize the inputs to the process. In calculating the optimal solution, an MPC controller assumes in its calculations that it can make several future moves of the manipulated variables. Only the first move is implemented. The procedure for an optimal solution is repeated every scan. The *control horizon* is the number of future manipulated variable moves that are taken into account in developing the optimal MPC solution.

Manipulated variables have *hard constraints,* which means that no violations of the limits are allowed at any time. Both *absolute* and *rate* or *incremental* constraints are set for manipulated variables.

Measured disturbances are also inputs to the process; however, they are not managed by MPC.

Controlled variables are process outputs kept at specific set points (targets) or within specified ranges. Process models predict the future values of controlled variables for a number of scans ahead. The *prediction horizon* is the range of process output prediction in scans.

Finally, *constraint variables* are a type of controlled variables with only range control and no set points. Constraint variables have so-called *soft constraints*. Violation of this type of constraint may occur temporarily to satisfy other criteria or constraints of the system.

Some use the term *controlled variables* both for *controlled* and *constraint variables*, differentiating them by using the terms *controlled variables with set points* for *controlled variables* and *controlled variables with limits* for *constraint variables.*

The process model is the basis for MPC technology. Most MPC implementations to date use step response models, which provide an explicitly available future prediction of process outputs. The future prediction is used to compute the predicted error vector as an input to the MPC controller.

The step response is represented by a number of coefficients (40 coefficients in our example). Every coefficient corresponds to the value of the model step response at a specific time instance (scan) in the future (Figure 2.17d). In MPC terms, the step response is a prediction of the process output up to the prediction horizon, for a unit step input that was applied at scan zero.

An MPC controller uses an incremental model. It means that real process input and output values are assigned to the model at model initialization. Later on, increments of the

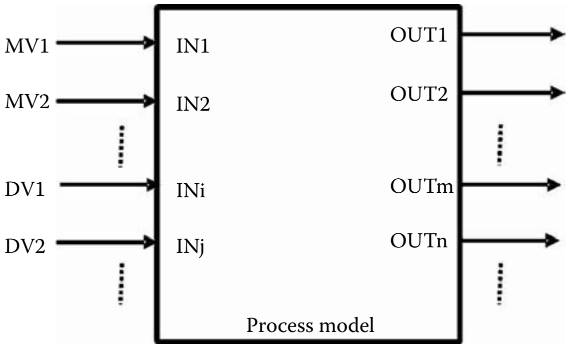

FIG. 2.17c
Multivariable MPC-controlled generic process configuration.

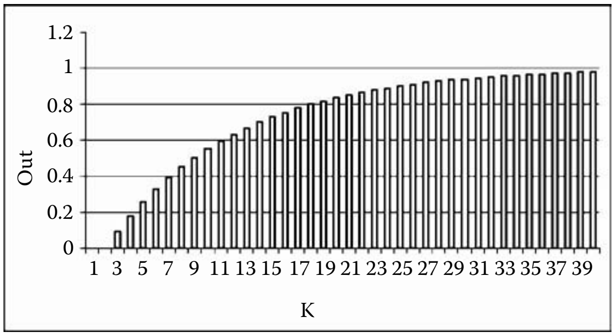

FIG. 2.17d
Step response with 40 coefficients.

inputs are accounted for and increments of the model outputs are calculated.

Process Modeling Equations

MPC application assumes a linear process model. Mathematically we can consider a predicted output trajectory of a process as a process state and use a modified state space form for process modeling. For single-input, single-output (SISO) process prediction, the equations are in the form:

$$\begin{aligned} \mathbf{x}_k &= \mathbf{A}\mathbf{x}_{k-1} + \mathbf{b}\Delta u_k + \mathbf{f}\mathbf{w}_k \\ y_0 &= \mathbf{C}\mathbf{x}_k \end{aligned} \qquad \textbf{2.17(1)}$$

where $\mathbf{x}_{k-1} = [y_0, y_1, \dots y_i, \dots, y_{p-1}]^T$ is the vector of process output prediction at a time $k - 1, 0, 1, 2, \dots p - 1$ steps ahead.

Matrix **A** is the shift operator defined for a self-regulating process as

$$\mathbf{A}\mathbf{x}_{k-1} = [y_1, y_2, \dots y_i, \dots, y_{p-1}, y_{p-1}]^T$$

$\mathbf{b} = [b_0, b_1, \dots, b_i, \dots, b_{p-1}]^T$ is the vector of p step response coefficients.

$\Delta u_k = u_k - u_{k-1}$ is the change in the process input/controller output.

$w_k = y^p - y^m = y^p - y_0$ is the process output measurement minus the model output (the mismatch between the process and the model that results from the noise, unmeasured disturbances, and model inaccuracy).

f is the p dimension filter vector with unity default values.

Matrix **C** is the operator for selecting the current model output defined as $y_0 = \mathbf{C}\mathbf{x}_{k+1}$.

The MPC controller updates prediction and control calculations every scan. This procedure is known as *receding horizon* control.

For n outputs and m inputs process, vector $\mathbf{x}_k$ has dimension $n * p$ and vector **b** becomes a matrix **B** with dimension $n * p$ rows and m columns. The graphical illustration of the equations in Figure 2.17e explains the prediction principles.

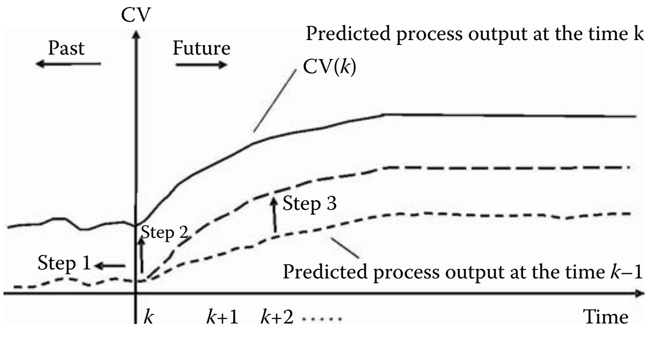

FIG. 2.17e
Illustration of linear process modeling. (Copyright © 2002, ISA—The Instrumentation, Systems, and Automation Society. All rights reserved. Used with permission of ISA—The Instrumentation, Systems, and Automation Society)

At any time instance k, the process output prediction (bottom curve) is updated in three steps:

1. The prediction made at the time $k - 1$ (the bottom dotted curve) is shifted one scan to the left.
2. The prediction curve is moved to the point to match the current measured process output, for filter coefficient = 1, or in general, prediction shift is $\mathbf{f}w_k$.
3. A step response, scaled by the current change on the process input, is added to the output prediction.

PROCESS MODEL IDENTIFICATION

MPC is used mainly for multivariable and highly interactive processes. Processes are tested by applying a special pulse test sequence instead of a single step. Then, a process model is built from process test data using mathematics.

Using test data, we can build equations for every output that equal the number of collected samples. The number of collected samples in test data is normally significantly higher than the number of unknown model coefficients. Such equations are solved using the least squares technique. This technique finds coefficients that may not fit perfectly in any equation but fit optimally for all equations, in such a way that the total squared error for all equations is minimal.

FIR and ARX Modeling

The form of the equations used for process modeling is defined by the identification modeling technique. There are a number of identification techniques used. The most common identification techniques are Finite Impulse Response (FIR) and Auto Regressive with eXternal inputs (ARX). FIR identifies pulse response coefficients, as in Equation 2.17(2) for a SISO process:

$$\Delta y_k = \sum_{i=1}^{p} h_i \Delta u_{k-i} \qquad \textbf{2.17(2)}$$

where p is prediction horizon, with a typical default value for MPC model 120; Δy_k is change in the process output at the time k; Δu_{k-i} is change in the process input at the time $k - i$; and h_i is the pulse response coefficient of the model.

Step response coefficients for the MPC controller are calculated directly from the pulse response as follows:

$$b_k = \sum_{i=1}^{k} h_i \quad k = 1, 2, \dots, p \qquad \textbf{2.17(3)}$$

An advantage of FIR is that it does not require any preliminary knowledge about the process. However, identifying step responses with full prediction horizon with as many as 120 or more coefficients results in low confidence levels of identified coefficient values. Therefore, a shorter horizon with about 60 points is more suitable for a FIR model.

A FIR model with a shorter horizon provides the initial part of the step response that is adequate for defining process dead times using a heuristic approach. On the other hand, the ARX model in Equation 2.17 (4) has fewer coefficients, which are defined with higher confidence, provided the process dead times are known.

$$y_k = \sum_{i=1}^{v} a_i y_{k-i} + \sum_{i=1}^{a} b_i u_{k-d-i} \qquad \text{for SISO process} \qquad \mathbf{2.17(4)}$$

where *a, v* are autoregressive and moving average equation orders of ARX; $a = 4$, $v = 4$ satisfy most applications; a_i, b_i are moving average and autoregressive coefficients of the ARX model; and *d* is dead time in scans.

Applying FIR first and defining dead times and then applying those dead times for ARX provide the best identification results. Step responses for the MPC controller with any prediction horizon are calculated directly from Equation 2.17(4).

For a MIMO process, superposition is applied from all inputs to every output both in FIR and ARX models. An identified model should be validated by applying real input data to the model inputs and comparing the model output with real output. An example of a validation plot is shown in Figure 2.17f.

The validation procedure also may include statistical techniques for calculating *confidence intervals.* Confidence intervals form an area around nominally defined step responses. The true value of the step response coefficients is found within confidence intervals with a predefined confidence (or probability). A 95% confidence interval is normally used.

The complete process model overview is presented in matrix form as in Figure 2.17g.

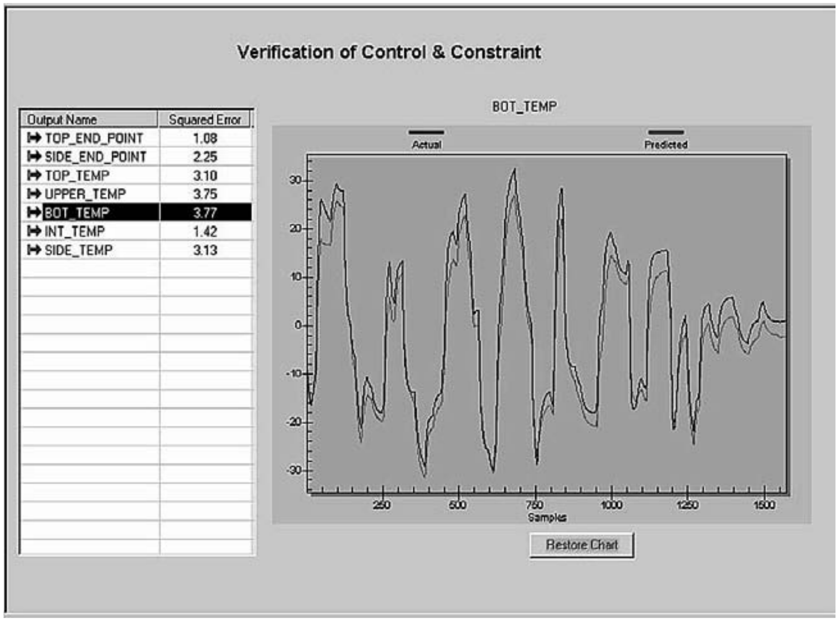
MODEL PREDICTIVE CONTROLLER

Dynamic matrix control (DMC) has historically been the most successful MPC implementation approach, based on a *dynamic matrix*. A dynamic matrix is used for developing an MPC controller. A dynamic matrix is built from step responses to predict the changes in the process outputs that result from moves of the manipulated variables over the control horizon. Dynamic matrix $\mathbf{S}^{\mathrm{u}}$ as in Equation 2.17(5), calculates prediction vector $\Delta\mathbf{x}_{\mathrm{k}}$ resulting from *c* future moves of MV, defined by the vector $\Delta\mathbf{u}_{(k)}$.

$$\Delta\mathbf{x}_k = \mathbf{S}^{\mathbf{u}}\Delta\mathbf{u}(k) = \begin{bmatrix} b_0 & 0 & 0 \cdots & 0 \\ b_1 & b_0 & 0 & 0 \\ b_2 & b_1 & b_0 & 0 \\ \vdots & \vdots & \vdots & \\ b_i & b_{i-1} & b_{i-2} & b_{i-c+1} \\ \vdots & \vdots & \vdots & \vdots \\ b_{p-1} & b_{p-2} & b_{p-3} & b_{p-c} \end{bmatrix} \begin{bmatrix} \Delta u_k \\ \Delta u_{k+1} \\ \Delta u_{k+2} \\ \vdots \\ \Delta u_{k+c-1} \end{bmatrix} = \begin{bmatrix} \Delta y_0 \\ \Delta y_1 \\ \Delta y_2 \\ \vdots \\ \Delta y_i \\ \vdots \\ \Delta y_{p-1} \end{bmatrix} \qquad \mathbf{2.17(5)}$$

MPC Controller Formulation

A general formulation of the MPC controller includes minimization of both the squared sum of predicted control error and the squared sum of calculated controller moves.



Output Name	Squared Error
➡ TOP_END_POINT	1.08
➡ SIDE_END_POINT	2.25
➡ TOP_TEMP	3.10
➡ UPPER_TEMP	3.75
➡ BOT_TEMP	3.77
➡ INT_TEMP	1.42
➡ SIDE_TEMP	3.13

FIG. 2.17f
Validation of identified model. (Courtesy of Emerson Process Management.)

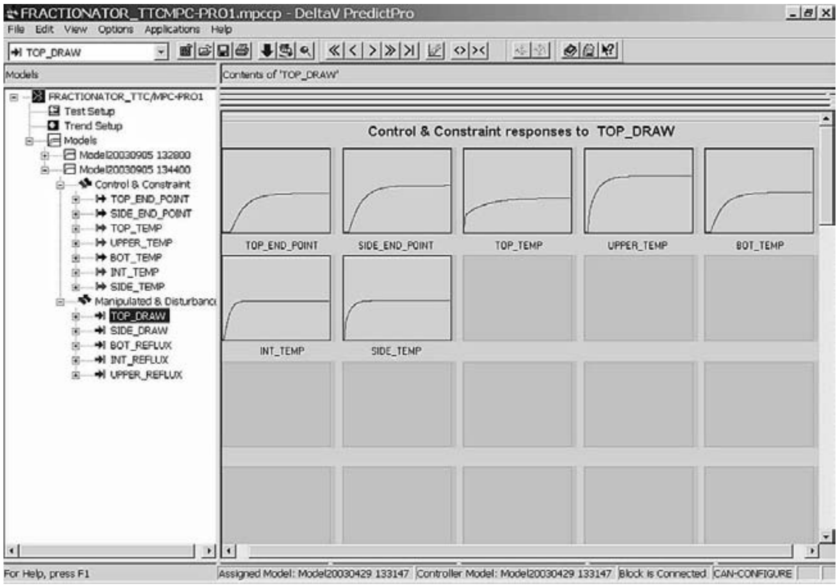


FIG. 2.17g
Step response model overview. (Courtesy of Emerson Process Management.)

To get the desired MPC controller performance, two tuning parameters called *penalty on moves* and *penalty on error* are used in the formulation.

The MPC controller objective for minimizing the squared error of the controlled variable includes the penalty on error over the prediction horizon. The objective for minimizing the squared changes in the controller output over the control horizon includes the penalty on moves in the following way:

$$\min_{\Delta \mathrm{MV}(k)} \{\| \boldsymbol{\Gamma}^{\mathbf{y}}[CV(k) - R(k)] \|^2 + \| \boldsymbol{\Gamma}^{\mathbf{u}} \Delta \mathrm{MV}(k) \|^2\} \qquad \mathbf{2.17(6)}$$

where CV(k) is the controlled output p-step ahead prediction vector; $R(k)$ is the p-step ahead reference trajectory (set point) vector; ΔMV(k) is the c-step ahead incremental control moves vector; $\boldsymbol{\Gamma}^{\mathbf{y}}$ is a diagonal penalty matrix on the controlled output error; $\boldsymbol{\Gamma}^{\mathbf{u}}$ is a diagonal penalty matrix on the control moves; p is the prediction horizon (number of scans); and c is the control horizon (number of scans).

MPC Controller Equations

The solution for the process with dynamic matrix $\mathbf{S}^{\mathbf{u}}$ satisfying Equation 2.17 is in the form:

$$\Delta \mathrm{MV}(k) = (\mathbf{S}^{\mathbf{u}T} \boldsymbol{\Gamma}^{\mathbf{y}T} \boldsymbol{\Gamma}^{\mathbf{y}} \mathbf{S}^{\mathbf{u}} + \boldsymbol{\Gamma}^{\mathbf{u}T} \boldsymbol{\Gamma}^{\mathbf{u}})^{-1} \mathbf{S}^{\mathbf{u}T} \boldsymbol{\Gamma}^{\mathbf{y}T} \boldsymbol{\Gamma}^{\mathbf{y}} E_p(k) \qquad \mathbf{2.17(7)}$$

where $\mathbf{S}^{\mathbf{u}}$ is the $p \times c$ process dynamic matrix built from the step responses of dimension $p \times c$ for a SISO model and $pn \times cm$ for a MIMO model with m manipulated inputs and n controlled outputs; and $E_p(k)$ is the error vector over prediction horizon.

The performance of the control algorithm is modified by the adjustable parameters: p, c, $\boldsymbol{\Gamma}^{\mathbf{u}}$, and $\boldsymbol{\Gamma}^{\mathbf{y}}$. From an implementation point of view, it is inconvenient to use p and c as tuning parameters. $\boldsymbol{\Gamma}^{\mathbf{u}}$ is a basic controller tuning parameter at the controller generation phase. Increasing $\boldsymbol{\Gamma}^{\mathbf{u}}$ elements makes control less aggressive, and while decreasing $\boldsymbol{\Gamma}^{\mathbf{u}}$ makes the control action more aggressive and the control response faster. It follows from experience that the dead time should be accounted for as a major factor in setting the penalty on moves.

The reference trajectory is applied for online tuning. One trajectory design acts in such a way that instead of penalizing any departure from the trajectory, only those deviations that are below the trajectory or above the set point value are penalized (area A and area C if range = 0, Figure 2.17h). In addition, the control error is considered zero if the controlled variable is within range (area C if range > 0).

Presenting MPC control equation in the form

$$\Delta\text{MV}(k) = \mathbf{K}_{\mathbf{mpc}} E_p(k) \qquad \textbf{2.17(8)}$$

where

$$\mathbf{K}_{\mathbf{mpc}} = (\mathbf{S}^{\mathbf{u}T}\boldsymbol{\Gamma}^{\mathbf{y}T}\boldsymbol{\Gamma}^{\mathbf{y}}\mathbf{S}^{\mathbf{u}} + \boldsymbol{\Gamma}^{\mathbf{u}T}\boldsymbol{\Gamma}^{\mathbf{u}})^{-1}\mathbf{S}^{\mathbf{u}T}\boldsymbol{\Gamma}^{\mathbf{y}T}\boldsymbol{\Gamma}^{\mathbf{y}} \qquad \textbf{2.17(9)}$$

is the MPC controller gain, one can see that MPC uses integral action. This, however, does not mean that there is a direct analogy between an MPC controller and a conventional, integral-only feedback controller. The major difference is that the MPC controller uses predicted errors and integrates over the prediction horizon.

INTEGRATING MPC, CONSTRAINTS, AND OPTIMIZATION

A typical MPC configuration includes both controlled variables and constrained variables. The unconstrained MPC controller does not manage constrained variables directly. A supervisory constraint-handling algorithm or optimizer performs the task.

The objectives of optimization are usually to maximize a product value and minimize a raw material cost. For processes with an objective function dependent on several manipulated or controlled variables, optimization techniques are essential components of model predictive control technology. The proven optimization technique is linear programming (LP) with steady-state models.

Linear programming is a mathematical technique for solving a set of linear equations and inequalities in order to maximize or minimize an additional function called an *objective function.* Usually, objective functions express economic value, such as cost or profit.

MPC optimization uses incremental values of MV at the present time or the sum of increments of MV over the control horizon and incremental values of CV at the end of the prediction horizon instead of positional current values, as in typical LP applications. With the prediction horizon normally used in MPC, this assumption guarantees a future steady state for self-regulating processes and perfectly satisfies requirements for proper optimizer operation.

Optimization Equations

The LP technique uses steady-state models and therefore a steady-state condition is required for its application. The basic steady-state process equation in the incremental form is:

$$\Delta\text{CV}(t+p) = \mathbf{A}\Delta\text{MV}(t+c) \qquad \textbf{2.17(10)}$$

where

$$\Delta\text{CV}(t+p) = \begin{bmatrix} \Delta cv_1 \\ \dots \\ \Delta cv_n \end{bmatrix}$$

changes in controlled and constraint variables up to the end of prediction horizon

$$\mathbf{A} = \begin{bmatrix} a_{11}\dots\ a_{1m} \\ \dots \\ a_{n1} \quad a_{nm} \end{bmatrix}$$

process steady-state gains matrix

$$\Delta\text{MV}(t+c) = \begin{bmatrix} \Delta mv_1 \\ \dots \\ \Delta mv_m \end{bmatrix}$$

changes in manipulating variables to achieve the desired state at the end of control horizon.

ΔMV change should satisfy limits both on MV and CV.

$$\text{MV}_{\text{MIN}} \le \text{MV}_{\text{CURRENT}} + \Delta\text{MV}(t+c) \le \text{MV}_{\text{MAX}} \qquad \textbf{2.17(11)}$$

$$\text{CV}_{\text{MIN}} \le \text{CV}_{\text{PREDICTED}} + \Delta\text{CV}(t+p) \le \text{CV}_{\text{MAX}} \qquad \textbf{2.17(12)}$$

The objective function for both maximizing output product value and minimizing input raw material cost is defined in the following way:

$$Q_{\min} = -\text{UCV}^T * \Delta\text{CV}(t+p) + \text{UMV}^T * \Delta\text{MV}(t+c) \qquad \textbf{2.17(13)}$$

where UCV is the cost vector for a CV change of unit value and UMV is the cost vector for an MV change of unit value.

Applying 2.17(10), we can express the objective function through MV only:

$$Q_{\min} = -\text{UCV}^T * \mathbf{A} * \Delta\text{MV}(t+c) + \text{UMV}^T * \Delta\text{MV}(t+c) \qquad \textbf{2.17(14)}$$

The LP solution is always located at one of the vertexes of the region of feasible solutions. An illustration for a two-dimensional problem explains the point (Figure 2.17i).

The region of feasible solutions for two controlled variables and two manipulated variables is an area contained within MV1 and MV2 limits, represented by vertical and horizontal lines, and CV1 and CV2 limits, represented by straight lines (see Equations 2.17[15] and 2.17[16]:

$$\text{CV1}_{\min} = a_{11}\text{MV1} + a_{12}\text{MV2} \qquad \text{CV1}_{\max} = a_{11}\text{MV1} + a_{12}\text{MV} \qquad \textbf{2.17(15)}$$

$$\text{CV2}_{\min} = a_{21}\text{MV1} + a_{22}\text{MV2} \qquad \text{CV2}_{\max} = a_{21}\text{MV1} + a_{22}\text{MV2} \qquad \textbf{2.17(16)}$$

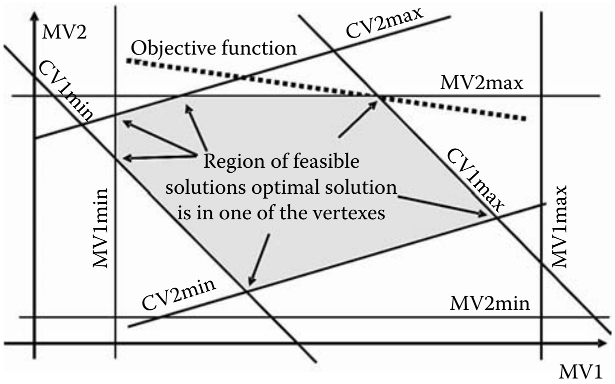

FIG. 2.17i
Optimization problem of a two-dimensional system. (Copyright © 2002, ISA—The Instrumentation, Systems, and Automation Society. All rights reserved. Used with permission of ISA—The Instrumentation, Systems, and Automation Society.)

The optimal solution is located at one of the vertexes marked by arrows. To find this solution, an LP algorithm calculates an objective function for an arbitrary vertex and improves the solution sequentially until the vertex with the maximum (or minimum) value of the objective function as an optimal solution is found.

MPC Optimal Controller

Optimal MV values are applied to the MPC algorithm as target values of MV to be achieved within the control horizon. If the MPC controller is squared, i.e., the number of MV is equal to the number of CV, then MV targets can be effectively achieved by a change in CV value.

$$\Delta \mathrm{CVT} = \mathbf{A} * \Delta \mathrm{MVT} \qquad \mathbf{2.17(17)}$$

where ΔMVT is the optimal target change of MVs and ΔCVT is the CVs target change to achieve the optimal MV. The CVs change is implemented by managing CV set points.

The MPC algorithm working with an optimizer therefore has two main objectives:

- Minimize CV control error with minimal MV moves within operational constraints.
- Achieve optimal steady-state MV values set up by the optimizer and target CV values calculated directly from MV values.

To satisfy these objectives, the original unconstrained MPC algorithm has been extended to include MV targets into the least square solution. The objective function for this MPC controller is

$$\min_{\Delta \mathrm{MV}(k)} \left\{ \|\mathbf{\Gamma^y}[\mathrm{CV}(k) - R(k)]\|^2 + \|\mathbf{\Gamma^u} \Delta \mathrm{MV}(k)\|^2 + \left\| \mathbf{\Gamma^o} \left[\sum \Delta \mathrm{MV}(k) - \Delta \mathrm{MVT} \right] \right\|^2 \right\} \qquad \mathbf{2.17(18)}$$

where $\mathbf{\Gamma^o}$ is a penalty on error of the sum of controller output moves over control horizon relative to the target optimal change of MV defined by the optimizer and $\sum \Delta MV(k)$ is the sum of the MV moves over control horizon. For simplicity of notation, the objective function is shown for the SISO control.

The first two terms are the objective function for the unconstrained MPC controller. The third term sets up an additional condition to make the sum of the controller output moves equal to the optimal targets. In other words, the first two terms set up objectives for controller dynamic operation, and the third term sets up steady-state optimization objectives. Graphically optimized MPC objectives are illustrated in Figure 2.17j.

The general solution for this controller, similar to that for the unconstrained MPC controller, can be expressed as

$$\begin{aligned} \Delta \mathrm{MV}(k) &= (\mathbf{S^{u}}^T \mathbf{\Gamma}^T \mathbf{\Gamma} \mathbf{S^u} + \mathbf{\Gamma^u}^T \mathbf{\Gamma^u})^{-1} \mathbf{S^u}^T \mathbf{\Gamma}^T \mathbf{\Gamma} E_{p+1}(k) \\ &= \mathbf{K}_{\mathrm{ompc}} E_{p+1}(k) \end{aligned} \qquad \mathbf{2.17(19)}$$

where ΔMV(k) is the change in MPC controller output at the time k and $\mathbf{K}_{\mathrm{ompc}}$ is the optimized MPC controller gain.

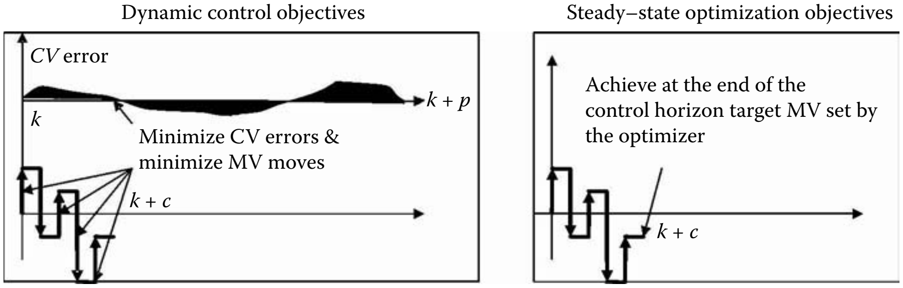

FIG. 2.17j
Optimized MPC control objectives. (Copyright © 2002, ISA—The Instrumentation, Systems, and Automation Society. All rights reserved. Used with permission of ISA—The Instrumentation, Systems, and Automation Society.)

Matrix $\mathbf{\Gamma}$ combines matrices $\mathbf{\Gamma^u}$ and $\mathbf{\Gamma^o}$. It is a square matrix of dimension $(p + 1)$ for the SISO controller and $[n(p + m)]$ for the multivariable controller. Superscript T denotes a transposed matrix.

MPC and Optimizer Integration

In operation, the optimizer sets up and updates the steady-state targets for the MPC unconstrained controller at every scan; thus, the MPC controller executes the unconstrained algorithm. Since the targets are set in a manner that accounts for constraints as long as a feasible solution exists, the controller works within the constraint limits. Optimization, therefore, is an integral part of the MPC controller. The integrated MPC controller and optimizer performs the following sequence of operations each scan:

1. Update CV and DV measurements.
2. Update CV predictions.
3. Determine optimal MV steady-state targets and calculate CV targets.
4. Provide MV outputs accounting for CV and MV targets.
5. Update MV.

Figure 2.17k illustrates communication and integrated operation of the optimizer and MPC algorithm. There is a typical situation when the optimizer cannot find an optimal solution because of too tight constraint limits, too many set points, or too severe disturbances. In these cases, the system constraints are relaxed by changing set points to range control and/or abandoning some constraints. This could be done by minimizing the squared error over a number of constraints or by abandoning constraints with the lowest priority sequentially.

Ill conditioning is another typical problem an optimizer has to deal with. As with the MPC algorithm, ill conditioning manifests itself as excessive changes in calculated MV targets even for minor corrections of constraints. Ill conditioning is removed dynamically by changing the configuration of active constraints (abandoning some constraints) or by removing the association between constraint or controlled variables and manipulated variables that have excessive moves.

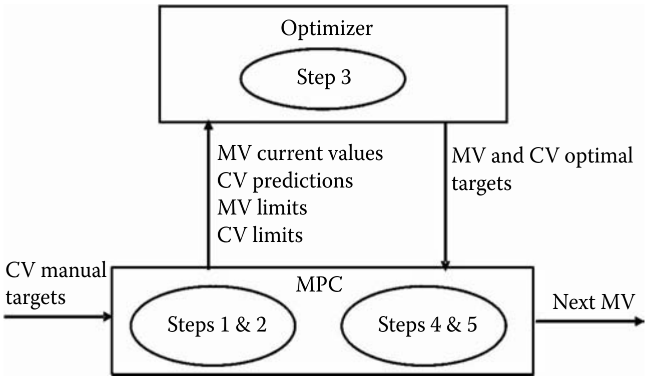

FIG. 2.17k
MPC and optimizer integration. (Copyright © 2002, ISA—The Instrumentation, Systems, and Automation Society. All rights reserved. Used with permission of ISA—The Instrumentation, Systems, and Automation Society.)

MPC APPLICATION DEVELOPMENT

Figure 2.17l illustrates a typical procedure of MPC application development consisting of the following basic steps:

1. Process analysis
2. MPC configuration development
3. Process testing
4. Process model development and controller generation
5. MPC simulation and tuning validation
6. MPC control evaluation and tuning adjustment

Process analysis should deliver a clear formulation of process control objectives and limitations as well as an understanding of how MPC control can achieve those objectives. Process analysis should result in *MPC configuration.* The process inputs and outputs are grouped into four different categories based on how they are utilized in the control of a process.

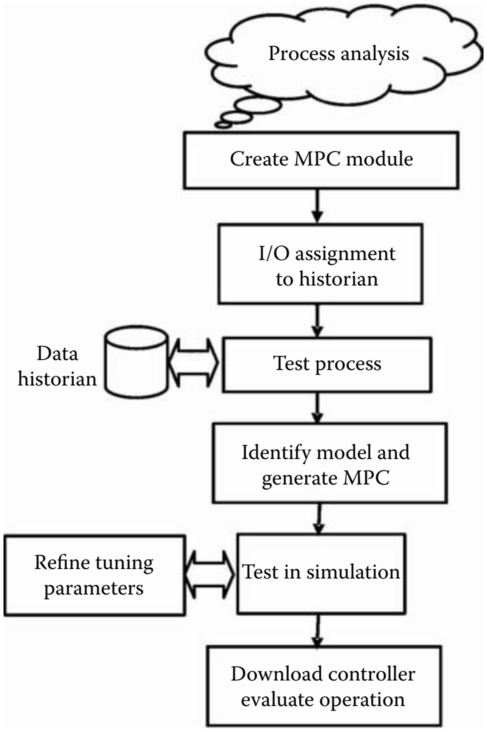

FIG. 2.17l
A typical procedure for MPC application. (Copyright © 2002, ISA—The Instrumentation, Systems, and Automation Society. All rights reserved. Used with permission of ISA—The Instrumentation, Systems, and Automation Society.)

The most common *process testing* procedure used today is pseudo random binary sequence (PRBS).

Process model development consists of test data review and model generation and validation. Controller generation computes the controller matrix defined by the process model and controller tuning parameters: *penalty on move* and *penalty on error.*

Penalty on move—Control sensitivity to changes in a process is determined by the controller robustness. The parameter used in controller generation that most impacts robustness is the penalty-on-move (PM) parameter. The PM defines how much the MPC controller penalizes changes in the manipulated output (MV). The penalty-on-move parameter is typically defined independently for every MV. High PM values result in a slow controller with a wide stability margin. With such settings, the control is relatively insensitive to a change in either the process or model errors. Low PM values result in a fast controller with a narrow stability margin. The penalty on move is also known as "move suppression" or an MV tuning weight.

Penalty on error—The penalty-on-error (PE) factor allows more importance to be placed on a specific controlled variable. In some systems an "equal concern" factor is used to account for differences in scale spans and engineering units, where a smaller equal concern places a greater importance on the error. The penalty on error is also known as a CV or AV tuning weight.

Testing in simulation—The user can influence the control behavior and robustness in online operation. A simulation environment permits operation in manual and automatic mode and allows for the introduction of noise and disturbance inputs and the acceleration of control execution.

Commissioning MPC Application

Before the new control is tried on the real process, the user must observe how well the control responds to set-point changes and load disturbances in simulation. If the process responds slowly to input changes, then it may take many hours in an operating plant to see the full control response. In a simulated environment, the process and control simulation can support faster than real-time execution to allow the response of even the slowest processes to be seen in a few minutes. Similarly, the ability to simulate the control and process response slower than real time is valuable when working with a very fast process. The ability to adjust the speed of execution allows the control response to be verified quickly for a variety of operating conditions. Through such testing, the user can gain confidence in the control performance.

In the *commissioning phase* of the MPC application, the user must first perform the obvious step of checking all communications between the process instrumentation and the MPC controller. Once the controller is operating in a stable manner, the performance elements that must be checked out during the commissioning phase include:

- Set-point changes
- Constraint control
- Steady-state giveaway
- Manipulated variable limitations
- Feedforward disturbances handling
- Optimizer functionality

Many issues of MPC application development have been addressed in modern MPC design. To provide a consistent environment for a configuration definition, MPC is implemented as a function block, and a simulation environment is automatically created based on the block definition, the identified process model, and the controller generated.

Once the controller has been generated, the MPC block is downloaded to the DCS controller to place the control online. Predefined applications are provided to allow each control, constraint, manipulated, or disturbance input to be placed on operator graphics. The trend display shows past plots and future predicted process outputs.

The tuning parameters associated with the generation of the MPC controller are automatically set based on the process dynamics. Thus, in most cases there is no need for users to make any adjustment to these tuning parameters.

CONCLUSIONS

Model predictive control and optimization are the primary techniques for achieving high performance unit operations. Modern MPC products, especially those integrated with DCS, are easy to apply and use. Good process understanding, however, is a major factor in setting the control objectives and in designing and commissioning an MPC application.

Definitions

Control horizon The number of future manipulated variable moves that are taken into account in developing the optimal MPC solution.

Dynamic matrix A matrix built from step responses to predict the changes in the process output that results from the moves of the manipulated variable over the control horizon.

Linear programming A mathematical technique for solving a set of linear equations and inequalities in order to maximize or minimize an additional function called an objective function.

Model predictive control (MPC) A model-based control technique that uses process output prediction and calculates several consecutive controller moves in order to satisfy control objectives.

Moving horizon control See **Receding horizon control**.

Penalty on error A parameter that ranks the importance of a specific controlled variable.

Penalty on move A parameter that defines how much the MPC controller penalizes changes in the manipulated variable.

Prediction horizon The range of process output prediction defined in scans.

Receding horizon control Control that is based on updating every scan output prediction over the prediction horizon.

Reference trajectory The future desired projection of the process output.

Set point trajectory See **Reference trajectory**.

2.18 Neural Networks for Process Modeling

B. A. JENSEN (1995) **J. ABONYI** (2005)

The design of control and process monitoring systems is currently driven by a large number of requirements posed by energy and material costs and by the demand for robust, fault-tolerant systems. These considerations introduce extra needs for effective process modeling techniques. Many systems are not amenable to conventional modeling approaches due to the lack of precise, formal knowledge about the system, due to strongly nonlinear behavior, high degree of uncertainty, or time-varying characteristics. Computational intelligence, the technical umbrella of artificial neural networks (ANNs), has been recognized as a powerful tool that is tolerant of imprecision and uncertainty and can facilitate the effective development of models by combining information from different sources, such as first-principle models, heuristics, and data.

Among the techniques of computational intelligence, ANNs attempt to mimic the structures and processes of biological neural systems. They provide powerful analysis properties such as complex processing of large input/output information arrays, representing complicated nonlinear associations among data, and the ability to generalize or form concepts/theory.

This section focuses on the promise of ANNs in the realm of modeling, identification, and control of nonlinear processes. The basic ideas and techniques of ANNs are presented in language and notation familiar to instrument engineers, and several examples are given of their industrial applications.

NEURAL NETWORKS FOR BLACK-BOX MODELING

Information for process modeling and identification can be obtained from different sources. According to the type of available information, three basic levels of model synthesis are defined:

- *White-box or first-principle modeling.* A complete mechanistic model is constructed from *a priori* knowledge and physical insight. Here, the dynamic models are derived based on mass, energy, and momentum balances of the process.
- *Fuzzy logic modeling.* A linguistically interpretable rule-based model is formed, which is based on the available expert knowledge and measured data.
- *Black-box model or empirical model.* No physical insight is available or used, but the chosen model structure belongs to families that are known to have good flexibility and have been “successful in the past.” The parameters of the models are identified based on measurement data.

This means that there may be situations where the most valuable information comes from input/output data collected during operation. In this case, the application of black-box models is the best choice. These black-box models are especially valuable when an accurate model of the process dynamics is needed. Therefore, nonlinear black-box modeling of process systems is a challenging and promising research field. The area is quite diverse and covers topics from mathematical approximation theory, via estimation theory and nonparametric regression, to algorithms and currently much-discussed concepts such as wavelets, fuzzy models and artificial neural networks (ANNs).

ANNs can learn complex functional relations by generalizing from a limited amount of training data; hence, they can serve as black-box models of nonlinear, multivariable static and dynamic systems and can be trained by the input/output data of these systems. Applications that are suitable for ANN solutions include those where:

- The solution is derived from highly interdependent variables that have no precise quantification.
- The problem requires qualitative or complex quantitative reasoning.
- Project development time is short, but sufficient data and neural network training time is available.
- Data are readily available but they are multivariate and intrinsically noisy or error-prone.

Conversely, applications that are not suited for neural net solutions include:

- Mathematically accurate and precise applications (i.e., accounts receivable and inventory)
- Applications that require deduction and stepwise logic

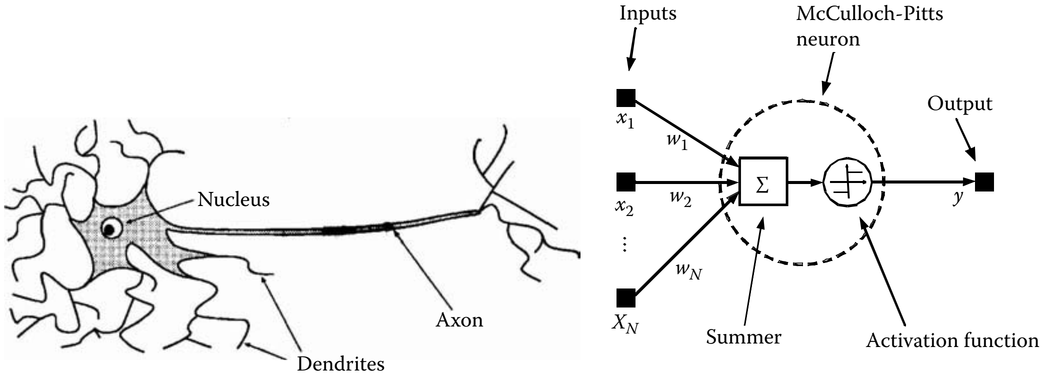

FIG. 2.18a
A biological neuron and its model (McCulloch–Pitts neuron).

STRUCTURE OF NEURAL NETWORKS

McCulloch–Pitts Neuron

It has long been known that learning in animals and humans can be achieved through observation of examples. The exact mechanism by which this learning takes place is still unknown, but science has yielded some clues.

The vertebrate brain consists of an enormous number of interconnected cells called neurons. It has become widely accepted that these neurons are the fundamental information processing elements of the brain. Neurons respond to electrical impulses collected from other neurons through connecting fibers called axons and dendrites. Prompted by studies in neuroscience, McCulloch and Pitts in 1943 developed a simple mathematical model for a neuron[1] (Figure 2.18a).

The McCulloch–Pitts neuron has multiple inputs and a single output. Each of the inputs has an associated weight. The weighed sum of the inputs is passed through a nonlinearity to the output of the neuron as follows:

$$y = f\left(\sum_{i=1}^{N} w_i x_i\right), \qquad f(z) = \begin{cases} 0 & z < 0 \\ 1 & z \geq 0 \end{cases} \qquad \mathbf{2.18(1)}$$

where x_i are the inputs, y is the output of the neuron, $f(z)$ is the nonlinear activation function in the form of the step function given above, and w_i are the strengths of the connections or weights. Given this particular neural model, it is important to understand what sorts of problems it can solve.

It can be used for pattern classification problems where input patterns have to be separated into two classes (Figure 2.18b). It is interesting that this simple model of a biological neuron is capable of emulating such a fundamental and important feature of natural intelligence. Although it demonstrates an example of how a simple element can perform a complex task, without a method of setting the connection weights and handling nonlinear separation problems it can be of little practical use. Hence, there was a period lasting from the late 1960s until the mid-eighties when interest of neural networks waned. It was not until 1986 that the vitality of the ANN field was restored by the publication by Rumelhart and McClelland.[2] This publication showed that the bane of neurons (perceptrons), the problem of linear inseparability, could be solved if perceptrons were bunched together in multiple layers to make multi-layer neural networks.

Feedforward Multi-Layer Neural Networks

The developed feedforward multi-layer neural network has one input layer, one output layer, and a number of hidden layers between them. For illustration purposes, consider an ANN with one hidden layer (Figure 2.18c).

The input-layer neurons do not perform any computations; they merely distribute the inputs x_k to the weights w_{jk}

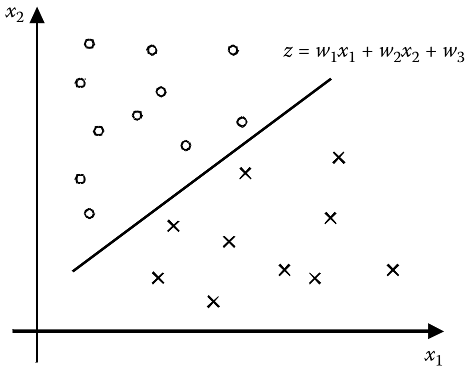

FIG. 2.18b
Graph showing how a line such as that defined by the weights in a McCulloch–Pitts neuron can be used to separate two classes of patterns.

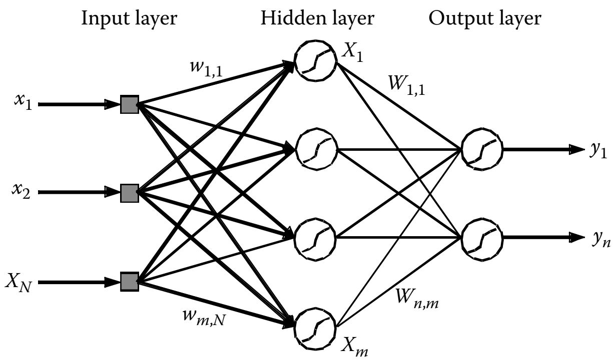

FIG. 2.18c
A multi-layer neural network with one hidden layer of neurons.

of the hidden layer. In the neurons of the hidden layer, first the weighted sum of the inputs is computed,

$$h_j = \sum_k w_{jk} x_k \qquad \mathbf{2.18(2)}$$

A nonlinear transfer function (also known as activation function and squashing function) is applied to the result to calculate each processing element's output,

$$X_j = f\left(\sum_k w_{jk} x_k\right) \qquad \mathbf{2.18(3)}$$

The transfer function adds nonlinearity and stability to the network. The most common differentiable transfer functions are listed in Table 2.18d.

TABLE 2.18d
Common Differentiable Transfer Functions

Name	*f(z)*
Sigmoid	$1/(1 + e^{-z})$
Hyperbolic tangent (tanh)	$(1 - e^{-z})/(1 + e^{-z})$
Linear	z
Sine	$\sin(z)$
Signum	1 if $z > 0$ -1 if $z < 0$
Percepton	z if $z > 0$ 0 if $z < 0$

The output value of the transfer function is generally passed directly to the output path of the processing element (although there are exceptions to this when a dynamical filter is used). The output path is then connected to input paths of other processing elements through connection weights. The outputs from the hidden units can then go through another layer of filters,

$$H_i = \sum_j W_{ij} X_j = \sum_j W_{ij} f\left(\sum_k w_{jk} x_k\right) \qquad \mathbf{2.18(4)}$$

and be fed through another layer of squashing functions to finally produce the outputs.

$$Y_i = f(H_i) = f\left(\sum_j W_{ij} f\left(\sum_k w_{jk} x_k\right)\right) \qquad \mathbf{2.18(5)}$$

If the network is being used for regression variables instead of classifying features, linear output functions should be used instead.

Contrary to the simplicity of this structure, this model is very general. It has been shown that with one hidden layer a network can describe any continuous function (if there are enough hidden units), and that with two hidden layers it can describe any function at all.[3] For local nonlinear basis functions, such as Gaussian RBFs, a single layer suffices.[4]

Example of an ANN

To illustrate the structure of ANNs, consider a fractionator example, where the product specifications are based on the Reid vapor pressure in the bottoms product and on the 95% boiling point of the distillate. Process analyzers have inherent dead time in producing these measurements, or the availability of analyzers to provide these measurements is limited.

Process models can be used to predict these properties, or other measurements can be used to infer them. However, if data exist regarding the measurements around the fractionator based on collected laboratory or analyzer results, as commonly recorded on log sheets, a nonlinear neural network model can be built. Shown in Figure 2.18e is a model with nine input nodes, four hidden nodes, and two output nodes with bias.

TRAINING OF FEEDFORWARD NEURAL NETS

Previously it was shown that neural networks consist of heavily interconnected processing elements that do not store information. The knowledge is stored by the way the processing elements are connected and by the importance of each connection, known as its weight. Training of the network means the adaptation of these weights such that the error between the desired output and the network output is minimized. Two steps are distinguished in this training procedure:

Feedforward Computation

From the network inputs $\mathbf{x}_n$, the outputs of the first hidden layer are first computed (by Equation 2.18[2]). Then using these values as inputs to the second hidden layer, the outputs

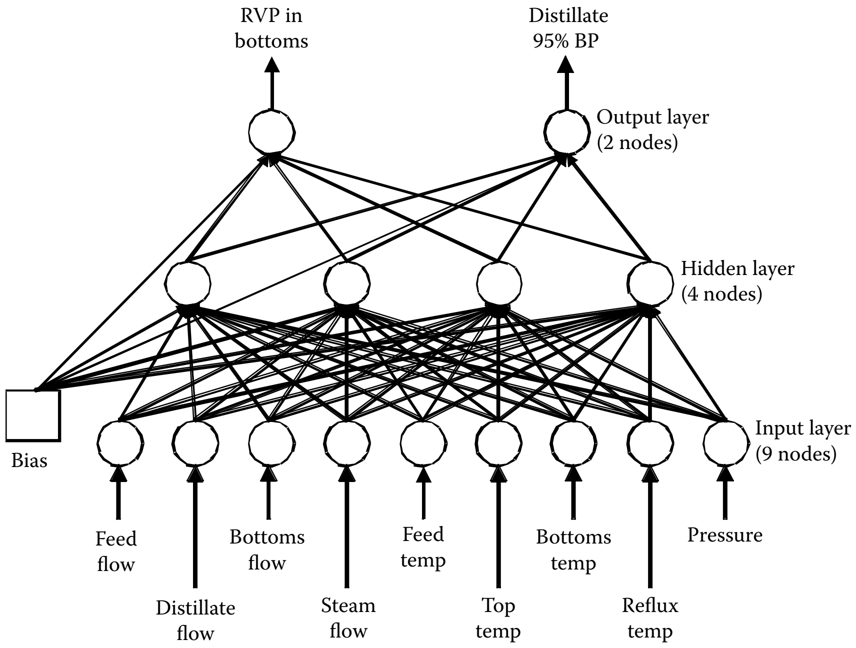

FIG. 2.18e
Example of a three-layer fully connected neural network describing the application of physical property prediction.

of this layer are computed (by Equation 2.18[3]), etc. Finally, the output of the network is obtained, $Y_i(\mathbf{x}_n)$ (Equation 2.18[5]).

Weight Adaptation

The output of the network is compared to the desired output, $y_i(\mathbf{x}_n)$. The difference between these two values, the error, is then used to adjust the weights first in the output layer, then in the layer before, etc., in order to decrease the error:

$$\begin{aligned}\min_{w,W} E^2 &= \frac{1}{2}\sum_n\sum_i [y_i(\mathbf{x}_n) - Y_i(\mathbf{x}_n)]^2 \\ &= \frac{1}{2}\sum_n\sum_i \left[y_i(\mathbf{x}_n) - f\left(\sum_j W_{ij} f\left(\sum_k w_{jk} x_{k,n}\right)\right)\right]^2\end{aligned} \qquad \mathbf{2.18(6)}$$

According to gradient-descent optimization, the updates step in the output weights can be found by differentiating the cost function given by Equation 2.18(6):

$$\begin{aligned}\Delta W_{ij} &= -\eta \frac{\partial E^2}{\partial W_{ij}} \\ &= \eta \sum_n \left[y_i(\mathbf{x}_n) - Y_i(\mathbf{x}_n)\right]^2 f'(H_i) X_j \equiv \eta \sum_n \Delta_i X_j\end{aligned} \qquad \mathbf{2.18(7)}$$

with the definition $\Delta_i = \eta[y_i(\mathbf{x}_n) - Y_i(\mathbf{x}_n)]^2 f'(H_i)$

The update in the input weights can be found from the chain rule:

$$\begin{aligned}\Delta w_{jk} &= -\eta \frac{\partial E^2}{\partial w_{jk}} \\ &= \eta \sum_n\sum_i [y_i(\mathbf{x}_n) - Y_i(\mathbf{x}_n)]^2 f'(H_i) W_{ij} f'(h_i) x_{n,k} \\ &= \eta \sum_n\sum_i \Delta_i W_{ij} f'(h_i) x_n \equiv \eta \sum_n \delta_j x_n\end{aligned} \qquad \mathbf{2.18(8)}$$

defining $\delta_j = \eta f'(h_i)\sum_i W_{ij}\Delta_i$.

The deltas for the input layer are found in terms of the deltas for the output layer by running them backwards through the network W_{ij}s. This is straightforward to generalize to networks with more than one hidden layer. Training a network by gradient descent, feeding the errors backwards through the network in this way, is called back propagation.

DEVELOPING AND BUILDING NEURAL NETWORKS

The phases of a neural network life cycle are concept, design, implementation, and maintenance.[5,6] In all phases, a strong emphasis is placed on experimentation. The user experiments under multiple development environments in order to refine, redesign, and reformulate network parameters to achieve the best outcome.

Concept

The concept phase plans the approach to building the application. The first step in implementing a neural network is to select a neural paradigm. Selection is based upon the traits of the problem (e.g., prediction, classification, association, conceptualization, filtering), size of the problem (number of input and output variables, size of the identification data), method of training (supervised/unsupervised), and time constraints.

Design, Implementation and Maintenance

The *design phase* specifies initial parameters and conditions for the selected neural paradigm. The type and number of processing elements (neurons), the number of layers, the connectivity of the layers, the transfer function, and the learning algorithm are design decisions that must be made.

Implementing the neural network involves applying the design criteria using customized or commercial environments. Experimentation is carried out with learning coefficients, momentum factors, noise injection, etc., in order to train the network most efficiently. Because of the nature of some learning algorithms, the method of presenting the training data can also affect the training results.

Maintenance involves modifying the deployed neural network application because of decreasing accuracy due to conditions encountered for which the network was not trained. In such cases, the training set must either be modified or replaced. Next, the network must undergo retraining and reevaluation in an iteration of the implementation phase. If reevaluation shows that the network performance is not to specification with the new data set, the design phase must be repeated.

In the following paragraphs, the most critical issues of this whole procedure are presented from the viewpoint of the identification data and the design parameters of ANNs.

Data Collection and Preparation

For a successful application of ANNs, as much training data as possible should be collected. Even more than volume, the quality and representativeness is important.[7] A good training set will contain routine, unusual, and boundary condition cases. In case of the identification of dynamic processes, a point worth noting is that unlike with linear models, data collected during pseudo random binary signal (PRBS) testing are unsuitable for nonlinear identification purposes.

It is important to consider the effects of feedback controllers when collecting data. If the model is to be used for control purposes then using data collected under closed-loop operation may introduce problems. If, however, the model is to be used for monitoring purposes then the process data should be collected with the system in its standard configuration. For example, if the system typically operates in closed loop then the data should be collected in closed-loop operation.

Preparing the data is an important consideration. The data may need to be converted into another form to be meaningful to the neural network. Hence, the preparation includes *transforming inputs* into the proper form (ratios, classes) and data types (binary, bipolar, continuous), and *normalizing* and *scaling* the data in order for the transform function to operate.

Following the cleaning of the process data, it is useful to determine the cause and effect variables and the major time constants and time delays present in the systems. The tools used for this analysis can include cross-correlation and multivariable techniques such as principal component analysis and principal component regression.

The results from these analyses can be subsequently discussed and validated with process operators and engineers. Such discussions usually prove extremely useful and provide greater insight into the operation of the process than is possible with the data analysis techniques alone.[7]

Applying the Data for Validation

It is important to note that the criterion function used for the training of the model accounts only for modeling errors during the training. This means that the obtained model depends on the training set used. Because of this dependence, the minimization of this criterion function does not guarantee a good neural model. To avoid problems, a common practice is to evaluate the generalization error in parallel with the iterative minimization process. The generalization error is obtained by testing the neural model with fresh data, i.e., data not used for the training.

Usually, the training error is reduced when the number of hidden neurons is increased (degree of freedom is increased) or when more training iterations are performed. "Over-training" may cause problems in both cases. In case of over-training, the fit on the training data becomes almost perfect, but the generalization error becomes worse. A plot of this phenomenon is presented in Figure 2.18f.

To avoid overtraining, most often methods are used that compare the training results with the test results. These methods

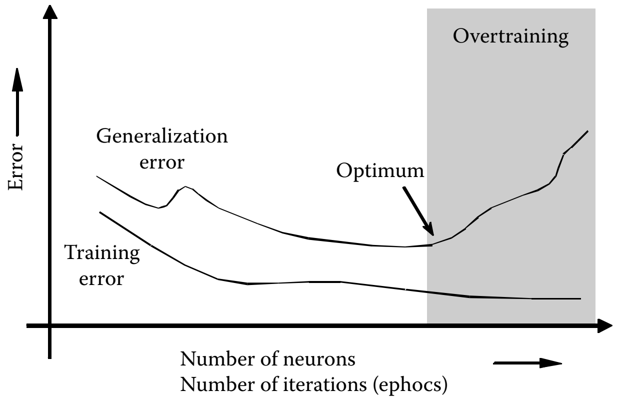

FIG. 2.18f
Training error and generalization error.

include “bootstrapping” or “cross validation.” The cross validation uses two data series, one for training the neural net, and the other to find the optimum, at the minimum of the generalization error. Hence, when the generalization error at a certain number of training iterations increases, the training is stopped and the weights are stored.

Hidden Layers, Nodes, and Algorithms

Determining the Number of Hidden Layers Hidden layers act as layers of abstraction and help the network generalize and even memorize. Increasing the number of hidden layers augments the processing power of the neural network but also significantly increases and complicates training, by requiring more training examples. Generally, most process modeling and control applications require only one hidden layer.

Determining the Number of Nodes Determining the number of nodes in a hidden layer is another experimental exercise. Rules of thumb give a starting point. One suggestion is that if one hidden layer is chosen, the number of processing elements may be equal to 75% of the size of the input layer.[5] Another suggestion is that the number of hidden nodes equals twice the square root of the sum of the number of input and output characteristics, rounded down to the nearest integer.[8]

In general, the more complex the relationship, the more processing elements are required in the hidden layer. Depending upon the number of total nodes in a network, a sufficient number of training sets must be provided in order to train the system adequately. Otherwise, the situation is the same as trying to fit a third-order polynomial with two data points, where an infinite number of sets of polynomial constants can satisfy the equation.

The situation of underspecification due to a lack of sufficient training examples is probably the single most common cause of problems for deployed networks.

Besides the previously presented cross-correlation analysis, many statistical tools can help determine the degree to which the network produces the correct outputs and to determine the number of hidden nodes.[9,10]

Tuning the Training Algorithm The initial choice of weights is very important to convergence. Small random numbers should be used, and equal weights should be avoided. It is possible for the system to require many iterations before convergence: 10,000 iterations are not uncommon.

Increasing the learning coefficient speeds up the learning. However, the higher the learning coefficient, the slower will be the convergence. Therefore, if the learning coefficient can be reduced as training proceeds, high learning and fast convergence can take place. Hence, a breakpoint table can be used to define the learning schedule. This table allows the learning coefficient to decay after a number of learning passes.

Gradient descent slows down near the minima and therefore the Levenberg–Marquardt method can be used to improve convergence. Although the searching process can easily get stuck in local minima, the situation can be improved by adding momentum so that the search rolls out of small wells. Another option is to add some random fluctuations to help kick the search out of minima.

APPLICATIONS

Neural networks have made an unusually rapid transition from laboratory experiments into the marketplace, overtaking other, better-established technologies. They are mostly used under human supervision or integrated with expert systems and fuzzy-logic systems. An indication of the commercial potential of neural networks for process control can be gauged from Boolean search of the U.S. Patents Database.[11] Among the 4848 neural network patents, 411 are related to process control, 121 to system identification, 62 to process monitoring, and 1596 to sensors.

In the next paragraphs, some of these applications of ANNs will be reviewed.

Identification of Dynamic Systems

ANNs can learn complex functional relations by generalizing from a limited amount of training data; hence, they can thus serve as black-box models of nonlinear, multivariable static and dynamic systems. Yet, the application of ANNs for the representation of dynamic systems is not so straightforward. While fundamental physical process models are mostly developed in continuous time, computer-based process control systems operate in discrete time; measurements are made and control actions are taken at discrete instants of time.

In addition, the available input/output data used for model identification are only available at discrete instants of time. Hence, neural network models of dynamical systems are mostly identified based on observed inputs $u(k)$ and outputs $y(k)$. In some cases simulated outputs $\hat{y}_u(k|\Theta)$, prediction errors $\varepsilon(k-n_e) = y(k-n_e) - \hat{y}(k-n_e \mid \Theta)$, and simulation errors $\varepsilon_u(k) = y(k) - \hat{y}_u(k \mid \Theta)$ are also used. According to the applied regressors, following the nomenclature of linear models, it is natural to coin similar nonlinear model structures:[12]

- NFIR, *Nonlinear Finite Impulse Response models*; in this case the regressor vector is composed as $\mathbf{x}_k = [u(k-1),\ldots,u(k-n_b)]$.
- NARX, *Nonlinear AutoRegressive with eXogenous input models*, which use regressors $\mathbf{x}_k = [y(k-1),\ldots,\hat{y}(k-n_a),\ u(k-1),\ldots,u(k-n_b)]$.
- NOE, *Nonlinear Output Error models,* which use $\mathbf{x}_k = [\hat{y}_u(k-1 \mid \Theta),\ldots,\hat{y}_u(k-n_b \mid \Theta),u(k-1),\ldots,u(k-n_b)]$.
- NARMAX, *Nonlinear AutoRegressive Moving Average with eXogenous input models,* where $\mathbf{x}_k = [y(k-1),\ldots\ y(k-n_a),\ u(k-1),\ldots,u(k-n_b),\ \varepsilon(k-1),\ldots,\varepsilon(k-n_e)]$.

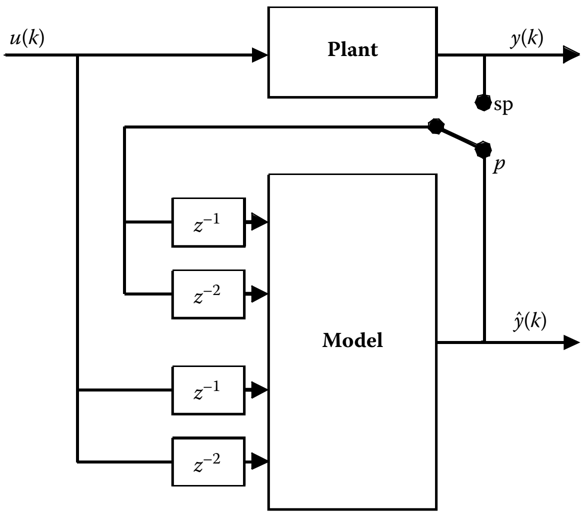

FIG. 2.18g
Series–parallel (sp) or parallel (p) identification methods. z^{-1} *is a backward shift operator.*

- NBJ, *Nonlinear Box-Jenkins models;* where the regressors are past inputs, past estimated outputs, estimation errors using past outputs, and the estimation errors using past estimated outputs $\mathbf{x}_k = [\hat{y}(k-1\,|\,\Theta),\ldots,\hat{y}(k-n_a\,|\,\Theta),\ u(k-1),\ldots,u(k-n_b),\varepsilon_u(k-1),\ldots,\varepsilon_u(k-n_u),\varepsilon(k-1),\ldots,\varepsilon(k-n_e)]$

The NARX model is often called a *series–parallel model*, while the NOE is referred to as a *parallel model*[13] (Figure 2.18g). The NARMAX, NOE, and NBJ models are recurrent models, because they use the estimated output that constitutes feedback. This makes the identification of these models difficult.

Because the NARX model structure is nonrecursive, its parameters are easier to estimate. Therefore, the NARX model is frequently used for identification. The identified NARX (series–parallel) model is often used and tested as a NOE (parallel) model, when the past outputs of the nonlinear model are used instead of the real plant outputs. By using this approach, a multi-step-ahead prediction can be made, using the former predictions of the system.

This procedure is often called "free run" simulation. The "free run" is a very rigorous test of the predictive power of the model because in this way small errors can accumulate and become major ones.

So far, only regressors that consist of previously measured input/output data have been used. However, based on *a priori* knowledge, semiphysical regressors can also be defined.[14] A special type of these regressors exists when the filtered input is used as a regressor.

Special dynamic networks can be realized by using recurrent networks in which neurons are arranged in one or more layers and feedback is introduced either internally in the neurons, to other neurons in the same layer, or to neurons in preceding layers.[15] Examples of these networks are the Elman network (Figure 2.18h) or the Hopfield network. This is a good thing to do if the network should learn to model such feedback behavior.

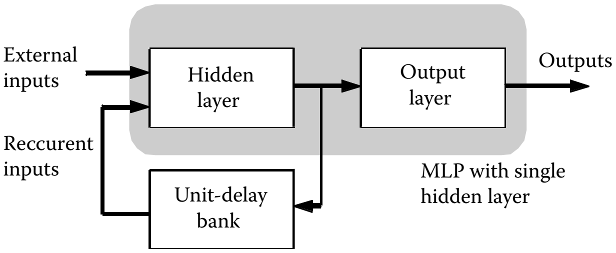

FIG. 2.18h
Example of a recurrent neural network model.

Gray-Box Modeling

Although neural networks are often deployed as stand-alone applications, they can also be integrated into overall solutions. They may be embedded within databases or expert system applications, act as preprocessors or postprocessors to other systems, or be linked in a distributed architecture. From the process modeling point of view, two main integration approaches can be distinguished: bias modeling and semimechanistic modeling.

The bias or parallel modeling approach assumes that a first-principle (white-box) model of the process can be obtained, but it is not possible to identify all the sources and statistical characteristics of disturbances. In this case, a neural network is trained to predict the difference (residual) between the process and its first-principles model.[16]

The semimechanistic model is based on a first-principle model.[17] Because the process is not perfectly known, the unknown parts of the white-box model are represented by black-box elements. To illustrate the structure of these models, consider the modeling of general chemical processes based on macroscopic balances, for instance, mass or energy balances. The following conservation principle describes these balances:

$$\frac{\begin{bmatrix}\text{accumulation of } S\\ \text{within the system}\end{bmatrix}}{\text{time period}} = \frac{\begin{bmatrix}\text{flow of } S\\ \text{into the system}\end{bmatrix}}{\text{time period}} - \frac{\begin{bmatrix}\text{flow of } S\\ \text{out of the system}\end{bmatrix}}{\text{time period}}$$
$$+\frac{\begin{bmatrix}\text{amount of } S\\ \text{generated}\\ \text{within the system}\end{bmatrix}}{\text{time period}} - \frac{\begin{bmatrix}\text{amount of } S\\ \text{consumed}\\ \text{within the system}\end{bmatrix}}{\text{time period}} \qquad \mathbf{2.18(9)}$$

where S is a certain quality, e.g., mass or energy. As in the modeling phase it becomes evident which parameters of this model structure are easier and which are more laborious

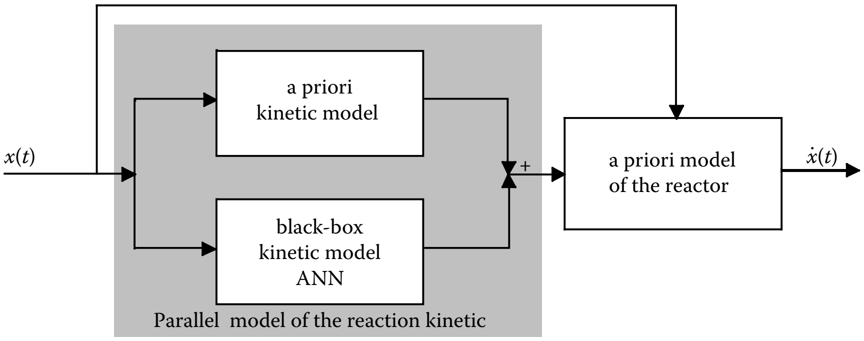

FIG. 2.18i
Series–parallel combination of white- and black-box models.

to obtain. Black-box models can be used to model the otherwise difficult-to-calculate parameters. For example, Hubert te Braake used this type of approach to model a continuously stirred tank reactor (CSTR).[18]

Thompson and Kramer combined the parallel and the hybrid modeling approaches into a series–parallel model (Figure 2.18i).[17] Of course, more complex combinations of white and black boxes can also be obtained. The key issue of this approach is the method to train these black boxes, which are based on input/output data. For this purpose, direct training data obtained from well-designed experiments or an extended Kalman filter can be used.

Neural Networks in Process Control

A neural controller is an automatic controller in which an artificial neural network is utilized in the process of calculating the control signal.[19] As described previously, the functionality of an ANN is usually wholly defined through learning by example. This implies that an important part of the design of a neural controller is the design of a mechanism by which learning exemplars can be collected and used to adjust the parameters of the ANN. This mechanism is very similar to that of adaptive controllers, so most neural controllers in fact are adaptive in their nature.

Figure 2.18j shows the hierarchical classification of ANN-based control algorithms. Each of the groups is briefly described in Table 2.18k.

The ability of neural networks to represent nonlinear relations leads to the idea of using networks directly in a model-based control strategy[20] (see Section 2.10 on Genetic Algorithms).

The concept is based on the capability of neural networks to learn both a system input/output relationship and the corresponding inverse relationship. In these solutions artificial neural networks are used for the construction of plant models and their inverses, and it is intended that they be used directly within the internal model control (IMC) structure[21] (Fiure 2.18l).

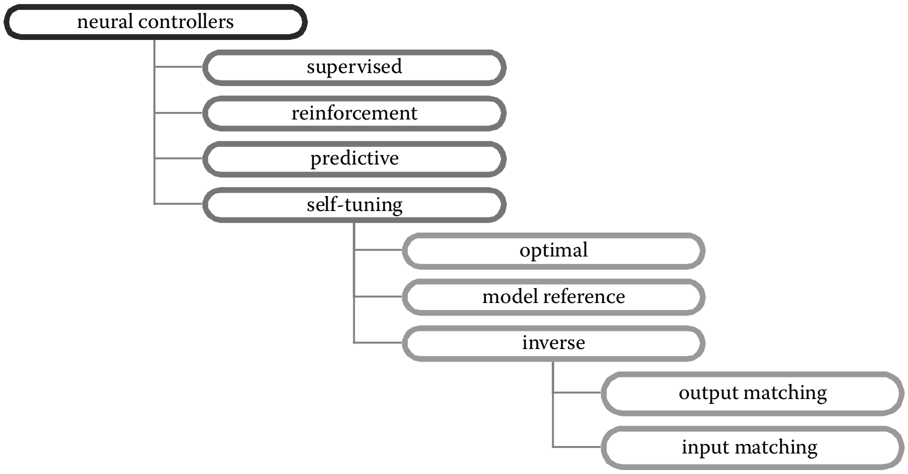

FIG. 2.18j
Neural controller classification scheme based on the method by which the error signal used for training the ANN is derived.

TABLE 2.18k

Brief Descriptions of a Variety of Neural Controller Classes

Class	*Description*
Supervised	ANNs trained to mimic another controller (e.g., a human operator)
Adaptive	Neural controllers defined by use of minimization of cost functions
Reinforcement	Neural controllers trained by means of reinforcement learning
Predictive	Neural controllers trained to match the output of an optimization routine operating on a plant emulator
Optimal	Nontrivial cost functions, i.e., ones that are not based purely on the current plant output or control signal error, are minimized
Model reference	Neural controllers trained to make the system track a reference model
Inverse	Inverse models of the plant are used as a controllers
Output matching	Methods aimed at minimizing the error between the plant output and the reference signal
Indirect output matching	Controller errors are calculated from plant output error signals by back propagating them through plant models
Direct output matching	Controller errors are calculated directly from plant output error signals without use of plant models
Input matching	Methods aimed at minimizing the error between a known control signal and the output of the neural controller
Indirect input matching	Controller errors are calculated using inverse plant models
Direct input matching	Controller errors are calculated using the controllers as inverse models

Following the standard IMC practice, the controller is selected as the plant inverse model. The model uncertainty is included in the feedback information; thus, the effect of the uncertainty on the system output will be reduced. The difference between the outputs of the actual plant and the internal model is caused not only by the model uncertainty, but also by disturbances acting on the plant. Therefore, internal model control can also reduce the disturbance effect on the system output.

Recent developments have resulted in theoretical frameworks to demonstrate stability for ANN-based nonlinear control, and these have arisen from combined developments in control theory and in numerical analysis. It is a telling development that traditional control expertise is even more necessary for the safe deployment of neural network controllers than it was for traditional three-term controllers.

Adaptive control (discussed in the previous section) applications are seen as one area where neural networks have much to offer. Again, further research is required in this area to increase the credibility of adaptive neural network solutions.

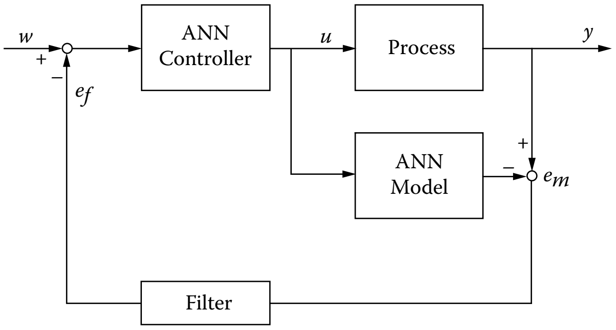

FIG. 2.18l

Application of ANNs in the internal model control structure.

Plant Monitoring and Fault Detection

The aim of plant monitoring is to compare actual plant operation with the desired one. Any deviation is indicative of plant malfunction, which can trigger a diagnostic search for the most likely fault, in real time. The benefit here is in obtaining earlier warning about incipient faults, as well as the potential for providing the operator with a ranked list of possible hazards (see Section 1.6).

The difference between using neural networks rather than purely knowledge-based systems for this application lies in the ability to integrate complex signals at a low level, yielding more complex advice than may be possible by representing the activity of individual sensors directly in symbolic form.[22]

The application of ANNs for nonlinear principal component analysis is an interesting example of information integration. While traditional PCA has been widely studied and successfully applied to process engineering, it has the limitation of being a linear operation.

Kramer presented a nonlinear principal component analysis method based on auto-associative neural networks, which was further improved by Dong and McAvoy.[23] The architecture of this network is shown in Figure 2.18m.

The bottleneck layer of the network performs the dimension reduction because the number of neurons in this layer is smaller than that in the input and output layers, so that the network is forced to develop compact representation of the input data.

Pham and Oztemel used an integrated neural network-based pattern recognizer and expert system for analyzing and

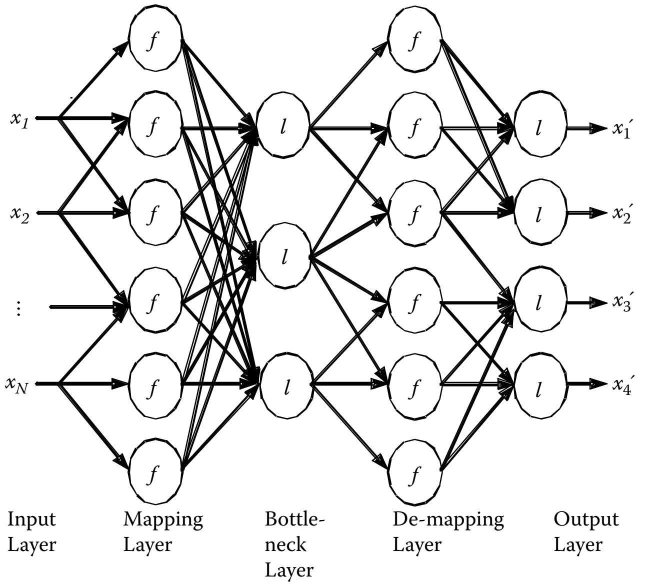

FIG. 2.18m
An auto-associative nonlinear PCA network with five layers. Transfer functions f are nonlinear and transfer functions l are linear.

interpreting control charts.[24] In another application, intelligent process monitoring functions based on a unique combination of rule-based expert systems and neural networks were developed to control a complex pulp and paper process.[25]

Fault detection in process systems has been the subject of numerous studies in the past few decades. Initial work in the area employed a variety of paradigms to both detect and characterize faults, including signal-based, model-based, and knowledge-based approaches. Model-based approaches traditionally employed linear state-space modeling techniques such as Kalman filters.

Fault detection is achieved in these methods through the analysis of the residuals produced by the models. As with model-based controllers, improvements to the accuracy of the monitoring procedure can be made through the utilization of ANNs if the system exhibits nonlinear characteristics. Examples of applications are fault classification; turning, tapping, and welding comparisons; and acoustic emission for tool condition monitoring.[26]

Intelligent Soft Sensors

Further gains are likely to result from the development in soft sensor technology (see Section 7.18 in Volume 1 of this handbook). Industrial demand for soft sensors is substantial. Safety benefits will arise from access to estimates of hidden state variables. An example of this would be estimating the amount of pulverized fuel in a coal mill, when wet coal can become trapped in the rolling chains of a coal feeder. In effect, what is needed is a sophisticated nonlinear observer that is capable of estimating the coal content of the mill for air temperature and differential flow measurements.

There are many other instances in the process industries where the direct measurement of variables that are key to either the detection of performance or to safety are unavailable. This is either because they are too expensive to measure accurately or are impossible to measure fast enough for closed-loop control. Examples of such cases include some pH and other measurements in loop reactors.

Industrial Applications

Although a number of process companies have applied ANNs, few have reported their results publicly. Some application examples involve Texas Eastman, which has used neural networks for steady-state modeling and has significantly improved the utilization of some costly intermediate chemical species.[27]

Neural network modeling was also used to identify operating cost savings in a municipal wastewater treatment facility.[28] Texaco has reported a feedforward control application on a refinery cooker, which greatly improved drum switchover.[29] DuPont has used neural networks as soft sensors, and for model-based control of an acid plant.[30]

Like expert systems, several good neural shells have come onto the market.[31] These shells offer a very good method of organizing and implementing an application. With these tools ANNs can be deployed either as stand-alone applications or as integrated overall solutions. They may be embedded within databases or expert system applications,[32,33] act as preprocessors or postprocessors to other systems, or be linked in a distributed architecture, combined with statistical validation. They have also been introduced as viable solutions for the control of manufacturing facilities.[34]

Among the biggest vendors of control systems, Emerson (former Fisher-Rosemount) offers an *Intelligent Sensor Toolkit* for creating virtual sensors. This tool can be also used for process analysis and knowledge discovery to help determine pieces of process model in a variety of control applications. NeuCOP II from NeuralWare (an AspenTech subsidiary in Pittsburgh, Pennsylvania) combines neural networks, statistics, and multivariable modeling techniques to create dynamic, nonlinear models from process data. The NeuCOP II controller incorporates these nonlinear models into a model-predictive control strategy with an embedded optimizer. It can compute optimal control actions without violating the operating constraints. The results can then be displayed to an operator for manual implementation or fed to a real-time control system, such as DMCPlus, for automatic implementation.

With this tool, neural networks can be installed in existing multivariable control applications to improve our ability to calculate inferential properties and to provide tighter control of highly nonlinear processes.

The Process Perfector from Pavilion Technologies (Austin, Texas) also combines neural networks with model-predictive control technology. Unlike traditional model-predictive controllers, however, the Process Perfector uses a nonlinear model that is applicable to a wider range of processes.[35]

CONCLUSIONS

The potentials of neural network technology in the process industries are vast. The ability of neural networks to capture and model process dynamics and severe process nonlinearities makes them powerful tools in model-based control and monitoring.

The theoretical and practical issues associated with using neural networks for industrial applications were reviewed in this section. Readers were also provided with an insight into the problems and benefits encountered when exploiting this technology.

In the future, neural networks will be used not only on their own, but also in conjunction with other advanced technologies. The fusion of neural networks and fuzzy logic in the form of neuro-fuzzy techniques is seen by many as the most promising way ahead for advanced process monitoring and control applications. An alternative field that also offers great potential is hybrid modeling, an identification methodology that complements simplified mechanistic models with either linear or nonlinear data-based models.

R. D. ROJAS (2005)

INTRODUCTION

This section discusses the conceptual approaches and tools of adaptive control and their applications to nonlinear processes. Adaptive control can be thought of as a system that automatically designs a control system. This technique has considerable potential for applications where the processes being controlled are not well understood or have significant nonlinearities or time-varying parameters.

Adaptive control utilizes the natural steps of control system design. These include process modeling and identification (Section 2.16), relative gain calculations (Section 2.25), controller design (for example, self-tuning controllers, Section 2.29), and optimization (Section 2.20).

At present, these approaches and ideas are being extended to include such new tools as artificial intelligence and as expert systems (Section 2.8), neural networks (Section 2.18), fuzzy logic (Section 2.31), and genetic algorithms (Section 2.10), among others. Therefore, it is suggested that all of these sections be studied if a thorough understanding of the subject matter is desired.

DEFINITIONS AND TERMINOLOGY

Most processes are nonlinear in some respects. The process gain can vary with load (for example, the gain of heat transfer processes will drop with rising load) or can change with time (for example, because of dirt or coating buildup). The dead time and with it the period of oscillation can also vary (for example, the transportation lag or dead time represented by a reactor jacket increases as the water flow rate through the jacket drops).

Feedback control loops are designed so that the controlled variable (the process output) is maintained at its set point even if disturbances occur or the dynamics of the process changes. When the process is operating close to the upper or lower boundaries of its performance range, the total loop gain will approach one of its limits. If it approaches its upper limit, it will cause undamped oscillation; if it drops near the lower limit, the loop becomes sluggish and cannot keep its controlled variable on set point. Similarly, because the process dead time constrains the oscillations of the feedback loops, when the dead time of the process changes, the control settings also need to be revised.

Adaptive control involves the automatic detection of changes that occur in the process parameters or in the set point and the readjustment of the controller settings, thereby adapting the tuning of the loop to the changing conditions. Adaptation can be based on the inputs entering the process (known operating conditions or measurable disturbances) or on the closed-loop performance (behavior of the controlled variable, c, or tracking error, e). In the first case, the system is adjusted on the basis of a measurement of the disturbance variable, which is called *feedforward adaptation* (or *gain scheduling*). In the second case, the system uses a measurement of its own performance, which is called *feedback adaptation* (or *self-adaptation*).

Steady-State and Dynamic Adaptation

The adaptation criteria can be specified in the steady state: an example is the goal of setting the air–fuel ratio of a boiler so that it will maintain the process to maximum efficiency (the minimum total-loss) point on its performance curve. This is called *steady-state adaptive* (or *optimizing*) *control.*

Another way to specify the adaptation criteria is on the basis of the process transient response. An example of this approach is the modification of tuning constants based on the damping of the controlled variable after an upset. In this case the adaptation method is called *dynamic adaptation.*

This method can be used, for example, to stabilize a PID-based pH control system. Without adaptation, when the process gain (K_p) rises as the process approaches neutrality, the increased process gain results in the loop becoming unstable (cycling). In this application the adaptive controller maintains the damping ratio (usually set for $^1/_4$). Therefore, when the controller realizes that K_p has risen, it starts to lower the controller gain (K_c) so that the total gain product of the loop ($K_pK_cK_vK_t$, where K_v and K_t are valve and transmitter gains, respectively) will remain at the desired value (usually 0.5).

An adaptive control system is one whose parameters are automatically adjusted to meet the corresponding variations in the behavior of the process being controlled in order to optimize the response of the loop. The significant difference is that adaptive control changes the controller *parameters* (*tuning settings*), which in PID control are normally fixed, as opposed to changing the outputs of a system, which are expected to vary.

The parameters set into controllers and control systems naturally reflect the characteristics of the processes they control. To maintain optimum performance, these parameters should change as the associated process characteristics change. If these changing characteristics can be directly related to the magnitude of the controller input or output, it is possible to compensate for their variation by the introduction of suitable nonlinear functions at the input or output of the controller.

Examples of this type of compensation would be the introduction of a square-root extractor in a differential pressure type flow-measurement signal to linearize it, or the selection of a particular valve characteristic to offset the effect of line resistance on flow. This step is not considered to be part of adaptive control, in that the controller functions remain fixed.

If the process nonlinearities are compensated by controller functions (i.e., by feedback linearization or by changing PID controller gain, integral, or derivative tuning settings) the controller is nonlinear. An example is a pH controller, where the controller gain is adjusted to compensate for the nonlinearities of the pH system titration curve. Changing controller gain as a function of the pH controller input (measured variable) is not strictly adaptive, but it is nonlinear.

APPROACHES TO ADAPTIVE CONTROL

Adaptive control has been an important field of theoretical research, but now it is also a good tool to solve real-world problems. Classical adaptive control techniques have shown to provide simple solutions to the control of nonlinear and time-variant systems; several texts and articles pursue the details of the approaches presented here.

Some good examples are the books of Astrom and Wittenmark,[1] Sastry and Bodson,[2] and Ioannou and Sun;[3] electronic versions of the latter two books can be obtained by free download from the authors' Web pages. They can be complemented with the Tao[4] book, which summarizes the recent fast growth of adaptive control applications and theory development.

With the increasees in the complexities of processes, including the effects of system component imperfections and nonsmooth nonlinearities, the adaptive control system is expected to provide greater robustness. These needs justify the emergence of such expert and artificial intelligence techniques as neural networks, fuzzy logic, and genetic algorithms.

Feedforward or Gain Scheduling

Where a measurable process variable produces a predictable effect on the gain of the control loop, or a known nonlinear behavior depends on the operating conditions, compensation for its effect can be programmed into the control system. This is the basis for *gain scheduling.* The most notable example of gain scheduling is the variation of dynamic gain with flow in pipes and other longitudinal equipment where no back-mixing takes place. This variation of dynamic gain is commonly seen in heat exchangers, but it causes a particularly severe problem in once-through boilers.

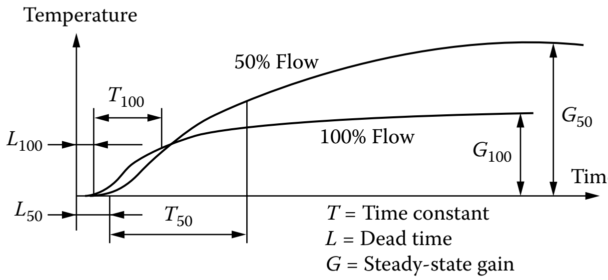

FIG. 2.19a

Step response of steam temperature to firing rate in a once-through boiler.

In a once-through boiler, feed water enters the economizer tubes, passes directly into the evaporative tubing and then into the superheater tubing, and leaves as superheated steam whose temperature must be accurately controlled. No mixing takes place as in drum-type boilers, so a sizable amount of dead time exists in the temperature control loop, particularly at low flow rates.

Figure 2.19a shows the response of steam temperature to changes in firing rate at two different feed water flow rates. At 50% flow, the steady-state gain is twice as high as at 100% flow, because only half as much water is available to absorb the same increase in heat input. The dead time and the dominant time constant are also twice as great at 50% flow.

The effect of these variable properties on the dynamic gain of the process is evidenced in Figure 2.19b. The same size load upset produces a larger excursion in temperature at 50% flow, indicating a higher dynamic gain. The difference in damping between the two conditions also reveals the

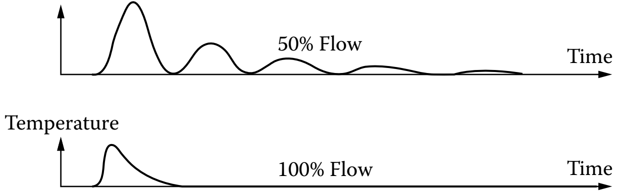

FIG. 2.19b

Response of the steam temperature loop to step changes in load without adaptation.

change in dynamic gain and so does the response, which is twice as fast at 100% flow. If oscillations were evident in the 100% flow response curve, their period would be much shorter than for 50% due to the difference in dead time. At 25% flow, oscillation periods would be still shorter and damping would disappear altogether.

If the only feedback mode used in this application were proportional, the period of oscillation would vary inversely with flow, as would the dynamic gain at that period. The only adjustment that could be made would be that of the controller gain (K_c), which should vary in direct proportion to flow. This would make the damping uniform, but with a plain proportional controller nothing can change the increased sensitivity of the process to upsets at low flow rates.

Since reset and derivative modes are normally also used to control temperature, some consideration should also be given to their adjustment as a function of changes in flow. The process dead time—hence the period of oscillation under proportional control—varies inversely with flow. Therefore, in order to complete the adaptation, the reset and derivative time constants should also be varied inversely with flow.

The equation for the flow-adapted three-mode controller is

$$m = K_c w\left(e + \frac{w}{T_i}\int e\,dt + \frac{T_d}{w}\frac{d}{dt}e\right) + b \qquad \mathbf{2.19(1)}$$

where w is the fraction of full-scale flow and K_c, T_i, and T_d are the proportional, integral, and derivative settings at full scale flow. Equation 2.19(1) can be rewritten to reduce the adaptive terms to two:

$$m = K_c\left(we + \frac{w^2}{T_i}\int e\,dt + T_d\frac{d}{dt}e\right) + b \qquad \mathbf{2.19(2)}$$

Other parameters can be substituted for flow in instances where the adaptation is based on variables other than flow.

Dead-Band Control Dead-band control is a frequently used form of nonlinear control. The dead-band action is typically a programmed nonlinearity or adjustment depending on whether dead band is set by a process variable or by a disturbance factor.

Dead-band control is not a stand-alone control function. Proportional, integral, and derivative modes can still be used. If this function is used, a dead band is placed around the controller error such that no control action occurs unless the error exceeds the dead-band range. If the error is within the dead band, the error is set to zero.

Dead-band control is also used to stabilize very fast or sensitive processes (guidance of missiles or other projectiles) where stability is gained by not making changes (in direction) unless the limits of the gap (control tunnel) are approached. Dead-band control has found application in pH control and in systems requiring two control valves—one large, one small—to overcome the rangeability problem.

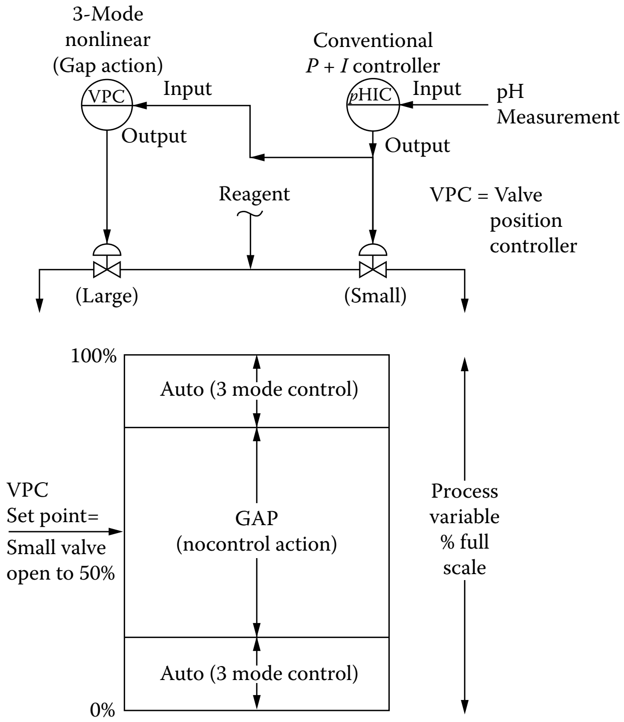

FIG. 2.19c
The valve position controller (VPC) measures the opening of the small valve and prevents it from fully opening or fully closing by becoming active only when such extreme positions are evolving.

For example, consider the control scheme shown in the top portion of Figure 2.19c. Here the dead-band controller is used to drive the large valve when the output of the conventional proportional and integral controller reaches a preset limit (top or bottom). The large valve makes a rough adjustment when the error is outside of its dead band or gap. Returning the pH back within the gap allows the small control valve to once again take control.

Figure 2.19c shows the regions where the dead-band control action is in operation. Depending on the relative size of the small (trim) valve and the response desired, the size of the dead band can vary widely. Commercial controllers and DCS or computer control packages are available with this dead-band feature.

Switching Controller Gains Another form of programmed adaptation or nonlinear control is referred to as variable breakpoint control. The proportional gain for this type of controller is changed at certain predefined values of the process variable or controller error (process variable − set point). In this type of application it is usually desired to set the controller gain at a low value at or around the set point, so that not much controller action would occur near the set point.

If the process moves to some preset distance from set point, the controller gain is increased to drive the process back into the set point region at a faster rate. This type of control action may also be used to compensate for very nonlinear process gain characteristics. In this case the controller gain is set high when the process gain is low and set low when the process gain is high in order to maintain a relatively constant (0.5 or so) closed-loop gain (i.e., consistent closed-loop performance throughout control range).

The pH control problem is a good example of nonlinear control. Consider the process gain characteristic of the neutralization system illustrated in Figure 2.19d. This is a typical strong acid, strong base neutralization process. The control set point is at pH = 7. The process has extremely high gain at this point (i.e., a small amount of reagent change results in a dramatic change in pH). The required controller gain between a pH of 3 and a pH of 9 must be small for stability. If the pH measurement were to move above 9 or below 3, this low gain would result in a very sluggish response because at those pH values the process gain is low. Therefore, above 9 and below 3 the controller gain is switched to a high value. The required controller gain is shown as a dashed line in Figure 2.19d.

Such nonlinear controllers are available both in the form of electronic hardware controllers or as DCS algorithms. They can also be implemented with more than two line segments, and in more sophisticated systems the controller gains can correspond to the mirror image of the process gain curve.

It is important to point out that the implementation of this algorithm does require more than just a simple switching of gain numbers at breakpoints. Care must be taken to ensure that the gain change does not result in a bump or discontinuity in control action.

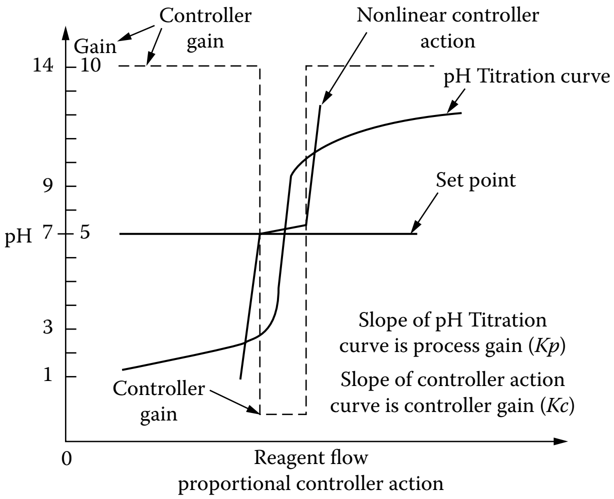

FIG. 2.19d
Variable breakpoint nonlinear control action is used for strong acid, strong base neutralization.

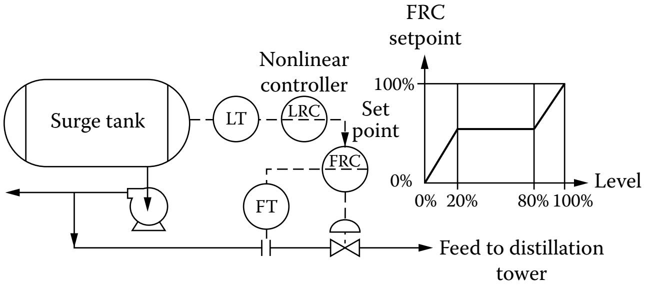

FIG. 2.19e
Nonlinear level control keeps the set point of its cascade slave (FRC) unchanged most of the time while allowing the level to float, but it still prevents flooding or draining of the surge tank.

An example of a process application where the discontinuity in controller gain can be tolerated, while the use of the nonlinear controller improves overall performance, is the case of surge tank level control. As the purpose of installing a surge tank is to absorb the differences in flows between plant sections, the intent is to let the level in these tanks float. When this level is cascaded to a flow controller (Figure 2.19e), it is even more desirable not to react to small level variations (which have no harmful consequence) by changing the flow controller set point, which if changed would upset the material balance of the downstream process.

Therefore, the nonlinear controller is an ideal cascade master for such an application. As shown in Figure 2.19e, the nonlinear controller can be adjusted to make no change at all in the slave (FRC) set point as long as the level is between 20 and 80%. This control system still protects the tank from draining or flooding by becoming active when the level goes outside this gap.

Continuous Adjustment of Controller Gains Just as in the programmed adaptation algorithm of Equation 2.19(1), in which the gain was multiplied by (and thereby was made a function of) the load variable, one can also adjust the controller gain (K_c) as a function of other parameters. One obvious option is to multiply the control gain (K_c) by some function of the error (e). For example, if K_c is substituted with $(K_c)(e^2)$, this will make the controller gain nonlinear and would result in the following PID algorithm:

$$m = K_c(e^2)\left(e + \frac{1}{T_i}\int e\,dt - T_d\frac{dc}{dt}\right) + b \qquad \mathbf{2.19(3)}$$

In Equation 2.19(3), the derivative mode acts on the measurement (c) only, instead of acting on the error (e) in order to make it insensitive to set-point changes. Note that this algorithm has a lower gain when the errors are small, and therefore this controller is less responsive to small errors.

This characteristic makes the nonlinear controller well suited for use in applications involving noisy measurements, such as flow or level, because instead of amplifying the noise, its response is minimal when the error is small. Naturally, it should be remembered that with large errors the controller gain rapidly gets very high and can cause stability problems and cycling unless some reasonable limit is placed on it.

When using "error squared" PID algorithms, a variety of configurations is available. In one configuration, the controller gain (K_c) is substituted with XK_c, where the value of X is found from Equation 2.19(4) below:

$$X = 1.0 + 90\ E/Y + 3{,}045\ E/Y^2 + 145{,}675\ E/Y^3 \qquad \textbf{2.19(4)}$$

where E = the normalized absolute value of the error (E is between 0 and 1.0) and Y = a constant that sets the severity of the desired nonlinearity in the controller action.

For example, if Y = 14%, it means that X will double after every 14% increase in the error. In other words, if X is 2 when the error is 14%, it will be 4 when the error is 28%, and it will be 8 when the error is 42%.

The multiplier X can be applied to the controller gain (K_c) and/or to its integral time (T_i). When both are chosen the algorithm is particularly suited to level control. For more detail on the control technique see Reference 5.

Gain scheduling obtained its name because it was originally used to accommodate changes in the process gain. Today it is also used, based on measurements of the operating conditions of the process, to compensate for the variations in process parameters or for known nonlinearities in the process.

Feedback Adaptation or Self Adaptation

Where the cause of changes in control-loop response is unknown or unmeasurable, *feedforward adaptation* or *gain scheduling* cannot be used. If an adaptive system is to be applied under these circumstances, it must be based on the response of the loop itself, i.e., it must be part of a *feedback adaptive scheme. Feedback adaptation* is a more difficult problem than *feedforward adaptation* because it requires an accurate evaluation of loop responses, ideally without the knowledge of the nature of the disturbance input.

The block diagram of a *feedback adaptive system* is given in Figure 2.19f. This system has all the problems that are associated with implementing *feedforward adaptation* plus the problems of evaluating the response and making a decision on the correct adjustment. Several *feedback adaptive techniques* that are currently being used in the process industry are briefly discussed below. These include the self-tuning regulator, the model reference controller, and the pattern recognition adaptive controller.

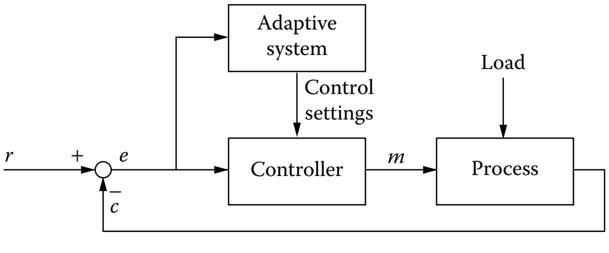

FIG. 2.19f
A self-adaptive system is a control loop around a control loop.

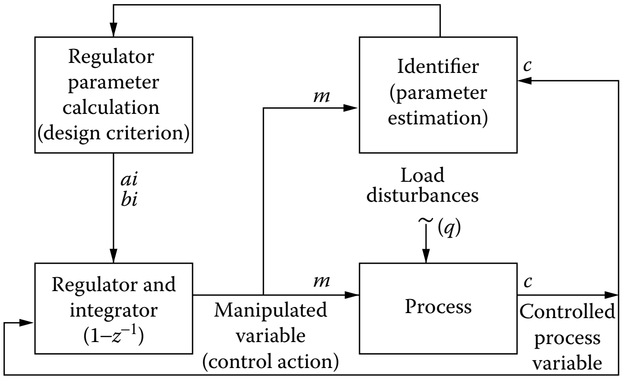

FIG. 2.19g
Self-tuning regulator.

Self-Tuning Regulator The self-tuning regulator (STR) is a name given to a large class of self-adaptive systems. The block diagram in Figure 2.19g shows the common structure of these STR systems. The figure indicates that all STRs have an identifier section, typically consisting of a process parameter estimation algorithm. Also common to all STRs is a regulator parameter calculation section. This section calculates the new controller parameters as a function of the estimated process parameters.

The methods used in these two blocks distinguish the type of STR being used. Popular varieties of STR include minimum-variance, generalized minimum-variance, detuned minimum-variance, dead-beat, and generalized pole-placement controllers. Reference 6 is a summary paper on basic STR technology. For a more detailed treatment of self-tuning controllers, refer to Section 2.29.

Model Reference Adaptive Controls Model reference adaptive control (MRAC) offers another method for the self-adaptive control problem. The controller is composed of a reference model, which specifies the desired performance; an adjustable controller, whose performance should be as close as possible to that of the reference model; and an adaptation mechanism. This adaptation mechanism processes the error between the reference model and the real process in order to modify the parameter of the adjustable controller accordingly.

Figure 2.19h schematically shows how the parts of a model reference controller are organized. Model reference adaptive controllers were originally designed to solve the deterministic servo problem, that is, control of the process-to-variable set

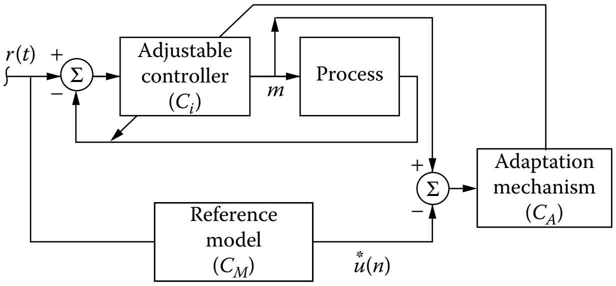

FIG. 2.19h
Model reference adaptive controller.

point reference signals. The design of MRAC has been mostly based on stability theory. For more information, see Reference 7 and also refer to Sections 2.13 and 2.16.

Pattern Recognition Controllers Other self-adaptive controllers exist that do not explicitly require the modeling or estimation of discrete time models. These controllers adjust their tuning base on the evaluation of the system's closed-loop response characteristics (i.e., rise time, overshoot, settling time, loop damping, etc.). They attempt to "cut and try" the tuning parameters and recognize the pattern of the response, thus the name "pattern recognition."

Pattern recognition controllers are commercially available from several instrument vendors. They are microprocessor based and usually heavily constrained with regard to the severity of allowable tuning parameter adjustments. They are gaining fair acceptance in operating plants.

INTELLIGENT ADAPTIVE TECHNIQUES

Process changes, such as flow disturbances and sensor noise, are common sources of inaccurate process information; because they degrade the control loop performance, the use of adaptive control is justified as the complexity of the process (nonlinearities and time-varying parameters) increases.

Adaptive control capability to deal with unknown or time-variant dynamics can be extended by using intelligent control (*intelligent identification and/or tuning*). Furthermore, economically optimal strategies have emerged to improve profitability. Many of these utilize switching operation points that require multiple models or multiple controllers or both (*multiple model adaptive control*).

To maintain optimal performance, the control system has to adapt continuously to the changes in the process and must perform well while it is adapting and while set points are also changing. In such cases, a supervised switching control strategy can be considered, where a variety of control algorithms can be chosen from a *supervisor* or *safety net* that is driven by a switching logic-based criterion, often realized using artificial intelligence or expert systems. Some of these will be discussed in the next paragraphs.

Intelligent Identification and/or Tuning

The overall goal of this approach is to use intelligent structures (fuzzy logic, neural networks, genetic algorithms) to substitute for either the identification, control, or adaptation tasks in the control scheme (see Figure 2.19i). As is discussed

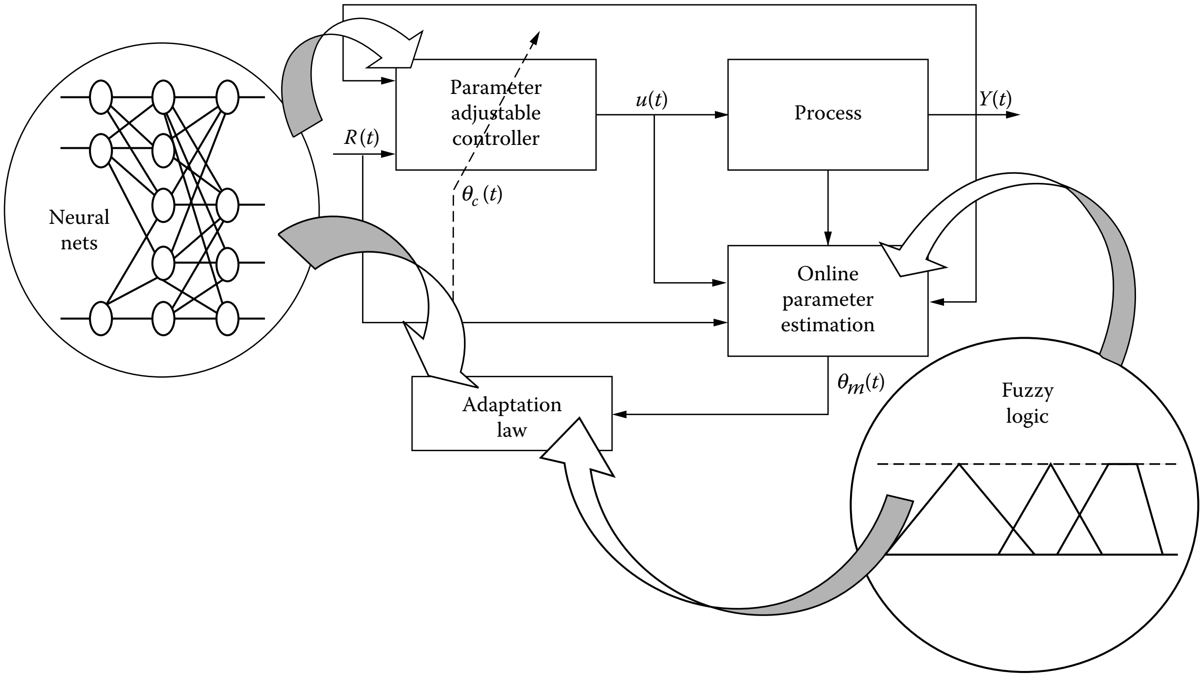

FIG. 2.19i
Intelligent identification and tuning in adaptive control.

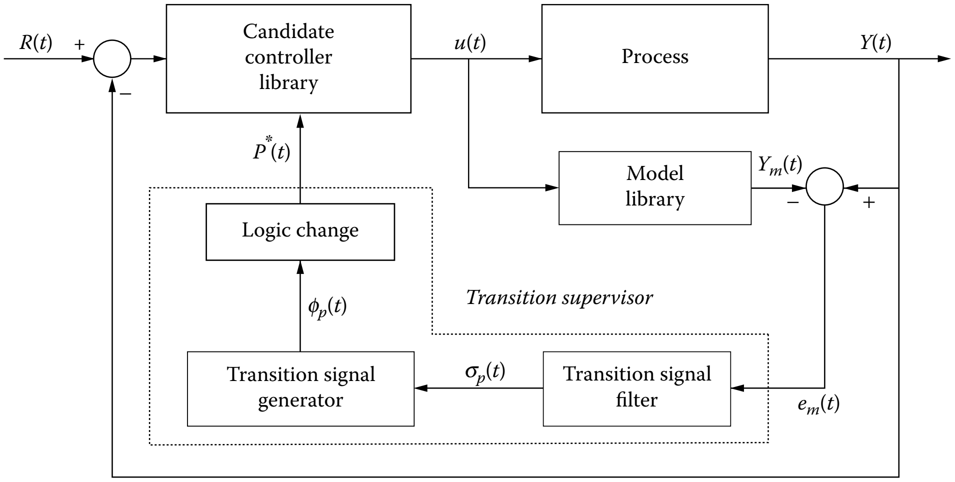

FIG. 2.19j
Adaptive control system for matching multiple process models to multiple process algorithms and selecting the best pairing in a supervised adaptive scheme.

in other sections of this chapter, control schemes combining neural nets with model predictive control (MPC) can tolerate inaccuracy and uncertainty in the model and can apply online training to continuously improve the model.[8]

Multiple Model Adaptive Control (MMAC)

Figure 2.19j illustrates the concept of multiple model adaptive control (MMAC).[9–11] This technique is based on the use of a library of process models, a library of controller algorithms, and an intelligent switching logic.

The MMAC system operates by identifying a process model in its library that closely resembles that of the actual process and, based on that knowledge, selecting a control algorithm (from the *Candidate Controller Library*) that is best suited for controlling such a process. The process model is usually selected on the basis of controlled variable (process output) pattern recognition, from the *Model Library*.

Once the process model is identified, a switching law is applied (*Logic Switching Supervisor* or *Transition Supervisor*) to adaptively select the correct matching between the model and its corresponding controller. The switching laws can roughly be divided into two categories: those based on process estimation and those based on a direct performance evaluation of each candidate controller.

MMAC Limitations and Suppliers MMAC is like a consultant in a box. Most consultants have hours, sometime weeks, to think about the best way of controlling a difficult process, while in the MMAC system, such decisions are automated and the options are those available in the libraries. Therefore, the selected process model will be as good as the library and its selection algorithm, and the same holds true for the controller library.

The main limitation of MMAC is that it is discontinuous; every time a new computer algorithm is selected from the library, it will upset the process. Another limitation of MMAC is its adaptation to start-up and shut-down conditions, where the process model is changing very fast. It should also be noted that at this time few adaptive controllers on the market can update their control strategies while the process is running.

References 12 and 13 provide further information on the suppliers and their products, and the reader can also visit their Web sites:

Adaptive model-based controllers such as Exact, BrainWave, QuickStudy, and Connoisseur generate their models automatically while the controller is online, using previously recorded historical process data. This is convenient when compared to classical controllers because in theory, such adaptive controllers can predict process trends and future behavior changes over time.

CyboCon skips the modeling step. Instead, CyboCon looks for patterns in the recent errors and the *learning* algorithm produces a set of gains or *weighting factors* that are then used as parameters for the control law.

CONCLUSIONS

Classically, the performance difference between gain scheduling and self-adaptive systems is analogous to that which exists between feedforward and feedback control.

A self-adaptive controller (comparable to feedback) cannot make an adjustment to correct its settings until an unsatisfactory response is encountered. Two or more cycles must pass before an evaluation can be made upon which to base an adjustment. Therefore, the cycle time of the adaptive loop must be much longer than the natural period of the control loop itself. Consequently, the self-adaptive system cannot correct for the present poor response but can only prepare for the response to the next upset, assuming that the control settings presently generated will also be valid then.

On the other hand, the gain scheduling system should always have the correct settings because it responds automatically to changes in process variables in a manner analogous to feedforward control. It does not have to "learn" the new process dynamics via adaptive loops.

MMAC with supervised switching offers the possibility of good performance and robustness over a wider range of operating conditions than do the traditional approaches, but it will take some time for it to mature. Its potential is best for those processes that are poorly understood and nonlinear with time-varying dynamics (dead times and time constants). There is a great deal of activity in the evolving field of AI-based model adaptive control.[14,15] Some believe that they will eventually eliminate the need for tuning and re-tuning of controllers, but we will have to wait for the fifth edition of this handbook to be sure.

2.20 Optimizing Control

F. G. SHINSKEY (1970) **C. G. LASPE** (1985) **B. G. LIPTÁK** (1995) **M. RUEL** (2005)

INTRODUCTION

Optimization of an industrial process usually means an increase in profitability while maintaining safety and product quality. The criteria for optimization vary with the process. Optimization in materials transportation systems (pumps, compressors, fans) usually means the full opening of all throttling devices so that all the energy introduced is used to transport materials and none of it is spent on overcoming artificially introduced friction elements, such as throttling valves and dampers.

The global trend is for higher product quality at a lower cost. The link between product quality and performance is not clearly defined in all cases. An in-depth analysis might be needed to determine the optimum performance for each piece of equipment, then each process, and finally for each control loop. What we do know is that for higher product quality, users must tighten their specifications.

The reader will discover that optimizing a process is similar to a conductor directing an orchestra: coordinate, accelerate here, slow down there, synchronize other parts, etc. The "conductor" must know about control but must also know about the process itself. We should move to multivariable systems when simple single-loop techniques fail, even if properly tuned. On the other hand, we should not make the common mistake of using advanced multivariable control with bad equipment or with control loops that are not tuned to deliver the expected performance.

When optimizing, it is important to consider design, equipment performance, control strategies, operation procedures, performance monitoring, logic, and special control strategies for startup, shutdown, grade changes, and abnormal conditions.

Defining Optimum Performance

The optimization of a batch reactor might mean to operate it at minimum cycle period, which in turn would imply a maximum but safe rate of heat-up, accurate determination of endpoint, and maximum safe rate of stripping. In continuous chemical reactors, optimization might mean maximized rate of conversion (maximum exothermic heat) and therefore an operation where the chilled water valve opening is "pushed" up to and maintained at a safe maximum opening.

The optimization of distillation towers might include the goal of minimizing the heat of separation. As the heat of separation is reduced when the liquids are boiled at lower temperatures, this aspect of optimization usually means that the columns are operated at a safe minimum pressure level.

The optimization of other processes is achieved by operating them at the minimum or maximum point of a cost or efficiency curve. For example, the point where one would like to operate all combustion processes is their minimum total loss point (Figure 2.20a). By plotting all the different forms of losses in a boiler or similar combustion process and adding up these losses to arrive at a total loss curve, it becomes possible to search for the minimum point on that curve. This minimum provides the optimum excess air set point for this process.

Similar total operating cost curves can be constructed for chillers and other types of cooling systems. Figure 2.20b shows the method of arriving at a total cost curve for a cooling tower (CT) system and using it to continuously determine the optimized set point for the approach controller. As the approach to the ambient wet bulb temperature increases (the cooling tower water gets warmer), the pumping costs increase (because more water is needed to provide the same cooling). At the same time, the cost of operating the CT fans drops (because less air circulation is needed as the CT water gets warmer).

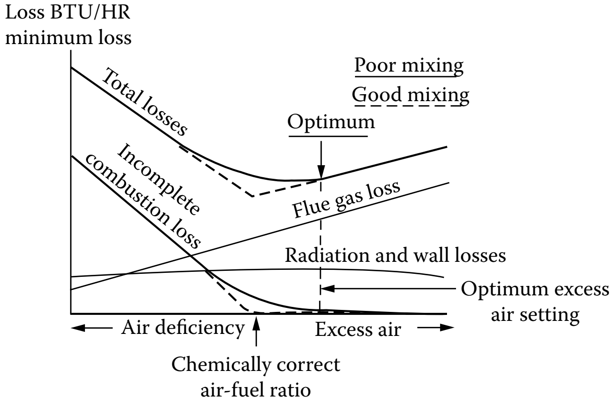

FIG. 2.20a
The optimum operating point for a combustion system is the minimum point of the total loss curve.[1]

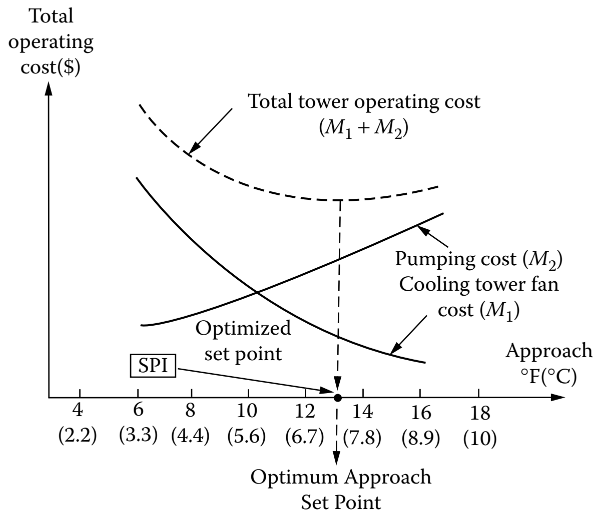

FIG. 2.20b
The set point for the optimum approach controller of a cooling tower is the point where the total system operating cost is the minimum.

Therefore, the sum of these two curves has a minimum point, which corresponds to the minimum cost of operation for the system.

Finding Minimum and Maximum Points

Any process where the operating cost has two components with opposite slopes relative to the load will have a total operating cost curve, with a minimum point. Chillers and heat pumps, for example, are in this category. The optimization of such devices always involves the searching for that minimum point and then making that point the set point of the associated controller.

The slope of the cost curve is zero at the minimum point on the curve. Because the optimization is often performed by differentiation and because the slope of the tangent at the minimum point is zero, one must be very careful to protect such optimization systems from noise and to take into account the low accuracy of differentiators.

The methods of searching for minimum and maximum points include both continuous and sampling techniques. This section will also discuss multidimensional optimization, for use when the optimum condition of a process cannot be described by a curve (two dimensions) but instead requires the climbing and evaluation of multiple peaks.

Optimizing control is essential in industrial processing today if an enterprise expects to retain viability and competitive vigor. The growing scarcity of raw materials aggravated by the dwindling of energy supplies has created a need to achieve the utmost in productivity and efficiency (Figure 2.20c).

"Optimization" means different things to different people. To some, it means the application of advanced regulatory control. Others have obtained impressive results from applying multivariable noninteracting control. To be sure, these latter techniques have merit and may actually comprise a subset of optimization.

It is the purpose of this section to guide the practicing process control engineer in a suitable course of action when

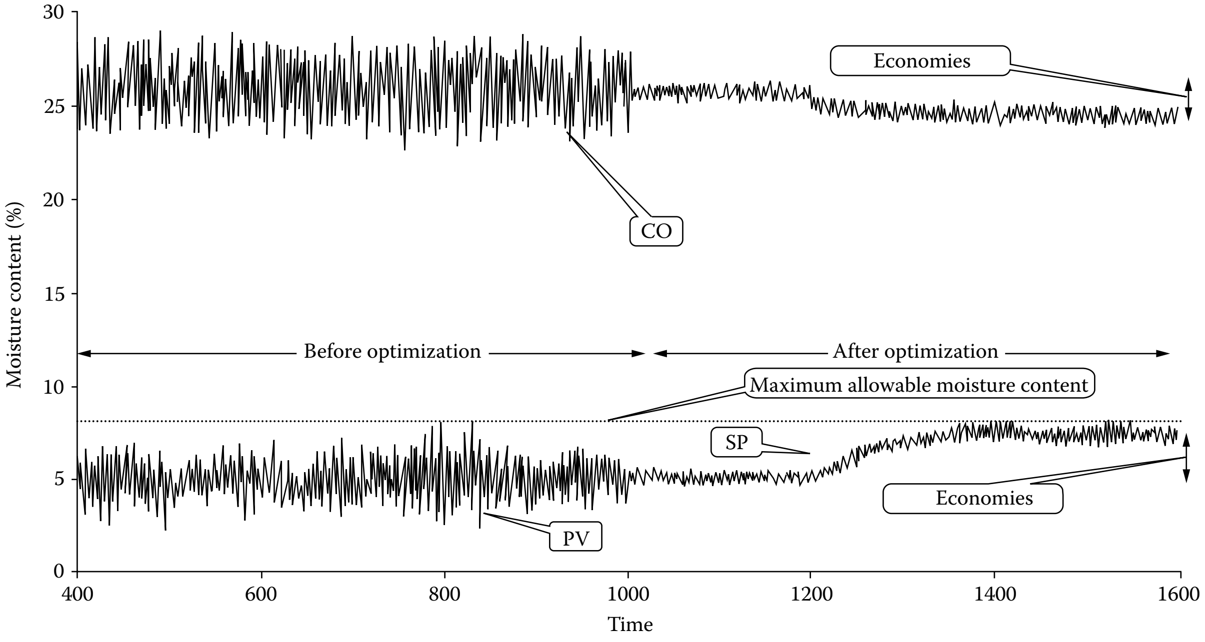

FIG. 2.20c
Minimizing energy consumption and increasing set point closer to the specification in a drying process.

confronted with a problem involving optimization. Topics emphasized include:

1. Defining the problem scope
2. Choosing between feedback or feedforward optimization
3. Mathematical tools available
4. Multivariable non-interacting control
5. Identifying and handling constraints

An extensive reference list and bibliography will be useful in amplifying the concepts and supplying details for the topics covered.

OPTIMIZATION CONSIDERATIONS

Optimization provides a management tool for achieving the greatest possible efficiency or profitability in the operation of any given production process. Changes in the operational environment, consisting of the current constraints and values for the disturbance variables, will inevitably alter the optimal position. Hence, optimizing control must be able to cope with change.

Perhaps the most difficult task in the design of an optimization control system is in the definition of the problem scope and in the subsequent choice of optimizing tactics. The need for an online optimizing system can only be ascertained following an in-depth feasibility study. It is the purpose of this section to provide some insights into the resolution of the above problems.

Processes that are the best candidates for optimizing control have these characteristics:

1. Multiple independent control parameters
2. Frequent and sizeable changes in disturbance variables affecting plant profitability
3. A required and necessary excess in the number of degrees of freedom in the independent control parameters

Figure 2.20d attempts to illustrate, in a simplistic fashion, the interrelationships that exist among the process system variables. The independent variables, $X(i)$, represent those variables that can be controlled by conventional regulatory systems. The disturbance variables, $Y(i)$, represent variables over which little or no control can be exercised, such as ambient conditions, feedstock quality, and possible changes in market demand.

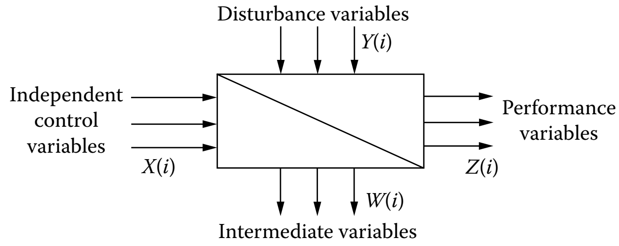

FIG. 2.20d
Process variable interrelationships.

The intermediate variables, $W(i)$, are those that describe certain complex and calculable process conditions, such as internal reflux rates, rates of conversion in reactors, and tube metal temperatures. The intermediate variables can be, and often are, constraining factors in the process operation. The performance variables, $Z(i)$, represent the objective or target values for the process, such as yields, production rates, and quality of product.

Once the scope of the problem has been defined, a choice between the strategies of either local or global optimization can be made. The local optimization problems, such as optimal boiler fuel/air ratio control, can be implemented using simpler control algorithms and hardware. On the other hand, for complex assemblages of equipment with a high degree of interaction in their operation, global optimization may be required.

Feedback or Feedforward Optimization

The feasibility study will normally indicate whether feedforward or feedback control will be more effective in optimizing the process operation. As a general rule, feedback optimization is used only in connection with local optimization problems. Feedforward, on the other hand, is eminently suited for larger, more global control problems.

Feedback optimization control strategies are always applied to transient and dynamic situations. Evolutionary optimization is a good example. Steady-state optimization, on the other hand, is widely used on complex processes, if they have long time constants and infrequently changing disturbance variables. Hybrid strategies are also employed in situations involving both long-term and short-term dynamics. Obviously, hybrid algorithms are more complex and require custom tailoring for a truly effective implementation.

Feedback control implies transitory, and the response time is mostly related to the dead time. Also, in feedback systems, when a disturbance occurs, during the time while the process is being brought back to set point, the errors could become unacceptable. Feedforward control, on the other hand, requires modeling and advanced mathematical tools, but the resulting control is better and tighter.

Reducing Set Point Variability

Variability is a measure of the range of variance in the controlled variable. It is expressed as a percentage of the mean value of the controlled variable, and this percentage allows one to compare the different processes. (For further information refer to the section on Statistical Process Control in this chapter.)

The equations for determining mean and standard deviation and to calculate variability based on them are given below:

Mean: $$\mu = \sum_{i=1}^{i=n} \frac{x_i}{n} \qquad \textbf{2.20(1)}$$

Variance: $$\sigma^2 = \sum_{i=1}^{i=n} \frac{(\mu - x_i)^2}{n-1} \qquad \textbf{2.20(2)}$$

Standard deviation: $$\sigma = \sqrt{\sigma^2 = \sum_{i=1}^{i=n} \frac{(\mu - x_i)^2}{n-1}} \qquad \textbf{2.20(3)}$$

Variability: $$\text{var} = \frac{2\sigma}{\mu} * 100 \qquad \textbf{2.20(4)}$$

Based on a normal distribution, the variability of data represents the area, which includes 95% of all points, the average ±2 standard deviations.

In a process control system, the goal is not to eliminate the variability of the controlled variable but to move it so that it can be directed. For example, consider a continuous drying process, where the energy used is steam. The goal is to deliver the end product at constant moisture content using the minimum energy and operating within the limits specified.

If the production rate varies, the total amount of drying energy needed also has to change. The total amount of drying energy needed also has to change if the temperature of the process material varies, or if disturbances occur in ambient conditions, steam quality (energy content depends on steam pressure and temperature), etc. The tuning of the moisture controller must consider all of these disturbances in order to ensure that they will not cause excessive variations in the moisture content of the product.

As shown in Figure 2.20c, if the variability of the product moisture content is reduced by optimization, the moisture controller's set point can be increased and the product quality will still be acceptable. As the variability is reduced, not only the product uniformity but also the amount of energy needed to produce it will improve. As illustrated in Figure 2.20c, if the price per ton of product remains the same, the profitability of the operation will be improved by reducing variability.

Evolutionary Optimization (EVOP)

Feedback control in certain situations can achieve optimal plant performance. Evolutionary optimization, or EVOP, is one such technique using feedback as the basis for its strategy. EVOP is an online experimentor. No extensive mathematical model is required, since small perturbations of the independent control variable are made directly upon the process itself. As in all optimizers, EVOP also requires an objective function.

EVOP also suffers from certain limitations. These include the need for the process to be able to tolerate some small changes in the major independent variable. Second, it is necessary to apply EVOP or feedback control to perturb a single independent variable at a time.

If in a particular process, two independent variables have major influences on the objective of optimization, then it may be possible to configure the controller to examine each variable sequentially in alternate sampled-data periods. This latter approach is feasible only if the process dynamics are rapid in comparison with the frequency of expected changes in the disturbance variables.

EVOP has been successfully used to maximize the thermal efficiency of industrial boilers when the fuel/air ratio was controlled by an oxygen-trim control system. In that application, EVOP was used to perturb the oxygen set point in evaluating the actual operation. The objective function consisted of an online calculation of the thermal efficiency (Figure 2.20a).

Feedforward Optimization

If numerous independent variables that affect the process performance of multivariable processes exist, they can best be optimized by the use of feedforward optimization. An absolute necessity for doing this is an adequate predictive mathematical model of the process. Such models are not used to perturb the process, but only to evaluate the consequences of changes in process variables.

In order to serve process optimization, the mathematical model must be an accurate representation of the process. To ensure a close to one-to-one correspondence with the process, the model must be updated prior to each use. Model updating is a specialized form of feedback operation in which the predictions of the model are compared with the actual operation of the plant. Any variances noted are then used to adjust certain key coefficients in the model to make it more representative of the actual process.

Figure 2.20e is a signal-flow block diagram of a computer-based feedforward optimizing control system. Process

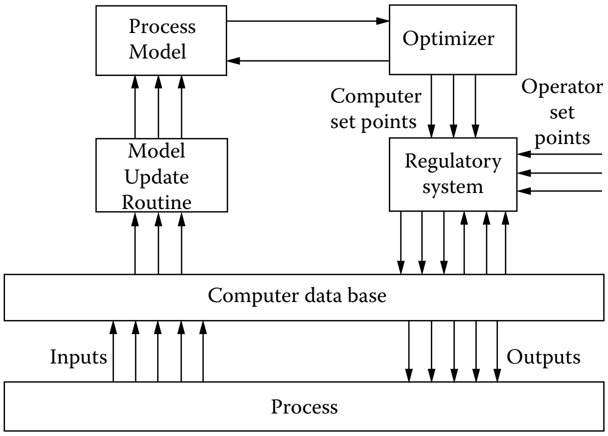

FIG. 2.20e
Block diagram of a feedforward optimizer.

variables are measured, checked for reliability, filtered, averaged, and stored in the computer database. A regulatory system is provided as a front-line control to keep the process variables at a prescribed and desired slate of values. The conditioned set of measured variables is compared in the regulatory system with the desired set points. Errors detected are then used to generate control actions that are transmitted to final control elements in the process.

The set points for the regulatory system are derived either from operator inputs or from the outputs of the optimization routine. Note that the optimizer operates directly upon the model in arriving at its optimal set-point slate. Also note that the model is updated by means of a special routine just prior to use by the optimizer.

The feedback update feature ensures adequate mathematical process description in spite of minor sensor or instrumentation errors and, in addition, will compensate for discrepancies arising from simplifying assumptions incorporated into the model.

The mathematical techniques and operating characteristics of some feedback optimization systems will be discussed more fully in the paragraphs that follow.

OPTIMIZING TOOLS

Calculus of variations is a classical mathematical approach that can be used to optimize the operation of dynamically changing processes. Though this technique has not found widespread use in industry, it should be considered in any batch chemical reactor problem in which the time–temperature–concentration relationship must be optimized. Theoretical considerations and some application data may be found in References 2 through 5.

Economic dispatch or optimal load allocation is a technique directed to the most effective use of the capabilities of parallel multiple resources to satisfy a given production requirement. As an example, the problem of steam load allocation among several boilers in an industrial utilities plant is quite frequently encountered.

A typical boiler efficiency curve is shown in Figure 2.20f. For all practical purposes, the curve may be represented by a quadratic equation.

$$\eta = \eta_0 - K(S - S_0)^2 \qquad \textbf{2.20(5)}$$

where η = efficiency at given steam load, S; η_0 = maximum efficiency at S_0; K = constant; and S, S_0 = steam loads (any consistent units, such as tons/hour).

The cost of producing a given amount of steam is defined by

$$C = \frac{F \times S}{\eta} \qquad \textbf{2.20(6)}$$

where F = cost per unit of steam.

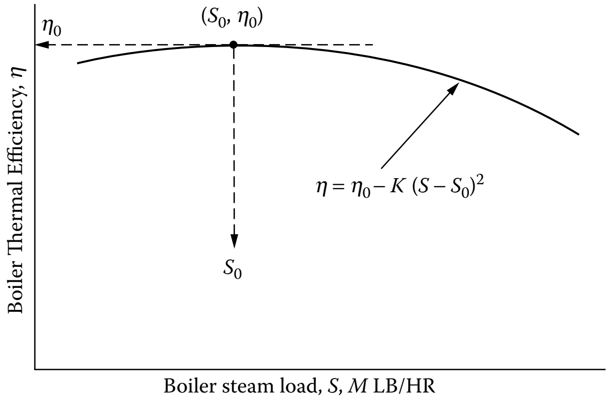

FIG. 2.20f
Typical boiler efficiency curve.

If the steam can be generated by multiple sources, use of calculus indicates an optimum when the incremental costs are equal for all boilers involved. Mathematically,

$$\frac{dC_1}{dS_1} = \frac{dC_2}{dS_2} = \frac{dC_3}{dS_3} \cdots \qquad \textbf{2.20(7)}$$

Also, to satisfy the total demand in the plant for steam, the following constraint equation must be satisfied:

$$S_1 + S_2 + S_3 + \cdots = S \qquad \textbf{2.20(8)}$$

Substituting Equation 2.20(1) into Equation 2.20(2) and then differentiating with respect to steam load S gives, for a given boiler,

$$IC = \frac{FK\left[\left(\eta_0 K - S_0^2\right) + S^2\right]}{[\eta_0 K - (S - S_0)^2]^2} \qquad \textbf{2.20(9)}$$

where IC = incremental cost.

In the above equation, the parameters η_0, K, and S_0 must be evaluated on the basis of experimental test data for each boiler in the system. Figure 2.20g is a plot describing a hypothetical three-boiler system showing a graphical solution to the load allocation problem. The horizontal line intersecting the incremental cost curves satisfies the plant load demand expressed in Equation 2.20(8).

Linear Programming

Linear programming is a mathematical technique that can be applied provided that all the equations describing the system are linear. In the field of industrial process control, the number of truly linear systems is limited, but one can occasionally be encountered. Simple physical ingredient blending problems such as in cement, glass, and certain alloy manufacturing plants are examples of these. A linear program can be

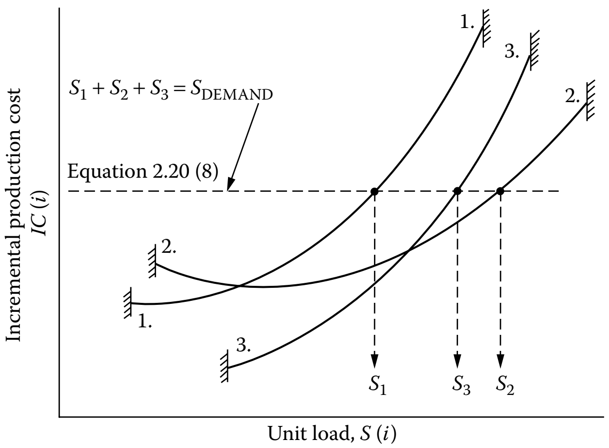

FIG. 2.20g
Graphical solution of an optimal load allocation problem.

used as an optimizing method if the problem can be reduced to the following set of relationships:

$$C = C_1X_1 + C_2X_2 + \cdots C_nX_n \qquad \mathbf{2.20(10)}$$

$$\left|\begin{array}{l} a_{11}X_1 + a_{12}X_2 + \cdots a_{1n}X_n = b_1 \\ a_{21}X_1 + a_{22}X_2 + \cdots a_{2n}X_n = b_2 \\ \quad\cdot \qquad\quad \cdot \qquad\quad \cdot \quad \cdot \\ \quad\cdot \qquad\quad \cdot \qquad\quad \cdot \quad \cdot \\ a_{m1}X_1 + a_{m2}X_2 + \cdots a_{mn}X_n = b_m \end{array}\right| \qquad \mathbf{2.20(11)}$$

Subject to:

$$\begin{array}{ll} X_i \geq 0 & i = 1, 2, 3, \cdots n \\ b_i \geq 0 & i = 1, 2, 3, \cdots n \end{array} \qquad \mathbf{2.20(12)}$$

where X = independent variables; C= associated cost factors; A = linear coefficients; and b = specified variables.

The b variables can represent specific desired concentrations, mass balance, or heat balance requirements. Note that the constants a or C can assume any value, including zero.

The objective function will either be maximized or minimized depending upon whether it represents profit or costs. Many excellent textbooks outline the procedures and algorithms used in the solution of a linear program.[6–9]

Nonlinear Programming

Most industrial processes, especially in the chemical and petroleum industries, cannot be described by linear equations over their complete operating range. These processes therefore require some type of nonlinear optimizer to achieve maximum profitability. Two types of nonlinear optimizers — the sectionalized linear program and the gradient search — have been successfully implemented in advanced computer control schemes.

The sectionalized linear program is especially useful for those processes that exhibit slight-to-moderate nonlinearities in their variable relationships. By restricting the permissible range of excursion for each independent variable, the small amount of nonlinearity can be assumed to be zero. In essence, the coefficients c and a in Equation 2.20(10) and Equation 2.20(11) are replaced by their partial derivatives. Thus, in general, the following approximations are made:

$$a(i, j) = \left(\frac{\delta b(i)}{\delta x(j)}\right)_{x(j)} \qquad \mathbf{2.20(13)}$$

Note that the partial derivatives are evaluated at the current value for the independent parameter $x(j)$. The resultant matrix or tableau of partials is used in the linear program to arrive at an interim solution. If the current or interim optimum is greater than the last value obtained, the whole procedure is repeated by "relinearizing" the process at the newly defined operating point. Examples utilizing the above technique may be found in References 10, 11, and 12.

An alternative to the sectionalized linear program is the use of a gradient or "hill-climbing" approach. The technical literature is replete with descriptions of the mathematical bases for numerous gradient optimization methods.[13–16] Likewise, many successful industrial applications have been reported and reviewed.[17–19]

In contrast to the linear program approach, which considers only one variable at a time in its serial and sequential search for the optimum, the gradient methods generally simultaneously perturb all the independent variables. The magnitude of perturbation applied to each variable is directly proportional to the direction cosine of that variable. Mathematically,

$$\frac{U \cdot \dfrac{\delta c}{\delta x(i)}}{\sqrt{\displaystyle\sum_{i=1}^{i=n}\left(\frac{\delta c}{\delta x(i)}\right)^2}} \qquad \mathbf{2.20(14)}$$

where U = unit step magnitude; c = value of objective function, such as profit; and $x(i)$ = the ith independent control variable.

Most gradient methods, once a path of steepest ascent has been established, continue to move along that path until no further improvement in the objective function is obtained. At this juncture, another gradient is established, and the entire system proceeds in this new direction until another ridge is encountered.

CONSTRAINT HANDLING METHODS

Optimization of a constrained nonlinear process requires a mathematical algorithm for searching along a constraint boundary. The two successful approaches that have been implemented are "hemstitching" and the use of penalty functions.

Figure 2.20h is a hypothetical representation of a two-dimensional process whose permissible operating range is

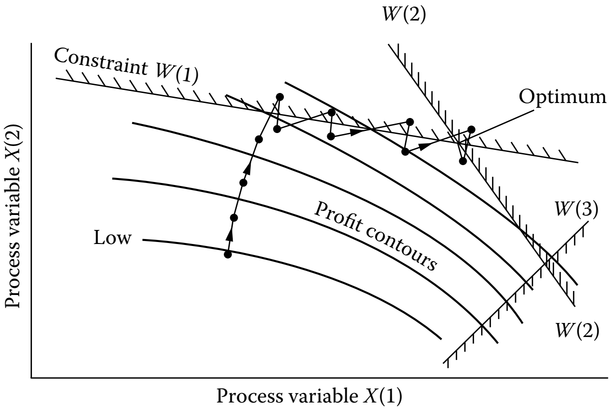

FIG. 2.20h
Gradient search using hemstitching for constraint handling.

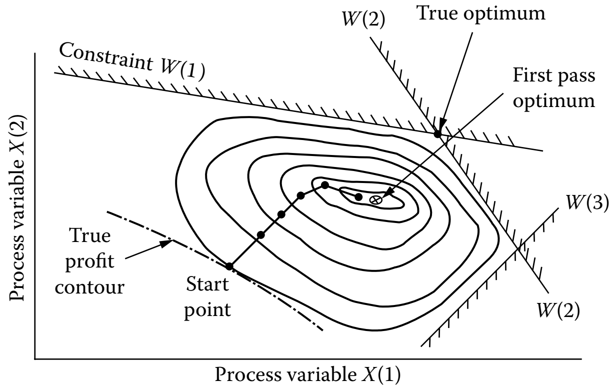

FIG. 2.20i
Gradient search using created response surface (first pass).

constrained by three variables $w(1)$, $w(2)$, and $w(3)$. Parametric lines of the objective function (profit) are also plotted. Although the lines of constraint are portrayed here as linear, in most circumstances they will be markedly curved.

Gradient Search Method

Beginning at the start point, the gradient search method proceeds up the hill in the direction of the steepest ascent. As soon as a constraint function $w(1)$ is violated, the algorithm must return the computed operating position to some point within the feasible region. Generally, this is accomplished by moving perpendicularly or normal to the constraint function. The slope of the constraint is evaluated from the model by two perturbations of $x(1)$ and $x(2)$. Thus:

$$\text{slope} = \left(\frac{\delta x(2)}{\delta x(1)} \right)_{w(1)} \qquad \mathbf{2.20(15)}$$

where the partials are evaluated at the particular constraint boundary. Now the quickest way to return to the feasible region is in the direction of the normal:

$$\text{normal} = \frac{-1}{\text{slope}} \qquad \mathbf{2.20(16)}$$

Once the constraint has been recognized, the algorithm must attempt to move along this boundary.

The method of a created-response surface suggested by C. W. Carroll[20,21] avoids many of the constraint searching problems. In this approach, the objective function is multiplied by a series of penalty terms, one for each active constraint. Thus, along each constraint boundary, the profit contour assumes a value of zero.

A typical response surface is shown in Figure 2.20i. Note that a fictitious hill is created whose summit is within the feasible operating range. Standard gradient search methods are then used to find the peak. Obviously, the peak is not at the true optimum as defined by the intersection of the constraints. If the true value of the objective function is greater than the value at the starting point, then a recentering is employed.

The profit contours passing through the peak are assigned a value of zero. This, along with the zero-valued constraints, permits the creation of a second hill. See Figure 2.20j. Note that the summit of the second hill is much closer to the true optimum. The foregoing recentering is repeated until the improvement in the true objective function is less than a desired and arbitrary value.

MULTIVARIABLE NONINTERACTING CONTROL

Many industrial processes exhibit considerable interaction among the control variables when attempting to regulate the values of the dependent variables. In general, a marked interaction problem will exist if the process can be described by the following set of mathematical relationships:

$$\left| \begin{matrix} Z(i) = fi(Xj,Yj) \\ W(i) = gi(Xj,Yj) \end{matrix} \right| \qquad \mathbf{2.20(17)}$$

for $j = 1, 2, \ldots n$ and $i = 1, 2, \ldots, m$.

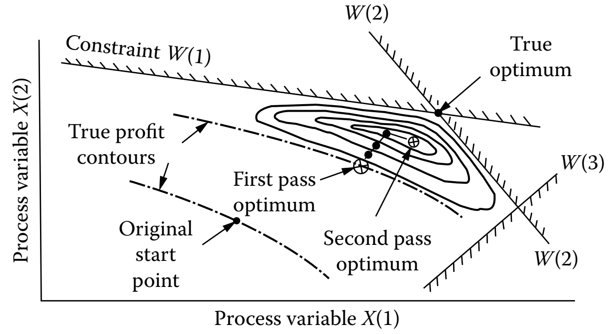

FIG. 2.20j
Gradient search using created response surface (second pass).

In the general case, the functions *fi* and *gi* are nonlinear in form and may be implicit in the independent variables *Xj* and *Yj*. This situation is very complex and requires a computer iterative solution in order to decouple the interaction effects.

However, for many applications the process can be linearized around the current operating point, thus providing a much more tractable solution to the control problem. Linearization reduces the variable interrelationships to the following mathematical form:

$$\begin{vmatrix} \frac{\delta W_1}{\delta X_1}\ \frac{\delta W_1}{\delta X_2} \cdot\cdot \frac{\delta W_1}{\delta X_n} \\ \frac{\delta W_2}{\delta X_1}\ \frac{\delta W_2}{\delta X_2} \cdot\cdot \frac{\delta W_2}{\delta X_n} \\ \frac{\delta W_3}{\delta X_1}\ \frac{\delta W_3}{\delta X_2} \cdot\cdot \frac{\delta W_3}{\delta X_n} \end{vmatrix} \times \begin{vmatrix} X_1 \\ X_2 \\ X_3 \\ \vdots \\ X_n \end{vmatrix} = \begin{vmatrix} W_1 \\ W_2 \\ W_3 \end{vmatrix} \tag{2.20(18)}$$

In the above equation set, the *Xs* are the independent control parameters and the *Ws* represent the dependent controlled variables. The matrix containing the partial derivatives is known as the sensitivity matrix. The noninteracting control problem arises when it is desirable to change the value of one dependent variable without affecting the current values of the remaining dependents. Or, alternatively, how should the independent *X* variables be set in order to achieve a desired slate of *W* values?

Using matrix algebra, the sensitivity matrix can be inverted, giving rise to the so-called control matrix:

$$\begin{vmatrix} \frac{\delta X_1}{\delta W_1} & \frac{\delta X_1}{\delta W_2} & \frac{\delta X_1}{\delta W_3} \\ \frac{\delta X_2}{\delta W_1} & \frac{\delta X_2}{\delta W_2} & \frac{\delta X_2}{\delta W_3} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \frac{\delta X_3}{\delta W_1} & \frac{\delta X_3}{\delta W_2} & \frac{\delta X_3}{\delta W_3} \end{vmatrix} \times \begin{vmatrix} \varepsilon W_1 \\ \varepsilon W_2 \\ \varepsilon W_3 \end{vmatrix} = \begin{vmatrix} \Delta X_1 \\ \Delta X_2 \\ \Delta X_3 \\ \cdot \\ \cdot \\ \Delta X_n \end{vmatrix} \tag{2.20(19)}$$

The error terms of the variable W are indicated by εWi and the required changes in control variables X are given by ΔXj.

Constraint Following

Unfortunately for plant managers, but fortunately for computers, many nonlinear constrained processes can be subject to two or more constraints at the same time. As a result of the latest optimization calculation, a slate of set points is provided to achieve the stated objective, such as maximizing profit. The optimizer will at the time identify which of the control variables should be at their limiting values.

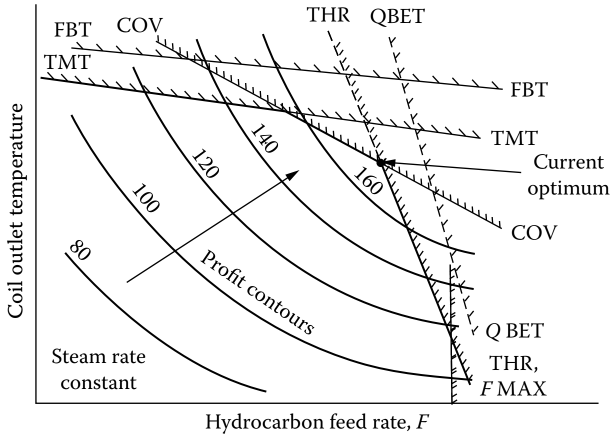

FIG. 2.20k
Typical profit surface for ethylene plant furnace cracking naphtha.

A practical example of the multi-constraint situation is depicted in Figure 2.20k, which shows the profit contours bounded by six possible constraints. For an ethylene plant pyrolysis furnace, where TMT = tube metal temperature; FBT = fire box temperature; COV = coil outlet velocity; THR = total heat release; QBET = quench boiler exit temperature; and FMAX = maximum feed availability.

As shown in Figure 2.20k, there are four active constraints that define the feasible operating region. In addition, several more constraints may become active if process loading or some other disturbance variable undergoes a change.

For the above example, visual inspection of Figure 2.20k indicates the optimum occurring at the intersection of the THR and COV constraints. To keep the process at optimum conditions in the interval between optimization calculations, a dual constraint–follower regulation scheme would be set in motion. The set points for these two controllers would be the maximum permitted values for THR and COV. Since interaction between these two constraints will occur, the multivariable noninteraction techniques discussed in the previous paragraph would be employed.

This section describes some of the basic PID algorithms and the early developments of process control-oriented computer languages. The more advanced expert systems utilizing artificial intelligence and other, more sophisticated methods are discussed in other sections of this chapter.

PID CONFIGURATIONS

The output of a PID controller is a function of the size of the error (proportional contribution), the time period during which the error existed (integral contribution) and of the rate at which the error is changing (derivative contribution). The standard or ideal PID configuration (also called noninteracting) is illustrated in Figure 2.21a and is described by Equation 2.21(1):

$$m = K_c\left(e + \frac{1}{T_i}\int e\,dt + T_d\frac{de}{dt}\right) + b \qquad \textbf{2.21(1)}$$

where m = controller output; e = error signal; K_c = proportional gain = 100/Proportional Band; T_d = derivative time constant (from seconds to hours); T_i = integral time constant (minutes/repeat) also called reset; and b = bias.

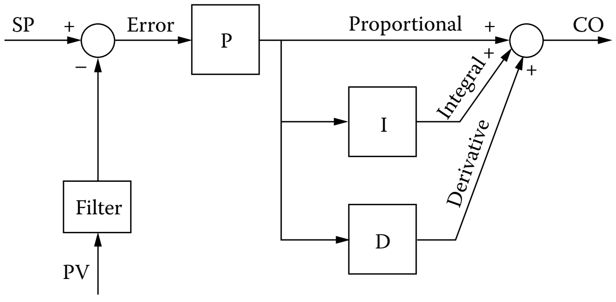

FIG. 2.21a
The standard or ideal PID configuration, which is also called noninteracting or the ISA version.

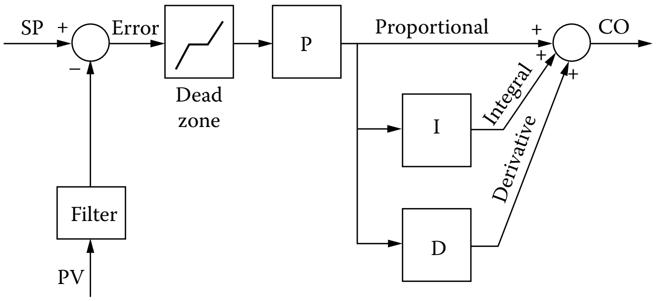

FIG. 2.21b
The gap-type PID configuration.

Equation 2.21(2) describes the interacting (also called series) and Equation 2.21(3) the parallel PID configuration:

$$m = K_c\left(e + \frac{1}{T_i}\int e\,dt\right)\left(1 + T_d\frac{de}{dt}\right) + b \qquad \mathbf{2.21(2)}$$

$$m = K_c e + \frac{1}{T_i}\int e\,dt + T_d\frac{de}{dt} + b \qquad \mathbf{2.21(3)}$$

There are a number of variations of these basic PID configurations. One option is to let some of the control modes (D or P&D) act on the process variable (PV in Figure 2.21a) and not on the error. These configurations eliminate the overshoot that otherwise can occur on set-point change. When frequent set-point changes are expected, another way to reduce overshoot is to use set-point filtering. Both of these methods allow for increasing the proportional gain (reducing the proportional band) and thereby make the controller more effective.[1,2]

Error-squared algorithms become more aggressive as the error rises. For that reason they are widely used on level control. Integral squared algorithms are effective on all variable dead time processes and cause no overshoot because when the variable is on set point, the integral contribution goes to zero. Figure 2.21b illustrates the gap-type PID controller, which does not change its output at all as long as the error is within the dead zone or gap. This configuration is well suited for controlling noisy process variables, which otherwise would cause the controller output to be unstable, reducing the life expectancy of the control valve or other final control element.

ALGORITHMS

An algorithm, by definition, is the description of a particular equation by the digital computer. It has also come to mean an equation for the implementation of a particular function on the computer. We will use the term in the second sense since we wish to describe several equations that have become particularly important in the process control field, especially for the implementation of PID control.

In DCS control, the digital computer calculates the required movement of the control valve or other final actuator. In supervisory control, on the other hand, the computer merely computes the required change in the variable's set point, and the actuation of the final control element is left to an analog controller.

Digital Algorithms

It should also be understood that when these algorithms are implemented in the digital world, what used to be integration in the analog world becomes summation, and what used to be time differential in the analog world becomes difference. The scan period of DCS systems is around 0.5 seconds or is selectable for each loop from 0.1, 0.2, 0.5, 1.0, 5.0, 10, or 30 seconds. As the DCS system does not continuously evaluate the status of each measurement, but looks at them intermittently, it increases the dead time of the loop by two "scan periods" (the time it takes to return to that measurement) and it makes its algorithm calculations on the basis of the "present" and the "previous" error. Two basic types of digital algorithms are in use. One is called positional. This means that the full output signal to the valve is recalculated every time the measurement is examined (Equation 2.21[4]).

$$m = K_c\left(e + \frac{1}{T_i}\sum_o^n e\,dt + \frac{T_d}{\Delta t}\Delta e\right) + b \qquad \mathbf{2.21(4)}$$

where Δt = scan period; Δe = change between the previous and the present value of the error; and $\sum_o^n e$ = the sum of all previous errors between time zero and time n.

The other calculation is called a velocity algorithm, and when it is used, the value of the previous output signal (m) to the valve is held in memory, and only the required change in that output signal is calculated (Equation 2.21[5]).

$$\Delta m = K_c\left(\Delta e + \frac{1}{T_i}\sum_o^n e\Delta t + \frac{T_d}{\Delta t}\Delta(\Delta e)\right) \qquad \mathbf{2.21(5)}$$

where $\Delta(\Delta e)$ = the change in the change in the error between the previous and the present scan periods.

The positional algorithm is preferred when the measurement is noisy because it works with the error and not the rate of error change when calculating its proportional correction. Velocity algorithms have the advantages of bumpless transfer and less reset windup (0 or 100%) and are better suited for controlling servomotor-driven devices. Their main limitations include noise sensitivity, likelihood to oscillate, and lack of an internal reference.

These two major approaches were initially introduced in the 1960s for digitally representing the action of conventional three-mode controllers: position and velocity algorithms.[3] They differ principally in the place where integration occurs. For the position algorithm, the computer output is the corrected valve (or other final element) position, because the integration is performed in the computer. For the velocity algorithm, the computer output is the change that the valve should undergo between sampling periods; therefore, integration must be performed by the final element via a stepping motor, integrating amplifier, or other similar device.

The Position Algorithm

The three-mode controller can be represented by

$$P_n = K_P e + K_D \frac{\Delta e}{\Delta t} + K_I \sum_0^n e\Delta t + P_M \qquad \textbf{2.21(6)}$$

$$e = S - V \qquad \textbf{2.21(7)}$$

where

P_n = valve position at time n
P_M = a median valve position
K_P = proportional-mode gain (K_c)
K_I = integral-mode gain (K_c/T_i)
K_D = derivative-mode gain (K_c/T_d)
e = error
S = setpoint
V = variable

In the usual representation of this controller by analog hardware, there is usually some interaction among the three modes as follows:

$$P_n = K_P\left(e + T_D\frac{\Delta e}{\Delta t} + \frac{1}{T_R}\sum_0^n e\Delta t\right) + P_M \qquad \textbf{2.21(8)}$$

Thus, $K_d = K_P T_D$, and $K_I = K_P/T_R$. Individual mode gains cannot be changed independently. In the process industry, the terms are

K_P = PB/100, where PB is proportional band (%)
T_D = rate time (minutes)
T_R = reset time or Ti, integral time (minutes)
$\frac{1}{T_R}$ = reciprocal time (repeats per minute)

Equations 2.21(6) and 2.21(7) are convenient to use with digital systems. However, reference must frequently be made to Equation 2.21(8) because of the nomenclature built around it.

Because of the vagaries of digital data and particularly due to the sampling of noisy data, the derivative expression in Equations 2.21(6) and 2.21(8) must be chosen carefully. A four-point difference technique, chosen because of convergence and accuracy considerations, is defined as follows:

$$\text{Let } V^* = \frac{V_n + V_{n-1} + V_{n-2} + V_{n-3}}{4} \qquad \textbf{2.21(9)}$$

where V is a variable and $n - 1$, $n - 2$, $n - 3$ denote times previous to time n. Then

$$\frac{\Delta V}{\Delta t} = \frac{\frac{V_n - V^*}{1.5\Delta t} + \frac{V_{n-1} - V^*}{0.5\Delta t} + \frac{V^* - V_{n-2}}{0.5\Delta t} + \frac{V^* - V_{n-3}}{1.5\Delta t}}{4} \qquad \textbf{2.21(10)}$$

$$\frac{\Delta V}{\Delta t} = \frac{\Delta e}{\Delta t} \text{(if the setpoint is constant)} \qquad \textbf{2.21(11)}$$

$$\frac{\Delta e}{\Delta t} = \frac{1}{6\Delta t}(V_n - V_{n-3} + 3V_{n-1} - 3V_{n-2}) \qquad \textbf{2.21(12)}$$

$$= \frac{1}{6\Delta t}(e_n - e_{n-3} + 3e_{n-1} - 3e_{n-2}) \qquad \textbf{2.21(13)}$$

The position algorithm requires that the computer recalculate the full value of the controller output at each time increment. In addition, if this value is to be transmitted to the valve positioner as an analog signal, this requires a digital-to-analog converter or the equivalent for each output.

The Velocity Algorithm

If the computer output is sent to a stepping motor or an integrating amplifier, the computer will only calculate the required change in valve position. The output is a digital pulse train. Where a stepping motor is used, the stepping motor can drive a slide wire, and the slide wire output is proportional to the correct valve position. Therefore, the combination of stepping motor (digital correction) and slide wire (analog signal to the final control element) acts as a digital-to-analog converter, and no separate digital-to-analog converter is required. An integrating amplifier will perform a similar action in an electronic loop.

The velocity algorithm output (ψ_n) is found by subtracting the outputs of two successive position algorithm calculations:

$$\psi_n = P_n - P_{n-1} \qquad \textbf{2.21(14)}$$

$$\begin{aligned}\psi_n &= K_p(e_n - e_{n-1}) + K_I e_n \Delta t \\ &\quad + \frac{K_D}{6\Delta t}(e_n + 2e_{n-1} - 6e_{n-2} + 2e_{n-3} + e_{n-4})\end{aligned} \qquad \textbf{2.21(15)}$$

The stepping motor, or its equivalent, serves to sum or integrate the position value, and

$$P_n = P_0 + \sum_0^n \psi_t = P_{n-1} + \psi_n \qquad \textbf{2.21(16)}$$

The derivative mode is optional, but some small amount of integration is always required for the velocity algorithm. The algorithm with derivative included can be written as

$$\begin{aligned}\psi_n &= K_p(V_n - V_{n-1}) + K_I(S - V_n)\Delta t \\ &\quad + \frac{K_D}{6t}(V_n - 2V_{n-1} - 6V_{n-2} + 2V_{n-3} + V_{n-4})\end{aligned} \qquad \textbf{2.21(17)}$$

Since the set-point appears only in the integral term, severe controller drift could occur unless this latter term is always included.[5]

In the discussion that follows, Equation 2.21(15) will be used as the basic control equation for the system. It can be represented as

$$\psi_{n_i} = F_i(e_i) \qquad \mathbf{2.21(18)}$$

where the subscript *i* is the index to the control loop in question. In general, where the *i* and *j* loops are considered in a cascade or a feedforward configuration, the higher index refers to the inner or downstream loop.

The velocity algorithm has a unique property. At any given sample time, the proportional and integral terms do not necessarily have the same signs as do the corresponding terms in the position algorithm. Examine the proportional and integral terms of the velocity algorithm:

$$\psi_n = K_P(e_n - e_{n-1}) + K_I e_n \Delta t \qquad \mathbf{2.21(19)}$$

These terms have the same sign when the control variable is moving away from the set point but have opposite signs when the control variable moves toward the set point (except for the first step of the variable in the direction of the set point). See Figure 2.21c for a sketch analyzing this action. As can be seen from the figure, the proportional terms can cause an oscillation as follows:

$$\begin{aligned} \text{Output } 1 &= K_p(e_1 - e_0) \\ &= -|\Delta e_1| K_p \\ \text{Output } 2 &= K_p(e_2 - e_1) \\ &= +|\Delta e_2| K_p \end{aligned} \qquad \mathbf{2.21(20)}$$

Thus, unless strongly overbalanced by the integral term, an uncorrected velocity algorithm can give the oscillatory response illustrated in the figure. An obvious remedy to this situation is to define the proportional term as follows:

$$\begin{aligned} \text{Output } P &= K_p(e_n - e_{n-1})(\text{Modified}) \\ &= K_P|\Delta e_n|(\text{Sign of the integral term}) \end{aligned} \qquad \mathbf{2.21(21)}$$

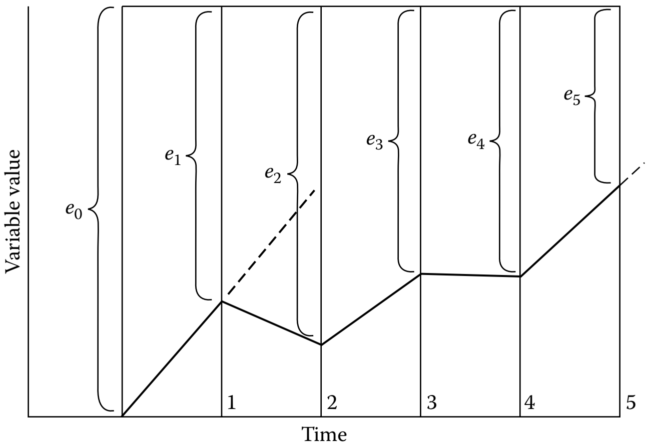

FIG. 2.21c
The action of the velocity algorithm without sign correction of the proportional term.

This property may also be used to help prevent integral overshoot and subsequent integral term oscillation. As the set point is approached, the opposing proportional term is desired for damping the integral action. When the control variable is some distance from the set point, all proportional terms are modified to have the same sign as the integral term just described.

This limited proportional action can be achieved by placing a band around the set point. Within the band all proportional contributions are accepted as calculated; outside the band all proportional terms have the same sign as the integral term. The control action can be further improved by having high proportional gain constants outside the band and much lower gain constants within the band. This allows a faster recovery from a process upset than with the conventional algorithm.

This modified velocity algorithm makes possible better control action than the positional algorithm. Analog values are scaled so that values from the analog-to-digital converters (ADC values) occupy the full computer variable range. This makes it possible to define the set-point bandwidth (S.B.) as some fraction of full scale. The following definitions and expressions can be used to modify the velocity algorithm in the described manner:

$$\begin{aligned} & e_n = \text{ADC}_{s_n}(\text{setpoint}) - \text{ADC}_n \\ & \Delta e = e_n - e_{n-1} \\ & \text{S.B.} \sim 0.07 \text{ full scale} \\ & |e_{n-1}| \le \text{S.B., add proportional term to velocity algorithm } \psi \\ & |e_{n-1}| > \text{S.B., do not add proportional term to } \psi \\ & \qquad (\text{if } \Delta e \text{ has sign different from } e_n) \end{aligned} \qquad \mathbf{2.21(22)}$$

(*Note:* ADC as used here refers to the raw count obtained by the analog-to-digital converter without correction to engineering units.)

The set-point band of 7% full scale gave good results on simulation tests of systems with first- and second-order time constants. Better control or finer tuning could be obtained if the set-point band could be adjusted for each loop since high inertia systems need wider bands to get more damping of integral action. Figure 2.21d illustrates Equation 2.21(22).

Advantages and Disadvantages

Position and velocity algorithms each have some specific advantages. The major benefit of the position algorithm is that it maintains its own reference value in the term P_M of Equation 2.21(8). Thus it need not depend upon an external

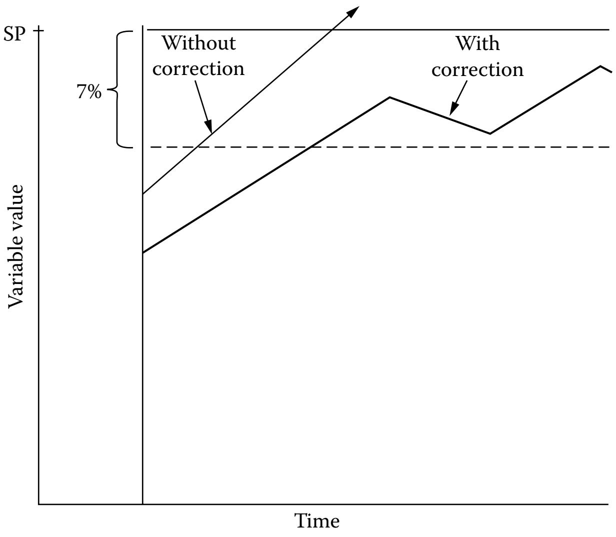

FIG. 2.21d
Effect of set-point band adjustment on velocity algorithm response.

device such as a stepping motor or integrating amplifier for a reference value. The position algorithm has two major drawbacks, however, which are thus advantages for the velocity algorithm.

These are its susceptibility to reset windup and its lack of bumpless transfer. Reset windup is the saturation of the integral mode of the position algorithm if the input is connected and the output is disconnected (such as in the test mode). Then a repeatedly computed correction term, without a corresponding process reaction to correct the error, will eventually cause the integral term to increase to its limit (saturated or "windup"). This will result in a major upset when the output is finally connected. Since it has no internal integration, the velocity algorithm does not exhibit this problem. This problem can, of course, be corrected for the position algorithm by activating the integral term only when the output is connected. This latter modification does impair the testing capabilities of the system, however.

Whenever a sudden and major change is made in the external set point of the process, a large error is detected by the algorithm. Unless special precautions are taken, this will cause a correspondingly large correction to be computed, with a resulting "bump" to the process. This can occur when the loop is initially closed if care is not taken to adjust the set point to be close to the output value of the loop. The velocity algorithm is not susceptible to this problem since its output is a pulse train that can be readily limited to some value that is within the capabilities of the process to respond.

Unlike the position algorithm, the velocity algorithm does not have an internal reference. A second major drawback to the velocity algorithm is its oscillatory response to large inputs.

An important point to keep in mind when using these or any other control algorithm is the effect of process sampling rate on systems gain, i.e., the effective value of K_P, K_I, or K_D, for example. This can be easily understood if one considers the following example:

Suppose that one has effectively tuned a control loop at some specified sampling rate. Suppose then that the sampling rate were doubled. Since the process response rate has not changed, the amount of error detected by the controller has doubled (twice as many readings of the same average values). If the same computations are made (i.e., same controller gains), the amount of correction sent to the valves will also be doubled. Therefore we can say that overall control loop gain is a direct function of process sensor sampling rate.

Cascade and Ratio Control

In analog control the primary or master controller computes the set point of the secondary controller in essentially the same manner as if its output signal were being sent to the final control element (see Figure 2.21e). This configuration

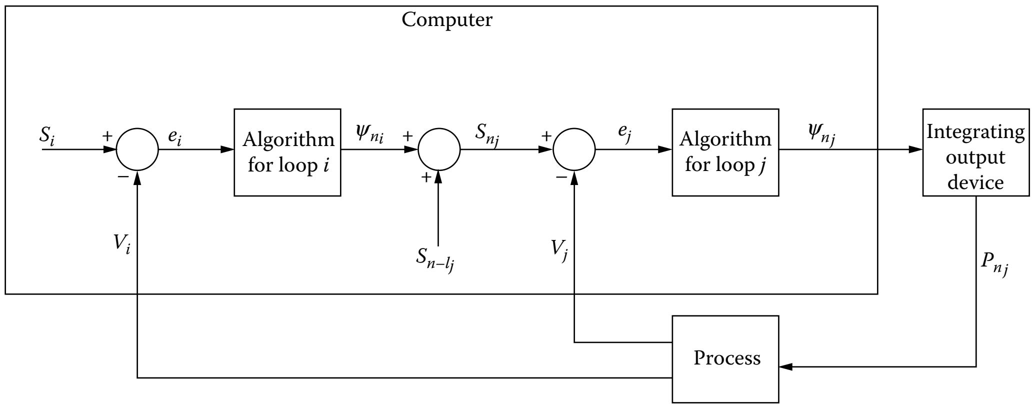

FIG. 2.21e
Cascade control.

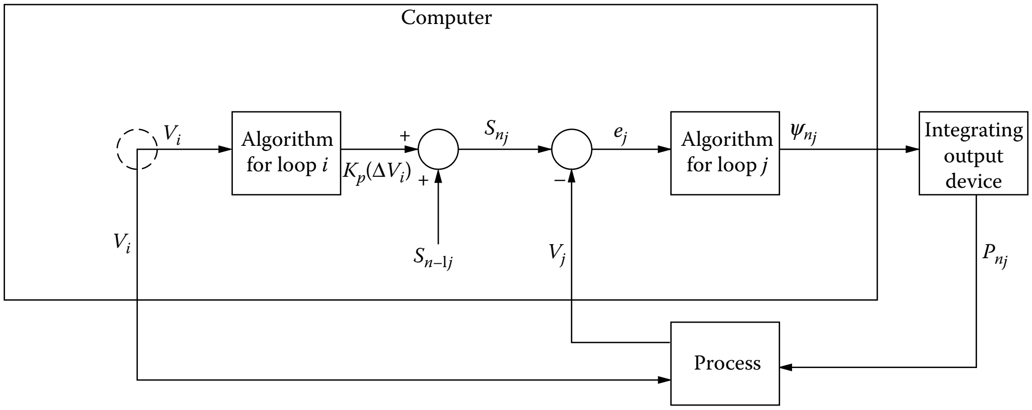

FIG. 2.21f
Ratio control.

is called cascade control. In terms of the developed nomenclature it may be expressed as follows:

$$S_{n_j} = S_{n-1_j} + \psi_{n_i} \tag{2.21(23)}$$

Another related method of process control is called ratio control, expressed as

$$S_{n_j} = RV_{n_i} \tag{2.21(24)}$$

where R is the ratio constant. However, this is also equivalent to

$$S_{n_j} = K_p V_{n_i} \tag{2.21(25)}$$

for the positional and to

$$S_{n_j} = S_{n-1_j} + K_P(V_{n_i} - V_{n-1_i}) \tag{2.21(26)}$$

for the velocity algorithm. Therefore, ratio control can be considered as cascade control where the set-point value S_i is numerically equal to zero (see Figure 2.21f).

Feedforward Control

Feedforward control looks at load changes, anticipates their effect on the process, and compensates for these effects before they have evolved. Feedforward improves control by inserting a function into the control loop that closely duplicates the process response to load change and final control element position.[4,5] Corrections, if applied too early, will introduce too much anticipation, resulting in over-control and oscillation.

Process models must be expressed in the form of transfer functions or differential equations because of the dynamic functions. Exact duplication of analog feedforward on the control computer would require integration, imposing a severe load on computer time. This makes it desirable to devise an approximation method that will adequately describe the process but will not overload the computer. The method described below approximates the open-loop step response of the process by a time delay followed by a ramp.

The response of chemical process systems to a step input can be approximated by one of the following transfer functions:[4,6]

$$\frac{Ke^{-T}DT^{s}}{(\tau_1 s + 1)(\tau_2 s + 1)} \tag{2.21(27)}$$

$$\frac{Ke^{-T}DT^{s}}{(\tau s + 1)^n} \tag{2.21(28)}$$

where K is the process gain constant, T_{DT} is its dead time, and τ, τ_1, and τ_2 are time constants of the process.

Other Digital Algorithms

While the algorithms described above are the basic ones, many others are used in implementing microprocessor-based systems. Some of these are described below, and many others are described in other sections of this chapter.

Dead-Band Control Often the establishment of a dead band about the set point (Figure 2.21b) is desirable to reduce the effects of noisy computer inputs. For example, consider level control of a reboiler on a distillation column. Surface turbulence caused by boiling makes the level signal quite erratic within a band around the set point. Dead-band control would be implemented as follows:

If $|e| = |(S_j - V_j)| < D$ (dead band), then $\psi_{n_j} = 0$

If $|e| >$ D, then use Equations 2.21(6) or 2.21(13)

Emergency Response In many plant emergency situations the correct valve action can be specified ahead of time. If a process alarm system or the computer detects an emergency, the necessary corrective action can be taken automatically.

This is easily handled by holding in memory a group of alternate set points for the controlled process variables, including zero and full open. When the emergency situation is detected, the computer immediately substitutes a new set point for the previous "normal operational" value, taking corrective action through the standard control algorithm.

Error Squared A method of effectively accomplishing the higher gain when away from the set point, as discussed earlier, is to use a square value of the error as part of the calculation of either the proportional or integral modes. This effectively achieves Equation 2.21(21) since squared values are always positive, as is the absolute value. At the same time, the higher value effectively acts as a higher gain on the original error value.

The technical literature from digital control system suppliers is a useful source of additional information on available digital control algorithms.

PROCESS CONTROL PROGRAMMING

The entire third volume of the *Instrument Engineers' Handbook* is devoted to the subject of control software and programming. For this reason, the subject is discussed only briefly here. The purpose of computer programming is to individualize the functions carried out by a particular computer system.

Programming for process control tended to lag somewhat behind the state-of-the-art programming for scientific and business applications because of number of process control applications is smaller. Nevertheless, the high cost of developing programs for specific applications from scratch has led to many developments. New programs tend to be developed from old ones that have been used previously for similar functions.

There is also a trend to make all programs as general as possible in order to enhance their use for more applications. By reducing the individuality of a program, suppliers also reduce the cost of development. In fact, a major segment of the computer industry does nothing else but produce these general programs.

Types of Programs

The desire for minimum individuality in process control computer programs has resulted in a program organization that consists of only three major parts:

1. The *operating system* or *executive program*
2. The *application program*
3. The *system support* software

The executive program consists of all the programs that supervise the overall operations of the computer system. The functions it performs are:

1. Scheduling and actually starting the execution of the application programs
2. Operating all hardware (e.g., allocating main memory to specific functions, loading programs into main memory from external bulk memory)
3. Supervising input/output operations
4. Servicing the priority interrupt system
5. Loading analog and digital inputs into memory
6. Controlling outputs to the plant actuators

Applications programs handle all of the specialized functions required for that particular installation. These functions may include:

1. Conversion of plant input data to engineering units
2. Scheduling, optimization, and control correction computations
3. Operator's console displays, logging, and other management presentations

Even though applications programs are individualized for each installation, every effort is made to use prewritten, general programs whenever possible and to minimize the contribution that is required by the user.

The system support software items are those programs that help the user to prepare the application programs. They include the following:

1. Assemblers and compilers that convert programs written in a specific assembly language or a higher-level language such as FORTRAN into the machine language of the computer.
2. Editors, linking-loaders, and similar packages, which allow segments of programs written separately to be incorporated into a single program in the computer.
3. Programs that help debug applications programs. These programs may not be carried in the computer's memory at all times but may be entered when needed from external storage (disk or tape).

One technique is *host compiling* or *host programming.* Here a large computer contains in its programming system an *emulator* of the smaller computer for which software is being developed. The emulator lets the large computer behave just like the smaller one. Since the larger computer is faster, has a larger memory, and is capable of utilizing more complex and capable system support software, it can develop better programs for the smaller computer than the latter could by itself. The machine language program developed by the large computer is then read into (downloaded to) the small computer as its object program. Thus the small computer need never have any system support software.

Features of Process Control Programs

Computer systems used for process control differ from those used for general scientific and business purposes in that they contain features that allow them to operate in a real-time environment. That is, process control systems perform time-relative operations that are governed by a real-time clock, and they respond to other externally generated occurrences through an external or priority interrupt system. They must also be able to read the values of external variables and transmit signals to external devices, including to human-interpretable systems such as an operator's console.

Obviously, the process control program used in the system must allow for these functions. Accommodating these functions comprises the major difference between programming in the process control field and programming in general scientific and business fields. Because the capability for priority interrupt vitally affects the overall management of the computer system, this function is usually included within the executive program of the process control computer. The other time-based and externally stimulated functions are included in the application program of the system.

A second major difference between process control programs and typical scientific or business programs is the great dependence upon *multiprogramming* or *parallel execution* functions. The time-based operation of the control computer and the large amount of time required to complete many functions (such as printing reports and reading process variables), and the necessity to check the status of many tasks means that the computer must shift its attention between many different functions while completing only small parts of any one function at any one time.

To keep track of the ongoing status of each of the several tasks under way at any one time requires a very sophisticated executive program. All successful process control executive programs must have this capability, while only the most sophisticated scientific and business systems require the computer sizes that are used for process control.

Figure 2.21g illustrates the operations that are executed by programming in the process computer system. The diagram shows the overall system as carried out by a single computer containing all functions. The modular system shown in the diagram allows any particular module to be modified without affecting any of the other modules. This greatly simplifies both the initial programming effort and any later program modifications. This is made possible by the use of the data tables indicated in the diagram. A further advantage of such a program system is that programs developed by others for any of the modules can be readily integrated into the overall program. The chance of finding a suitable existing module is obviously much greater than that of finding an existing overall program for any particular application.

The Executive Program

The executive program apportions computer time to tasks that must be carried out by the computer according to their relative urgency.[7] Response-critical events occurring online must be taken care of at once, resulting in priority tasks execution. When no such urgency exists, the executive program assigns time to background operations.

The executive software function is basically a timesharing one. It resolves process situation conflicts, switching computing facilities back and forth between critical and noncritical demands. Figure 2.21h is a schematic representation of this timesharing function, in which available computer time is

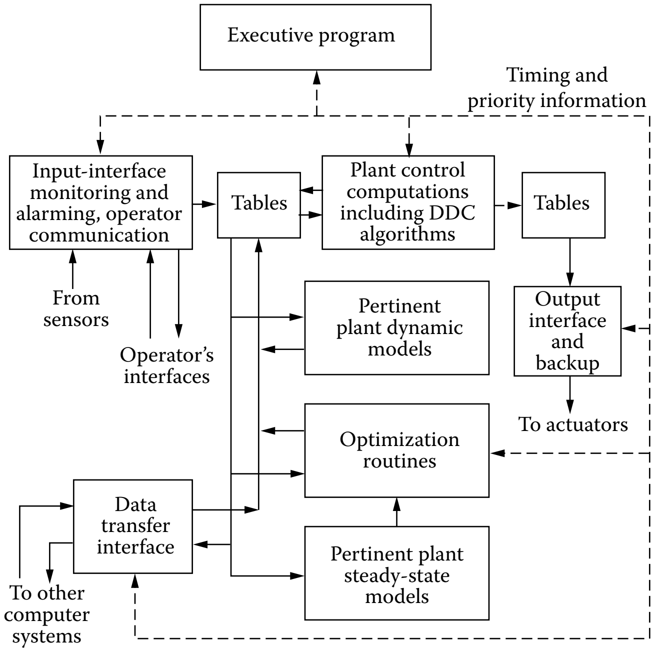

FIG. 2.21g
Modular process control programming system.

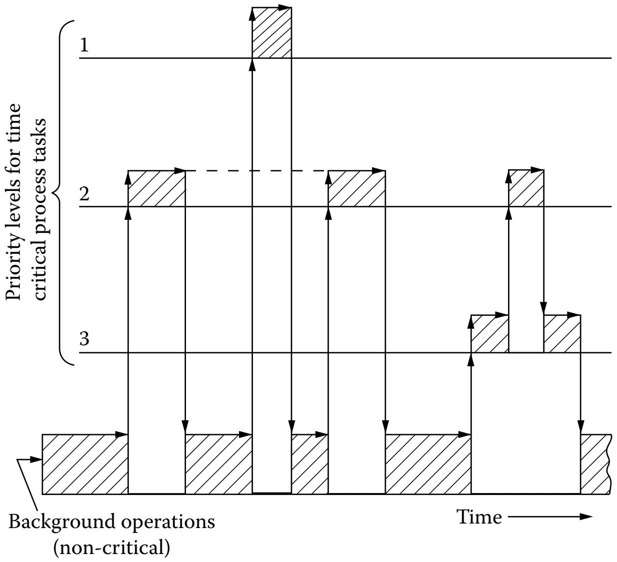

FIG. 2.21h
Operation of the executive program's timesharing function.

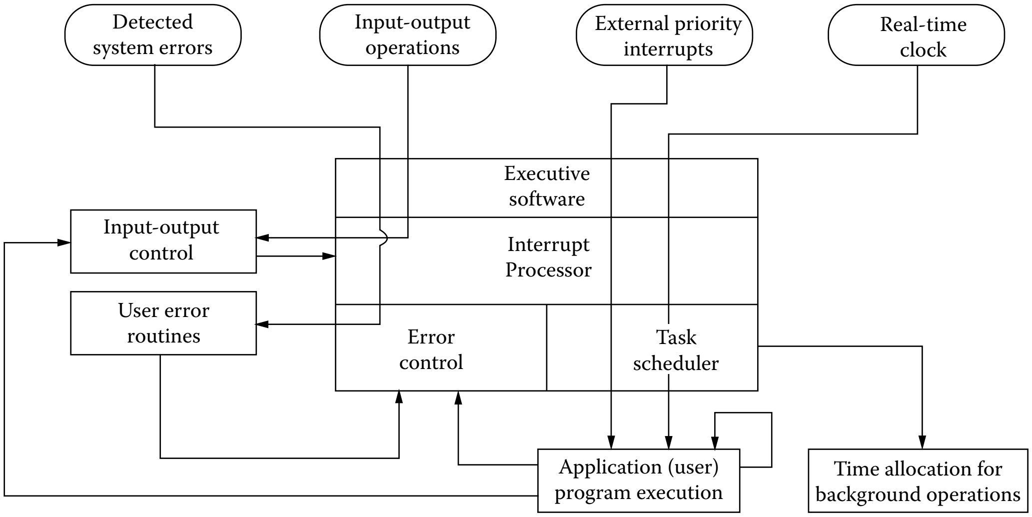

FIG. 2.21i
Principal executive software functions and lines of communication with external events or other software.

allotted among events of varying priority. Preestablished priority rules are used to determine which situation is attended to at any point in time. As process tasks and problems are resolved, computer time is returned to noncritical operations.

The principal programs contained in the executive software are the interrupt processor, task scheduler, and error control. Figure 2.21i shows these functions, as well as other sources of data or routines with which the executive program regularly communicates.

Interrupt Processor and Task Scheduler The *interrupt processor* plays a central role in the control system. Events in the outside world that require response usually appear as external interrupts. The interrupt processor must be capable of sensing the degree of urgency and assigning computer time in proper order of priority. At the same time, the internal registers and the status of an interrupted program must be "saved" to properly restore service.

The *tasks scheduler* must accommodate random interrupts as well as the periodic monitoring of live input values to determine if present limits have been violated or if control corrections are necessary. Thus the executive software must control the use of hardware timer interrupts (the real-time clock) and provide a periodic response to the user program. Aside from controlling periodic monitoring, task scheduling is usually carried out in response to a random demand for program execution. Simple algorithms are often used to assign priorities to these demands. But more sophisticated applications require that the user vary priorities. In some cases user software may dynamically assign priorities that take into account complex combinations of process events.

Error, I/O and Diagnostics *Error control* is probably the most difficult function in the executive software. This function is responsible for the proper handling of errors originating either in hardware or created by software. Some errors can be handled with no response from the user; others require user intervention to minimize the effect on the process being controlled. In extreme cases, error handling requires computer control backup to prevent a catastrophe. In general, error handling routines initiate actions that are unique to each application.

The principal purpose of the *input-output* (*I/O*) *software* is to optimize the use of peripheral devices, resolve conflicts arising from concurrent requests for their use, and provide a simple interface with peripheral and process equipment for programming ease. I/O devices may be peripheral to the computer, such as printers and tape readers, or they may be functional units in the process.

The best *hardware diagnostics* can often be built into the user program. For example, input A/D can be verified for reasonableness prior to being applied to the actuation of an output device. Again, based on availability of output member feedback, the program can require verification that the output motion has actually taken place.

In many process control applications, down time for maintenance is not practical. This is true, for example, of I/O devices that are on call for random service. But devices such as typewriters, card readers, punches, and disks can be diagnosed online if there is a backup capability. Online diagnosis is also possible if the application is designed to be carried out under degraded conditions — an important consideration in control programming.

Programming Languages for Process Control

Because they are easier to use than assembly languages, the so-called higher-level languages are used for all types, including process control programming. Assembly languages permit the knowledgeable programmer to take advantage of programming tricks and of the design details of the particular computer to optimize the operating speed of the system while minimizing the need for memory. In other words, assembler languages permit more efficient use of the computer.

However, the ever-increasing speed and capacity and the ever-shrinking cost of computers make such sophisticated programming techniques and the extensive experience required to apply them unnecessary. Thus, the use of the assembler languages is disappearing, except perhaps for operating systems and for a few very large microcomputer applications where any possible savings resulting from optimum use of the computer's capacity are critical. Thus our emphasis in this section will be on higher-level programming languages.

Higher-Level Languages Higher-level languages for process control can be divided into two major branches: general-purpose languages and problem-oriented languages. Figure 2.21j shows these two branches and their further subdivision into several different categories. Higher-level languages have two major advantages over an assembler or any other so-called lower-level language. First, the same program can be run on any type of computer for which the corresponding translator program has been written. That is, the higher-level languages are not usually machine architecture–dependent as are assemblers.

The translators, called compilers or interpreters, are discussed below. The second advantage is that their symbology is usually more readily interpreted by the average user than are the assembler or machine languages they replace because they are more like normal English or mathematical statements.

A compiler takes the code (program) as written by the programmer and converts it completely to the machine language of the particular computer. This translation may include converting the program into an assembler language as an intermediate step.

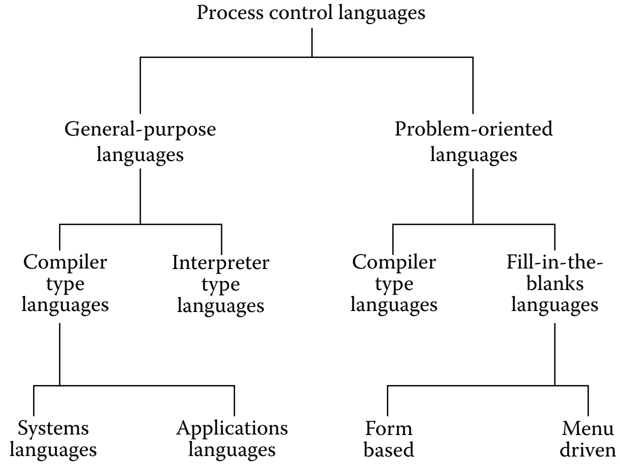

FIG. 2.21j
Organization of higher-level languages for process control.

An interpreter, on the other hand, stores the program in the computer in approximately the form developed by the programmer. The computer then executes the program a line at a time by interpreting, or converting, each line to machine language and carrying out the instructions included therein before going on to the next line.

It can be readily understood that programs to be used with an interpreter must be somewhat simpler than programs to be used with a compiler. When compiling a program, the computer can sense the complexity of the entire program and incorporate some means to handle it. This "look-ahead" capability is, by definition, not available with the interpreter.

Compiler Languages Compiler languages differ in terms of their capabilities. Those that permit complex programs to be readily written in them are called "systems programming languages." Some of these can be used in the preparation of very difficult programs, such as large computer operating systems or executive programs. Otherwise, these programs must be written in the assembler language of the particular computer.

Problem-oriented languages are those that have been especially developed for a particular type of application. Process control is a particularly important application category in this regard. In fact, many problem-oriented languages have been especially developed for relatively narrow types of applications within process control, such as the control of batch reactors.

As indicated in Figure 2.21j, problem-oriented languages can be further divided into compiler-type languages and "fill-in-the-blanks" languages. One of the major types of "fill-in-the-blanks" programs originated with the General Process Control Programming system (GPCP), developed by Humble Oil and Refining Company.[8] The system was later picked up by IBM as PROSPRO[9] and by General Electric as BICEPS.

Compiler-type languages are usually modified or extended versions of the general-purpose compiler languages. FORTRAN and BASIC have been especially popular as the basis for such efforts. A well-known example of this kind of program is AUTRAN (Automatic Utility TRANSlator), which was developed originally by the Merck, Sharp and Dohme Automation Department.

The fill-in-the-blanks system is a largely prewritten, interpreter-type program that offers a large number of choices in its execution in addition to a well-developed skeleton database. By means of responding to a series of questions or a "menu" displayed on a CRT screen, the system developer or programmer is able to make a proper choice of algorithms for each of the control loops from the available options. The programmer can also supply all of the necessary system parameters to the computer's database.

The result is a completely operative control program for the process, developed from the CRT-displayed options. Program development may also be handled by means of a set of preprinted forms, one for each control loop, one for each analog or digital input, one for each process function, etc.

These forms are then converted and are read into the computer's memory.

The prewritten fill-in-the-blanks program must be interpretively executed since it is developed with no knowledge of how the final programmer will organize the execution of the final program or how many and what type of functions will be involved.

Deficiencies of Compiler Programs FORTRAN and BASIC are popular scientific computation languages because programs written in these languages strongly resemble normal mathematical expressions. As a result they are widely used as a basis for university teaching, and a great number of people are familiar with their use.

This same mathematical formula-like representation makes these languages viable candidates for process control programming. However, because they were both originally developed only for batch scientific programs, they were incapable of readily expressing many of the operations vital to process control. These operations are primarily related to the process computer's need to interface with its surroundings and to carry out logic functions. These operations can be listed as follows:

1. Bit string manipulation (i.e., all the logic functions, bit counts, bit testing, and bit movements within a computer word)
2. Input/output data handling (analog and digital input and output)
3. Task scheduling and priority interrupt functions (mainly executive program functions)
4. Some aspects of file handling

Because of the popularity of FORTRAN and its obvious potential as a basis for a process control language, nearly every process control computer vendor provides a FORTRAN compiler as part of its programming systems. The deficiencies of FORTRAN for process control (as listed above) have been circumvented by providing nonstandard extensions to the language that mechanize the missing functions in a FORTRAN-like manner.

Standardization of Process Control Languages Almost since the appearance of the first high-level languages and language extensions for real-time applications, there has been a demand—especially from users—to standardize the languages in the same way as languages for "conventional" applications have been standardized. There are several good reasons for this demand, but the most important one is the need for portability of user programs. Portability of user programs has been made possible in principle by higher-level languages, but it has been thwarted repeatedly by the existence of numerous high-level languages and by the appearance of "language-dialects" of otherwise standard languages.

Standardization should therefore serve two purposes:

1. It should keep the number of different programming languages for one problem area as small as possible.
2. It should discourage the development of dialects.

The benefits of standardization to users are obvious, but vendors, too, will find it profitable because they will have to provide fewer different compilers for any one specific computer.

Much work has been done over the years to develop a standard programming language for process control. Fortunately, this work has now come to fruition and has achieved wide acceptance. The first of these efforts was directed toward the possible standardization of the FORTRAN language for process control applications. This work was carried out by the International Purdue Workshop on Industrial Computer Systems, its predecessor, and associated organizations throughout the world.

In the early days, FORTRAN standardization efforts were carried out by ISA[10–12] and by international groups,[13] while international BASIC standardization efforts were initiated by ECMA[14] (European Computer Manufacturers Association). The major part of future programming by user groups will be carried out using problem-oriented languages (POLs). These can be developed specifically for individual projects. Standardization would be achieved by having their own compilers written in the overall standard language. Thus even though the application of the language is specific, its compilation could be handled on any computer. Thus, transportability would still be achieved.

In the area of process control, separate computer languages been developed for batch type processes,[15] for tuning PID algorithms,[16] for large-scale process control systems,[17,18] and for batch manufacturing,[19] and DCS software was developed for the design of multivariable control systems.[20]

As is discussed in other sections of this chapter, an explosion of new programming is in progress today. These efforts aim at artificial intelligence, neural networks, hiararchical optimization, multivariable control, statistical process control, model-based and model-free optimization, fuzzy logic, envelope control, and many other expert system applications.

2.22 Process Gains, Time Lags, Reaction Curves

P. S. SCHERMANN (1995) **W. GARCÍA-GABÍN** (2005)

INTRODUCTION

An understanding of a process can be obtained by developing a theoretical process model using energy balances, mass balances, and chemical and physical laws; however, this complicated and time-consuming effort can be omitted in many cases. A good approximation of process dynamics can be obtained by using simplified calculation methods, thus reducing the work required to design control systems.

The dynamic behavior of typical processes in industrial applications (pipe–vessel combinations, heat exchangers, transport pipelines, furnaces, boilers, pumps, compressors, turbines, and distillation columns) can be described using simplified models composed of process gains, dead times, and process dynamics.

In this section the concepts of process gain and dead time and their roles in control system design are explained. Practical guidelines are given for developing experimental models using reaction curves for various equipment categories that are frequently used in the process industry. The effect of instrumentation on loop dynamics is also examined. Although mathematical derivations are minimized in this section, full descriptions and applications of the mathematical tools can be obtained from the bibliography.

PROCESS GAINS

Process gain is determined by a number of factors. These include the physical properties of the equipment such as the vessel volumes, compressor characteristics, and connecting piping dimensions; process variables such as pressure, temperature, and fluid velocity; and various laws of physics and chemistry. While some of the associated gains are a function of the process, considerable improvement can be made by revising the control systems, because the instrumentation has a strong effect on the loop dynamics. A transmitter gain, for example, can be modified by adjusting the measurement range.

The process gain indicates how much a process property (output) changes per unit of input change. The input can be a flow that is set by a valve opening; it affects the output, which can be a process property, such as temperature. The gain defines the sensitivity relating the output and input variables. It can be calculated as follows:

$$K = \frac{\Delta \text{ Output [Transmitter units]}}{\Delta \text{ Input [Controller units]}} \qquad \textbf{2.22(1)}$$

The transmitter and controller signals can be expressed in milliamperes [mA], pounds per square inch [psig] or percentage [%] units, if pneumatic or electronic analog instrumentation or DCS systems are used, respectively.

The process gain frequently depends on the load or operating point. For example, the gain changes when the cross-section of a vessel varies (this is the case with horizontal cylindrical tanks), or if the load is modified (for example, the gain of heat transfer processes will drop with rising load).

These variations introduce nonlinearities, making the process gain highly dependent on the operating point. This means that the process gain is a function of the operating point, which must be taken into account in designing the control system. The control system engineer should be aware of the phenomenon of process gain variation, and the variations in loop gains must be compensated for. The use of adaptive (Section 2.19) or robust (Section 2.26) control can sometimes compensate for gain variations.

DEAD TIMES AND TIME CONSTANTS

Time lag, transportation lag, time delay, or dead time (t_d) is commonly present in industrial processes. Dead time can result from measurement lag, analysis and computation time, communication lag, or the transport time required for a fluid to flow through a pipe.

For example, if a concentration analyzer is located downstream of a reactor, it takes a certain dead time before the fluid leaving the reactor arrives at the concentration measurement point. Dead time is also a result of analysis time and communication time between field (instrument and final control element: valve) and the control room.

The effect of these lags in the process response is shown in Figure 2.22a. This figure illustrates the performance of a loop, when at time = 1, a step change was applied to the set point of a controller (an input step change) in the control

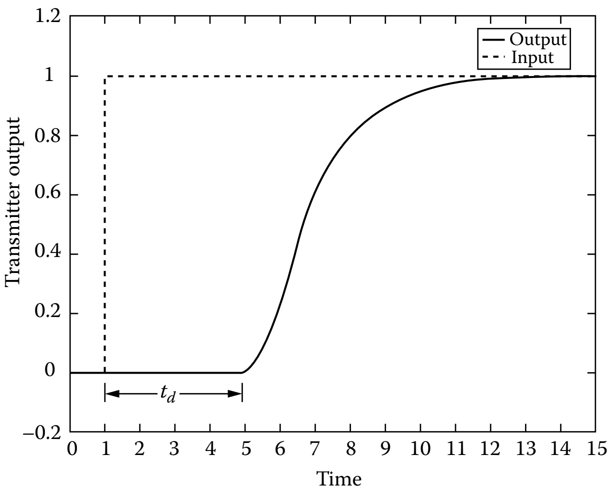

FIG. 2.22a
The response of a process having both dead time and a time constant.

room. This input step change resulted in the noted response of the controlled variable (the output response), which started after a dead time (t_d) had passed and reached a new steady state after the passing of the time constant (τ).

The presence of dead time significantly complicates the analysis and design of feedback control loops. It degrades the control loop's performance because it introduces an unstable behavior, which makes it difficult to achieve a satisfactory control. Special care should be taken when the dead time–to–time constant ratio (t_d/τ) exceeds 1, because the PID controller cannot handle such processes and such control structures as the Smith predictor could be required.

Instrumentation Effect on Process Dynamics

The instrumentation and final control element are not part of the process but are part of the control loop. Yet they affect the dynamic behavior of the process, and the location of the sensor and/or final control element also changes the total dead time.

The process control engineer must know both the speed of detection and the time it takes to transport that information. These times can change considerably as a function of measurement variable and type of instrumentation used.

The time constants of pressure and differential pressure measurements are on the order of 0.1 s. Temperature measurements are slower. Their time constants are usually between 1 and 10 s. Composition measurements (analyzers) are even slower, varying from 5 s to 10 min.

Measurement signal propagation delays are negligible with electronic instrumentation, but signal processing delays can occur in digital systems because the loops are processed sequentially, one by one. The scan period of inputs and outputs normally varies between 0.1 and 1 s, and processing delays inside DCS systems are of the same order of magnitude.

Depending on the length and diameter of tubing between I/P converter and control valves, pneumatic control valves can introduce considerable delays. The use of valve positioners can considerably reduce this delay. The stroking times of conventional (pneumatic) valves vary from 2 s to 1 min, while high-speed electric and hydraulic actuators can reduce them to the millisecond range. As an example, a 10 in. (0.254 m) valve without positioner and with 1/4 in. (6.35 mm) pneumatic tubing of 300 ft (91 m) length between controller and valve has a time constant of about 30 s.

Transportation Lag

When material or energy is physically moved in a process plant, there is a dead time associated with that movement. For instance, if a temperature change travels through a pipe with the fluid, without mixing, the resulting dead time is a function of the length of the pipe. If the pipe is considered to be long (its length is much greater than its diameter), "plug flow" occurs. The resulting dead time between two points on the pipeline can be calculated by

$$t_d = \frac{V}{F_v} = \frac{L}{v_v} \qquad \textbf{2.22(2)}$$

where
t_d is the deadtime
V is the volume of the pipe
F_v is the volume flow rate
L is the length of pipe
v_v is the fluid velocity

This dead time equals the residence time of the fluid in the pipe. Note that the dead time is inversely proportional to the flow rate. The fact that the dead time drops as the production rate of the plant rises must be taken into account when designing the control system.

Even when the plug flow assumption is not valid, transportation lag usually can approximately be modeled by a pure dead time. For liquid flow in a pipe, the plug flow assumption is most accurate when the axial velocity profile is flat, a condition that occurs when Newtonian fluids are transported in turbulent flow. For non-Newtonian fluids and for laminar flow, the fluid transport lag can still be modeled as a pure dead time, which is calculated on the basis of the average fluid velocity.[1]

EXAMPLE

Suppose that a process stream is flowing through a pipe in plug flow. The stream is an incompressible fluid. The pipe is perfectly insulated and has a length of $L = 200$ ft (60.96 m). The fluid flows at a constant velocity of $v = 20$ ft/s (6.096 m/s) and is initially at a constant temperature of $T_0 = 100$°F (37.778°C) throughout the length of the pipe. In this case, the transportation lag of a

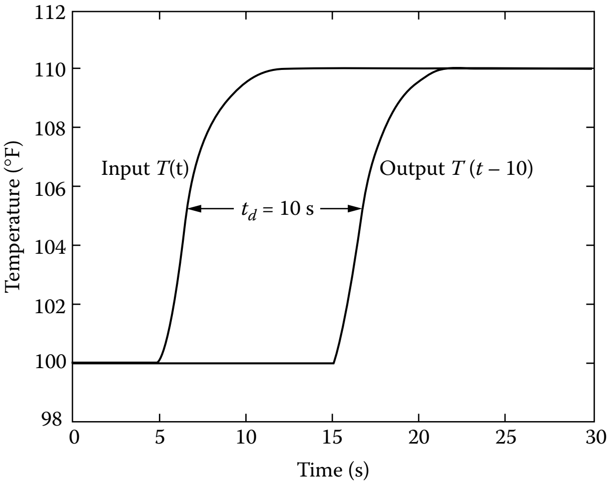

FIG. 2.22b
Transportation lag resulting from plug flow in a pipeline.

temperature change between some points of input and output is given by

$$t_d = \frac{L}{v_v} = \frac{200 \text{ ft}}{20 \text{ ft/s}} = 10 \text{ s} \qquad \textbf{2.22(3)}$$

Figure 2.22b illustrates this input/output transportation lag.

Dead Time Representation

Dead time representation varies according to the mathematical model. Table 2.22c shows different ways to represent the dead time.

Dead Time Approximations

The frequency (Laplace) domain is frequently used to study control systems. In this case the dead time is represented by $e^{-t_d s}$. Because the methods used to analyze and design control systems cannot incorporate exponential functions, polynomial functions are used to represent such exponential terms. The most common representations are Padé approximation, Taylor series expansion, and first-order systems series approximations.[2]

TABLE 2.22c
Dead Time Representation

Domain	*Input*	*Output*
Time	$T(t)$	$T(t - t_d)$
Laplace	$T(s)$	$T(s)e^{-t_d s}$
Discrete t_m : sample time	$T(z)$	$T(z)z^{-\frac{t_d}{t_m}}$

Padé Approximation Padé approximation represents the $e^{-t_d s}$ term by the ratio of low-order polynomials in the Laplace domain,

$$e^{-t_d s} = \frac{M_k(s)}{N_k(s)} \qquad \textbf{2.22(4)}$$

where k is the order approximation and $M_k(s)$ and $N_k(s)$ are polynomials:

$$M_k(s) = m_0 + m_1 t_d s + m_2 (t_d s)^2 + \cdots + m_k (t_d s)^k \qquad \textbf{2.22(5)}$$

$$N_k(s) = n_0 + n_1 t_d s + n_2 (t_d s)^2 + \cdots + n_k (t_d s)^k \qquad \textbf{2.22(6)}$$

They are calculated by

$$M_k(s) = \sum_{i=0}^{k} \frac{(2k-i)!k!}{2k!i!(k-i)!}(-1)^i (t_d s)^i \qquad \textbf{2.22(7)}$$

$$N_k(s) = \sum_{i=0}^{k} \frac{(2k-i)!k!}{2k!i!(k-i)!}(t_d s)^i \qquad \textbf{2.22(8)}$$

Taylor Series Expansion The Taylor series expansion of the exponential term $e^{-t_d s}$ is defined as

$$e^{-t_d s} = 1 - t_d s + \frac{(-t_d s)^2}{2!} + \frac{(-t_d s)^3}{3!} + \cdots \frac{(-t_d s)^k}{k!} + \cdots \qquad \textbf{2.22(9)}$$

However, simulations require the polynomial numerator degree to be equal or smaller than that of the denominator; for this reason, instead of Equation 2.22(9), the following approximation is used in practical applications:

$$e^{-t_d s} = \frac{1}{e^{t_d s}} = \frac{1}{1 + t_d s + \frac{(t_d s)^2}{2!} + \frac{(t_d s)^3}{3!} + \cdots \frac{(t_d s)^k}{k!} + \cdots} \qquad \textbf{2.22(10)}$$

First-Order Systems Series (FOSS) An exponential term is $e^{-t_d s}$ equivalent to a system composed of an infinite sequence of first-order systems series (FOSS):

$$e^{-t_d s} = \text{Lim}_{k \to \infty} \frac{1}{\left(\frac{t_d}{k} s + 1\right)^k} \qquad \textbf{2.22(11)}$$

Table 2.22d summarizes the transfer functions of the Padé, Taylor, and FOSS approximations. It presents only first-, second-, and third-order approximations because they are the most common in practical control applications.

EXAMPLE

Using the following dead time system:

$$G_1(s) = e^{-s} \qquad \textbf{2.22(12)}$$

TABLE 2.22d
Transfer Function Approximations of the Exponential Term ($e^{-t_d s}$) of Dead Time

Order	*Padé*	*Taylor*	*FOSS*
1	$\dfrac{1-\frac{t_d s}{2}}{1+\frac{t_d s}{2}}$	$\dfrac{1}{1+t_d s}$	$\dfrac{1}{1+t_d s}$
2	$\dfrac{1-\frac{t_d}{2}s+\frac{t_d^2}{12}s^2}{1+\frac{t_d s}{2}+\frac{t_d^2}{12}s^2}$	$\dfrac{1}{1+t_d s+\frac{t_d^2}{2}s^2}$	$\dfrac{1}{\left(1+\frac{t_d}{2}s\right)^2}$
3	$\dfrac{1-\frac{t_d}{2}s+\frac{t_d^2}{10}s^2-\frac{t_d^3}{120}s^3}{1+\frac{t_d s}{2}+\frac{t_d^2}{10}s^2+\frac{t_d^3}{120}s^3}$	$\dfrac{1}{1+t_d s+\frac{t_d^2}{2}s^2+\frac{t_d^3}{6}s^3}$	$\dfrac{1}{\left(1+\frac{t_d}{3}s\right)^3}$

Different approximations have been compared to show how close the various approaches are to the exponential term. Figures 2.22e and 2.22f show Bode diagrams for first- and second-order approximations. Padé approximation is too close to the exponential term in the magnitude diagram, but the phase lag is inadequately approximated at higher frequencies. Taylor and FOSS produce a similar approximation; they match reasonably the exponential term in magnitude and phase at low frequencies, but they are unsuccessful at high frequencies. The Padé approach provides better results for the same approximation order than Taylor and FOSS.

In order to illustrate how the Padé, Taylor, and FOSS approximations modify the time response, a step is applied to a pure dead time system (Equation 2.22[12]). In this case, the ideal output would be the same input with a dead time (t_d). This ideal output has been compared with first- and second-order dead time approximations, respectively, in Figures 2.22g and 2.22h.

Taylor and FOSS approaches produce better approximations in the time domain for a unit step response than does the Padé approximation. The Padé approximation has right half plane zeros (RHPZ); also, the number of RHPZ increases with the order of approximation. The presence of RHPZ in the transfer function is responsible for the inverse response. It is also the source of a considerable amount of difficulty in controller design. Some control algorithms have stability problems when controlling a process with RHPZ. This occurs

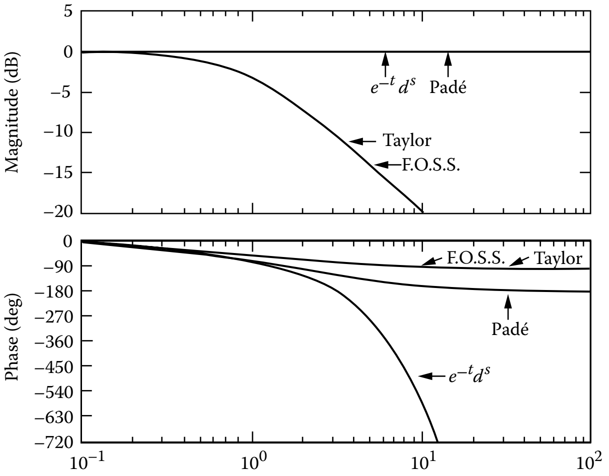

FIG. 2.22e
Bode diagram of a dead time system (Equation 2.22[12]) using first-order approximations.

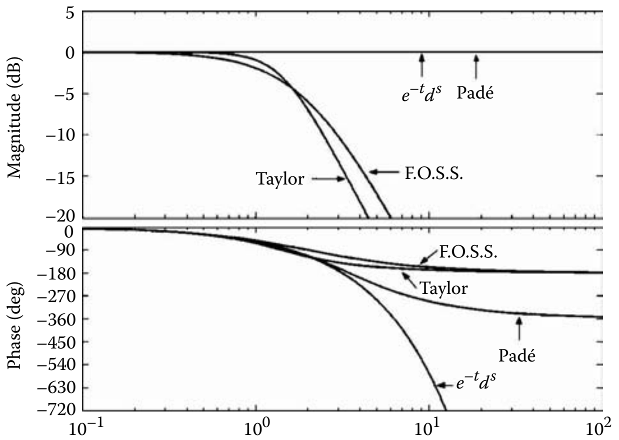

FIG. 2.22f
Bode diagram of a dead time system (Equation 2.22[12]) using second-order approximations.

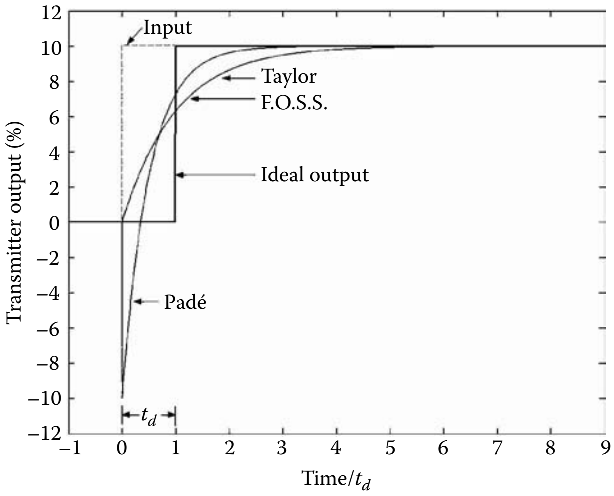

FIG. 2.22g
Step response of a dead time system (Equation 2.22[12]) using first-order approximations.

when the controller contains an inverse model of the process and high performance is desired.

In summary, Padé is a better approximation than Taylor and FOSS, but Padé approximation presents RHPZ, which can cause the controller to become unstable. In such cases the Taylor or FOSS approximations can result in a better choice to approximate the exponential term.

REACTION CURVES

A complete mathematical description of the process can be constructed using mass and energy balances, engineering relations, valve equations, etc. It is a difficult and time-consuming job to develop a dynamic process model. An approximation of the dynamic process model can be obtained by using the reaction curve method. This provides a simple and fast procedure to determine an approximated linear process model.

This experimental technique is based on applying a change in the manipulated variable (input of the process) with the loop open (controller in manual) and recording the response of the controlled variable (output of the process). The parameters of the linear model are calculated on the basis of the locations of some specific points in the output response.

The linear model represents an approximate model that is adequate for many engineering purposes; however, it is only valid in an operating point and it does not take into account the high-order behavior and nonlinearity of the process. Most of the industrial processes can be represented by a first-order plus dead time model. Other processes can be approximated by a second-order underdamped plus dead time system or by an integrating plus dead time system.

The following procedures can be used to approximate linear models for these kind of processes.

First-Order Plus Dead Time Processes

A high percentage of all chemical process can be modeled by using first-order plus dead time systems.

$$G(s) = \frac{K}{\tau s + 1} e^{-t_d s} \qquad \textbf{2.22(13)}$$

where
K is the steady-state gain
τ is the time constant
t_d is the dead time

The parameters of the process model, K, t_d, τ are obtained by using the following procedure:

1. The control loop is opened by switching it to manual.
2. This is done when the controlled variable (system output) is at a constant value and no disturbances or other upsets are allowed to occur, while the reaction curve is developed.
3. A step change is applied to the manipulated variable (controller output, which is an input to the process). The step changes are usually 5 to 10%. The step time should be long enough for the manipulated variable (system input) to reach a new steady state.
4. The manipulated variable (system input) response is recorded to provide good visibility on both the amplitude and time scales.

Two slightly different graphical techniques are utilized in these procedures. These methods are explained in the next paragraphs.

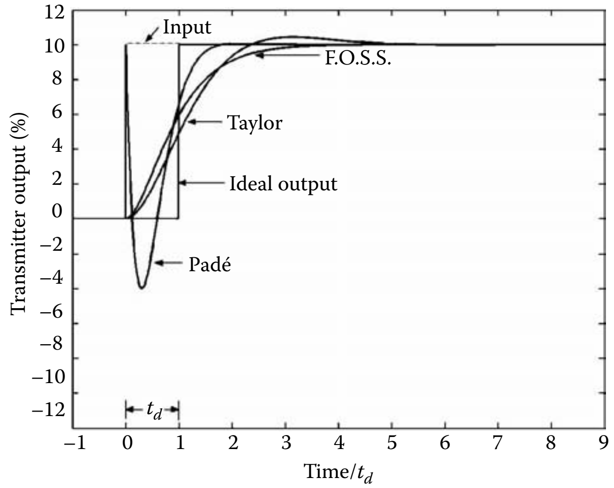

FIG. 2.22h
Step response of a dead time system (Equation 2.22[12]) using second-order approximations.

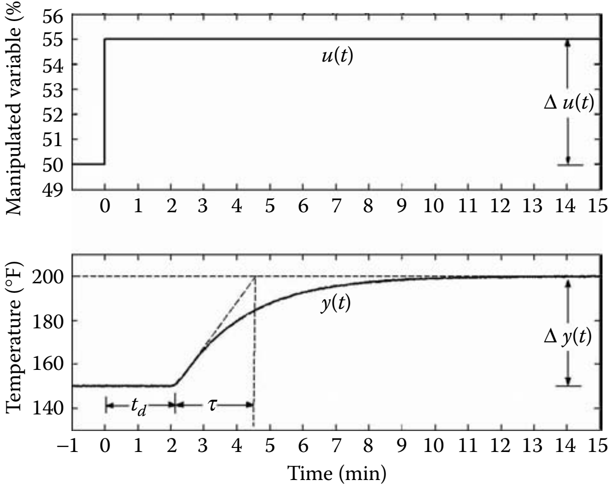

FIG. 2.22i
Reaction curve evaluation using the "first method" to determine dead time and time constant of a first-order plus dead time process.

First Method The first method uses a tangent to the initial process response curve, drawn at the point of maximum slope; the point where it intercepts the final steady-state value is noted. In this case, the process time constant is the time between the tangent intercepting the original and the new steady-state lines. The dead time is measured as the time it takes between applying the step change and the beginning of the time constant.

EXAMPLE

In Figure 2.22i, a 5% step change to the manipulated variable (controller output) has been applied, and process response in terms of the controlled temperature is recorded. If the first method is utilized, the model parameters are

$$K = \frac{\Delta y(t)}{\Delta u(t)} = \frac{50°\text{F}}{5\%} = 10\frac{°\text{F}}{\%} \qquad \textbf{2.22(14)}$$

$$\tau = 2.4\ \text{s}, \qquad \textbf{2.22(15)}$$

$$t_d = 2.1\ \text{s} \qquad \textbf{2.22(16)}$$

Second Method The second method eliminates the need to draw a tangent. This approach proposes that the values of τ and t_d are so selected that the model will coincide with the process response at two points.[3] On the time scale, these two points are at times when the controlled variable (system output) reaches 28.3 and 63.2% of its final steady-state value. Once these points match, the parameters of the process model are calculated using Equations 2.22(17) to 2.22(19).

EXAMPLE

As shown in Figure 2.22j, a step change in the manipulated variable is applied to the process, and the response of the controlled variable is evaluated. The model parameters can be calculated using the following equations:

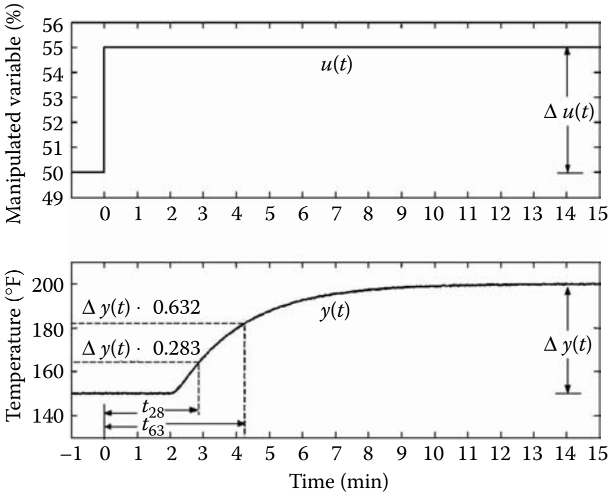

FIG. 2.22j
Reaction curve evaluation using the "second method" to determine dead time and time constant of a first-order plus dead time process.

$$K = \frac{\Delta y(t)}{\Delta u(t)} \qquad \textbf{2.22(17)}$$

$$\tau = \frac{3}{2}(t_{63} - t_{28}) \qquad \textbf{2.22(18)}$$

$$t_d = t_{63} - \tau \qquad \textbf{2.22(19)}$$

thus,

$$K = \frac{50°\text{F}}{5\%} = 10\frac{°\text{F}}{\%} \qquad \textbf{2.22(20)}$$

$$\tau = \frac{3}{2}(4.2 - 2.9) \approx 2.0\ \text{s} \qquad \textbf{2.22(21)}$$

$$t_d = t_{63} - \tau = (4.2 - 2.0) = 2.2\ \text{s} \qquad \textbf{2.22(22)}$$

The first and second methods are compared with the process response in Figure 2.22k. The second method results in a better approximation than the first one. One limitation of the first method is that drawing the tangent line at the point of maximum slope is not an easy task. The other reason why the second method is superior is because it matches the process response curve at two points in the region of maximum slope, instead of one.

Figure 2.22l shows how the second method can be used to obtain a rude approximation of a nonminimum phase system by a first-order plus dead time approximation. The principal idea is to approximate the inverse response by a dead time.[3]

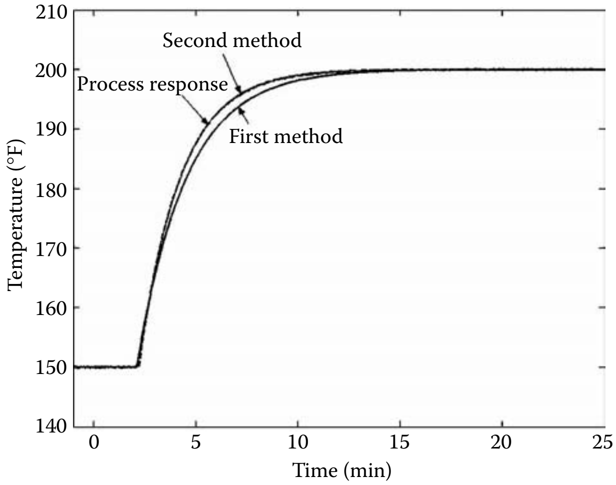

FIG. 2.22k
Comparison between the first and second methods of approximating the process responses.

Underdamped Processes

Chemical processes rarely are underdamped; however, electrical–mechanical systems with time lag (due to communication lags or signal analysis lags) typically are, when an input step change is applied. A reaction curve can be used to obtain the parameters for a second-order underdamped with dead time process in the same way as was done with a first-order plus dead time system.

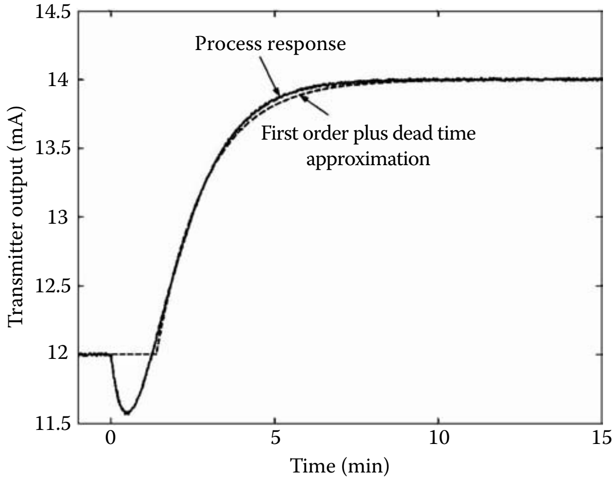

FIG. 2.22l
Approximation of a nonminimum phase process by a first-order plus dead time model using the "second method."

Closed-loop chemical processes are often tuned to have an underdamped response. In that case, a process model is calculated using the online step response.[4] A process that is underdamped with dead time can be approximated by the equation below:[5]

$$G(s) = \frac{K}{\tau^2 s^2 + 2\tau\xi s + 1} e^{-t_d s} \qquad \textbf{2.22(23)}$$

and the parameters of this model can be estimated from the following expressions:

$$\mathrm{OR} = \frac{\Delta y_{\mathrm{OR}}}{\Delta y} \qquad \textbf{2.22(24)}$$

$$\theta = \arctan\left(\frac{-\pi}{\ln \mathrm{OR}}\right) \qquad \textbf{2.22(25)}$$

$$\tau = t_{\mathrm{OR}} \frac{\sin(\theta)}{\pi - \theta} \qquad \textbf{2.22(26)}$$

$$\xi = \cos\theta \qquad \textbf{2.22(27)}$$

where

K is the steady-state gain
t_d is the dead time
OR is the overshoot ratio
t_{OR} is the time to reach the maximum overshoot
Δy_{OR} is the maximum peak overshoot
τ is the time constant
ξ is the damping factor

EXAMPLE

A step test signal, $u = 10\%$, is applied at $t = 0$ min to the manipulated variable (process input). The output response (velocity) is shown in Figure 2.22m. The figure also identifies the readings that have to be made to calculate the second-order underdamped model parameters.

$$\mathrm{OR} = \frac{\Delta y_O}{\Delta y} = \frac{125\ \mathrm{rpm}}{100\ \mathrm{rpm}} = 0.25 \qquad \textbf{2.22(28)}$$

$$\theta = \arctan\left(\frac{-\pi}{\ln 0.25}\right) = 1.16\ \mathrm{rad} \qquad \textbf{2.22(29)}$$

$$\tau = 4.3\frac{\sin(1.16)}{\pi - 1.16} = 2.0\ \mathrm{s} \qquad \textbf{2.22(30)}$$

$$\xi = \cos 1.16 = 0.4 \qquad \textbf{2.22(31)}$$

$$K = \frac{\Delta y}{\Delta u} = \frac{100\ \mathrm{rpm}}{10\%} = 10\frac{\mathrm{rpm}}{\%} \qquad \textbf{2.22(32)}$$

$$t_d = 1\ \mathrm{s} \qquad \textbf{2.22(33)}$$

Finally, the approximated model is as follows:

$$G(s) = \frac{10}{s^2 + 0.8\ s + 1} e^{-s} \qquad \textbf{2.22(34)}$$

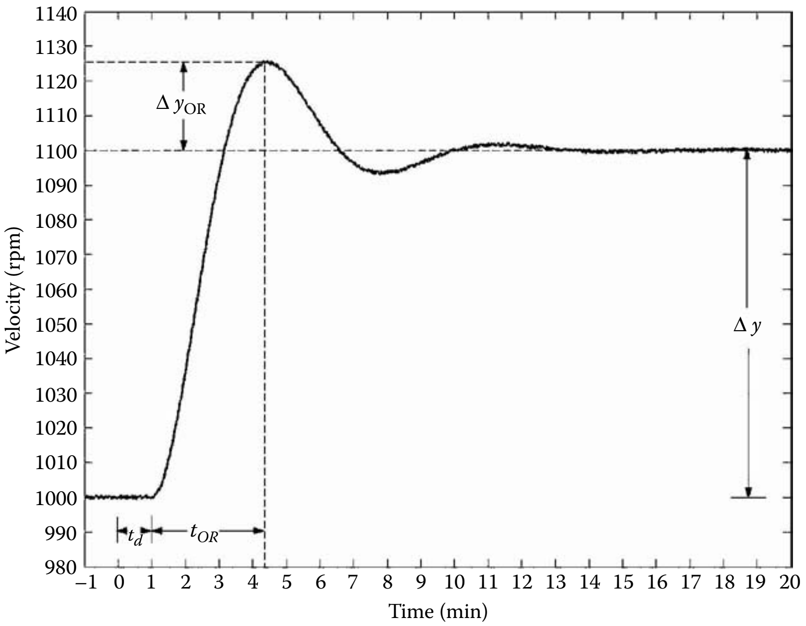

FIG. 2.22m

The approximation of an underdamped, second-order plus dead time process requires the measurement of the noted four values from the process response curve.

Integrating Plus Dead Time Processes

Sometimes industrial processes contain pure integration elements. They are not self-regulating processes and do not have a steady state. Therefore, any step change will cause the controlled variable (process output) to increase or decrease linearly with time.

This is the case with controlling level in a tank, when the manipulated variable is feed flow rate into the tank. The following model in Laplace domain can approximate an integrating system with dead time:

$$G(s) = \frac{K}{s} e^{-t_d s} \qquad \textbf{2.22(35)}$$

where

K is the process gain
t_d is the dead time

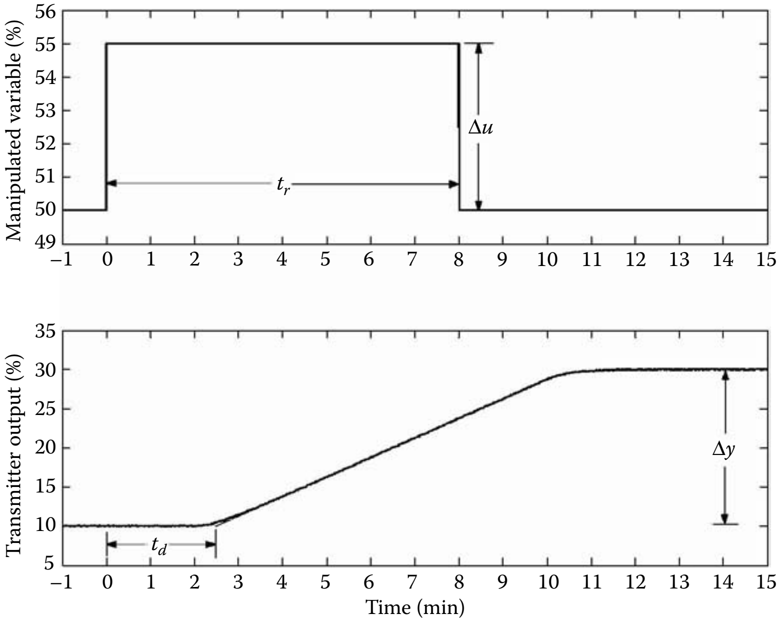

FIG. 2.22n

A pulse test is used to establish the dynamic characteristics of an integrating plus dead time process.

The process model of an integrating process is obtained by applying a pulse test and not a step test because the latter would produce an output curve that will change linearly, without reaching a steady-state value. The gain of the integration element can be calculated by[5]

$$K = \frac{\Delta y}{\int_0^{t_r} u(t)dt} \qquad \textbf{2.22(36)}$$

When a pulse step is applied, Equation 2.22(36) can be rewritten as

$$K = \frac{\Delta y}{\Delta u t_r} \qquad \textbf{2.22(37)}$$

The readings that need to be obtained are shown in Figure 2.22n, consequently

$$K = \frac{\Delta y}{\Delta u t_r} = \frac{20\%\ \text{MV}}{5\%\ \text{TO}\ 8\ \text{s}} = 0.5\frac{\%\ \text{MV}}{\text{TO s}} \qquad \textbf{2.22(38)}$$

$$t_d = 2.5\ \text{s} \qquad \textbf{2.22(39)}$$

CONCLUSION

The dynamic behavior of most chemical processes can be approximated by the use of first-order plus dead time models. Other methods, also described in this section, included the methods of modeling second-order underdamped and integrating plus dead time processes.

The reaction curve methods were used to model the dynamic characteristic of the processes. These are input/output (black-box) linear models that do not take into account nonlinearities or high-order dynamics. These models are usually valid only in a region near the operation point of the process, but they are powerful tools in the design and tuning of control loops.

2.23 Ratio Control

F. G. SHINSKEY (1970, 1985) **B. G. LIPTÁK** (1995) **J. E. JAMISON, A. ROHR** (2005)

INTRODUCTION

Ratio control systems maintain a relationship between two variables to provide regulation of a third variable. Ratio systems are used primarily for blending ingredients into a product or as feed controls to chemical reactors. An example would be the addition of a gasoline additive under ratio control in order to maintain the required octane number of the product, which number may or may not be measured.

Ratio systems portray an elementary form of feedforward control (Section 2.9). In the above example, if the load input to the system (gasoline flow) changed, it would cause a variation in the controlled variable (octane number). This variation can be eliminated by an appropriate adjustment of the manipulated variable (additive flow rate).

The load, or wild flow, as it is called, may be uncontrolled, controlled independently, or manipulated by other controllers that respond to the variables, such as pressure or level.

FLOW RATIO CONTROL

Ratio control is applied almost exclusively to flows. Consider maintaining a certain ratio R between ingredients A and B:

$$R = B/A \qquad \mathbf{2.23(1)}$$

There are two ways to accomplish this. The more common method is to calculate and manipulate the set point of a flow loop as follows:

$$\text{Set Point} = B = RA \qquad \mathbf{2.23(2)}$$

This system is shown in Figure 2.23a. The set point for the flow ratio controller (FFC-2) is calculated by an adjustable-gain device, which is known as the ratio station. If the ratio station (FY in Figure 2.23b) is outside the control loop, it does not interfere with the secondary loop's response.

The second method is to calculate the ratio R from the individual measurements of flows A and B (Equation 2.23[1]) and use this calculated ratio as the measurement input (controlled variable) into a manually set ratio controller (RIC). Such a scheme is shown in Figure 2.23c. The principal disadvantage of this configuration is that it places a divider inside a closed loop. If flow B responds linearly to the opening of valve B, the gain of the loop will vary because of this divider. The differentiation of Equation 2.23(1) explains why this is true:

$$\frac{dR}{dB} = \frac{1}{A} = \frac{R}{B} \qquad \mathbf{2.23(3)}$$

Equation 2.23(3) shows that the loop gain varies both with the ratio R and the flow B. In most applications, the ratio R would not often be subject to change, but the flow B would. Because the loop gain varies inversely with flow B, this can cause instability at low rates. Therefore the use of an equal-percentage valve characteristics is essential to overcome this danger. If the ratio were inverted,

$$R = A/B \qquad \mathbf{2.23(4)}$$

then

$$\frac{dR}{dB} = -\frac{A}{B^2} = -\frac{R}{B} \qquad \mathbf{2.23(5)}$$

and the result is essentially the same.

The square-root extractors in Figures 2.23c are shown in broken lines to indicate that the control system will also function without them, as it can use the flow-squared signals. If that is the case, the controlled variable is

$$R^2 = B^2/A^2 \qquad \mathbf{2.23(6)}$$

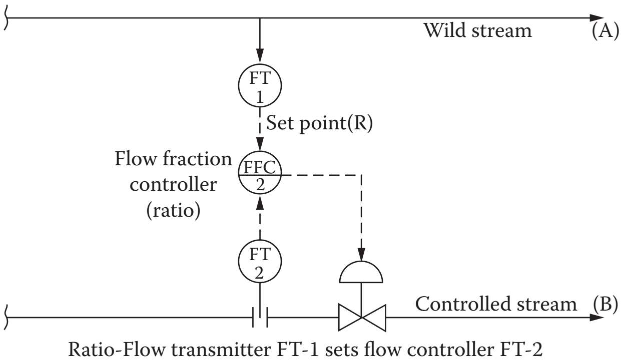

FIG. 2.23a
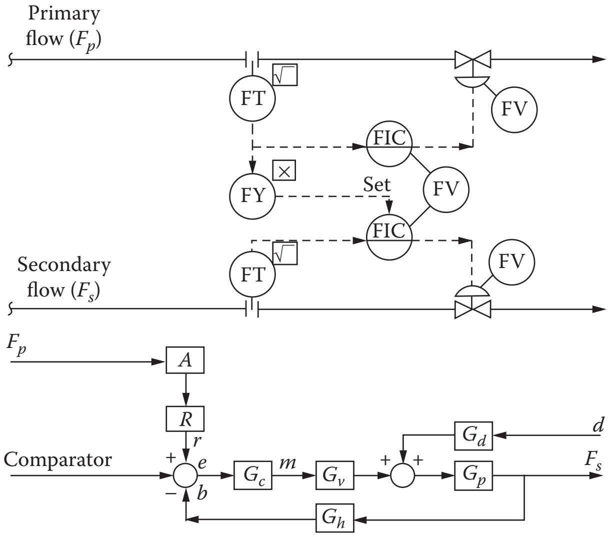
Controlled stream is manipulated to maintain a constant ratio (R) of controlled flow (B) to wild flow (A).



A = Input element.
b = Feedback variable.
d = Disturbance or load Variable.
e = Error (deviation) signal.
F_p = Primary flow.
F_s = Secondary flow.
G_c = Controller transfer function.
G_d = Disturbance or load transfer function.
G_h = Feedback sensor transfer function.
G_p = Process transfer function.
G_v = Control valve transfer function.
m = Manipulated variable.
r = Reference (set-point) Input.
R = Desired ratio.

FIG. 2.23b
If the ratio calculation is made outside the secondary flow control loop, its setting does not change the dynamics or response of the loop.

As a consequence, the scale of the ratio controller or ratio station has to be nonlinear. Differentiating Equation 2.23(6):

$$\frac{d(R^2)}{dB} = \frac{2B}{A^2} = \frac{2R}{A} = \frac{2R^2}{B} \qquad \textbf{2.23(7)}$$

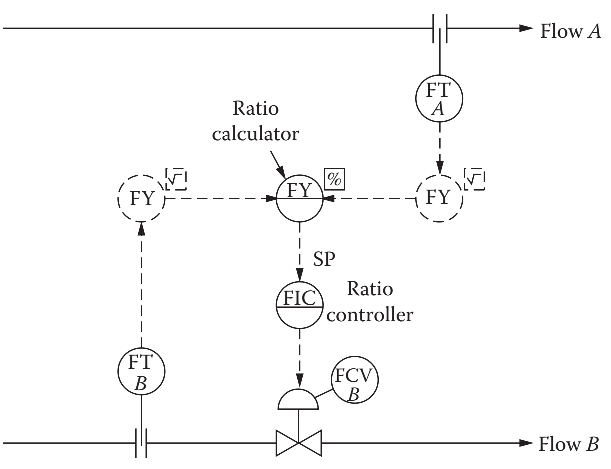


FIG. 2.23c
Here the ratio of flows A and B is calculated by a divider within the closed ratio control loop (FIC). The disadvantage of this approach is that the loop gain changes every time the ratio setting of flow B changes.

In this case too, for the configuration shown in Figure 2.23c, the loop gain varies inversely with flow.

Advantages and Disadvantages

The principal advantage of using the ratio control system is that the controlled variable — flow ratio — can be kept constant and can be directly recorded to verify control performance (Figure 2.23c). In contrast, using the loop configurations in Figures 2.23a or 2.23b would require two records and their evaluation for ratio verification.

The disadvantage of using analog transmitters in ratio control is that it has no memory. For example, in a blending system, if the controlled flow for any reason cannot match the required value, even temporarily, the resulting incorrect composition cannot be automatically corrected because there is no memory of the amount of past error.

One way to try to correct this situation is to add a totalizer per stream to verify the overall correctness of total blended product. If such information is available, subsequent operator intervention can bring the average composition of the blend to the desired value. Naturally, this assumes that a correct mean ratio is acceptable for the purposes of the process, rather than continuously maintaining a correct ratio.

While head-type flow meters were used in the earlier examples, the general comments that were made are equally valid when positive displacement (PD) or turbine-type flow detectors are used. When the plant is controlled by microprocessor-based digital controllers or DCS systems, the reconfiguration of such ratio control loops requires much less effort. If the flow measurement signals are transmitted utilizing bus-based technologies, the associated dead time should be considered in the tuning of the flow ratio control loops.

RATIO STATIONS

No matter what portion of the ratio control loop is implemented in hardware or in software, a computing element must be used whose scaling requires some consideration. The ratio station (FY in Figure 2.23b) normally has a gain range of about 0.3 to 3.0. The primary flow signal *Fp*, in percent of scale, is multiplied by the gain setting to produce a set point for the secondary flow controller (*Fs*), in percent of scale. The true flow ratio must take into account the scales of the two flowmeters. The setting of the ratio station is related to the true flow ratio by

$$R = (\text{true flow ratio})(\text{Scale of } Fp)/(\text{Scale of } Fs) \qquad \textbf{2.23(8)}$$

As an example, assume that the true flow ratio of the additive to gasoline is to be 2.0 cc/gal (0.53 cc/ℓ). If the additive flow scale is 0 to 1200 cc/min, and the gasoline flow scale is 0 to 500 gal/min (0 to 1890 ℓ/m), then:

$$R = 2.0 \text{ cc/gal} \frac{500 \text{ gal/min}}{1200 \text{ cc/min}} = 0.833 \qquad \textbf{2.23(9)}$$

TABLE 2.23d
Comparing the Actual Ratio Settings Required for Linear and Head-Type Flowmeters to Obtain the Same Flow Ratio

	Actual Ratio (Gain) Setting Required to Achieve the Desired Ratio	
Flow Ratio Desired	If Signals Are Linear	If Flow-Squared Signals Are Used and the Scale Is Linear
0.6	0.6	0.36
0.8	0.8	0.64
1.0	1.0	1.0
1.2	1.2	1.44
1.4	1.4	1.96
1.6	1.6	2.56

When head-type flowmeter signals are used and the scale is linear, such scale should show the square root of R in order to be meaningful. Table 2.23d compares the gain of a ratio station (corresponding to linear flow ratio) with the ratio setting for head-type flowmeters. As shown by Table 2.23d, the available range of ratio settings is seriously limited when using squared flow signals.

A ratio controller (FFC-2 in Figure 2.23a) combines the ratio function and the controller in one unit. If implemented in hardware, it saves cost and panel space. Such algorithms are also available in digitally based control systems.

Since ratio stations are used with remote-set controllers, some means must be available for setting flow locally during start-up, or during abnormal operation. An auto-manual station is sometimes provided for this purpose. With the ratio controller, this feature requires two scales on the set point mechanism—one reading in ratio for remote-set operation, the other reading in flow units for local-set operation.

When using a divider with linear flow signals as the ratio calculator, the scale factor for the divider should be 1/2. This places a ratio of 1.0 at midscale:

$$R = \frac{1}{2}\frac{B}{A} \qquad \textbf{2.23(10)}$$

Equal flow signals will produce a 50% output from the divider, and the full ratio range is then 0 to 2.0, linear. If flow-squared signals are used, the divider should have a scale factor of 1/3 to provide a full range of 0 to 1.73, with a square root scale. This places a ratio of 1.0 ($A = B$) at 0.58 on the square root scale.

$$R^2 = \frac{1}{3}\frac{B^2}{A^2} \qquad \textbf{2.23(11)}$$

If a scale factor of 1/2 were used, the ratio range would be restricted to 0 to 1.41.

SETTING THE RATIO REMOTELY

When a divider is used to calculate the flow ratio (Figure 2.23c), the set point for this ratio can come from other, related segments of the plant's process. In order to do this correctly, a multiplier must replace the ratio station (Figure 2.23b). If the flow measurement signals are linear, the usual choice of scaling factor for such a multiplier is 2.0:

$$B = 2RA \qquad \textbf{2.23(12)}$$

In this way, a ratio of 1.0 appears at mid-scale of the ratio input ($R = 50\%$), when $A = B$. If squared flow signals are used, a scaling factor of 3.0 provides a ratio range of 0 to 1.73:

$$B^2 = 3R^2A^2 \qquad \textbf{2.23(13)}$$

One reason for using a multiplier to set the flow ratio (Figure 2.23b) is the availability (even in hardware) of very narrow ratio ranges for those applications in which the need for precision, not rangeability, is paramount. Ratio ranges of 0.9 to 1.1, 0.8 to 1.2, etc. are possible.

A typical application would be the accurate proportioning of ammonia and air to an oxidation reactor for the production of nitric acid. If the compositions of the individual feeds are constant, only a very fine adjustment of the ratio is required.

RATIO CONTROL APPLICATIONS

Blending

Figure 2.23e shows a combination of cascade and ratio controls of blending fluids A and B and sending the mix into a blend tank. In this process, the liquid level in the blend tank is affected by total flow, hence the liquid level controller sets flow A, which in turn sets flow B proportionately. (Whenever adjusting the set point of a head-type flow controller in a

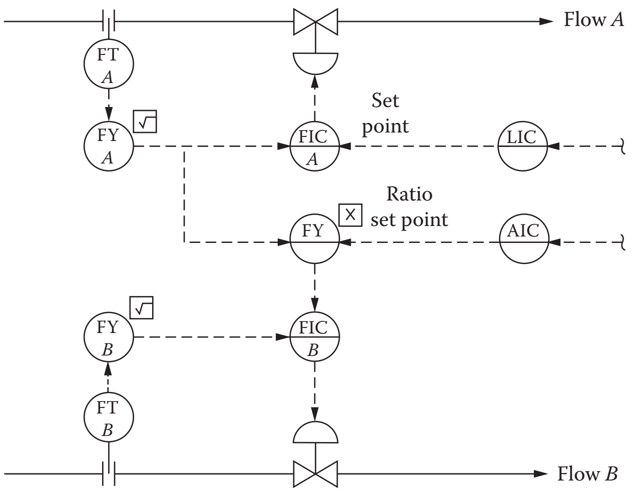

FIG. 2.23e
The level controller manipulates flow rate and the composition controller manipulates flow ratio.

cascade manner, in order to prevent instability at low flows, the square root is removed from the flow measurement signal and linear flow signals are used.)

Conversely, composition is not affected by the absolute value of either flow but only by their ratio. Therefore, to make a change in composition, the AIC controller must adjust the ratio set point of the multiplier (FY). To minimize the interaction of the composition controller with blend tank level control (through its manipulation of flow *B*), flow *B* should be the smaller of the two streams.

Distribution Controls A special case of ratio control is distribution control. When a common supply of some material is to be distributed among three or more destinations, an additional degree of freedom is created. Therefore, in addition to setting the individual flow controllers to some percentage of the total flow, one can also make sure that the system pressure drop is minimized. Because equal flow distribution can be achieved with all the valves nearly open, nearly closed, or anywhere in between, one must introduce an additional control variable.

This new controller (VPC in Figure 2.23f) is usually selected to be the opening of the most-open control valve. If the most-open valve is held nearly fully open while the flows are equally distributed, the control system is fully defined and is also efficient because it provides the minimum resistance to flow. This approach is applicable to all liquid or gas distribution controls, and its use is illustrated by the example of distributing the returning cooling tower water among several cooling cells.

The purpose of the control system in Figure 2.23f is not only to distribute the returning water correctly between cells but also to make sure that this is done at minimum cost of operation. The operating cost in this case is pumping cost, and it will be minimal when the pressure drop through the control valves is minimal. This is the function of the valve position controller (VPC) in Figure 2.23f. As long as even the most open valve is not nearly fully open, the VPC adds a positive bias to all the set-point signals of all the flow fraction controllers (FFICs). As a result, all valves open and keep opening until the most open valve reaches the desired 95%. This technique enables the meeting of the dual goals

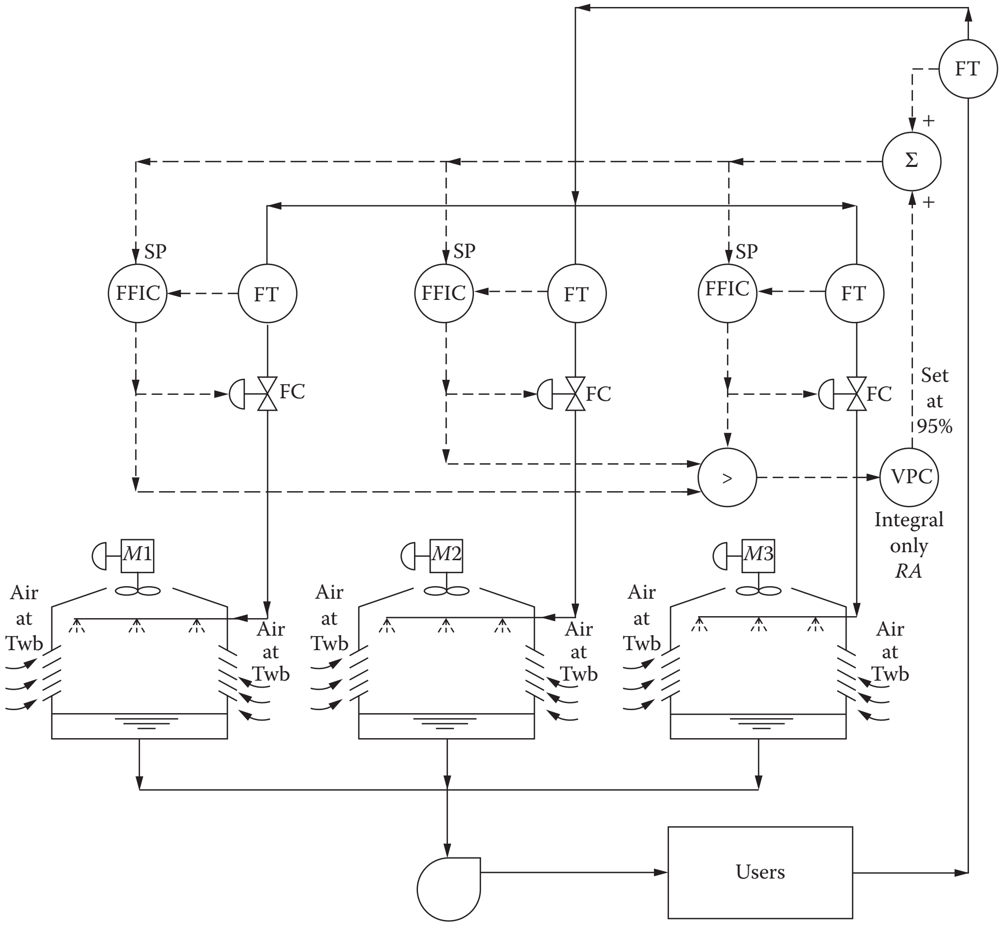

FIG. 2.23f
Pumping costs can be minimized automatically by operating water distribution systems at minimum pressure drop and therefore with the most open control valve nearly fully open.

of providing the correct flow distribution and doing it at a minimum cost in pumping energy.

When cooling tower cells are manually balanced, it is not unusual to find all balancing valves throttled to some extent or to see the same water flow when the fan is on or off. Both of these conditions are undesirable because they will increase operating costs. The savings from automatic balancing can more than justify the instruments required for implementing it.

Surge Control of Compressors

In compressor surge protection applications, the ratio that is controlled is not between flows. The surge line of variable speed compressors closely approximates a parabola if the pressure rise across the machine (*Pd* − *Pi*) is plotted against the volumetric inlet flow rate (Figure 2.23g). If the pressure rise across the compressor (*Pd* − *Pi*) is plotted against the orifice differential (*h*) of a head-type flow sensor located in the inlet to the compressor (Figure 2.23h), the surge line becomes an almost straight line.

Because surge occurs at low flows, the control system is so configured as to keep the compressor operations to the right of the surge line. Therefore, the set point for the surge protection FIC is the surge line itself ($m(\Delta P)$) plus a safety bias (b). This in effect locates the control line parallel with and to the right of the surge line.

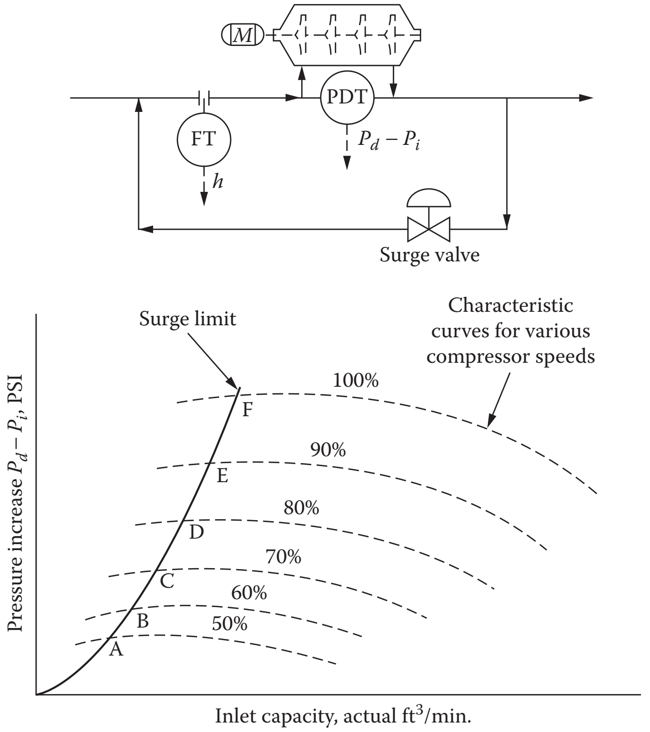

FIG. 2.23g
The surge line of a variable speed centrifugal compressor is parabolic if the pressure rise across the machine (Pd − Pi) is plotted against inlet volumetric flow rate.

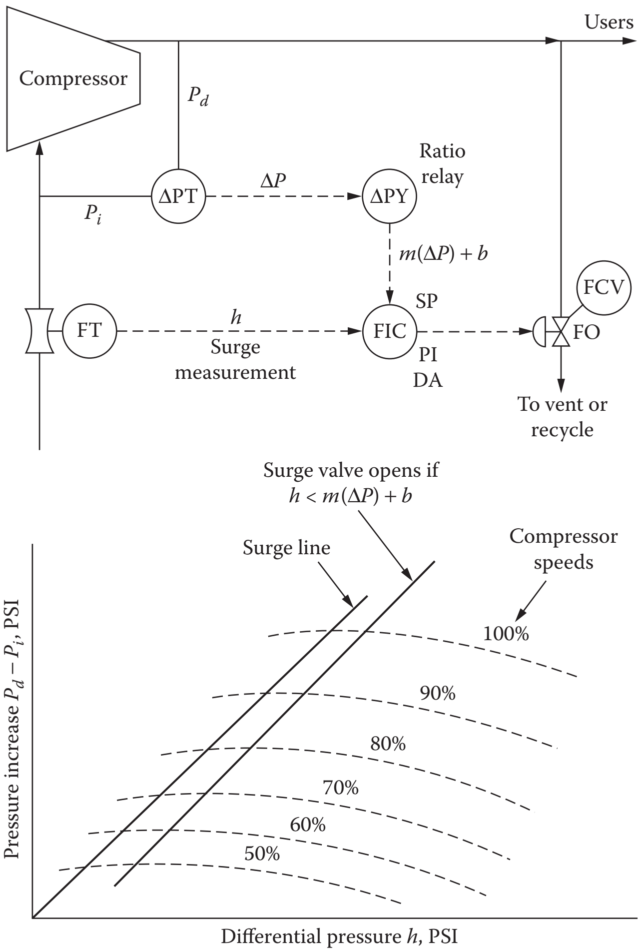

FIG. 2.23h
The parabola shape of the surge line changes to a straight line if the pressure rise across the compressor (Pd − Pi) is plotted against the orifice differential (h) of a head-type flow meter.

The slope *m* of the surge line is

$$m = (Pd - Pi)/h \qquad \textbf{2.23(14)}$$

where (*Pd* − *Pi*) is the head of the compressor and *h* is the differential pressure across the flow element. A safe set point for the flow controller (FIC) is

$$h = (Pd - Pi)/m + \text{bias} \qquad \textbf{2.23(15)}$$

The complete surge control loop is shown in Figure 2.23h. The figure shows both the surge line and the control line at which the surge valve opens.

2.24 Real-Time Performance Assessment

J. P. GERRY (2005)

INTRODUCTION

To optimize the regulatory control loops in a plant, one first needs to assess the current performance. How are the loops operating now? Could they be performing better? By assessing the performance in real time, a number of benefits can be obtained:

- Knowledge, on a real-time basis, of the health of the plant, unit operations, and loops can be acquired.
- Poor-performing loops can easily be flagged.
- Continual performance assessment allows one to record the history of performance, so that differences in performance between time periods can be compared. For example, one can evaluate the effect of the following variables on performance:
  - Seasonal changes
  - Grade changes
  - Feed changes
  - Shift changes
  - Equipment changes

The tools of optimization should be readily accessible in the performance monitor.

PLANT ASSESSMENT AND MONITORING

Process variable, set-point, and controller output data should be collected from the plant for every control loop. In order to maintain accuracy, these data should be collected while all software compression is turned off. Ideally, the data should be collected at intervals of roughly 1/10 of the dead time of the loop. Generally once per second is adequate, but the collection frequency of some loops such as temperature can be longer. As of this writing, standard connection methods are available using OPC or Ole for Process Control, which is a standard developed by the OPC Foundation (www. opcfoundation.org).

Loop Performance and Health Assessment

The overall performance of a control loop or loop health may be different for different businesses. It can also vary from plant to plant depending on the business objectives. For example, in paper mills, the variability of the paper is often a key variable to be assessed, whereas in refineries the average temperature error can be a key of assessment.

The definition of loop health can also vary from loop to loop. For example, a flow loop may have different performance objectives than the level in a surge tank. A flexible definition is the best since it allows for improvements and refinements over time.

Loop health can be evaluated by considering the key assessments, baselines, thresholds, and economic significance.

Assessment Criteria of Loop Health Assessments are calculated over "assessment intervals." This interval should be defined for each unit operation and should be at least 6 times longer than the longest cycle in the unit or at least 100 times the longest process dead time. Generally, the assessment interval should be 4 hours or longer.

Loop health can be evaluated and assessed on the basis of many criteria, and the reader should be familiar with the related terminology, described below in alphabetic order. Any of the following criteria or their combinations can be used as key assessments, which refer to criteria that are relevant to the health of a control loop:

- *Average error* is the average of the absolute error that has existed between the setpoint and measurement during the assessment period.
- The *Harris Index* (normalized) is defined as the ratio between the error (PV – SP) variance during this assessment over the variance achievable by a minimum variance controller. The larger the value of the Harris Index, the poorer the performance of the loop. The Harris Index will vary as a number between one and infinity. A value of one is perfection or minimum variance control. As the quality of loop performance drops, the index rises. However, sluggish tuning usually causes the Harris Index to drop. Cyclic response or overly aggressive tunings will make the Harris Index rise. The Harris Index is considered to be high when it is between 50 and 100, but it can get much higher. However, these numbers may vary from loop to loop and also depend on the occurrence of set-point changes and load upsets. The amount and pattern of noise can greatly influence the Harris Index.

- *Noise band* is determined on the basis of statistical analysis of the noise, which during the assessment period is superimposed on the process variable, expressed in percentage. The noise band is the standard deviation (sigma) of the process variable during the quietest time. The minor variations in the process variable that are not caused by the controller, by set point changes, or by load upsets are considered to be normal process noise. Such noise may be caused by electrical interference, magnetic fields, flow turbulence loops, waves in a tank in level loops, etc. Generally, the larger the noise band, the poorer the performance of the loop. The cycling of a process variable in an unstable and fast control loop might also appear as noise to this assessment.
- *Oscillation detection confidence value* is a value between 0 and 100%, where 100% indicates full confidence that the loop is continuously oscillating. This assessment is performed by analyzing the pattern of the error signal.
- *Oscillation diagnosis confidence value* is between 0 and 100%, where 100% indicates full confidence that the oscillation is caused by one of the three causes: valve stiction or hysteresis, bad tuning, or causes external to this loop.
- *Output standard deviation* is the standard deviation in the controller output during the assessment period.
- *Output at a limit* is the percentage of time that the controller output was at a limit.
- *Probable Performance Increase Index* is a measure of the performance increase, which is possible by using the fastest PID tuning with a safety factor of 2.5. It is the "percent probable" performance increase in integrated absolute error (IAE) terms, when the loop is responding to a load upset, assuming the controller does not overshoot with either settings. This index shows the improvement in process response to upsets with the new tuning. This index is often proportional to the savings that the plant can achieve from improved control loop tuning.
- *Set-point crossings* is the number of times the process variable (PV) crosses the set point in one day.
- *Time in Normal* is the term for the time period in percentage that the loop spends in the Normal mode. Most often the Normal mode is the Automatic mode, but not always.
- *Valve travel* is the total distance the controller output moves during the assessment period, which is normalized to be on a 24-hour basis. It is found by summing the absolute value of the controller output changes that occur between each sample.
- *Valve reversals* is defined as the number of times the controller output changes direction during an assessment period normalized to a 24-hour basis. It is a value between zero and infinity. This value is of interest because more reversals usually result in more valve wear.
- *Variability* is the relative value of variance (defined in the next paragraph) in the process variable during the assessment period. It is expressed as a percentage of the mean and so allows comparison between the level of variability in different processes.

$$\text{Variability} = 2(\text{Standard Deviation})(100/\text{Abs(Mean)}) \qquad \textbf{2.24(1)}$$

where Abs = absolute value; Standard Deviation = sqrt(Variance); and Variance = $\text{sum}(\text{Mean} - x(i))^2/(\text{npts} - 1)$.

- *Variance* measures the spread or dispersion of the process variable during the assessment period. "Variance, normalized" is dimensionless because it has been normalized with 100 divided by the span of the PV, squared:

$$\text{Variance} = [\text{sum}(\text{Mean} - x(i))^2\,(100)^2]/[(\text{npts} - 1) \times (\text{span of PV})^2] \qquad \textbf{2.24(2)}$$

Related Assessments Criteria

The following assessments provide beneficial diagnostics but are not contributors to loop health.

- *Three largest oscillation periods and strengths.* This value is obtained by spectral analysis of the error data during the assessment time. The three oscillations of the process variable having the most power (and their amplitudes) provide the six assessments. The power should be evaluated using a cluster of peaks and not just a single peak, and the zero frequency component should be ignored. This assessment can provide some very beneficial diagnostics but is not viewed as a contributor to loop health. For example, if the cause of loop oscillation is unknown, by sorting the loops by oscillation period, one can identify the loops having the same period of oscillation — even when it is "hidden" in other information. This can help in pinpointing the cause of oscillation.
- *Process model parameters.* These are parameters of the process model — dead time, gain, lag times, and integration time, including second-order coefficients that allow for imaginary roots. The process model is usually not a key assessment of control loop health.
- *Model quality.* This is an assessment of the accuracy of the fit between the actual process and its model. The quality of the process model is usually not a key assessment criterion in the evaluation of the health of the control loop.
- *Robustness.* Robustness is a relative number giving an indication of how robust or sensitive the loop is to process upsets or changes. The larger this number, the more robust the loop. There is always a tradeoff

between fast tuning and robustness. The robustness number is discussed in detail in Section 2.26 in this handbook. The robustness number is normalized since it uses gain and dead time ratios. It can be used as a comparison between loops.

- The *relative response time* (*RRT*) is a relative indicator of the speed of the control loop. The smaller the relative response, the faster the loop. The higher the relative response value, the slower the loop. This number is used for comparison purposes. The RRT is dependent on the controller's speed of response and can be changed by adjusting the PID settings. If one uses fast tuning, the controlled process variable often will oscillate around the set point after it is changed. The period of this oscillation in the time response is roughly the same as the RRT. The value of the RRT is found by:
  1. Calculating the closed loop frequency response to a load upset
  2. Finding the frequency where the amplitude ratio peaks
  3. Converting this to a time period

  Interacting loops and RRT. In order to prevent interaction, the PID tuning settings should be so adjusted that the RRTs of the loops differ by a factor of three. For example, if there are three interacting loops and the fastest one has a period of 1 second, the tuning of the other two controllers should be readjusted so that their RRTs are at least three and nine.

  Cascade Loops and RRT. For cascade loops, the master (outer) loop should have an RRT that is three times slower than that of the inner loop. This relationship is obtained by first tuning the slave (inner) loop, and then the master. If the cascade master loop has an RRT that is less than 3 times that of the slave (inner) loop, the master should be de-tuned so that its RRT will be 3 times that of the slave.

Baseline and Threshold Values The baseline time is a window or period of time when the plant is running well. The baseline time can be used as a reference for comparison. The length of the baseline period should exceed six and should preferably equal 30 assessment periods. For statistical methods of evaluation, at least 30 assessments are suggested.

Every assessment can have a baseline value. A baseline value represents either the ideal value or the value from a time when the plant was running well. For example, a baseline value for average error might be zero, since zero error is ideal. The baseline for process dead time might be the average or minimum dead time that is present during the baseline time period.

Thresholds represent values of the assessed criteria that one would prefer not to exceed. Thresholds represent limits or boundaries between which the assessment criteria would remain if the plant is running well. All thresholds should be bidirectional. For example, a threshold may be set above the baseline and/or below the baseline.

For example, a threshold for variability might be calculated by looking at a number of assessments from a period when the plant was running well. In that case, one should find the standard deviation and average value of the variability during these assessments. The standard deviation is also called the sigma value. X number of sigma values over the average value is called the X sigma value. So setting the threshold of variability to six standard deviations over the average would be setting it to the six sigma value. This is one strategy for setting thresholds.

Thresholds could also be set to the minimum or maximum value of an assessment over the baseline time.

Loop Health Calculation The calculation of loop health should be flexible enough to allow for different interpretations depending on the nature of the plant or process. It should allow for different categories of loops to have different health requirements. For example, a temperature loop may need to be fast and responsive whereas a level loop may need to allow for large level variations before causing a change in flow.

Loop health calculation should also allow different loops to have different priority ratings based on the relative importance of the loops.

Key Assessment Criteria

In order to quantitatively evaluate the performance of a loop, one has to select assessments that in combination define the loop's health. These are called key assessments. The key assessments should be those that are important to the operation of the plant, and any assessment can therefore be selected to be a key assessment.

Percent towards Threshold Every assessment can potentially provide a contribution to describing the health of the loop. For each assessment during every assessment period, a "Percent towards Threshold" is found:

$$\text{Percent towards Threshold} = (\text{Current Value} - \text{Baseline})/(\text{Threshold} - \text{Baseline})100 \qquad \mathbf{2.24(3)}$$

Next, an "Average Percent towards Threshold" is found. The Average Percent towards Threshold is the average of all the Percent towards Threshold values for all the key assessments during an assessment period. Using this calculation, lower values of Average Percent towards Threshold mean a better-performing loop. Larger values mean a poorer-performing loop. A patent is pending for this technology, which is used in performance assessment.

$$\text{Loop Health} = (\text{Average Percent towards Threshold})/(\text{Economic Significance}) \qquad \mathbf{2.24(4)}$$

Economic Significance is a divisor that incorporates a factor of economic importance to the health of each loop. For example, if two loops are exhibiting the same "Average Percent towards Threshold" the one with the higher economic significance (lower divisor) will bubble to the top of a priority list of loops.

Historization of Assessments The assessments for every loop should be historized. This allows for performance comparisons at different time periods. This information can be very valuable in troubleshooting and optimizing operations.

Accessibility and Presentation of Results Currently, the most accessible method for distribution of the results seems to be via a browser-based interface. This means the performance monitoring system should be a Web server; it should be able to serve up the performance results in an easy-to-read format for plant personnel. Most plant personnel are already familiar with navigation in browser interfaces and Web pages. Any personnel with access to a computer that is connected to the plant local area network (LAN) will have access to such information.

A network bridge allows this same connectivity on the office LAN. A network bridge uses two network interface cards in the server machine running the plant monitoring software. Using two cards enables the plant LAN to be totally separate from the office LAN. A Web server running the monitoring software can send assessment results to the office LAN.

Results should be shown in both graphical and tabular form. All of these results should be up to date on a real-time basis as much as possible.

Plant Overview

An overview window should provide an assessment of loop health in the various sections of the plant and also in the overall plant. Each plant area should have a history of assessments in that area. For example, Figure 2.24a shows a table and plot of loop health for 1 week. The two lines at the top and bottom represent two plant sections (unit operations), while the line in the middle describes the health of the entire plant. In the table below the chart, the health of the two unit operations making up the plant is listed as the third and fourth rows.

Prioritization of Problem Areas

The interface for users of assessment software should allow for default and for the generation of priority lists, which are configured by the user. The user should be able to sort the control loops in the plant on the basis of any combination of assessment criteria chosen by the user.

Priority List of Loops Having Most Impact One of the lists that is generated includes, in their order of priority, the loops needing attention. Both the engineering and plant maintenance

departments should find this list useful. The order of the loops in the list should reflect their potential for improving the productivity of the operation. To allow the user to obtain more information about the various unit operations, a clickable "drill down" can be provided, with more detail about the area in question. Figure 2.24b shows an example of such a page.

Listing Oscillating Loops The system should also include a list of oscillation assessments. Time of oscillation detection, diagnosis, period, and strength are some of the valuable data collected. Sorting by "oscillation detection" shows all loops that are oscillating.

Sorting by oscillation period groups the loops by their periods of oscillation. If the oscillation of several loops is caused by the same problem, they are likely to have similar oscillation periods. The top three oscillation periods for each loop should be included in the sort so that any secondary oscillations can be picked up.

Model and Quality Loop List A list containing columns of Model Quality and Probable Performance Increase Index makes it possible to improve the tuning of many PID loops all at once. In the list, high model quality means that good identification exists and hence good PID tuning is possible and is readily available for that loop. For those loops with a high model quality and where the Probable Performance Increase shows that better tuning is available, the improvements can be made to several loops simultaneously.

In such cases, the user, using the analysis software for each loop, would request the data used by the performance monitoring software to arrive at the model. As is discussed in more detail later, the analysis software displays the optimal PID tuning along with time simulations and robustness analysis.

Custom Loop Lists The loop performance assessment software allows users to create their own lists of loops. The rows and columns are selected by the user and can contain both custom loop lists and custom assessment lists as they are chosen by the user. Once set up, the software allows the user to recall the custom loop lists.

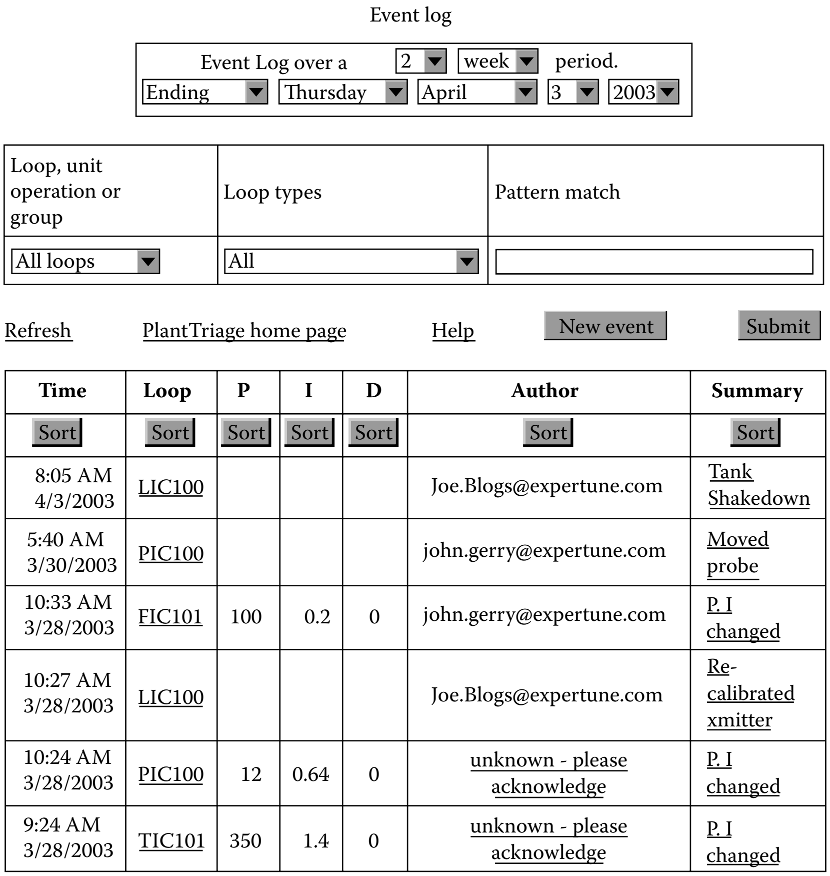
Recording Tuning Changes PID tuning values and changes are recorded by the performance monitor. A time window of the history of these changes is available for viewing in the browser-based Web interface. This feature also allows the user to enter notes or events. When several tuning adjustments are made to a PID loop, this information can be used as an indication that a problem exists with that loop.

Figure 2.24c shows events that were automatically picked up by the performance monitor and also shows some user-entered events. The data in the rows containing PID settings were detected and automatically entered by the system.

Performance Monitoring Software Capabilities

A brief listing is provided here of the types of testing and reporting that should be available as part of the performance monitoring software:

- *Stiction and hysteresis testing and reporting.* Many plant oscillation problems are caused from poorly operating valves
- *Valve wear analysis.* This analysis compares valve travel and reversals with differing PID tuning values and with and without the use of various types of process variable filters.



Event Log over a 2 week period.

FIG. 2.24c
Part of an event log listing.[1]

- *PV filter analysis.* This analysis finds the largest possible filter that will reduce valve movement but will not inhibit speed of response or reduce robustness.
- *Unfiltering capability.* The software should have the ability to remove the effects of a PV filter so the unfiltered PV can be viewed graphically by the user and the analysis software.
- *Model identification and display.* The model is used by the analysis software for time simulations, robustness analysis, and valve wear analysis. The model should be identified with minimal prior user knowledge of the dynamics; the software should find the best model structure and dead time without the user estimating these. The model can be used by model predictive controllers.
- *Optimal PID tuning.* A variety of methods including set point or lambda tuning should be used to minimize load upsets (minimum IAE).
- *Robustness*. There is always a tradeoff between tuning for fast response and sensitivity to process load changes. Robustness analysis is critical to providing practical PID tuning settings for the loop. Robustness analysis should reflect the changes that occur in process dead time and process gain.
- *Simulating the loop performance using a variety of tuning settings and PV filter values.* Simulations must include both set-point response simulations and responses to load upsets. The simulations should display and compare the performance with both the existing and the proposed settings. Simulations should describe the response of the loop to noise and should compare the response of the model of the process to that of the real process.
- *Linearization analysis including characterization and characterizer builder.* This allows linearization of nonlinear loops through the use of a characterizers. This software should be suitable to both the types of processes whose linearity changes with load and those whose nonlinearity depends on setpoint (pH).
- *Power spectral density.* This allows a detailed analysis plot of power in a signal at all frequencies or periods.
- *Statistical analysis including a histogram.* This allows for the generation of statistical comparisons to evaluate and document the benefits of work done.
- *Time line analysis.* This analysis describes time relationships between components.
- *Integrated reporting.*

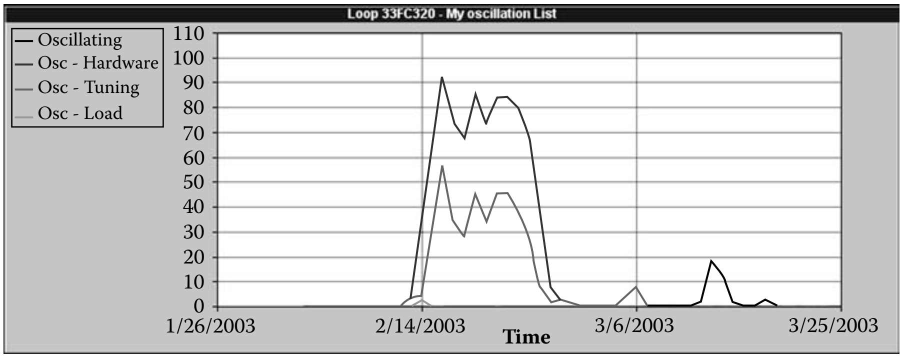

FIG. 2.24d
The oscillation of a flow loop on a paper machine was detected by the assessments of "oscillation detection" and "oscillation from tuning," signaling a need to re-tune the PID when the paper grade is changed.[1]

CASE STUDIES

Model Predictive Controlled Refinery

In a refinery, model predictive controllers (MPC) tend to move the process toward its constraints as far as possible to maximize the resulting economic gain. How close the controller can push the process to its constraints is related to setpoint crossings, average absolute error, and variability. These criteria of assessments infer the ability of the control loop to closely approach the constraint. High-quality performance is indicated when this assessment value is low and if the baselines are lower than thresholds.

In order for an MPC controller to work, the loops tied to it need to be in their normal operating mode and not at a limit. The assessments "time in Normal" and "output at a limit" assess the performance of these. Time in Normal should be maximized and should have a high baseline and low threshold whereas output at a limit should be minimized: it should have a low baseline.

In a fluidic catalytic cracker the side valves are very expensive—costing upwards $100,000 each, and the entire unit must be shut down when the valve needs service. Therefore, the assessments of "valve reversal" and "valve travels" can be used to measure the wear and tear on these valves. The lower the assessment values the better. Baselines should be low and thresholds high for these assessments.

Grade Change in a Pulp Mill

Figure 2.24d describes the assessment of the oscillation of a flow loop in a pulp mill. The two lines reflect the assessments of "oscillation detection" and "oscillation from tuning" or a diagnosis that the oscillation was caused by the PID controller with the wrong tuning settings.

Later, it was learned that the plant changed the paper grade, which would have required re-tuning and resulted in oscillation. It was noted that oscillation can be avoided if the tuning settings are automatically changed whenever that grade of paper is run.

CONCLUSIONS

Assessing the performance of a plant in real time requires the careful selection of the appropriate software, but the benefits are also compelling. Process plants will benefit from considering this option.

2.25 Relative Gain Calculations

B. D. CAMPBELL, P. G. FRIEDMANN (1995) **F. G. SHINSKEY** (2005)

Most processes require multiple control loops to operate efficiently, and these loops usually do not act independently. Changes made in the output of one controller can be a source of upset to another loop. That interaction may pass in one direction only; for example, changing the feed rate to a process upsets the composition of the product leaving it. However, there are also processes where the disturbed controller responds by sending another disturbance back to the first loop. For example, a top-composition controller on a distillation column manipulating reflux flow can upset bottom composition, whose controller manipulating heat input reacts by upsetting top composition. This *bidirectional* interaction comprises an additional feedback loop passing through both controllers in series and is a cause of instability to the process.

When two or more manipulated variables affect a single controlled variable, or when a single manipulated variable affects two or more controlled variables, a question arises of how best to pair the manipulated and controlled variables together in closed loops. With a two-loop process, only two possible single-loop structures exist: variable c_1 can be controlled by manipulated variable m_a and variable c_2 controlled by m_b, or vice versa. If one pairing, say c_1-m_a and c_2-m_b, performs well, the other pairing will not and may even be unstable. It is also possible that both pairings will perform equally poorly. In some cases, the more-effective pairing may be obvious, but in others it will not. The number of possible single-loop structures increases factorially with the number of loops, reaching 120 for a five-loop distillation column.

The relative gain method of interaction analysis solves this problem, providing a quantitative measure of loop interactions that is surprisingly easy to use and universally applicable. The relative gains calculated are dimensionless numbers arranged in an array, which by their values indicate the best single-loop pairings and where decoupling is advisable. The method was first proposed by Bristol,[1] and it was then named and applied by Shinskey.[2,3] Its applications include integrating processes[4,5] and those with unequal numbers of manipulated and controlled variables.[6] It has been extended to include dynamic considerations[7] in the analysis of interactions.

Much of the Relative Gain Array (RGA) literature is devoted to distillation,[8–10] particularly to top and bottom composition control. Relative gain calculation for distillation applications is covered in Chapter 8 of this book. Other applications include power systems, blending, combustion, and heat transfer controls.

This section presents the computation, interpretation, and application of relative gain arrays. It also provides examples that illustrate RGA application to simple processes.

THE RELATIVE GAIN ARRAY

The relative gain for a selected pair of variables is defined as the ratio of the open-loop gain for that pair with all other loops open to their open-loop gain when all other loops in the process are closed, with their variables held at set point by their controllers:

$$\lambda_{ij} = \frac{\left.\dfrac{\partial c_i}{\partial m_j}\right|_m}{\left.\dfrac{\partial c_i}{\partial m_j}\right|_c} \qquad 2.25(1)$$

where λ_{ij} is the relative gain of any pair of variables c_i controlled by manipulating m_j. The numerator is the open-loop gain determined with all other manipulated variables constant, and the denominator is the open-loop gain determined with all other controlled variables constant, which literally applies to a steady state. Therefore the above applies strictly to steady-state gains.

Because the same dimensions appear in both numerator and denominator, the relative gain numbers are dimensionless. They are also independent of scale and of common terms appearing in both open-loop gains. They are unaffected by nonlinearities at any given operating point. If the process is nonlinear, however, the calculated relative gains can be expected to change with the operating conditions.

The RGA is a table of λ_{ij} values arranged in rows c against columns m:

$$\Lambda = \begin{array}{cccccc} & m_1 & . & . & m_n \\ c_1 & \lambda_{11} & . & . & \lambda_{1n} \\ . & . & . & . & . \\ . & . & . & . & . \\ c_n & \lambda_{n1} & . & . & \lambda_{nn} \end{array} \qquad 2.25(2)$$

where n is the number of variable pairs in the system. An important property of the RGA is that the numbers in each of the columns and each of the rows add to 1.0. To fill out a 2×2 array, then, only one λ needs to be calculated; the others in the same row and the same column are complementary, and the diagonal value is identical. To fill out a $n \times n$ array then, $(n-1)^2$ values must be calculated. An important corollary to this property is that for every λ that exceeds 1.0, there must be a negative number in the same row and in the same column, and control-loop pairs with negative numbers, as described below, must be avoided.

Properties of λ

The values of λ cover all possible numbers from –infinity to + infinity. They can be separated into six distinct regimes, each with its own set of properties.

λ = 1.0 The most desirable value of λ is 1.0, which indicates that numerator and denominator of Equation 2.25(1) are equal. This means that the closing of other loops has no effect on the behavior of the loop being examined. So in evaluating an RGA, it is advisable to connect those loops having relative gains close to 1.0. This is not an absolute guarantee of best performance because it does not include dynamic considerations, but it does guarantee steady-state stability. One-way interaction could still exist: if either m_j does not upset other controlled variables, or c_i is not affected by other manipulated variables, the relative gain will be 1.0. But without two-way interaction, no hidden feedback loops exist, and hence the stability of the loop in question is not affected by the closure of other loops.

λ = 0 If λ is zero, it is because the numerator in Equation 2.25(1) is zero, but the denominator is not. In this case, the loop in question cannot be closed successfully alone, but could possibly control quite well when the other loops in the system are closed. This is usually the case when one of the other controlled variables is liquid level. A continuous process must have its level loops closed before any of the others can function properly. In a complex multivariable process such as distillation, it is usually necessary to assign the level loops first and then evaluate the relative gains of the composition loops. This eliminates zeros from the RGA. This procedure is described in detail in Section 8.20.

λ = ±∞ As the denominator in Equation 2.25(1) approaches zero, λ will approach infinity, and a plus-infinity anywhere in the array will require a minus-infinity in the same row and in the same column. These loops cannot be controlled independently because the variables have essentially the same effects on each other. While calculating a result of infinity is not always achievable, any relative gain whose absolute value exceeds 100 qualifies — the variables are essentially dependent and the loops should not be closed.

λ < 0 Negative relative gains indicate the presence of conditional stability because the numerator and denominator in Equation 2.25(1) have opposite signs. If the loop in question has been configured to be a negative feedback loop while other loops are open, it will become a *positive feedback loop* when the others are closed. Positive feedback causes the controlled variable to run away from set point rather than approach it and so must be avoided in a regulatory system.

It is possible to reconfigure the loop in question to have negative feedback when the other loops are closed by reversing the action of one controller. But its dynamic response will be poor because it contains additional process elements, along with other controllers. However, the principal danger is that the opening of another loop, either by placing its controller in manual or by its output reaching a limit, will leave the reconfigured loop as positive feedback. Therefore, loops with negative relative gains should never be connected.

0 < λ < 1.0 Relative gains in the zero to one range indicate the existence of an additional *negative* feedback loop formed by interaction. If $\lambda = 0.5$, that loop is as strong as the intended single loop, and lower values indicate it is even stronger. To return the intended loop to the same stability it had when operating alone, the proportional gain of the controller would have to be multiplied by λ. The additional feedback loop contains more dynamic elements as well, requiring an increase in integral time. Two-by-two systems where all the relative gains are 0.5 are common; an example is control of boiler pressure and flue-gas oxygen by fuel and air flows. Since neither configuration of single loops is effective, decoupling is required. In the case of the boiler, flue-gas oxygen content is controlled by the fuel-to-air ratio.

λ > 1.0 Relative gains > 1.0 indicate the existence of an additional *positive* feedback loop formed by interaction. As that loop increases in strength, λ also increases. (When the positive feedback loop dominates, λ is negative.) The positive feedback loop has 180 degrees less phase shift than the negative feedback loop and therefore does not significantly slow the dynamic response of the negative feedback loop. In the case of two interacting loops having similar dynamics and $\lambda = 10$ or more, both controller gains need to be halved when both loops are closed, but integral and derivative settings may be left as they were for single-loop operation.

CALCULATION METHODS

The RGA can be evaluated in a number of different ways, with the choice depending on the availability of information about the process to be controlled.

The Ratio of Partial Derivatives

This method solves Equation 2.25(1) directly for each of the needed $(n-1)^2$ elements in the array. The numerator is obtained by a partial derivative of c_i with respect to m_j in

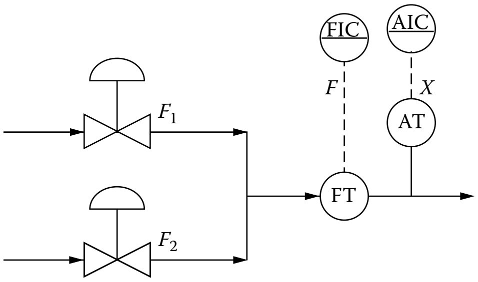

FIG. 2.25a
A simple two-component blender has two interacting loops.

terms of the other manipulated variables held constant. As an example, consider the blending of two streams into a single product of composition x flowing at rate F, as shown in Figure 2.25a. The total flow is the sum of the two manipulated flows:

$$F = F_1 + F_2 \tag{2.25(3)}$$

where the individual flows are expressed as linear with controller output. (Relative gain is independent of nonlinearities and common factors, allowing such simplifications.) Then,

$$\left.\frac{\partial F}{\partial F_1}\right|_m = 1.0 \tag{2.25(4)}$$

To formulate the denominator, the partial differentiation has to be repeated in terms of the other controlled variable, in this example, x. Let stream 2 contain none of the measured ingredient, and stream 1 have a concentration of $x_{\max}$. Then the concentration in the blend will be

$$x = \frac{x_{\max} F_1}{F} \tag{2.25(5)}$$

Now the partial may be evaluated in terms of x:

$$\left.\frac{\partial F}{\partial F_1}\right|_x = \frac{x_{\max}}{x} \tag{2.25(6)}$$

Dividing the first partial by the second gives the relative gain:

$$\lambda_{F1} = x/x_{\max} = x' \tag{2.25(7)}$$

The RGA then looks like this:

$$\begin{array}{ccc} & F_1 & F_2 \\ \Lambda = F & x' & 1-x' \\ x & 1-x' & x' \end{array} \tag{2.25(8)}$$

This method gives the advantage of a solution in terms of the variables themselves, in this case x. The solution then applies generally to a class of processes, e.g., two-component blending, where it can be used again.

Two Loops Open

Process models are often formulated as a set of linear equations with gains K:

$$\begin{aligned} c_1 &= K_{11}m_1 + K_{12}m_2 \\ c_2 &= K_{21}m_1 + K_{22}m_2 \end{aligned} \tag{2.25(9)}$$

If the process is limited to two pairs of variables, a simple formula applies:

$$\lambda_{11} = \frac{1}{1 - K_{21}K_{12}/K_{11}K_{22}} \tag{2.25(10)}$$

This formula gives some important insights. If there are an odd number of negative signs among the gains, λ_{11} will fall between zero and 1.0. Otherwise, λ_{11} will fall outside of that range and be negative if the product of the off-diagonal gains exceeds that of the diagonal gains — dominant positive feedback.

Two Loops Closed

Some process models solve for values of the manipulated variables that will produce designated values of the controlled variables:

$$\begin{aligned} m_1 &= H_{11}c_1 + H_{12}c_2 \\ m_2 &= H_{21}c_1 + H_{22}c_2 \end{aligned} \tag{2.25(11)}$$

Again, for two pairs of variables, we have the same formula:

$$\lambda_{11} = \frac{1}{1 - H_{21}H_{12}/H_{11}H_{22}} \tag{2.25(12)}$$

The Two-Slope Method

Open-loop testing can provide still another way to calculate relative gains in a two-loop system. From a steady state, m_1 can be stepped with m_2 constant, and the resulting changes in the two controlled variables divided. The ratio of their changes $(\Delta c_1/\Delta c_2)_{m2}$ is also the ratio K_{11}/K_{21}. Then m_2 is stepped with m_1 constant, with these changes divided, $(\Delta c_1/\Delta c_2)_{m1}$ being the same as the ratio K_{12}/K_{22}. Substitution of those ratios into Equation 2.25(10) gives

$$\lambda_{11} = \frac{1}{1 - (\partial c_1/\partial c_2)_{m1}/(\partial c_1/\partial c_2)_{m2}} \tag{2.25(13)}$$

This formula applies particularly well to distillation composition loops, where the product compositions can be plotted against one another while various manipulated variables are held constant. This is the method used in Section 8.20.

The Matrix Method

Equations 2.25(9) and 2.25(11) are sets of linear simultaneous equations that can be expanded to any number of variables. When the number exceeds two pair, however, it is easier to express the relationships using matrix algebra. Accordingly, Equation 2.25(9) could be expressed as

$$\mathbf{c} = \mathbf{K}\mathbf{m} \qquad \mathbf{2.25(14)}$$

where **c** is a vector of n controlled variables, **m** is a vector of n manipulated variables, and **K** is the $n \times n$ matrix of open-loop gains relating them. Similarly, Equation 2.25(11) could be expressed as

$$\mathbf{m} = \mathbf{H}\mathbf{c} \qquad \mathbf{2.25(15)}$$

Matrix **H** is the inverse of matrix **K** (but its elements are not the inverse of the elements in the **K** matrix):

$$\mathbf{H} = \mathbf{K}^{-1} \qquad \mathbf{2.25(16)}$$

If one matrix is available, the other may be obtained by inverting it using standard matrix inversion procedures. Then each relative gain element λ_{ij} may be found by multiplying the element K_{ij} by the corresponding element H_{ji}:

$$\lambda_{ij} = K_{ij} \cdot H_{ji} \qquad \mathbf{2.25(17)}$$

The subscripts are reversed because H_{ji} relates c_i and m_j, as does K_{ij}.

Where a zero appears in the **K** matrix, one will also appear in the RGA. Other than that observation, the calculations need to be done to determine the RGA. A numerical example follows. Given that

$$\mathbf{K} = \begin{bmatrix} 2.2 & 0.80 & 0.40 \\ 1.2 & 1.6 & 0 \\ 0 & 0.70 & 0.50 \end{bmatrix}$$

Then

$$\mathbf{H} = \begin{bmatrix} 0.495 & -0.074 & -0.396 \\ -0.371 & 0.681 & 0.297 \\ 0.520 & -0.953 & 1.584 \end{bmatrix}$$

and

$$\Lambda = \begin{bmatrix} 1.089 & -0.297 & 0.208 \\ -0.089 & 1.089 & 0 \\ 0 & 0.208 & 0.792 \end{bmatrix}$$

The best pairing appears to be along the diagonal—not surprising, given the two off-diagonal zeros.

Reducing the Array

Arrays larger than 3 × 3 may present misleading information, principally due to dynamic effects. In general, fast loops can upset slow loops, but slow loops cannot upset fast ones. In this light, the pairing of the fast loops in a system can be arbitrarily assigned, reducing the array to include only the slower loops. This is the approach used to evaluate relative gains for distillation in Section 8.20. A typical column has five loops: two compositions, two levels, and one pressure. Arbitrary assignment of the level and pressure loops reduces the RGA to the two composition loops. However, there are several of these 2 × 2 RGAs to be evaluated, one for each assignment of the level and pressure loops. Each of these RGAs needs to be evaluated to determine which has the most favorable relative gains.

DECOUPLED RELATIVE GAINS

Relative gain analysis is not limited to evaluating interactions among single loops. Controller *outputs* can drive mathematical combinations of manipulated variables, such as their sums, differences, or ratios. Controller *inputs* can also be mathematical combinations of controlled variables. Selection of these functions should be logical and meaningful to those who operate the loops.

Partial Decoupling

As an example, return to the blending system of Figure 2.25a. The composition of the blend is obviously determined by the ratio of the two feed flows, F_1/F_2. The output of the composition controller then ought to manipulate that ratio, rather than one of the individual flows. This is done by inserting a multiplier [×] in the output of the composition controller, as shown in Figure 2.25b. The other input to the multiplier is

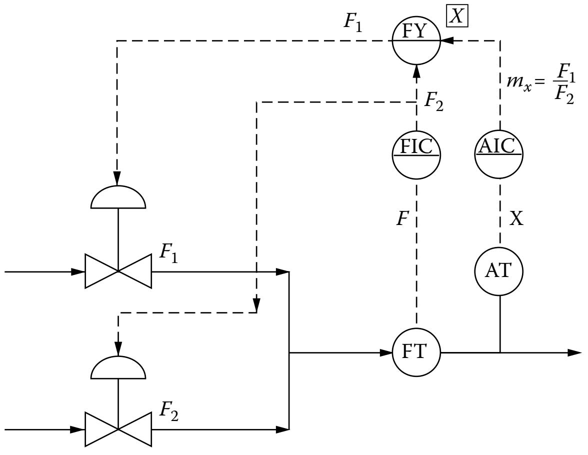

FIG. 2.25b
Partial decoupling is enough to drive relative gains to one and zero and protect the costly variable against upset.

F_2, and the output of the multiplier is the driven value of F_1. Calculating F_1 from F_2 in this way means that the controller output $m_x = F_1/F_2$.

To evaluate the effectiveness of this configuration, it is only necessary to calculate one gain. Beginning with Equation 2.25(5), we substitute for F_1—which is no longer an independent manipulated variable—the product m_xF_2:

$$x = x_{\max}\frac{F_1}{F_1+F_2} = x_{\max}\frac{m_xF_2}{m_xF_2+F_2} = x_{\max}\frac{m_x}{m_x+1} \tag{2.25(18)}$$

As can be seen, the second manipulated variable F_2 drops out of the equation, leaving composition x unaffected by it:

$$\left.\frac{\partial x}{\partial F_2}\right|_{mx} = 0 \tag{2.25(19)}$$

With its numerator at zero, $\lambda_{x2} = 0$. Then the RGA becomes

$$\Lambda = \begin{array}{ccc} & m_x & F_2 \\ F & 0 & 1 \\ x & 1 & 0 \end{array} \tag{2.25(20)}$$

The system is now decoupled.

However, the configuration in Figure 2.25b is only a *partial* decoupler. While composition is no longer upset by changes in the output of the flow controller, total flow *is* changed every time the composition controller moves its output. This is not usually considered a problem because the flow loop is so much faster than the composition loop. The output of the composition controller will tend to move so slowly that any upset in total flow will be small and easily corrected by the faster flow controller.

Partial decouplers are usually preferred to full decouplers in that they accomplish the principal objectives of eliminating the third feedback loop—which created the stability problem—and of protecting the slower and more costly variable from upsets. A full decoupler, which would only provide the (unnecessary) protection of the faster variable, also adds a potentially dangerous feedback loop[11] and complicates operation of the system.

It will be observed that a partial decoupler is implemented in the same way as a feedforward loop. There is no real distinction between them. Feedforward uses an independent load variable and the output of a feedback controller to calculate its manipulated variable, whereas a decoupler uses another manipulated variable in place of the load. Both protect the controlled variable from disturbances, but the decoupler also breaks a hidden feedback loop.

2.26 Robustness: A Guide for Sensitivity and Stability

J. P. GERRY (2005)

In process control there is always a tradeoff between good, stable performance and speed of response or sensitivity to process or set point changes. This sensitivity of the control system can be called the robustness of the loop. Understanding the tradeoff between control loop robustness and stable (optimal) controller performance is important to achieving good control system design.

The system robustness is quantifiable and can be shown graphically, which makes it easier to examine the tradeoff between sensitivity and stability of the loop.

ROBUSTNESS PLOTS

Figure 2.26a shows process dead time on the vertical axis plotted against process gain on the horizontal axis. If the control loop or the controlled process is located on this plot, that can be called the robustness plot of the loop or process.

On a plot of robustness, a line separates the region in which the control loop will be stable and the area where it will not. As shown in Figure 2.26b, the two regions are separated by a line, which is the curve of marginal stability. A control loop is marginally stable if it responds to an upset by the controlled variable drawing a sine wave and the loop sustaining that oscillation.

An increase in either the gain or the dead time of the control loop will make it less stable; the curve shows the values of various combinations of loop gain and dead time at which the control loop will become marginally stable. As was shown in Figure 2.1x, the gain of the loop is the product of the process and the controller gains, while the dead time of the loop is the sum of the process and controller dead times.

In the lower left region of the plot, the process gains and dead times are the smallest. Hence the lower left area of the plot represents a region where the control loops are likely to be stable. Conversely, in the upper right area of the plot, they are likely to be unstable. Areas above and to the right of the marginal stability curve define the unstable region. Areas below and to the left of the marginal stability curve represent a stable region.

On Figure 2.26b, a cross identifies the control loop in its present state. The location of the cross corresponds to the dead time and gain of the controlled process or of the loop. In order to easily compare the effects of the various control loop configurations that are being evaluated and their corresponding robustness, the scales of the two axes of the plots are adjusted

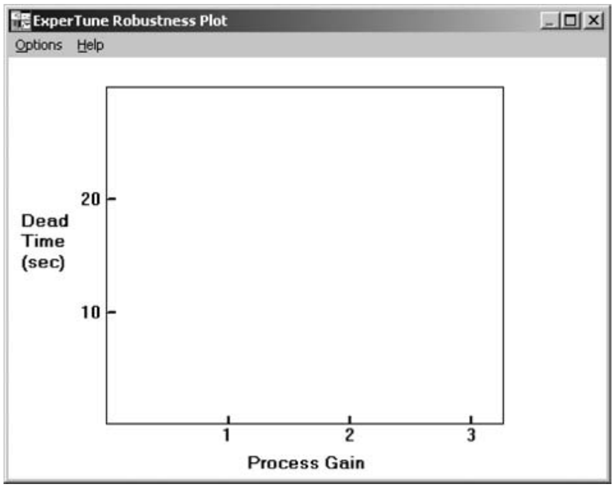

FIG. 2.26a
The process robustness plot locates the particular control loop on a plot of process dead time against process gain.

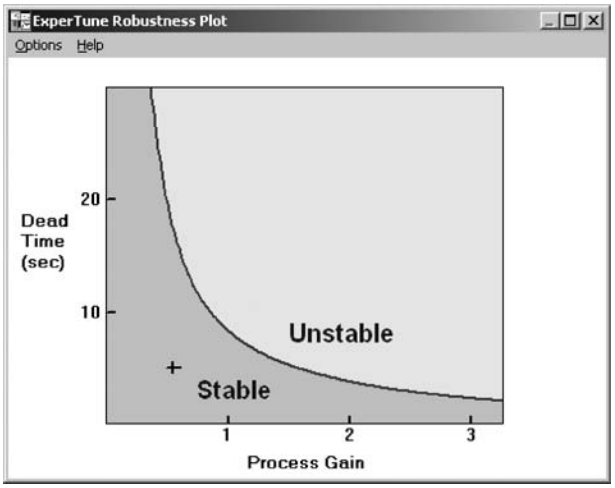

FIG. 2.26b
The marginal stability line separates the stable area from the unstable region on a robustness plot.

so that the current system gain and dead time (see cross in Figure 2.26b) occur at the same location on every plot.

Dynamic Parameters

Dead time is the limiting element of good control performance and robustness, yet almost all control loops contain some dead time. The small dead times and transportation lags of the control loop add up and combine to form the total loop dead time.

Changes in time constants (lags) change the shape of the marginal stability curve. Large lags and integration times affect the low-frequency stability of the loop; hence, the upper left portion of the marginal stability curve will change the most. Changing high-frequency components of the controller, such as the derivative mode settings, will change mostly the shape of the lower right portion of the curve.

Gain is used as the other axis of the robustness plot. System gain is the product of all the gains in the loop, including the process gain and controller gain. Changing any of the gains in the loop will shift the marginal stability curve to the left or right, but the shape of the curve will not change. Increasing the loop gain will move its operating point (cross in Figure 2.26b) closer to the marginal stability curve and closer to instability.

As the dynamics of a loop move down and to the right on the marginal stability curve, the frequency of sustained oscillation will increase.

Design Guidelines

Figure 2.26c shows a recommended region for design stability. The four-sided object in Figure 2.26c has four corners at a factor and divisor of two in both the gain and dead time axis. The top corner of the object represents twice the system dead time with the gain unchanged, and the bottom corner of the object represents half the system dead time. The right corner of the object represents twice the system gain with the dead time unchanged. The left corner represents half the system gain. The four corner points are connected with curving lines that on a log–log plot would be straight.

This recommended safe operating area is used because a factor of two is often considered a reasonable safety margin for operating process control systems.

With a design goal of a stability margin of two in any direction, the noted region represents the area that the marginal stability line should not touch or cross. If the marginal stability line moves inside this region, the margin of stability would drop below two. The purpose of identifying such a safe operating area is not to set a hard rule but only to provide a design aide.

EXAMPLE

In Figure 2.26c, the control loop shown by the cross has a dead time of 5 seconds and an overall system gain of 0.5. If the dead time of this control loop remained constant while the gain of the loop increased, this would shift the cross that represents the loop dynamics horizontally toward the right. If the system gain were to increase by a factor of three (to about 1.5), the cross would reach the curve of marginal stability, and the control loop would become marginally stable.

If the gain of this control loop remained constant while its dead time increased, this would cause the cross, representing the control loop, to move vertically upwards. If the dead time of the loop increased by a factor of three (to about 15 seconds) the cross would reach the curve of marginal stability, and the loop would become marginally stable.

If both the gain and dead time of the loop increased, this would result in moving the cross, which represents the control loop dynamics up and to the right; with enough of an increase the system would become unstable when the marginal stability line was crossed.

Figure 2.26d illustrates the condition when the control loop gain has increased, shifting the curve to the left, reaching marginal stability. When this happens, the control loop itself becomes unstable. This means that the

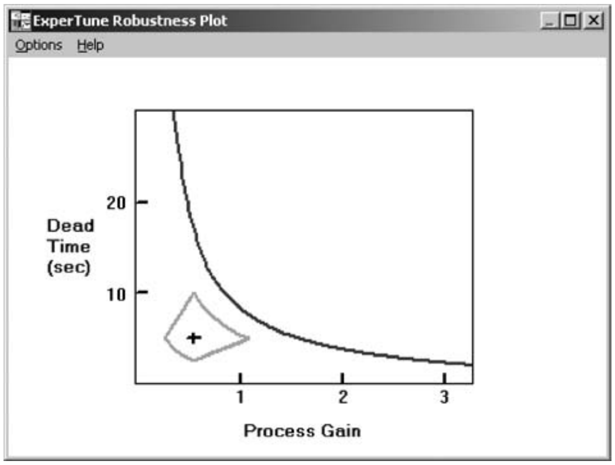

FIG. 2.26c
Robustness plot showing the recommended safe operating area for a control loop that will maintain a stability margin of two.

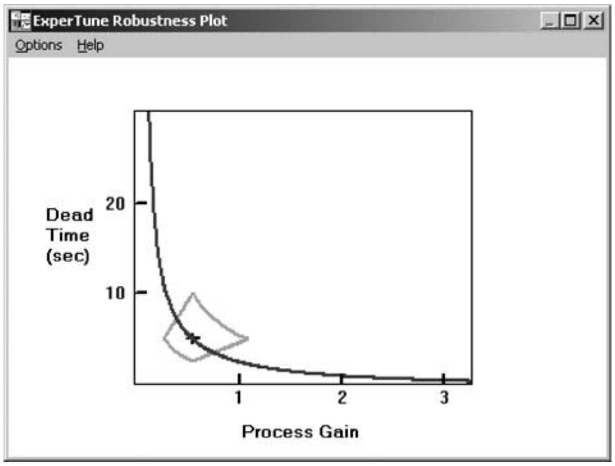

FIG. 2.26d
Robustness plot illustrating a condition where the control loop is in sustained oscillation.

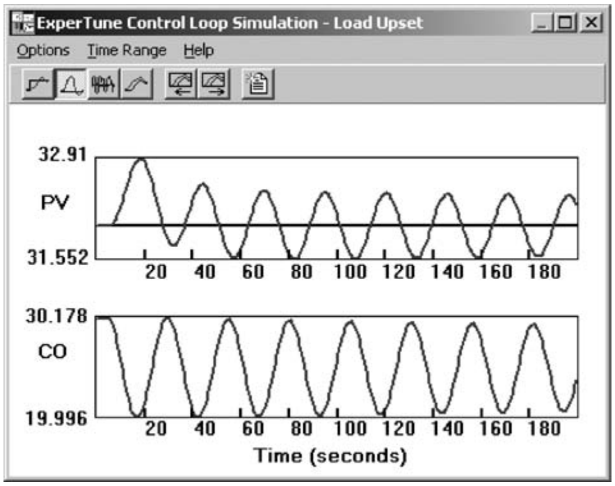

FIG. 2.26e
When the control loop has reached the state of marginal stability, both the controlled (PV) and the manipulated (CO) variables are in sustained and undampened oscillation.

controller output (manipulated variable) starts to cycle and as a consequence, the controlled process variable (PV) will also start to cycle.

Figure 2.26e illustrates this marginal stability condition where both the controlled and the manipulated variables (PV and CO) are in continuous, undampened oscillation. If the control loop dynamics worsened and moved further into the unstable region in Figure 2.26d, the sustained, undampened oscillation would turn into runaway oscillation. Under these conditions, if some safety constraint does not shut the system down, accidents can occur.

CONCLUSION

A balance between loop sensitivity and stability always exists. When tuning a control loop (see the later sections in this chapter on tuning), the goal should always be to reach a reasonable balance between the two goals. Robustness plots can be convenient graphical tools because they can show the safety margin that the control system has before it would become unstable.

2.27 Sampled Data Control Systems

J. HETTHÉSSY, R. BARS (2005)

The main characteristic of digital control is that it utilizes and operates on sampled data. This section discusses the nature and characteristics of SDCS (sampled data control systems), which in this age of the computer, tend to dominate process control. The section also describes the nature and the mathematical derivation of the various digital control algorithms.

Although simple examples are used to illustrate the theoretical background, the mathematical steps involved in the development of these control algorithms can be useful to those readers who are involved in the design of digital algorithms. The section concludes with a discussion of Smith predictors, used to control dead time processes and with such practical issues as the selection of the sampling frequency in digital control.

SAMPLED DATA CONTROL SYSTEMS

The configuration of a sampled data control system is shown in Figure 2.27a. In this section it will be assumed that the controlled processes are continuous and that both the manipulated variables sent to the process and the measurement signals received from the process are also continuous. These continuous (analog) signals are made available for digital processing by A/D converters to provide the data in discrete form as a sequence of numbers. Consequently, the analog world of the process is interfaced to the world of digital computations.

A/D and D/A converters implement this interface. As shown in Figure 2.27a, a real-time clock is governing the operation of the digital computer by controlling the sampling and holding of data.

Symbols Used

In this section, in order to distinguish the analog and discrete versions of the signals involved in sampled data control systems, the following notations will be used:

- $x(t)$: continuous-time signal
- $x[k] = x(kh)$: discrete-time signal, where h denotes the sampling time and $k = 0, 1, 2, \ldots$ assigns the sampling instant

Sampling according to $x[k] = x(kh)$ is also called mathematical sampling. The heart of the control scheme is a digital control algorithm realized in a real-time software environment. The interfaces applied are to accomplish the following functions:

- Sampling the analog process variables to deliver discrete-time information for the control algorithm
- Delivering control signals calculated by the control algorithm for the actuators
- Receiving set-point requests from the man–machine interface (MMI) or via the communication network

In the field of process control, as elsewhere, there is a general trend toward digital implementations. The advantages of sampled data control systems over their analog counterparts can be listed as follows:

- The digital technology applied is more reliable and cheaper.
- Flexibility is superior, considering both the implementation and the variety of the control algorithms.
- Possible modifications and/or extensions are easier to accomplish.
- Accuracy is kept constant over a long period of time.
- It is simple to deliver the set-point value for the controller, to overwrite the controller parameters, as well as to monitor the controller operation.

On the other hand, special care is required in the following areas:

- Between two samples, the control system is left to operate in open loop.
- The sampling rate should be carefully selected to be in harmony with the dynamics of the process and to comply with the capabilities of the real-time environment (performance and the number representation applied).
- The output of the digital controller (also called the manipulated variable) must be interpolated from a digital sequence to a continuous-time function, thus the waveform of the control signal is limited.
- Sampling introduces additional difficulties when the process dynamics are nonlinear or contain substantial dead time.

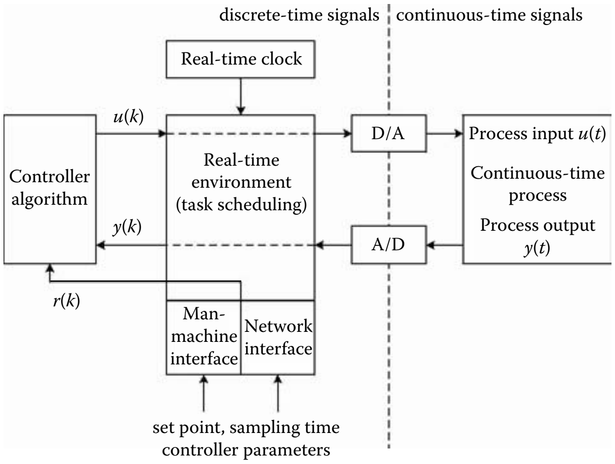

FIG. 2.27a
The main components of sampled data control systems.

Properties of SDCS

Figure 2.27a shows a simplified block diagram of a digital control system. Note that the holding device is an absolutely necessary component in sampled data control systems because the continuous process needs to be controlled by a continuous signal. To generate the analog signals, D/A converters are used. They are updated in each sampling period and this results in a staircase-type output (see Figure 2.27b).

The digital computer provides wide flexibility in the availability of control algorithms. In this section only linear, single-input single-output control systems having one degree of freedom are discussed.

EXAMPLE

In this discussion, the terms and concepts developed in the age of analog control will be used; however, none of the results will automatically be reused. To illustrate, consider the following continuous process:

$$P(s) = \frac{1}{(1+5s)(1+10s)} \qquad \textbf{2.27(1)}$$

which is closed-loop controlled and controlled by a proportional controller $C(s) = K$. According to the classical control theory, any $K > 0$ will stabilize the system because the loop transfer function $L(s) = KP(s)$ exhibits a *structurally stable* system.

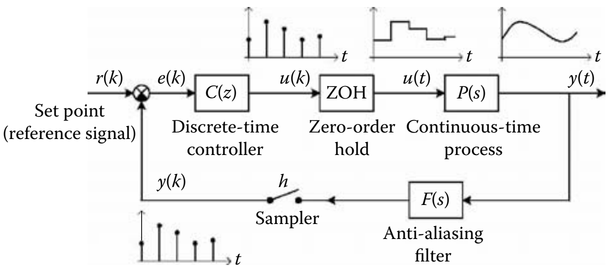

FIG. 2.27b
The components and signals used in sampled data control systems.

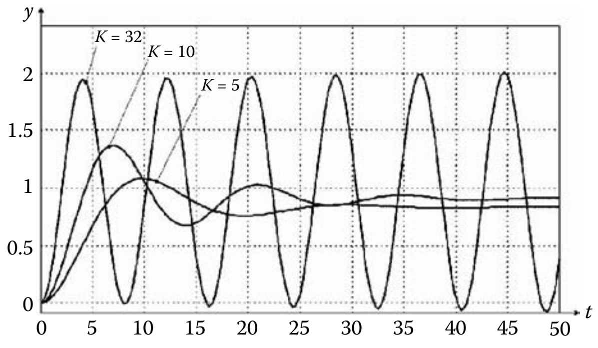

FIG. 2.27c
Step responses of the closed-loop system at various controller gains. The controlled variable (y) becomes unstable when the gain of the plain proportional controller reaches K = 31.2.

Now consider the sampled data version of the control loop using a sampling time of $h = 1$ sec. Figure 2.27c shows the results obtained as a function of the gain settings of the proportional-only controller. Unlike the analog control loop, the digital sampled data version will go unstable when the gain is $K > 31.6$. A quick stability analysis can verify this, but first a conceptual explanation is desired.

Figure 2.27d illustrates the effect of sample and hold (S&H) on detecting a sinusoidal input and generating a staircase-type output. A phase delay exists between the analog sinusoidal signal and the first harmonic component of the output generated by the holding device. The size of this delay depends on the sampling time and the frequency of the sinusoidal signal applied; in this example, it is around the half of the sampling time. The consequence is that the zero-order holding (ZOH) device introduces a time delay; thus, the structural stability is lost.

Mathematical Aspects of SDCS

Sampling In this section, for the sampling of analog signals, *periodic sampling*, where the sampling instants are equally spaced, will be considered. The frequency of the sampling is considered to be correct if the spectrum represented by the samples is identical to the spectrum of the converted analog signal. Shannon's sampling theorem says that if an analog signal contains no frequencies above $\omega_{\max}$, then it can be

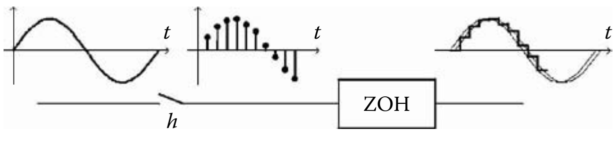

FIG. 2.27d
The effects of sample and hold (S&H) and of zero-order hold (ZOH) in signal conversion.

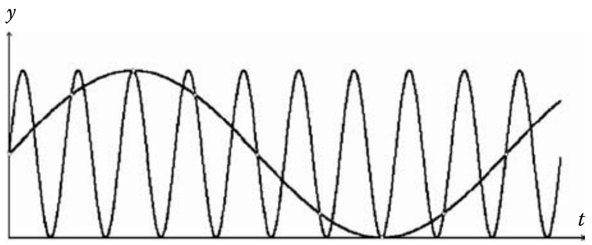

FIG. 2.27e
When sampling a high-frequency sinusoidal analog signal at a slow sampling rate, the analog signal will appear to be of low frequency due to the aliasing (frequency folding) effect.

completely reconstructed from its samples if $\omega_s \geq 2\,\omega_{\max}$ holds for the sampling frequency ω_s.

On the other hand, if the sampling rate is not high enough, a high-frequency analog signal will be interpreted as a low-frequency signal. This phenomenon is called *aliasing* or *frequency folding.* Figure 2.27e, where samples of a high-frequency sinusoidal signal appear to be a low-frequency signal due to aliasing, illustrates this phenomenon. To avoid aliasing, a low-pass filter (also called an antialiasing filter) must be placed between the analog measurement signal and the A/D converter. The purpose of the low-pass filter is to filter out the signal components above the frequency of $\omega_{\max}$.

Zero-Order Hold (ZOH) The function of the ZOH unit is to generate an output at the instant of sampling that is identical to its input and to hold this value constant for the rest of the cycle, until it is time for the next sample to arrive. Figure 2.27f verifies that a parallel combination of an integrator by $1/s$ and a delayed integrator by $e^{-\mathrm{sh}}/s$ satisfies this required functionality. Thus the transfer function of the zero-order hold unit is

$$G_{\mathrm{zoh}}(s) = \frac{1-e^{-\mathrm{sh}}}{s} \qquad \textbf{2.27(2)}$$

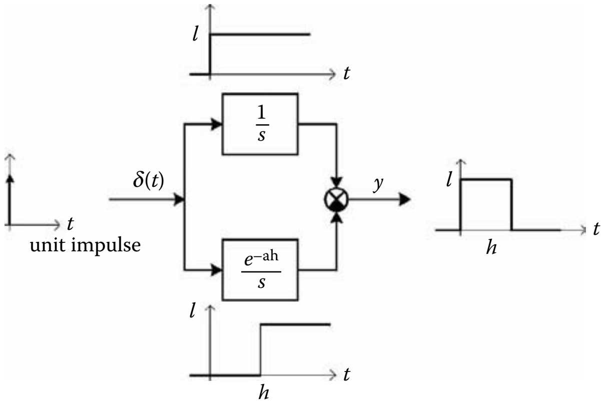

FIG. 2.27f
The transfer function of the zero-order hold (ZOH) unit.

Discrete-Time Models One way to describe discrete-time systems in the time domain is to express the input/output relation by a *difference equation,* e.g.,

$$\begin{aligned} &y[k+2]-1.7236y[k+1]+0.7408y[k] \\ &\quad = 0.0091u[k+1]+0.0082u[k] \end{aligned}$$

To derive a more compact form, one may introduce the forward shift operator q as follows:

$$qx[k] = x[k+1]$$

then

$$q^2y[k]-1.7236qy[k]+0.7408y[k]=0.0091qu[k]+0.0082u[k]$$

is obtained.

The most widely used tool to handle discrete-time systems is the Z-transformation defined by

$$Z\{x[k]\} = X(z) = \sum_{k=0}^{\infty} z^{-k}x[k] \qquad \textbf{2.27(3)}$$

where $z = e^{\mathrm{sh}}$ is the operator of the Z-transformation (s is the Laplace operator). Taking the Z-transform of the input and output samples, respectively, *the discrete or pulse transfer function*:

$$G(z) = \frac{Y(z)}{U(z)} \qquad \textbf{2.27(4)}$$

uniquely determines the input/output behavior at the sampling instants, for zero initial conditions.

Discrete-Time Process Models The components of the closed loop shown in Figures 2.27b and 2.27g included both analog and digital (both continuous-time and discrete-time) signals. To set up a closed-loop model with purely discrete transfer functions, the continuous elements between the hold and sample units in the loop should be converted from a continuous to a discrete model. Note that the process and the ZOH are combined and taken into account in the following transformation (see Figure 2.27g):

$$P(z) = Z\{L^{-1}[G_{\mathrm{zoh}}(s)P(s)]_{t=\mathrm{kh}}\} = (1-z^{-1})Z\left\{\frac{P(s)}{s}\right\} \qquad \textbf{2.27(5)}$$

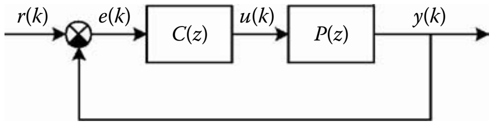

FIG. 2.27g
Components of the discrete-time closed-loop model.

As an example, consider a continuous-time process of

$$P(s) = \frac{1}{(1+5s)(1+10s)}$$

sampled by $h = 1$ sec. Straightforward substitution to Equation 2.27(5) (for those using MATLAB, the c2dm command) gives

$$P(z) = \frac{0.0091z + 0.0082}{z^2 - 1.7236z + 0.7408} = \frac{0.0091(z + 0.9048)}{(z - 0.9048)(z - 0.8187)}.$$

This is exactly the example discussed earlier to illustrate a difference equation form. Note that the numbers in this example indicate a numerical difficulty: the magnitude of the zeros and poles of the discrete transfer function are all close to unity. This is especially true if h is small, selecting, e.g., $h = 0.1$ sec, the discrete-time model turns out to be

$$P(z)\big|_{h=0.1} = \frac{(9.901z + 9.802)\cdot 10^{-5}}{z^2 - 1.9702z + 0.9704} = \frac{9.9006(z + 0.99)\cdot 10^{-5}}{(z - 0.99)(z - 0.9802)}.$$

With $P(z)$ having been introduced according to Equation 2.27(5), now the stability condition referred to earlier can be verified. The closed-loop characteristic equation is

$$1 + K \cdot P(z) = 0$$

or

$$z^2 + (0.0091K - 1.7236) + 0.0082K + 0.7408 = 0.$$

According to $z = e^{sh}$, the left side of the s-plane (i.e., the stability region for the continuous-time systems) is mapped into the unit circle in the z-plane. Consequently, the unit disc represents the stability region for discrete-time systems. For $K = 0$ the poles are located at $p_1 = 0.9054$ and $p_2 = 0.8182$ in the z-plane. For $K > 0$ the poles will move toward the unit circle, and $K = 31.6$ results in closed poles $p_{1,2} = 0.718 \pm j0.696$ just sitting on the unit circle as $|p_{1,2}| = 1$. For $K > 31.6$ the closed-loop poles will be outside of the unit disc leading to an unstable system.

Historically, the *delta transformation* was first introduced as a tool to handle discrete-time systems by

$$D\{x[k]\} = X_\delta(\gamma) = \sum_{k=0}^{\infty}(1+\gamma h)^{-k} x[k]h \qquad \textbf{2.27(6)}$$

where

$$\gamma = \frac{e^{sh} - 1}{h},$$

which involves

$$z = 1 + \gamma h.$$

A key property of delta transforms is that they converge to the associated Laplace transforms as $h \to 0$:

$$\lim_{h\to 0} X_\delta(\gamma) = X(s)_{s=\gamma}.$$

This is why design techniques based on the delta transforms are very close to continuous-time design concepts, especially in case of fast sampling. Also, the numerical difficulties outlined for the Z-transforms are not experienced here. One way to see the numerical difficulties associated with the Z-transforms is to consider the stability region (i.e., the unit disc), which is much smaller than the left side in the s-plane.

Therefore poles and zeros need a precise number representation. Using Z-transforms, the high sensitivity with respect to the changes in the parameters becomes even more serious if a fast sampling rate has been selected. The delta transformation overcomes the numerical difficulties outlined above; here, the stability region expands as the sampling rate becomes faster.

Design Aspects

Recalling the introductory block diagram of sampled data control (Figure 2.27b), the closed-loop system is a hybrid system in the sense that it contains both continuous and discrete components. Consequently, a digital controller can be designed in several ways:

- *Hybrid pole-placement.* This technique is based on the classical pole placement of analog technology. The discrete-time controller is developed in a step-by-step way, where the replacement of a selected pole of the analog process is accomplished by expanding the controller with a discrete-time PI or PD term in each step.
- *Approximate continuous design.* Here too the classical design methods learned from analog practice are utilized such that a continuous controller is designed and then converted to a discrete form.
- *Direct discrete-time design.* In this case a discrete-time model of the process is first developed, and then a discrete-time controller is designed for that model.

Within each of the above classes several approaches are used. It should be emphasized that the actual design method may combine a number of underlying methodologies, such as loop shaping, pole placement, internal model control, and state-variable feedback. In this section, four methods will be described:

- Hybrid pole placement
- Approximate continuous-time design using w or delta transforms
- Dead-beat controller design
- Smith predictor

Some numerical examples will also be described in order to illustrate the characteristic steps involved.

Hybrid Pole Placement In the low-frequency region, sampled data systems can be approximated with their continuous counterparts modified by the addition of some extra dead time. While restricted to manipulations in the low frequency region, this is a convenient and easy method to directly design a discrete-time controller. The design is based on the classical *pole cancellation technique* and evolves by sequentially applying discrete-time PI and PD elements.

In this design, the unfavorable poles of the plant are cancelled by the zeros of the controller. Integrators are introduced, depending on the steady-state accuracy requirements. Finally, a controller gain is chosen to achieve the desired phase margin. Assuming that T_1 is a time constant of the continuous process (typically, T_1 is the largest time constant of the process), which is to be cancelled and to be replaced by a PI element:

$$C_1(z) = \frac{z - e^{-h/T_1}}{z-1} \qquad \mathbf{2.27(7)}$$

Similarly, to cancel a continuous time process pole associated with a time constant T_2, a PD controller element by

$$C_2(z) = \frac{z - e^{-h/T_2}}{z} \qquad \mathbf{2.27(8)}$$

is added (more precisely serially connected) to the PI element.

As more elements are added in a similar way, a controller gain A is determined such that the phase margin exhibited by the frequency function of the loop transfer function $L(z) = C(z)P(z)$ is at a prescribed value (typically ~60°). Note that when using MATLAB for the design, a simple *dbode* MATLAB command delivers the required gain value. The complete discrete-time controller then becomes

$$C(z) = AC_1(z)C_2(z) = A\frac{(z - e^{-h/T_1})(z - e^{-h/T_2})}{(z-1)z} \qquad \mathbf{2.27(9)}$$

EXAMPLE

A continuous-time process can be described by the equation:

$$P(s) = \frac{e^{-s}}{(1+10s)(1+5s)} \qquad \mathbf{2.27(10)}$$

The goal is to design a discrete-time controller by applying a sampling time of $h = 1$ sec to achieve a phase margin $\cong 60°$ and to ensure $j = 1$ (type number) in order to be able to follow a unit step change in the set point with no steady-state error. The discrete-time process model is

$$P(z) = z^{-1}(1-z^{-1})Z\left\{\frac{P(s)}{s}\right\} = 0.0091\frac{(z+0.9048)}{\left(z - e^{-\frac{h}{10}}\right)\left(z - e^{-\frac{h}{5}}\right)z}$$

$$= 0.0091\frac{(z+0.9048)}{(z-0.9048)(z-0.8187)z}$$

Designing the discrete-time controller to cancel the continuous pole at $p_1 = -0.1$ requires that

$$C_{\mathrm{PI}}(z) = \frac{z-0.9048}{z-1},$$

while the pole at $p_2 = -0.2$ is handled by

$$C_{\mathrm{PD}}(z) = \frac{z-0.8187}{z}.$$

Then the controller will have the following form:

$$C(z) = A\frac{z-0.9048}{z-1}\frac{z-0.8187}{z}.$$

Finally, to ensure a phase margin of 60°, assuming a unit step in the set point, A should be set as 15.13. The process input/output plots are shown in Figure 2.27h.

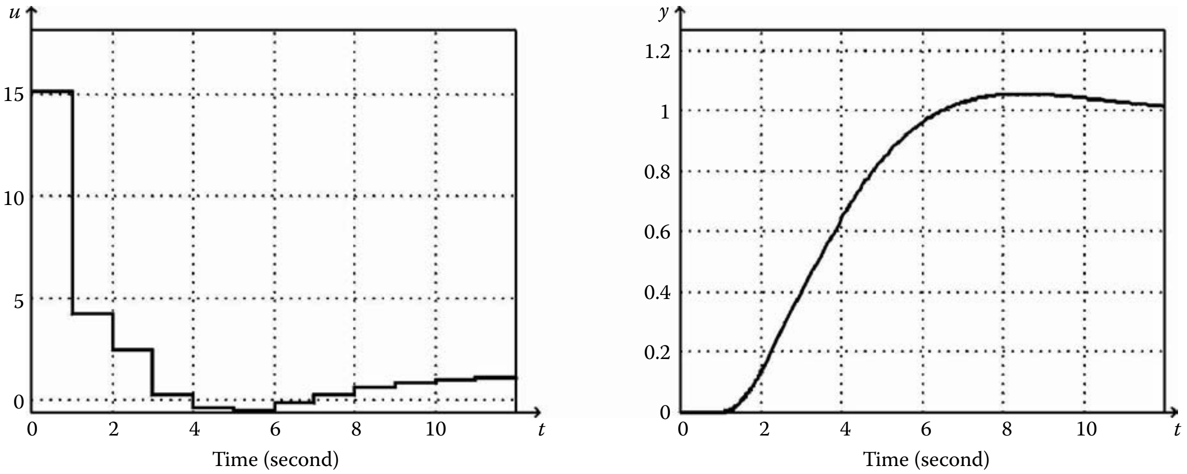

FIG. 2.27h
Records of the manipulated variable (u) and controlled variable (y) when the control algorithm was obtained by the hybrid pole placement design.

Using w or Delta Transforms Another way to utilize the experience with analog design is to combine a continuous-time design technique with a discrete-to-continuous conversion technique.

Design with w-Transforms The concept behind the *w*-transformation (also called Tustin or bilinear transformation) is a numerical integration method performing trapezoidal approximation for each sample period. The approximation leads to the following formula to convert the discrete system to a closely equivalent continuous one and vice versa:

$$w = \frac{2}{h} \cdot \frac{1 - z^{-1}}{1 + z^{-1}}$$

$$z = \frac{1 + \frac{wh}{2}}{1 - \frac{wh}{2}} \qquad \mathbf{2.27(11)}$$

Here *w* stands for a complex frequency operator. The notation $P(w)$ is used for a transfer function of a continuous-time system, indicating that this transfer function has been transformed from a discrete-time system by *w*-transformation. The steps of the design can be summarized as follows:

- Find the discrete-time transfer function of the process and the zero-order hold by using

$$P(z) = (1 - z^{-1}) Z \left\{ \frac{P(s)}{s} \right\} \qquad \mathbf{2.27(12)}$$

- Find the *w*-transform of $P(z)$ by

$$P(w) = P(z)\Big|_{z = \frac{1 + \frac{wh}{2}}{1 - \frac{wh}{2}}}.$$

- Design a continuous-time controller $C(w)$ for the process given by $P(w)$. The design may be based on the frequency function of $P(w)$, which is

$$P(j\nu) = P(w)\Big|_{w = j\nu}.$$

- Find the discrete-time controller by

$$C(z) = C(w)\Big|_{w = \frac{2}{h} \cdot \frac{1 - z^{-1}}{1 + z^{-1}}}.$$

- To complete the design, realize the discrete-time controller and check the closed-loop system properties.

Checking will reflect the fact that the frequency axis used while completing the design has been distorted according to the relation between frequency ν and the actual frequency ω:

$$\nu = \frac{2}{h} \cdot \tan\left(\frac{\omega h}{2} \right) \qquad \mathbf{2.27(13)}$$

The frequency distortion is small if the selected sampling time is sufficiently small. If the sampling rate cannot be chosen to be sufficiently fast, the design steps should be repeated using a scaled version of the *w*-transformation, which avoids the frequency distortion at the expected cutoff frequency (ω_c) of the loop transfer function:

$$w' = \frac{\omega_c}{\tan(\omega_c h/2)} \cdot \frac{1 - z^{-1}}{1 + z^{-1}} \qquad \mathbf{2.27(14)}$$

The transformation according to the above relation is called *w*-transformation with *prewarping*. Another problem with the *w*-transformation–based design is that $P(w)$ is a nonminimum phase transfer function requiring special care to design $C(w)$.

Design with Delta Transforms The direct application of the delta transformation may lead to results similar to those obtained by the sophisticated *w*-transform method. The concept is that a continuous-time controller $C(s)$ is to be designed for the continuous-time process $P(s)$. Then derive the delta form of the controller by substituting

$$\gamma = \frac{e^{sh} - 1}{h}$$

for *s* in $C(s)$: $C(\gamma) = C(s)\big|_{s=\gamma}$.

The key point then is to apply (γ^{-1}) as a building block to implement the control algorithm without converting back to the *Z*-form. The delta building blocks can be manipulated in much the same way as integrators are handled in the implementation of continuous-time models.

The various approximately continuous design techniques, in general, lead to rather similar closed-loop control properties. In deciding which to use, careful analysis of expected modeling error, parametric sensitivity, CPU performance, etc., is recommended.

Dead-Beat Controller Algorithm

In sampled data control systems, the software provides the freedom to implement sophisticated control algorithms. Some discrete-time algorithms can achieve performance that is not achievable by analog control. One class of these algorithms ensures that after an upset, the controlled variable (the continuous output signal from the process) will accurately settle within a finite settling time.

It should be noted that this zero error is guaranteed only at the sampling instants; in the intersampling period (i.e., in continuous-time), error should still be checked. In the literature these algorithms are referred to as dead-beat control algorithms.

To understand the essence of this method — for the sake of simplicity — consider a stable control loop that experiences a step change in set point. A design procedure will be derived in three steps. In the first step a control algorithm will be designed to achieve the fastest possible transient response, i.e., the output signal will be settled in the minimum number of sampling steps. The controller output signal can be very high, and oscillations (also called ripples) can occur between the sampling points.

In the second step the design will be modified to avoid the unwanted intersampling oscillations. It is known, however, that cancellation of discrete-time process zeros outside of a well-defined area within the unit circle is the reason for the oscillations. Separating and not cancelling those zeros, a modified version of the fundamental control algorithm will be derived. The modified algorithm will moderate the control effort, but it will increase the settling time.

The design will be executed in the z operator domain. A remarkable feature of the design method is that the undesired time-domain properties (oscillations, large excursions of the control signal) can be avoided.

The first step is to transform the hybrid control problem to a pure discrete-time problem. To do so a sampling time h should be selected, then the pulse transfer function $P(z)$ of the plant combined with the D/A converter should be derived. Once the discrete-time controller algorithm $C(z)$ has been determined, the closed-loop system performance is to be checked.

To illustrate the design procedure, consider the following continuous process:

$$P(s) = \frac{e^{-s}}{(1+10s)(1+5s)} \tag{2.27(15)}$$

According to the nature of the process, the earliest time instant to see $y[k] = 1$ (i.e., zero error) is $k = 2$. This requirement can directly be expressed by the overall pulse transfer function:

$$\frac{C(z)P(z)}{1+C(z)P(z)} = z^{-2} \tag{2.27(16)}$$

Hence, the pulse transfer function of the control algorithm is expressed as

$$C(z) = \frac{1}{P(z)(z^2-1)} \tag{2.27(17)}$$

Handling now $P(z)$ as a ratio of two polynomials

$$P(z) = \frac{B(z)}{A(z)} = \frac{0.0091(z+0.9048)}{(z-0.9048)(z-0.8187)z}$$

and the control algorithm turns out to be

$$C(z) = \frac{A(z)}{B(z)(z^2-1)} = \frac{109.9(z^3-1.7236z^2+0.7408z)}{z^3+0.9048z^2-z-0.9048}$$

Figure 2.27i shows the result, which is clearly unacceptable. The oscillations are introduced by the control algorithm itself since its poles are responsible for the ripples between the samples. If unstable or lightly damped zeros are not cancelled by associated poles, no oscillations will occur in the continuous output signal. The area of the well-damped process zeros can be determined analytically.

Let us analyze the contour of a conjugate complex pair with a given damping factor in the z domain. Recall that in the s domain the constant ζ lines are straight lines by $s = \sigma + j\omega$. For a given σ value

$$\omega = \frac{\sigma}{\zeta}\sqrt{1-\varsigma^2}$$

along a constant ζ. Then $z = e^{sh}$ maps this line to the z-plane.

As an example, Figure 2.27j shows the area where the damping is constant at $\zeta = 0.4$. If one separates the zeros of the process pulse transfer function according to

$$B(z) = B_1(z)B_2(z) = 0.01733(0.525z + 0.475)$$

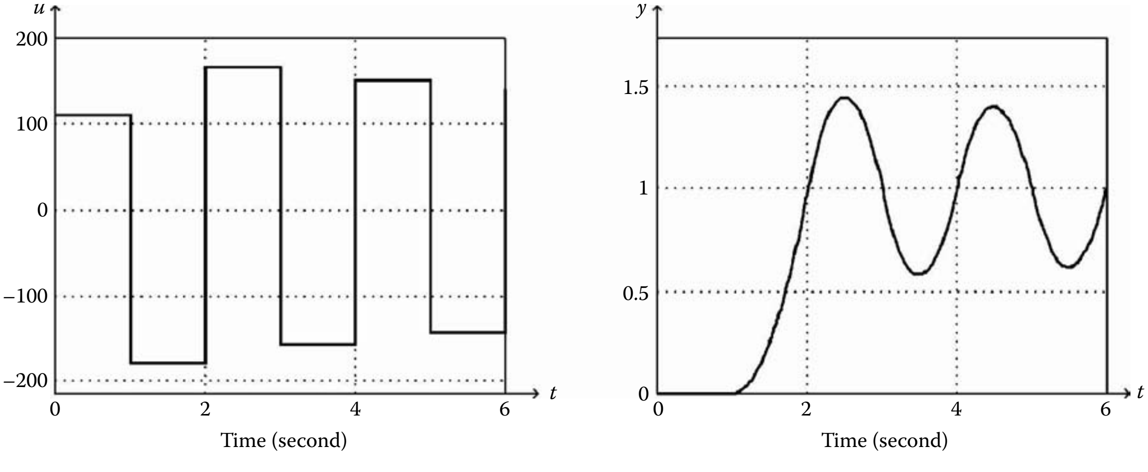

FIG. 2.27i
Records of the manipulated variable (u) and controlled variable (y) when the control algorithm was obtained by a dead-beat algorithm designed with minimum settling time.

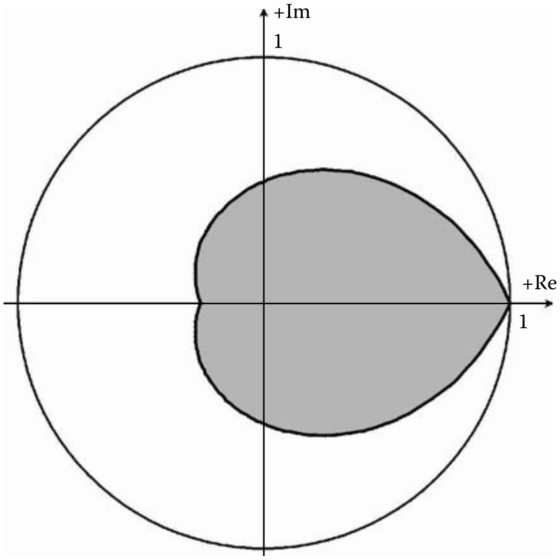

FIG. 2.27j
Region of $\zeta \geq 0.4$ in the z-plane.

where $B_1(z) = 0.01733$ contains the well-damped zeros (no such zero exists here) and $B_2(z) = 0.525z + 0.475$ contains the lightly damped zeros (one such zero exists at $z = -0.9048$). Observe that $B_2(z)$ is normalized by $B_2(1) = 1$. The overall transfer function is planned to be

$$\frac{C(z)P(z)}{1+C(z)P(z)} = B_2(z)z^{-2-\deg(B_2)} = B_2(z)z^{-3} \qquad \mathbf{2.27(18)}$$

where $\deg(B_2)$ is the degree of polynomial $B_2(z)$. Expressing $C(z)$, the controller is

$$C(z) = \frac{A(z)}{B_1(z)[z^3 - B_2(z)]} = \frac{57.7(z^3 - 1.7236z^2 + 0.7408z)}{z^3 - 0.525z - 0.475}.$$

The input/output plots are shown in Figure 2.27k. No oscillations are present, and the overexcitation in the manipulated and controlled variables is also reduced. The control system becomes slower, and the manipulated variable (controller output signal) needs three steps to reach its steady-state value.

On the other hand, the maximum value of the manipulated variable (u, the control signal at 57.7 maximum value) is still too high, and the average control valve actuator would be unable to respond to it. For these reasons, it is necessary to modify the design in order to reduce the step size in the controller output signal (by a factor of five), while keeping the settling time reasonably short (corresponding to five samples).

The following design polynomial can be added to the original algorithm:

$$T(z) = 0.2z^2 + 0.3z + 0.5$$

It increases the finite settling to five samples, while the initial size of the step in the manipulated variable (the controller output signal) is decreased by a factor of five.

The closed-loop control equation with the design polynomial $T(z)$ is

$$\frac{C(z)P(z)}{1+C(z)P(z)} = T(z)B_2(z)z^{-2-\deg(B_2)-\deg(T)} = T(z)B_2(z)z^{-5}$$

2.27(19)

and therefore, the controller algorithm becomes

$$C(z) = \frac{A(z)T(z)}{B_1(z)[z^k - B_2(z)T(z)]} = \frac{11.54(z^5 - 0.2235z^4 + 0.6555z^3 - 3.198z^2 + 1.852z)}{z^5 - 0.105z^3 - 0.2525z^2 - 0.405z - 0.2375}.$$

Observe that $T(1) = 1$, so the design polynomial does not affect the zero steady-state error. The input/output plots for this control algorithm are shown in Figure 2.27l.

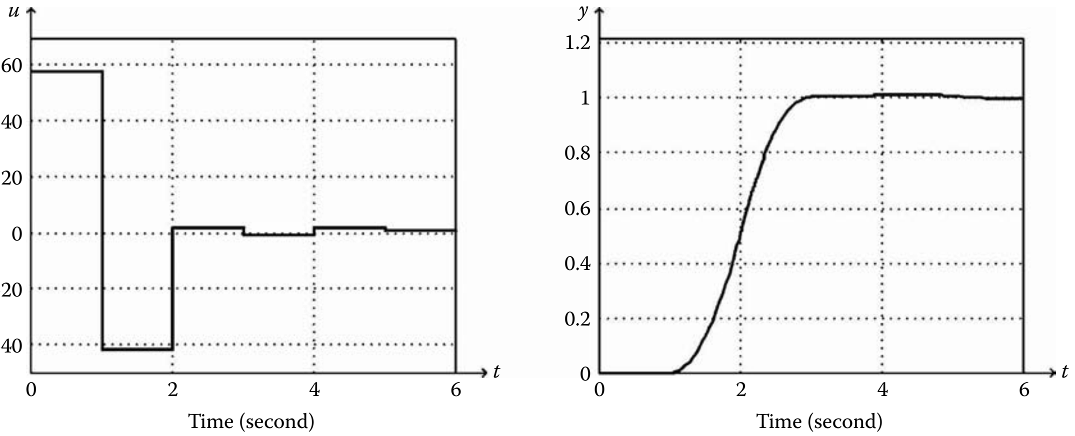

FIG. 2.27k
The proces input–output records obtained when the dead-beat control was revised by not canceling purely damped process zeros.

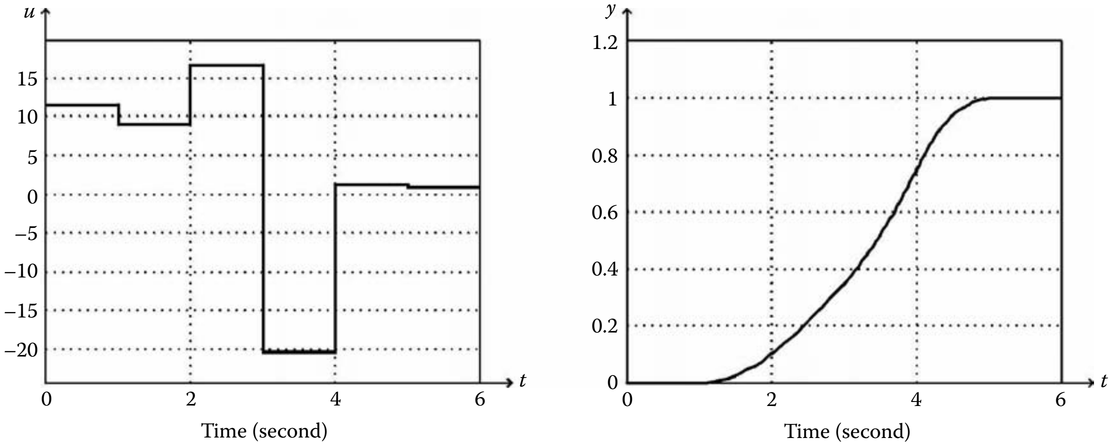

FIG. 2.27l
The process input–output records obtained when the dead-beat control was revised by adding a design polynomial of $T(z) = 0.2z^2 + 0.3z + 0.5$.

Smith Predictor Design

In the 1950s, Smith suggested a control algorithm that can be used to control processes that have significant dead times. Using discrete-time design, the pulse transfer function of the process has the following form:

$$P(z) = z^{-d}P'(z) \qquad \textbf{2.27(20)}$$

where $P'(z)$ is the part of the process with no dead time, and d corresponds to the dead time as an integer multiple of the sampling time. The main idea is that the operating feedback control loop is converted into an equivalent fictitious control loop, in which the dead time is outside the feedback loop (Figure 2.27m). In this case the control algorithm can be designed for the process without dead time.

This control strategy ensures a much faster response than does the PID controller, which is tuned to control a process with dead time. Applying simple block diagram algebra, the equivalence of the transfer functions of the two closed-loop systems leads to

$$C(z) = \frac{C'(z)}{1 + (1 - z^{-d})C'(z)P'(z)} \qquad \textbf{2.27(21)}$$

The first step in developing the control algorithm is to design $C'(z)$ for a process with no dead time and then calculate the discrete-time controller by the Equation 2.27(21) relation. Theoretically, the Smith predictor can be used both for continuous and sampled data control systems. However, as the dead time appears directly in the controller algorithm, the discrete-time applications are far more preferred because the dead time term is easier to generate.

CONCLUSIONS

Considering the practical applications of sampled data control systems, the hardware issues include selecting the right resolution for the D/A and A/D converters. The resolutions of the D/A and A/D converters should be in the range of 12 to 16 and 8 to 12 bits, respectively.

As to the controller algorithm to be used, 1) the errors from converter quantization, 2) round-off errors in the arithmetic operations, and 3) the errors due to quantization of the controller parameters will have an impact on the control algorithm selection.

Bumpless Transfer and Controller Windup

Bumpless transfer is essential so that when the control loop is switched from manual to automatic or back to manual, the controlled variable is not upset. This goal is served by an implementation algorithm in the form of setting appropriate initial conditions for the iterative program schemes based on the measurement signal (control input).

Reset or integral windup occurs, for example, if an error exists while the controller is in manual and the PID algorithm is active. As the integral mode keeps integrating the area

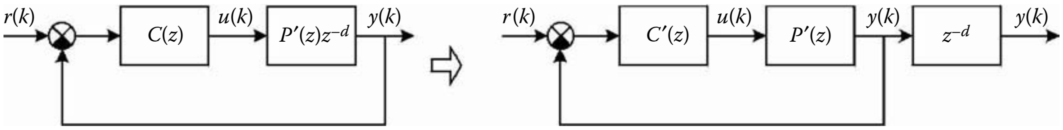

FIG. 2.27m
The concept of the Smith predictor.

under the error curve, when the loop is switched back to automatic, the controller output signal (manipulated variable) can be saturated, meaning that it has reached its maximum limit (constraint).

One should prevent the controller from such windup, because it can cause overshoots followed by cycling or other forms of instability. Integrators are components that can wind up, and *antireset windup* refers to the stopping of integration once the control signal has been saturated.

For digital control applications a number of antireset windup algorithms have been developed. A common characteristic of each is the use of a feedback signal from the manipulated variable (the controller output signal), to keep that signal from reaching saturation.

Selection of the Sampling Rate

The selection of the sampling time depends on the application. The selection will set conditions for the real-time computing power requirements. If the sampling rate is too slow, fast-occurring process disturbances might not be detected and can cause upsets. Too-fast sampling, on the other hand, can increase the computing demand without substantially improving control quality.

Rules of thumb suggest that the sampling frequency should be set as a function of the dead time and should correspond to 1/10 of it. Other criteria suggest to have four to ten samples in each transient response period or to ensure a sampling rate at least five times higher than the bandwidth to be achieved by the closed-loop control.

2.28 Selective, Override, and Limit Controls

F. G. SHINSKEY (1970) **J. P. SHUNTA** (1985, 1995) **J. E. JAMISON, A. ROHR** (2005)

INTRODUCTION

In this section some examples are given of control configurations where more than one controller can manipulate the same process and where the selection of the active controller is dictated by some prearranged logic.

In some control systems, more variables need to be controlled than there are variables that can be manipulated. When this is the case, logic must be provided to decide which controllers should have access to the manipulated variables and which should be temporarily blocked. Switching controller outputs can be easily and smoothly accomplished by a variety of hardware and software signal selectors.

In selective control applications, the signal selectors choose the lowest, highest, or median signal from among two or more signals. Such selectors are available both as analog hardware or as digital software in DCS control packages.

In most applications, selective control is a form of multivariable control where the selectors facilitate the online modification of control strategies as a function of changing operating conditions. The selectors allow the control strategies to be changed smoothly and without disturbing the process. Selective control applications include:

- Protecting process equipment by keeping operating variables within their design limits
- Automatic startup and shutdown
- Protection against instrument failures
- Selection of one from among several signals

OVERRIDES

In override configurations one controller can take command of a manipulated variable away from another controller when otherwise the process would exceed some process or equipment limit or constraint.

Selective control is less abrupt than the use of interlocks, which usually shut down equipment in order to avoid exceeding a limit or constraint. Overrides usually keep some process variable from reaching an unsafe condition, and therefore the interlock trip points are not reached. Thus, selective control keeps the equipment running although perhaps at a suboptimal level.

This concept is illustrated in Figure 2.28a. The "hard" constraint denotes the point at which the interlock trips. Overrides come into play at some point before the interlocks are actuated and therefore are sometimes called "soft" constraints.

Signal selectors can facilitate the overriding of one controller by another. Often, overrides are preferable and therefore are activated before the safety interlocks would be, but in most applications the overrides are backed up by interlocks. Overrides can be defined as:

> Controllers that remain inactive until a constraint is about to be reached or exceeded, at which point they take over control of the manipulated variable from the normal controller through a selector and thereby prevent the exceeding of that constraint.

Some common applications of override include the prevention of:

- Flooding in distillation columns, by throttling boil-up or feed flow rates
- Exceeding level ranges by draining or flooding
- High pressure or temperature caused by a runaway reaction when heat input is reduced
- The development of low oxygen levels in furnace off-gas streams, by reducing fuel flow

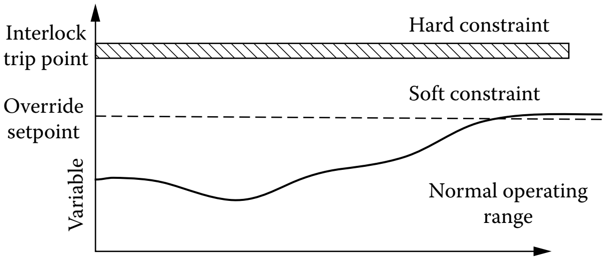

FIG. 2.28a
Illustration of the nature of "hard" and "soft" constraints. An interlock is a "hard" constraint because it usually shuts down the protected equipment, while selective overrides are called "soft" because they keep the process variable from reaching such "hard" limits.

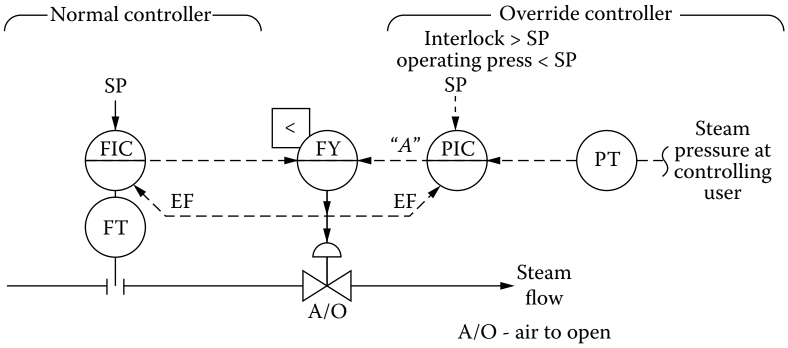

FIG. 2.28b
Flow control with pressure override limits the steam pressure to a safe value. Both controllers are provided with external feedback (EF) to prevent reset windup and thereby guarantee bumpless transfer.

- The development of high steam header pressures, by diverting some of the steam to a low-pressure header or condenser

Figure 2.28b shows an override control loop in which the normal control maintains flow (FIC) while the safety override control is based on pressure (PIC). In this configuration, the outputs of both controllers are fed to a low-signal selector, which selects the lower of the two. The override controller set point is set at the maximum steam pressure that the process can tolerate, but below the safety interlock set point.

As long as the pressure controller set point is not exceeded, the output of the override PIC controller (signal "A") is blocked by the low selector and cannot reach the steam valve. When the pressure of the steam that is being sent to the users exceeds the set point of the override PIC, that controller's output signal decreases, and when it drops below the flow controller's output, it is selected for throttling the steam control valve. This way, the PIC override will prevent the steam pressure from rising above the controller's set point.

Both the FIC and the PIC control algorithms require "external reset feedback" to avoid integrating their errors when they are idle ("reset windup"), because their output is not selected for control. As was discussed in more detail in Section 2.2, the controllers do not receive their own output signal as reset feedback, but both of them receive the signal selected by the low signal selector (FY). This makes the transfer between the controllers bumpless.

Overriding at a Fixed Point

Figure 2.28b illustrates the case when the override variable (steam pressure) had to be limited to a specific value. Another example of this type of application is shown in Figure 2.28c, where the controls involve cooling with river water. In this application the concern is heat exchanger fouling because if the water outlet temperature exceeds 50°C, exchanger fouling becomes rapid.

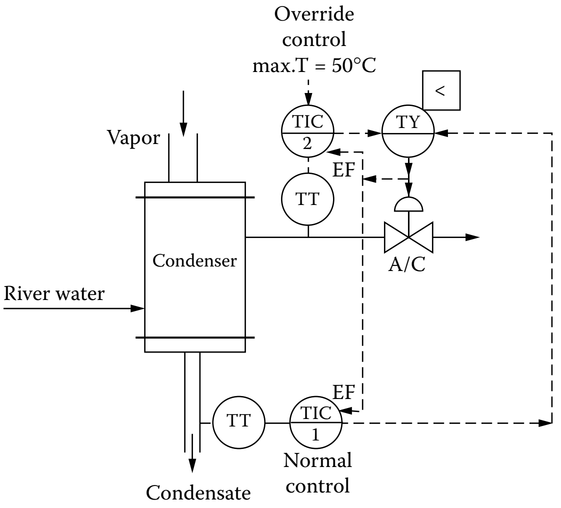

FIG. 2.28c
When the river water outlet temperature rises to 50°C, the override controller (TIC-2) overrides the normal controller (TIC-1) and prevents the outlet temperature from rising beyond 50°C.

Normally, the river water flow is throttled to control the condensate temperature by TIC-1. However, if the river water outlet temperature reaches or exceeds 50°C, the high-temperature override controller (TIC-2) takes over the control of the flow of river water and opens the control valve. This limits the river water outlet temperature to a maximum of 50°C. As a consequence, the condensate temperature will drop below the set point of TIC-1, but the fouling of the heat exchanger will be prevented, and that is the higher priority.

Figure 2.28d describes a control system that protects against overpressurizing a reactor. This protection is provided by overriding the temperature controls and reducing the heat input. In this application a cascade loop throttles the steam flow and controls the reactor temperature if the pressure in the reactor is safe. On the other hand, when the overhead condenser becomes overloaded and its capacity to condense the overhead vapors is insufficient for the rate at which the vapors are generated, the reactor pressure will rise. The pressure controller (PC) provides the high pressure override by taking command of the steam valve (through the low signal selector FY) and throttling down the valve as needed. Both the PC and the FIC are provided with external feedback (EF).

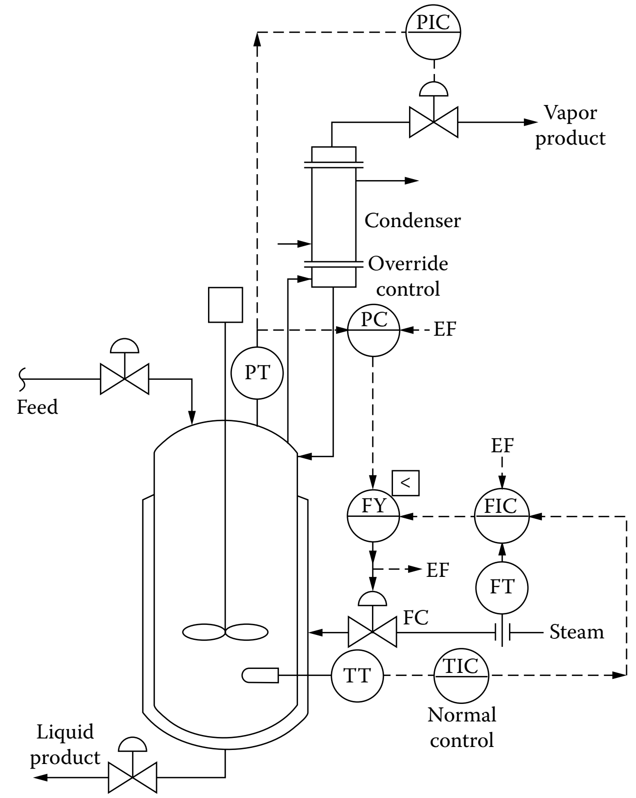

FIG. 2.28d
The temperature controlling cascade loop is overridden in this reactor control configuration when the pressure is high.

Override to Guarantee Valve Closure

Figure 2.28e illustrates another type of override control. Instead of a PID controller, here the high-level override is provided by a signal scaler (LY). The purpose of the high-level override is to make sure that the feed valve of the distillation column is closed when the base level reaches 100%.

The override in this case protects against potential restrictions in the tails (bottoms) flow causing the flooding of the column. A scaler is used because the gain and bias of the LY output must have a preset relationship to the input. This cannot be obtained with a PID controller because the controller output cannot be predicted for a given input.

The scaler output $[f(x)]$ can be predetermined as a gain (K) multiplied by the level transmitter output in percentage ($\%x$) plus a bias (b):

$$f(x) = Kx + b \qquad \textbf{2.28(1)}$$

The scaler can therefore be calibrated to behave in accordance with the relationship shown on the right of Figure 2.28e, where the output is 0% when the level is 100% and the output is 100% when the level is under 75%. This behavior is obtained by setting $K = -4$ and $b = 400$:

$$f(x) = -4x + 400 \qquad \textbf{2.28(2)}$$

As level increases beyond 75%, the output of the scaler will gradually decrease and at some point will drop below

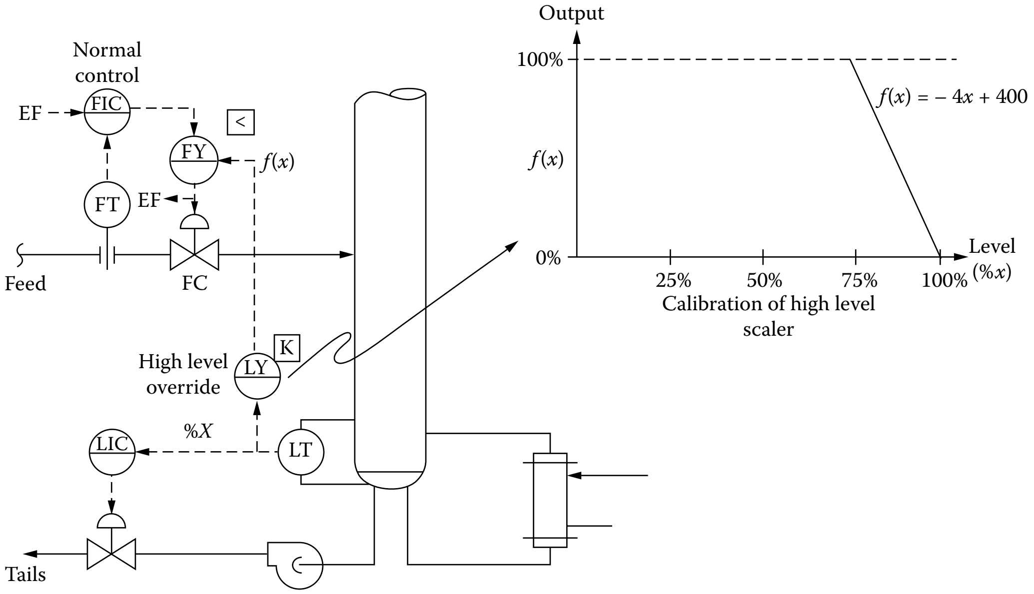

FIG. 2.28e
Instead of a high-level controller, a scaler can also provide a high base level override, which will also prevent the flooding of the column by closing the feed valve.

that of the feed flow controller (FIC), at which point the low signal selector (FY) will select it. At that point LY will override the normal controller (FIC) and will start to throttle the feed valve. The exact point of takeover cannot be predicted because the PID controller output cannot be predicted. However, we definitely know that when the level is 100%, the feed valve will be closed.

The gain of 4.0 was chosen to provide a smooth and stable response. It could be higher or lower depending on how fast or slow the override action should be. The lower the gain, the more likely it is that the override will interfere with flow control when the level is not yet critical. Thus the gain should be set high enough to prevent that while still providing stability.

The scaler does not have an integral mode; it acts like a proportional-only controller. Therefore it will not wind up and does not require external feedback (EF), while the FIC does.

Start-Up and Shut-Down Overrides

Some process startups are too complex to be handled by the operator without the aid of some automatic controls. Automatic start-up controls typically include a ramping signal to open valves and override controls to prevent the violation of constraints. Signal selectors decide which control signal should manipulate each valve. Figure 2.28f illustrates such a strategy for a distillation column.

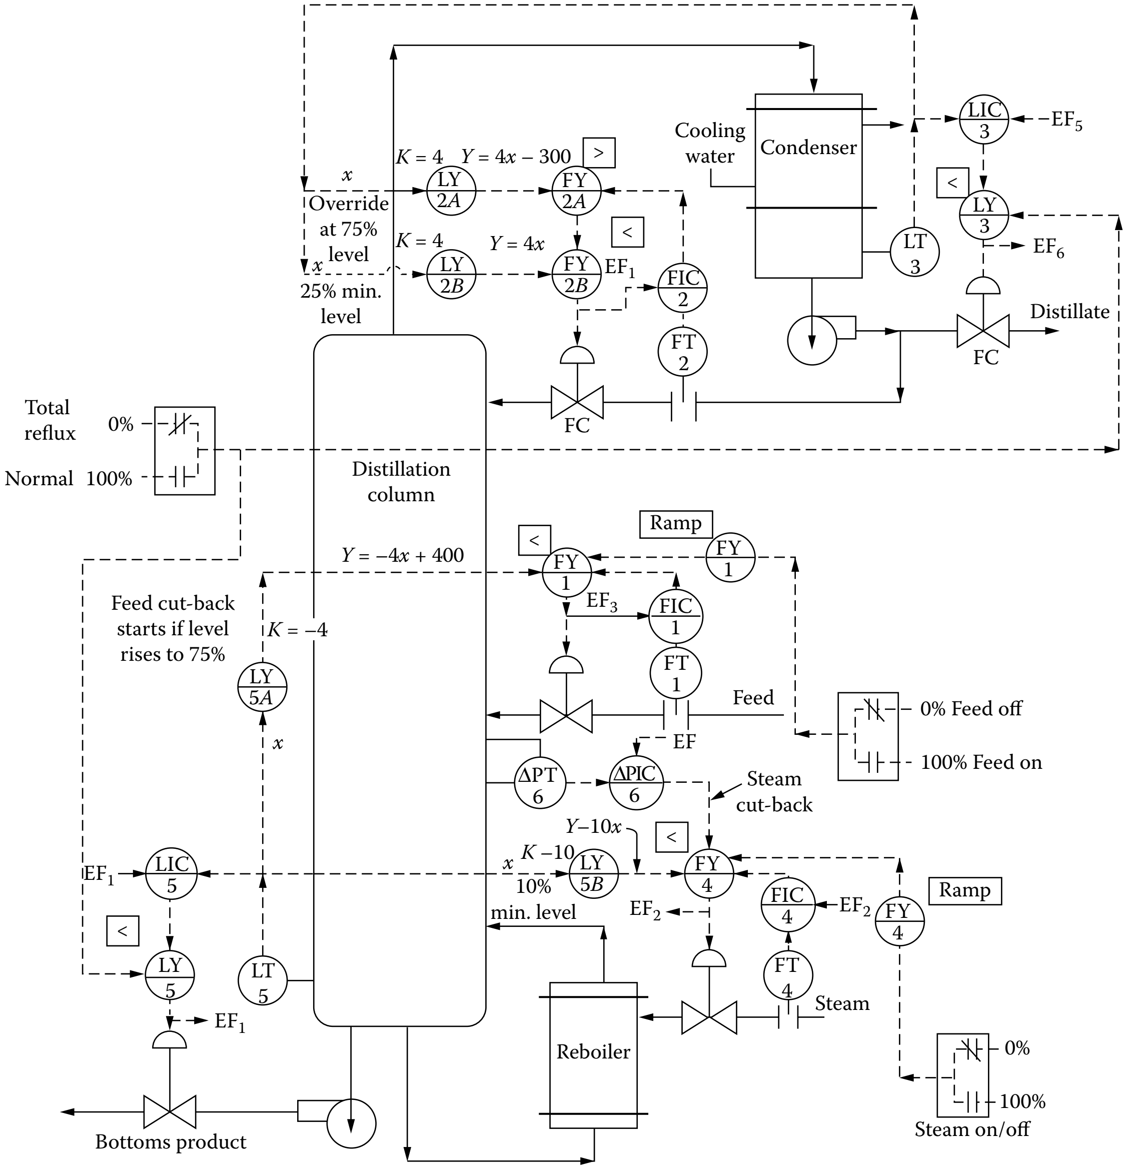

FIG. 2.28f
Overrides required to automatically start up or shut down a distillation tower.

Startup proceeds by opening the cooling water to the condenser first. After that, all the controllers are switched to automatic, maintaining their set points. External reset feedback connections are provided to keep the idle controllers from winding up. For the initial phase of the startup, the total reflux mode is selected, which means that the distillate and tails valves are closed.

The operator turns on the feed by "ramping" the feed valve until the flow set point is reached on FIC-1. As the process fluid accumulates in the base, the operator can turn on the steam. The low-level override (LY-5B) will guarantee that the steam does not come on before a 10% level is established in the base. The steam valve will be ramped open, and the liquid in the reboiler will begin to boil. If the base level gets too high, another override (LY-5A) will throttle back on the feed. This override was described in detail in Figure 2.28e.

As steam comes on, the high delta pressure override (PIC-6) protects the column from "flooding," which can occur when a high pressure differential does not allow the liquid to flow down the column, causing liquid backup on the trays.

As overhead vapors are condensed, the condensate will accumulate in the condenser. As its level rises, the low-level override output (LY-2B) will rise, allowing the reflux flow to come on after the reflux pump was started. The high- and low-level overrides (FY-2A and FY-2B) will return all the condensate to the column (full reflux).

As the temperatures are established in the column, the operator can switch from the total reflux mode of the startup phase to the normal operating mode and thereby the bottoms (tails) and distillate valves will start to open under the direction of their normal controllers (LIC-3 and LIC-5).

The following overrides were used in Figure 2.28f to facilitate automatic startup:

- Low base level (<10%) pinches steam.
- High delta pressure pinches steam.
- High base level (>75%) pinches feed.
- High level in condenser (>75%) increases reflux.
- Low level in condenser (<25%) pinches reflux.

SELECTIVE CONTROL

Limited Availability of Manipulated Variable

In some control applications only one controlled variable exists, but a choice of manipulated variables is present. A typical example is the firing of a process heater with either of two fuels. The choice between the fuels is usually made on the basis of availability.

Fuel *A* may be burned to the limit of its availability and when that limit is reached, it has to be supplemented with fuel *B*. The availability limit can be set manually or by a controller that detects the amount of fuel *A* in storage.

A control system of this type must have the following two features:

1. Capability of manipulating the variable with limited availability while staying below its limit
2. Smooth transition from using one manipulated variable to the other without adversely affecting the controlled variable

Accommodating these requirements necessitates the coordinating of the manipulated variables and the weighing of their effects on the process.

Burning Multiple Fuels Figure 2.28g shows a control in which the temperature of the process is controlled by manipulating two fuels, of which one is of limited availability. Since fuel *A* is less expensive, the objective is to use that fuel to the limit of its availability before starting to use fuel *B*.

In the control system, the set point of the fuel "*A*" flow controller (FIC-A) is limited by the low signal selector (FY-C) to a high limit. This limit could be set manually or could come from the output of a pressure controller on the fuel header.

The computations shown in Figure 2.28g are needed to guarantee the smooth transition between the two modes of operation. The first step in the computation is to convert the difference between the output of the temperature controller

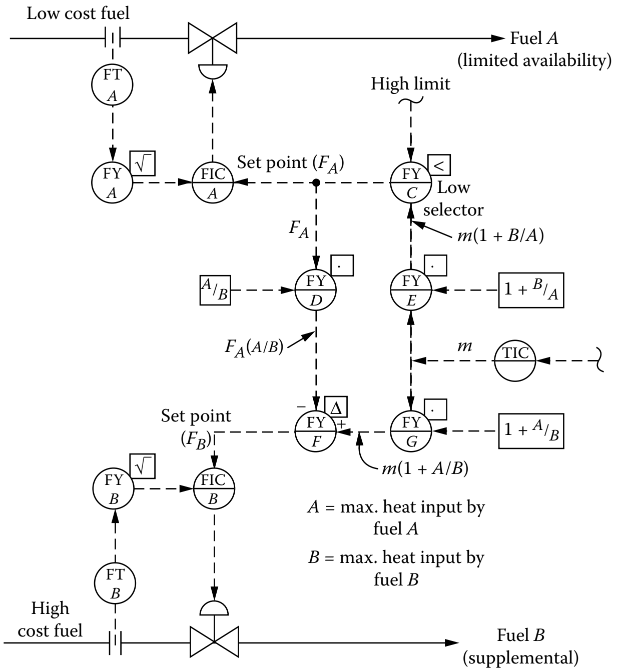

FIG. 2.28g
Temperature is controlled by manipulating the preferred fuel A to the limit of its availability and supplementing it with fuel B as required.

(m) and the equivalent flow of fuel A into a set-point signal for the supplemental fuel flow controller (FIC-B).

The temperature controller output represents the total heat input requirement of the system, which has to be met by the two fuels. This total is converted into the fuel A set point in FY-E, where m is multiplied by a factor of $(1 + B/A)$. Here, B/A is the ratio of the full-scale heat input that can be generated by fuel B to that of fuel A. Through this correction, the controller output and the fuel A set point will be on the same scale. As long as the requirement for fuel A is at or below the high limit set on FY-C, the two inputs to the subtracting relay (FY-F) will cancel one another:

$$m(1 + A/B) - m(1 + B/A)(A/B) = 0 \qquad \textbf{2.28(3)}$$

When the high limit on FY-C is exceeded, the fuel A set point (F_A) becomes that high limit (a constant), and the fuel B set point starts increasing smoothly from zero without affecting the gain of the temperature control loop. The system will also work when the fuel A controller is in manual, as long as the heat load is above the amount that fuel A can supply.

Note that when fuel A is constrained, the temperature controller drives to increase the flow of fuel B. In this control system, external reset feedback is not required in the temperature controller.

Selecting from Multiple Transmitters

Measurement reliability can be improved by selecting a valid transmitter signal from among several signals. Figure 2.28h illustrates the feed controls to a reactor where it is critical to keep the ratio of feed streams within very tight limits. Losing a measurement signal because of a transmitter failure could cause one of the valves to open wide and result in exceeding the ratio limit.

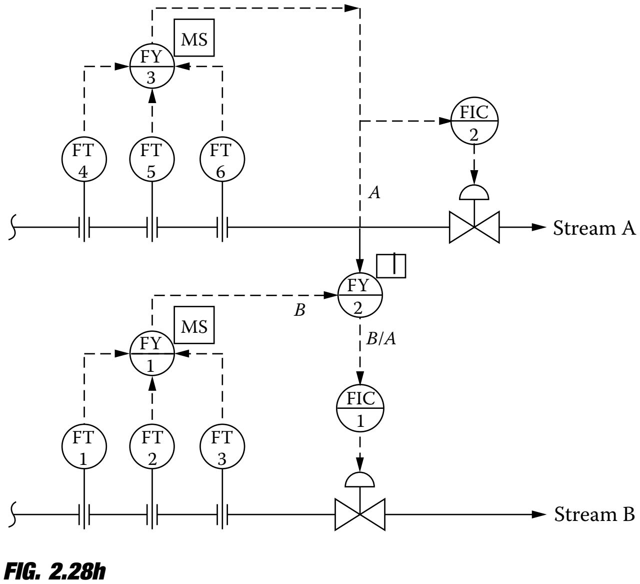

FIG. 2.28h
Selecting the median output of multiple transmitters will keep the control system in operation even if one of the transmitters fails.

If redundant transmitters monitor the flow and a median selector is used to select the signal in the one, that possibility is minimized because two transmitters would have to fail at once for the multiple transmitter configuration to malfunction.

Redundant transmitters or redundant sensors are commonly used in hostile environments (high-temperature, corrosive, dirty, or vibrating surroundings) where transmitter failure rates are high. High or median selectors will keep the control loops operational even if one transmitter fails, avoiding costly shutdowns.

High–Low Selection

Signal selectors can also be used to allow for the selection of the highest or lowest of several measurements for safe control. For example, in order to eliminate the possibility of damage, it is desirable to control fixed-bed chemical reactors on the basis of the hottest temperature, while the location of that temperature can change with both flow rate and time. Thus, temperatures at several locations should be measured and the highest selected as the temperature for control.

ANTIRESET WINDUP OVERRIDES

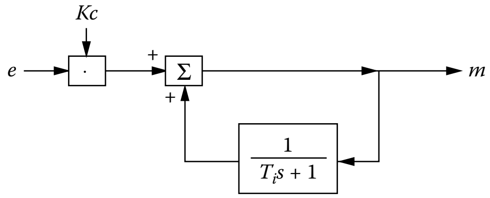
Integral or reset action in a PID controller will cause the controller output to saturate if the controller is off set point because it has no access to the manipulated variable. When the controller experiences such a sustained error, this is called reset windup. It can occur in control loops, where a selector chooses one for active operation from among the outputs of two or more PID controllers while blocking the other. In that case, only one controller at a time commands the valve, while the output(s) of the blocked controller(s) will wind up, unless something is done to limit the reset action.

The PI Controller

The output signal from a PI controller is

$$m(t) = Kc\, e(t) + Kc/Ti \int e(t)\, dt + b \qquad \textbf{2.28(4)}$$

When the PI controller is in automatic but its output is blocked from reaching the valve, and the deviation $e(t)$ is not zero, the error will be integrated until the controller saturates its output either at 100 or 0% depending on the action of the controller.



When $e \neq 0$, positive feedback will cause m to eventually increase to the limit.

FIG. 2.28i
This block diagram illustrates that if the output signal (m) of a controller is blocked from reaching its control valve (the manipulated variable), the resulting sustained error will be integrated until the output (m) reaches a saturated value (100 or 0%).

In the Laplace domain, the PI controller can be described as

$$m(s) = Kc(1 + 1/Ti\ s)\ e(s) \qquad \textbf{2.28(5)}$$

where s is the differential operator d/dt. Equation 2.28(5) can be rearranged to obtain

$$m(s) = Kc\ e(s) + m(s)/(Ti\ s + 1) \qquad \textbf{2.28(6)}$$

The equivalent block diagram of Equation 2.28(6) is given in Figure 2.28i. Here it is shown that the PI controller output signal (m) consists of a "proportional" component ($e(s)$ multiplied by the controller gain Kc) and an integral component that is obtained by feedback of output $m(s)$ through a first-order lag. When $e(s)$ is not zero, $m(s)$ increases (or decreases) to its limit through the positive feedback loop created by the lag function.

Figure 2.28j shows a way to limit this reset windup by breaking the internal feedback loop and providing an external feedback signal (EF) to be fed back through the lag function. For simple loops, the feedback signal can be the signal that is throttling the valve taken from the outlet of the selector.

When the controller is selected for control, the feedback signal is its own output, and when it is not selected, the feedback signal is the output of the selected controller. In the second case, the blocked controller tracks the output of the selected controller through its reset lag.

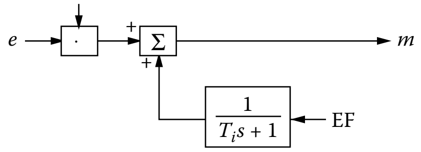


FIG. 2.28j
This block diagram illustrates that in order to eliminate reset windup the blocked controller does not integrate its own output but rather receives an external feedback (EF) from the signal that is operating the control valve (the output of the selector).

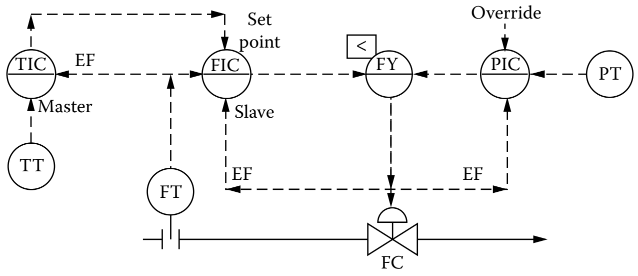

FIG. 2.28k
For TIC, the cascade master, the external feedback signal is the slave measurement. If the slave (FIC) can be overridden by a pressure controller (PIC), the external feedback to both is the manipulated variable going to the valve.

The tracking speed is governed by the integral (reset) time. The longer the integral time, the slower the tracking. Slow integral can be a problem in control configurations where the integral times of the controllers feeding the selector have vastly different values. This is because the slower controller can be wrongly selected due to it not being able to track the selector output fast enough. For this reason, it is sometimes necessary to adapt (automatically change when the controller is blocked) the integral time in the unselected controller to a short time to make sure that the controller will track rapidly.

In the steady state, the unselected controller tracks the selected controller with an offset of $Kc\ e(t)$.

$$m(t) = Kc\ e(t) + F(t) \qquad \textbf{2.28(7)}$$

Cascade and Feedforward Loops Figure 2.28k illustrates the use of external feedback in a cascade loop, and Figure 2.28l illustrates its use in a loop that contains a feedforward signal.

In Figure 2.28l, the external feedback (EF) for the master controller in a cascade loop, which is setting the ratio of flows A and B, is the actual measured flow ratio variable (B/A). The external feedback of this TIC master, whose output is modified by a feedforward signal when it is *multiplied* by A, is the inverse of the feedforward function because the secondary variable B is *divided* by A (Figure 2.28l).

One other type of external reset algorithm is created by modifying the standard PI algorithm by adding a term that integrates the difference between the controller output and the feedback signal.

$$m(t) = Kc\ e(t) + Kc/Ti \int e(t)\ dt + 1/Ti \int [F(t) - m(t)]\ dt \quad \textbf{2.28(8)}$$

When the controller is not selected, the controller output and feedback signal will be different, and integration occurs. The new term cancels out the normal reset action so, in effect, reset action is stopped until that controller resumes control. Equation 2.28(8) behaves exactly like the method used in Figure 2.28j.

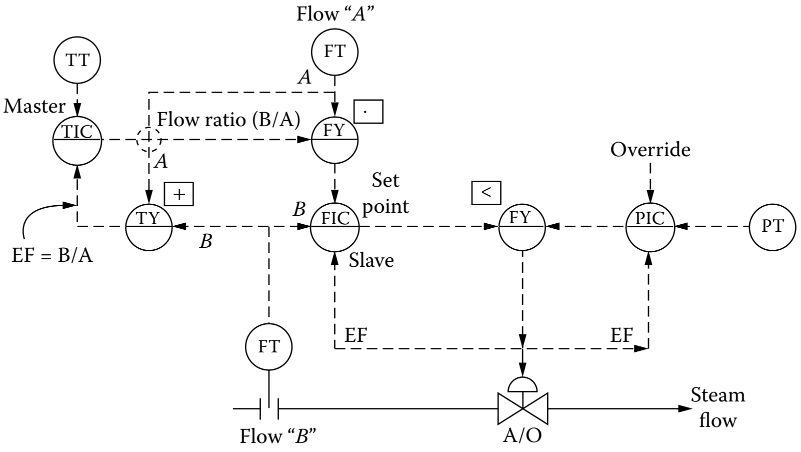

FIG. 2.28l
If the cascade master (TIC) is modulating the ratio of two streams (B/A), the external feedback signal to it will be the actual measured ratio of those flows (B/A). As the slave (FIC) can be overridden by a pressure controller (PIC), the external feedback to both is the manipulated variable going to the valve.

DESIGN PROCEDURE

When designing a control system that includes the feature of selecting the output of one of two controllers, one must consider:

1. The process variables that are to be controlled by the manipulated variable
2. The failure position of the final control element (valve)
3. The safe set points for the controllers
4. The required controller actions
5. The type of selector required (high, low, other)

In the majority of safety applications, a low signal selector is used because control valves, which are installed for reasons of safety, should always fail safe, and one of the possible causes of failure is air failure.

As an application example, consider a unit process consisting of a suction drum, a reciprocating compressor, and a discharge vessel (Figure 2.28m). The purpose of the control system is to prevent the formation of vacuum in the suction drum and the development of excessive pressure in the discharge vessel. Both of these goals can be satisfied by recirculating some of the gas from the discharge vessel to the suction drum. As was discussed in general terms earlier, the design steps include:

Step 1: An open valve failure position must be selected because if the valve is open both the development of vacuum in the suction drum and overpressure in the discharge vessel are prevented.

Step 2: Sensors are placed to detect the variables of interest, namely the vacuum on the suction and the overpressure on the discharge side.

Step 3: Because the development of either high vacuum or high pressure will require the opening of the recirculating valve, the controller actions must be set accordingly.

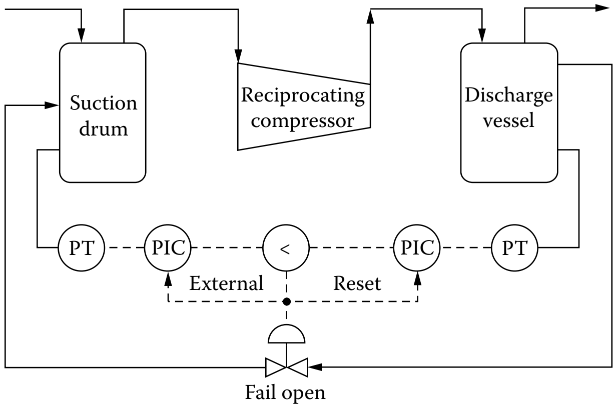

FIG. 2.28m
Safety override controls on a compressor prevent the development of both vacuum in the suction drum and overpressure in the discharge vessel.

Step 4: The action of the suction controller shall be direct (as the measured pressure drops = vacuum rises, the output also drops). The action of the discharge controller shall be reverse (as the measured pressure increases, the output decreases).

Step 5: Because safety is served by opening the recirculating valve, the selector should pick that controller output, which requires a higher valve opening. With a fail open valve, that means a Low Signal Selector.

Step 6: To complete the design, an external reset should be specified for both controllers, which provides them with feedback from the output of the signal selector.

2.29 Self-Tuning Controllers

P. E. WELLSTEAD (1995) **B. G. LIPTÁK, S. RENGANATHAN** (2005)

Types of Products on the Market:	A. Stand-alone hardware mostly for temperature control B. Stand-alone hardware for tuning all process loops C. Offered as part of DCS supplier's package D. Self-tuning software package
Partial List of Suppliers (Product Names):	ABB Process Automation, U.S. (MC 5000) (B) (www.abb.com/us/instrumentation) Asea Brown Boveri, Sweden (Novatune) (B, C) (www.abb.com) CAL Controls, U.S. (9900 Autotune) (A) (www.cal-controls.com) Control Techniques, U.K. ("Expert") (B) (www.controltech.co.uk) Eagle Controls, U.K. (Eagle Mini 948) (A) (www.applegate.co.uk) Emerson Process Measurement, U.S. (RS3) (B) (www.emersonprocess.com) Eurotherm, U.S. (815, 8181) (A) (www.eurotherm.com) FGH Controls, U.K. (5900, 556) (A) (www.fgh.co.uk) Fuji Electric, Japan (CC-S) (B) (www.fujielectric.co.jp) Honeywell, U.S. (UDC 6000, E-Max, D-Max) (B) (www.iac.honeywell.com) Invensys, Foxboro, U.S. ("Exact" 761, 760) (B) (www.foxboro.com) Jumo, U.S. (Dicon 5) (A) (www.jumousa.com) Philips, U.K. (KS 4290) (A) (www.philips.co.uk) Self-Tuning Friend, U.K. (D) (www.csc.umist.ac.uk) Siemens, Germany (Sipart dr) (B) (www.sea.siemens.com) Toshiba, Japan (EC300, 2150) (B) (www.tic.toshiba.com) Yokogawa, U.S. (UP25, YEW80) (A) (www.yokogawa.com/us)

INTRODUCTION

In Section 2.18, the methods of process modeling using artificial neural networks (ANN) were described. Some of the concepts used in designing self-tuning controllers use the concepts of the ANN family (Figure 2.29a). Before reading this section, it is advisable to become familiar not only with ANN, but also with the basics of PID controllers, their tuning, and the related subjects of model-based and adaptive controls, which are all covered in this section.

The selection of controller settings that will provide optimum performance is called controller tuning. If the controller is manually tuned and the dynamics of the controlled process change, the tuning has to be done again. If on the other hand, the tuning is done automatically periodically, then it is known as self-tuning. Some DCS and other control system suppliers provide the means to allow the operator or a timer to initiate controller tuning.

Self-tuning controllers are capable of automatically readjusting the controller tuning settings. They are also referred to as auto-tuning controllers and can be stand-alone products, integral parts of distributed computer control systems (DCS), or software packages. The market is dominated by stand-alone products, most of which are able to communicate with other systems or other controllers.

The standard operating principles include self-tuning regulators (STR) and self-tuning temperature controllers using feature-extraction–type tuning methods, which are obtained from step response information taken at startup or when load changes occur. General-purpose stand-alone units can tune by pattern recognition methods (e.g., Foxboro Exact) or by model-based methods (e.g., ABB Novatune).

EVOLUTION

The first self-tuning controllers came from Europe in the early 1970s. The original methods used optimal regulation[1,2] with optimal control,[3] followed by pole-placement[4] somewhat later. The subsequent development involved new algorithms,[5,6] stability theory,[7] and the industrial development of commercial self-tuning controllers. A comprehensive treatment of algorithms

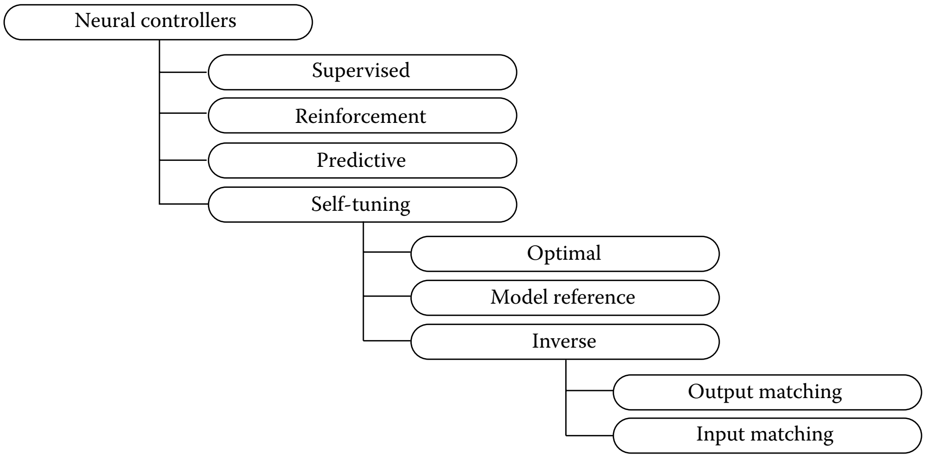

FIG. 2.29a

A hierarchical classification of ANN-based control algorithms. Self-tuning controllers belong to the family of neural controllers, which are distinguished from each other by the way they use the error signal to train the ANN.

for self-tuning control is provided in Reference 8, while nonlinear and adaptive controls are covered in another section of this chapter.

The general principle of operation of the family of self-adaptation is described in Figure 2.29b. This approach is applied when the cause of changes in the control loop response is either unknown or unmeasurable and the adaptation therefore must be based on the response of the loop itself. Several self-adaptive systems are described in the paragraphs that follow, including the self-tuning regulator, the model reference controller, and the pattern-recognizing adaptive controller.

Self-Tuning Regulator (STR)

The main components of a self-tuning regulator are shown in Figure 2.29c. They are as follows:

1. *A system identifier* — This element consists of a process parameter estimation algorithm, which estimates the parameters of the process.
2. *A controller synthesizer* — This synthesizer calculates the new controller parameters as a function of the estimated process parameters specified by the control objective function.
3. *A controller implementation block* — This is the controller whose parameters are updated at periodic intervals by the controller parameter calculator.

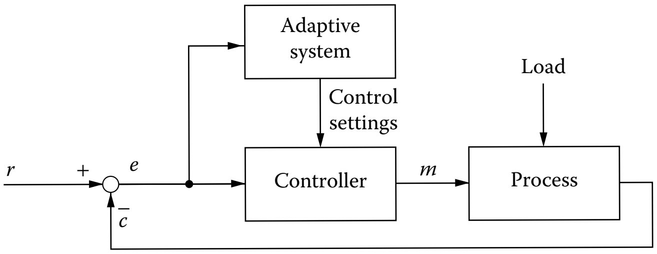

FIG. 2.29b

In self-adaptation, the correction is based on the response of the loop itself. One can view a self-adaptive system as a control loop around a control loop.

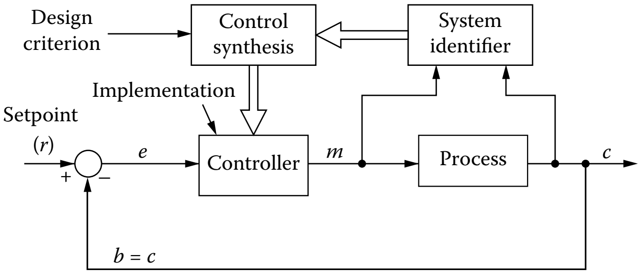

FIG. 2.29c

The main components of a self-tuning regulator.

The STRs are distinguished on the basis of their identifiers and synthesizers. Popular varieties include the minimum-variance, generalized minimum-variance, detuned minimum-variance, dead-beat, and generalized pole-placement controllers.

As shown in Figure 2.29c, the system identifier determines the response of the controlled variable (c) to a change in the manipulated variable (m). Model-based self-tuning algorithms use some method based on recursive estimators. Many commonly used industrial products, however, use pattern recognition or expert/fuzzy logic methods to extract key dynamic response features from a transient excursion in the system dynamics.

The transient excursion can be deliberately introduced by the controller, or preferably, it is the start-up transient or a normally occurring transient of the process. The desired tuning settings for PID, optimal, or other types of control are determined by the control synthesis block, which is also called the controller parameter calculator. The control synthesizer can be simple or sophisticated depending on the rules used.

MODEL-BASED METHODS

There are two classes of model-based self-tuners: optimal and response specification types. Both of these controllers are composed of a reference model, which specifies the desired performance; an adjustable controller, which sets the manipulated so as to bring the process performance as close as possible to that of the reference model; and an adaptation mechanism.

Figure 2.29d schematically shows the organization of the reference model controller.

Optimal Self-Tuning Optimal self-tuning algorithms use optimal regulation theory as their design rule in the controller parameter calculator. The design methods used are minimum variance (MV), generalized minimum variance (GMV), and generalized predictive control (GPC). The MV and GMV methods are, as the names imply, aimed at minimizing the mean square deviation of a process variable from its set point. The minimum variance methods have deficiencies when the process time delay is unknown or variable because they can, if unprotected, become unstable.

The related optimal method GPC was developed to overcome this deficiency by using prediction horizon ideas that occur in DMC (dynamic matrix control).[9] These methods are used in turn-key applications by research and consulting companies. Few industrial controllers use them because of the sophisticated knowhow required, although the ABB Novatune is a widely installed and respected product that uses optimal methods.

Transient Response Self-Tuner Another class of model-based self-tuners uses the desired closed-loop frequency or the transient response characteristics of the loop as the basis for operating the self-tuning algorithm. The accepted technique for this is pole-placement (PP) or pole-assignment (PA). This procedure asks the designer to select the desired closed-loop pole positions, and the self-tuner selects a controller that does this.

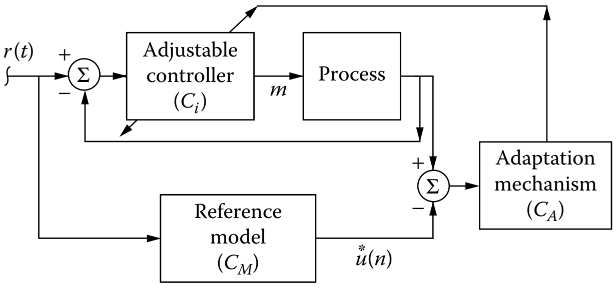

FIG. 2.29d
The main building blocks of a model reference adaptive controller.

The response specification methods can be linked to the optimization methods via various techniques.[8] Pole-placement can handle systems with unknown and variable dead times but requires more computational effort than most optimization-based methods do. Several commercial products offer these methods in one form or another, usually tailored to the requirements of the specific applications.

The model-based methods require that a persistent excitation or "dither" signal be injected into the process. This is normally done in the open loop or at startup, but start-up transients alone are not normally considered sufficient for these self-tuners. The form of the control law is usually a discrete time difference equation that is suitable for digital implementation.

Pattern Recognition Methods

The self-tuning of controllers that utilize pattern recognition procedures is widely used in industrial applications. This method relies upon the introduction of a perturbation of a specified form into the process. This usually is a step or pulse signal. Often the start-up transient is used, which is particularly useful in systems where a special start-up procedure exists, such as the one with temperature controllers.

The process response is then analyzed to extract the key transient performance indicators of the process, which are then used to select the correct controller tuning values. The transient performance indicators can be estimates of rise time, dead time, peak-overshoot, and so on. Some methods use fuzzy or qualitative performance measures, such as the criterion of whether "the time to first overshoot" is very fast, fast, medium, or slow.

The main difference between pattern recognition and the model-based methods is that in the case of pattern recognition no model of the process is constructed. This eliminates problems due to incorrect modeling but limits the usefulness of these methods to processes that can be handled in this way. For example, some of these methods might only work if a dead time and time constant can fully describe the controlled process.

Self-tuners of this type are restricted to three-term (PID) control algorithm applications. In these systems, the PID tuning constants are adjusted according to some tuning rules based upon the measured open-loop transient behavior of the process. The tuning rules are often proprietary variations of such well-known process tuning procedures as the Zeigler Nichols method or others.

A subclass of algorithms is based on testing the stability of the loop. These methods will usually cause the loop to oscillate as in the Zeigler Nichols periodic oscillation (closed-loop) method. Special precautions are applied to avoid runaway oscillation. The period and the controller gain that caused the oscillations are then measured and used to tune the controller.

Eliminating Process Upsets Self-tuning controllers that operate by introducing pulses or other forms of perturbations

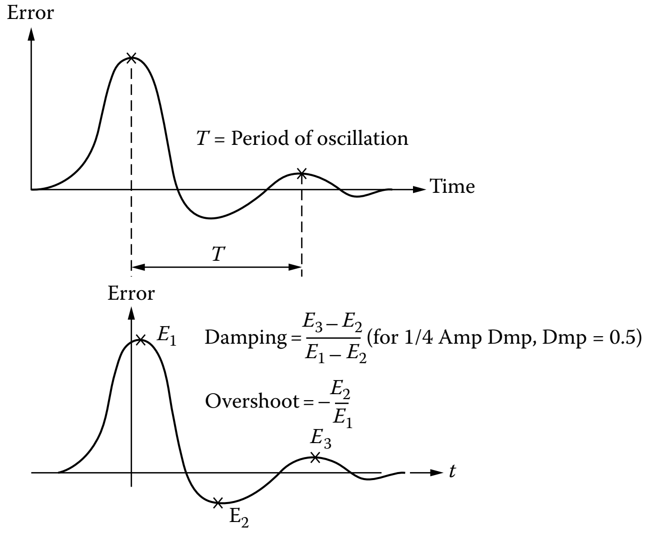

FIG. 2.29e
The control loop tuning is diagnosed by evaluating the period of oscillation (T), the decay or damping ratio, and the amount of overshoot to determine whether the controller is correctly tuned.[10]

are not widely accepted in the process control industry. It is felt that the control loops are unstable enough as it is, and nobody wants additional sources of perturbation.

Therefore, preference is given to self-tuning controllers that do not introduce any upsets but evaluate the controller's response to set-point changes or to other, naturally occurring load variations and other upsets as they take place. In such cases the self-tuning algorithm is usually kept "dormant" (inactive) until an error of some predetermined value (usually at least 1%) develops.

At that point the self-tuning subroutine is activated. After the error has evolved, the self-tuning subroutine checks the response of the controller in terms of the controlled variable's period of oscillation, damping, and overshoot (Figure 2.29e).

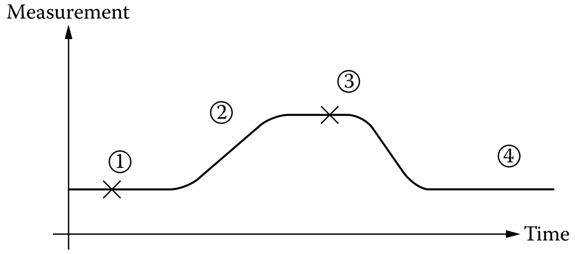

FIG. 2.29g
After evaluating the process response to a step change that increased the process load, another step change is introduced to return the process load to its original value.[10]

Start-Up Sequence As shown in Figure 2.29f, when starting up a control loop for the first time (the pretune phase), the controller is first manually brought to its normal load level of operation. After that, an adjustable-size step change in its output signal to the control value (m) is introduced. This step change in the manipulated variable (m) will cause the controlled variable (c) to draw an S-shaped steady-state reaction curve. From this response curve one can obtain the steady-state process dead time, process sensitivity, and process gain in response to a load increase.

The pretune sequence is continued, as shown in Figure 2.29g, by moving the controller output (m) through another step change back to its original value and determining again the steady-state gain, dead time, and process sensitivity in response to a decrease in load. After these data have been collected and after the "noise-band" of the measurement been identified, these readings are used to automatically determine the start-up PID settings of the controller.

After this pretune or start-up sequence, the self-tuning controller reevaluates its performance after each upset, using the criteria given in Figure 2.29e.

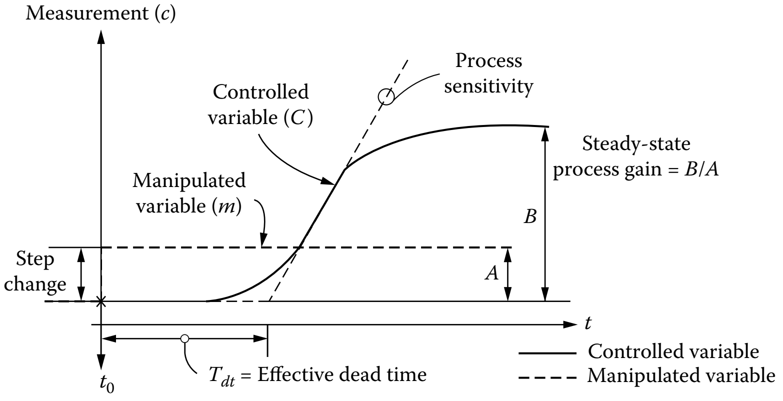

FIG. 2.29f
In the start-up or pretune phase, the self-tuning controller determines the dead time, gain, and sensitivity of the controlled process variable by evaluating its response to a step change.[10]

PERFORMANCE

The performance of such self-tuning controllers has been evaluated on different types of processes. The test results are shown in Figure 2.29h, where the performance ratio between conventionally tuned and self-tuned loops is on the vertical.

The conventionally tuned controllers were tuned for the worst condition, and their performance relative to the self-tuning controllers was evaluated on the basis of the integrated absolute error (IAE), which is the total area under the error curve in Figure 2.29e. In evaluating the test results, one can conclude that the improvement in control quality is impressive for slow processes (low gain) having little or no dead time. These are easy processes to control because they start responding to a correction immediately and can be controlled with high gain (narrow proportional band) controllers.

On the other hand, as the ratio of dead time to time constant rises and as the process becomes faster (process gain increases), the performance of self-tuning controllers deteriorates. When the process gain exceeds two and the dead time exceeds the time constant, the performance of the self-tuning controller actually drops below that of the conventionally tuned loop.

This is not surprising because as the dead time rises, the time it takes for evaluating a response also gets longer, which in turn increases the area under the error curve. For this reason, the use of PID control is not recommended for mostly dead time processes. In such cases a sample-and-hold algorithm (see Section 2.2 in this chapter) is recommended.

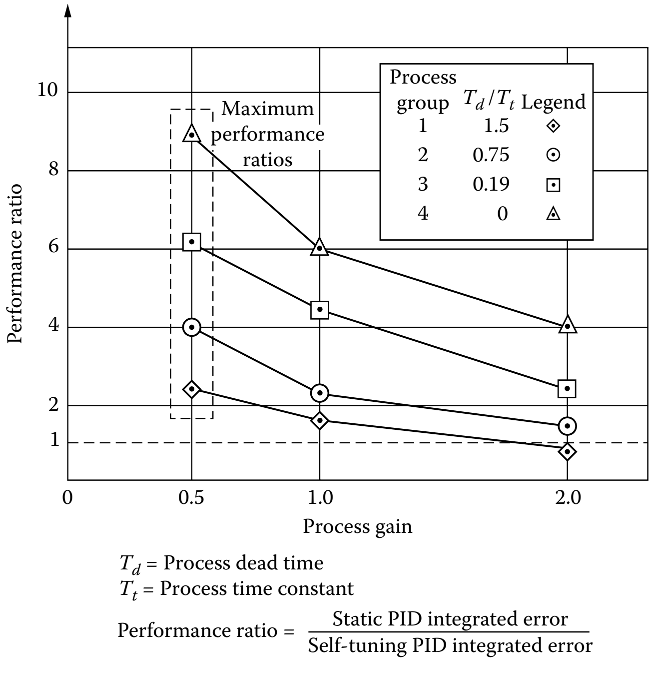

FIG. 2.29h

For slow processes with little dead time, the self-tuning controller outperforms the statically tuned PID controller.[10]

CONCLUSIONS

Process controllers with self-tuning capabilities are mostly stand-alone units that are used for single-loop applications, but self-tuning features are also available in DCS installations or in software packages. The software can be resident in a DCS, or it can be used in general-purpose computers, or perhaps as an external tuning aid.

A special class of self-tuning controllers has evolved for temperature-control applications. These are provided with special tuning procedures (usually based on the response during the warm-up phase or to a set-point change) and include constraints such as minimum overshoot.

Self-tuning controllers used for general-purpose process applications are more sophisticated and are often provided with provisions for multiple loop tuning, feedforward control, gain scheduling, and compensation for actuator and sensor nonlinearity. Most self-tuning controllers will self-tune during startup and will retune both on request and also when upsets occur naturally.

A few self-tuning controllers operate on the basis of continuously introducing excitations into the process. Such excitations can be deterministic set-point steps or doublets (used in pattern recognition methods) or can be persistent set-point variations (often pseudo noise, and usually on the order of 5% of set point).

Self-tuning controllers have gone through substantial development and improvement during the last decades. The better systems no longer depend on pulses or set-point changes for detecting the response of the loop but instead analyze the response to naturally occurring process upsets. These self-tuning controllers give control performance that is superior to that of manually tuned, static PID controllers when the process gain and the process dead time are both low. As the process gain and/or the dead time–to–time constant ratio rises, their performance deteriorates.

2.30 Sliding Mode Control in Process Industry

O. CAMACHO (2005)

Sliding mode control (SMC) is a powerful robust nonlinear control (see Section 2.19) technique that has been intensively developed during the last 35 years.[1,2] Sliding mode control has, for many years, been accredited as one of the key approaches for the systematic design of robust controllers for complex nonlinear dynamic systems operating under conditions of uncertainty. The most important advantage of sliding mode controllers is their innate insensitivity to parameter variations and disturbances once in the sliding mode, thereby eliminating the necessity of exact modeling.[1] Another distinguishing feature is their capability of order reduction, which enables the simplification of design and the decoupling of the system. With these advantages, sliding mode control is a promising area of study for both theoretical and application-oriented problems.

The potential of control resources may be used to the fullest extent within the framework of nonlinear control methods since the actuator limitations and other performance specifications may be included in the design procedure. The scope of SMC studies includes varied problems such as mathematical methods, design principles, and applications.[2–5]

The SMC design is composed of two steps. In the first step, a custom-made surface should be designed. While on the sliding surface, the plant's dynamics is restricted to the equations of the surface and is robust to match plant uncertainties and external disturbances. In the second step, a feedback control law should be designed to provide convergence of a system's trajectory to the sliding surface; thus, the sliding surface should be obtained in a finite time. The system's motion on the sliding surface is called the *sliding mode*.[1,2,5] Perfect tracking can be achieved at the price of control chattering.[7] *Chattering* is a high-frequency oscillation around the desired equilibrium point. It is undesirable in practice because it involves high control activity and can excite high-frequency dynamics ignored in the modeling of the system.[1–7]

The aim of this section is to present the overall concept of sliding mode control. Some references to industrial applications in electromechanical systems are discussed, and a practical approach, using a reduced-order model of chemical processes, for single-input single-output (SISO) systems and multiple-input multiple-output (MIMO) systems is also presented. Furthermore, a proposed SMC implementation of a PID algorithm is also suggested.

DESIGN PROCEDURE

The idea behind SMC is to define a surface along which the process can slide to its desired final value.[1] The structure of the controller is intentionally altered in accordance with a prescribed control law as its state crosses the surface.

First Step

The first step in SMC is to define the sliding surface, $S(t)$, which represents a desired global behavior, such as stability and tracking performance. The $S(t)$ selected in this work, presented by Slotine and Li,[6] is a proportional, integral-differential equation acting on the tracking-error expression:

$$S(t) = \left(\frac{d}{dt} + \lambda\right)^n \int_0^t e(t)dt \qquad \textbf{2.30(1)}$$

where $e(t)$ is the tracking error, that is, the difference between the reference value or set point, $r(t)$, and the output measurement, $x(t)$, namely $e(t) = r(t) - x(t)$. λ is a tuning parameter that helps to define $S(t)$. This term is selected by the designer and determines the performance of the system on the sliding surface. n is the system order.

The control objective is to ensure that the controlled variable is equal to its reference value at all times, meaning that $e(t)$ and its derivatives must be zero. Once the reference value is reached, Equation 2.30(1) indicates that $S(t)$ has reached a constant value, meaning that $e(t)$ is zero at all times; it is desired to set

$$\frac{dS(t)}{dt} = 0 \qquad \textbf{2.30(2)}$$

Equation 2.30(2) is called the *sliding condition.*[1,2]

Second Step

As a second step, once the sliding surface has been selected, attention must be turned to designing the control law that drives the controlled variable to its reference value and satisfies Equation 2.30(2).

The SMC control law, $U(t)$, consists of two additive parts: a continuous part, $U_C(t)$, and a discontinuous part, $U_D(t)$. That is

$$U(t) = U_C(t) + U_D(t) \qquad \textbf{2.30(3)}$$

The continuous part is given by

$$U_C(t) = f(x(t), \quad r(t)) \qquad \textbf{2.30(4)}$$

where $f(x(t), r(t))$ is a function of the controlled variable and the reference value.

The continuous part of the controller is obtained by combining the process model and sliding condition, Equation 2.30(2). The discontinuous part is nonlinear and represents the switching element of the control law.

The discontinuous part of the controller is discontinuous across the sliding surface. Mainly, $U_D(t)$ is designed based on a relay-like function, i.e., $U_D(t) = K_D$ sign $S(t)$, because it allows for changes between the structures with a hypothetical infinitely fast speed. In practice, however, it is impossible to achieve the high switching control because of the presence of finite time delays for control computations or limitations of the physical actuators, thus causing chattering around of the sliding surface.[1–7]

The aggressiveness to reach the sliding surface depends on the control gain (i.e., K_D), but if the controller is too aggressive it can collaborate with the chattering. To reduce the chattering, one approach is to reattach the relay-like function by a saturation or sigma function,[7] which can be written as follows:

$$U_D(t) = K_D \frac{S(t)}{|S(t)| + \delta} \qquad \textbf{2.30(5)}$$

where K_D is the tuning parameter responsible for the reaching mode. δ is a tuning parameter used to reduce the chattering problem.

Figure 2.30a shows the effect of δ variations on the process output. Figure 2.30b shows the effect of K_D variations on the system trajectory on a phase plane, which illustrates how the rate of the trajectory moves to reach its final value from an initial state to a final state. For example, when $K_D = K_3$ is used, the error rate moves faster, reducing the error until the final value is reached, than when $K_D = K_1$ or K_2 are used to tune the controller. Therefore, K_D represents a gain, which provides the aggressivity of the controller. Figure 2.30c confirms the previous conclusion in the time domain.

In summary, the control law usually results in fast motion to bring the state onto the sliding surface, $U_D(t)$, and a slower motion to proceed until a desired state $U_C(t)$, is reached. See Figure 2.30d.

APPLICATIONS

Although a large number of reports talk about SMC applications, few process companies have reported their results publicly. Therefore, the information presented here will be limited to the contents of the reports found in the literature. Two types of applications will be described, first to electromechanical systems and second, the applications for chemical processes.

Electromechanical Systems

Sliding mode control has most been often used in the electrical control of machines, including the control of induction motors, speed control, servo systems applications, power systems, power supply switching, robotics, gas turbines, and turbojet engines, as well as in aircraft systems and anti-skid automotive systems. Good references for electromechanical system applications can be found in Utkin, Guldner, and Shi[8] and Edwards and Spurgeon.[9] A special issue of ASME[10] is also recommended for readers interested in applications in this control field.

Chemical Systems

Even though SMC has been widely investigated for a variety of processes, as mentioned earlier, to the best of our knowledge none of the previous works have resulted in a general approach for process industry. Since industrial chemical processes modeled using first principles tend to be of higher order and complexity, the traditional SMC procedures present disadvantages in their application.

An efficient alternative could be the use of empirical modeling methods. Empirical methods use low-order linear models; usually, first-order plus deadtime (FOPDT) models are adequate for process control analysis and design. This kind of model is able to adequately represent the dynamics of many industrial processes, especially chemical processes, over a range of frequencies,[11,12] and is easily obtained from the popular reaction curve (Section 2.22).

Although reduced order models cause uncertainties, which arise from the imperfect knowledge of the model, and nonlinear effects of the process contribute to performance degradation in the controllers, a sliding mode controller (SMCr) could be designed on the basis that the robustness of the controller will compensate for modeling errors that arise from the linearization of the nonlinear model of the process. Thus, if a general reduced-order model of the process can be obtained and chattering can be reduced, this control strategy can

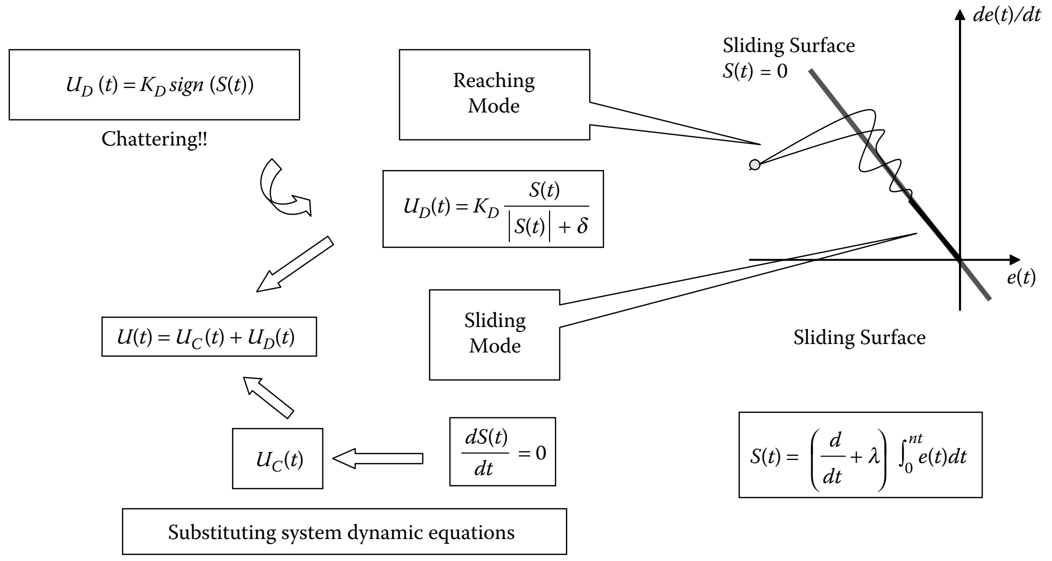

FIG. 2.30d
Sliding mode control components.

become one of the most important discoveries in the field of process control.

SMC for SISO Chemical Process Control

Here a general equation of the SMCr for SISO systems is presented. First, it is discussed in connection with self-regulating processes. After that, the subjects of inverse response, integrating, and a robust dead time compensation are covered.

Self-Regulating Processes SMCr is a type of model-based control (MBC) (Section 2.13), and the order of the model is proportional to the numbers of tuning parameters. The controller equation was derived by using an FOPDT process model, which is the recommended approach[11,12] (see Figure 2.30e). The controller obtained significantly simplifies the application of SMC to industrial processes having this type of dynamics.

Based on the references,[13,14] the complete SMCr is

$$U(t)=\left(\frac{t_0\tau}{K}\right)\left[\frac{X(t)}{t_0\tau}+\lambda_0 e(t)\right]+K_D\frac{S(t)}{|S(t)|+\delta} \qquad \textbf{2.30(6a)}$$

with

$$S(t)=\text{sign}(K)\left[-\frac{dX(t)}{dt}+\lambda_1 e(t)+\lambda_0\int_0^t e(t)dt\right] \qquad \textbf{2.30(6b)}$$

Figure 2.30f shows a schematic of the controller. These equations present advantages from the process control point of view. First, they have a fixed structure depending on the λ parameters and the characteristic parameters of the FOPDT model; second, the action of the controller is considered (in the sliding surface equation), by including the term sign(K). Note that sign(K) only depends on the static gain; therefore, it never switches. For industrial applications, Equation 2.30(6b) represents a PID algorithm.[15]

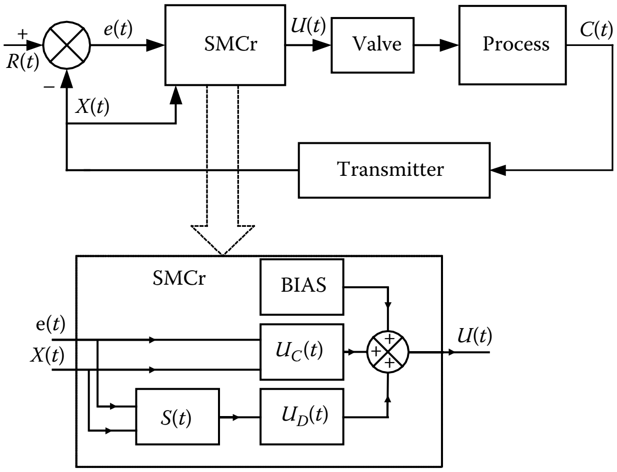

FIG. 2.30e
Schematic of a sliding mode controller.

To complete the controller, the following tuning equations can be considered:[13,14]

- For the continuous part of the controller and the sliding surface,

$$\lambda_1=\frac{t_0+\tau}{t_0\tau}\ [=]\ [\text{time}]^{-1} \qquad \textbf{2.30(7a)}$$

$$\lambda_0\le\frac{\lambda_1^2}{4}\ [=]\ [\text{time}]^{-2} \qquad \textbf{2.30(7b)}$$

- For the discontinuous part of the controller,

$$K_D=\frac{0.51}{|K|}\left[\frac{\tau}{t_0}\right]^{0.76}\ [=]\ [\text{fraction CO}] \qquad \textbf{2.30(7c)}$$

$$\delta=0.68+0.12(|K|\,K_D\lambda_1)\ [=]\ [\text{fraction TO/time}] \qquad \textbf{2.30(7d)}$$

Equations 2.30(7c) and 2.30(7d) are used when the signals from the transmitter and controller are in fractions (0 to 1). Sometimes, the control signals are scaled in percentages, so the signals are in 0-to-100% ranges. In these cases, the values of K_D and δ are multiplied by 100.

Inverse Response Systems When the initial direction of the process response is contrary to the direction of the final steady state, the process is called a nonminimum phase or inverse response process. This characteristic is only related to the input/output behavior of a process. Several chemical processes can have this kind of response, such as drum boilers, reactors, and reboilers.

This kind of system can be described by the following transfer function,

$$G_1(s)=\frac{K(1-\tau_1 s)}{(\tau_2 s+1)\cdot(\tau_3 s+1)\cdots(\tau_n s+1)} \qquad \textbf{2.30(8)}$$

It can be approximated by

$$G_1(s)\cong K\frac{e^{-t_o s}}{\tau s+1} \qquad \textbf{2.30(9)}$$

This means that the step response of the nonminimum phase system (Equation 2.30[8]) can be approximated by an

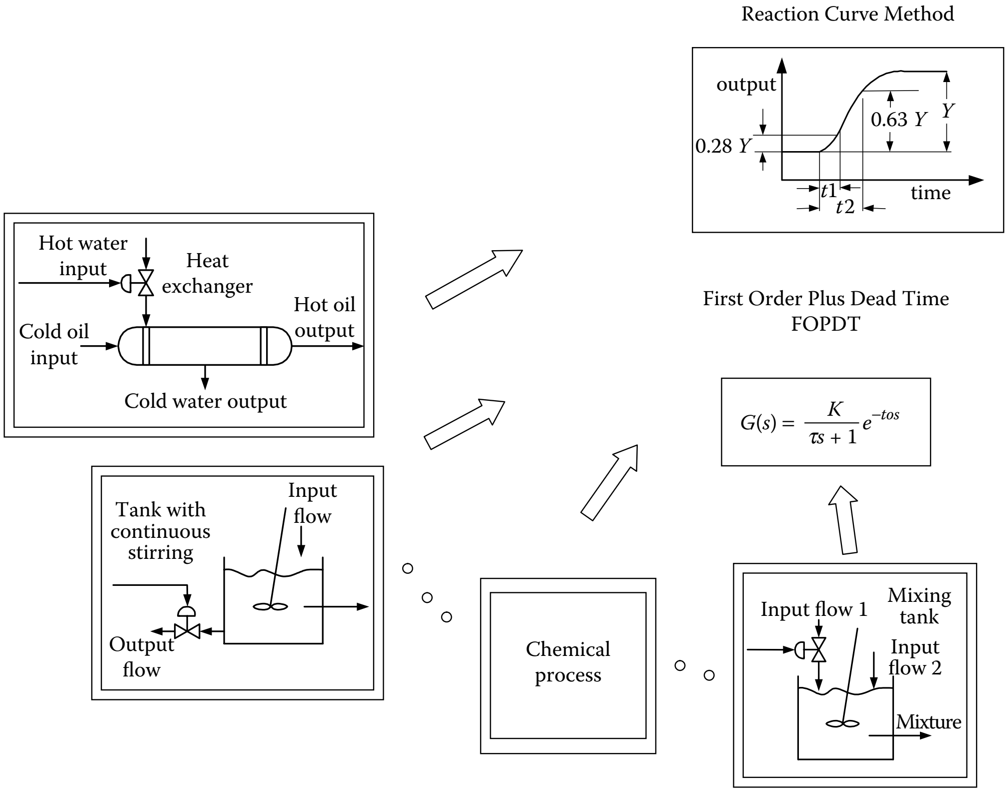

FIG. 2.30f
Empirical model to design Sliding mode controllers for chemical processes.

FOPDT model, such as the one in Equation 2.30(9) (see Section 2.22). Therefore, the design procedure for systems represented using FOPDT models can be applied.[14,16] The resulting SMCr is similar to the ones given by Equation 2.30(6a) and 2.30(6b). The equations for the first tuning estimates of the controller parameters were obtained[16] and are listed in Table 2.30k.

Integrating Systems In general, the following model can approximate integrating systems with dead time:

$$G(s) = K\frac{e^{-t_o' s}}{s} \qquad \textbf{2.30(10)}$$

The identification of the characteristic parameters of this model (K, τ, and t_o) is included in Section 2.22. Using Equation 2.30(10) and the procedure described previously, the controller obtained is[17]

$$U(t) = \frac{\lambda_o t_o'}{K} e(t) + K_D \frac{S(t)}{|S(t)| + \delta} \qquad \textbf{2.30(11)}$$

Equation 2.30(11) does not have the term that includes the deviation of the controlled variable; it suggests a modification, which is summarized in Figure 2.30g. Tuning settings for integrating processes are listed in Table 2.30k.

Robust Dead Time Compensator Dead time is present in many industrial processes, where it creates a serious control problem. The performance of feedback control systems will drop drastically as the ratio of dead time to time constant increases. The Smith predictor (SP—see Section 2.27) or dead time compensator (DTC), as it is also known, has many weak points, including possible instability and poor performance, if the model is inaccurate, and poor response to disturbances.[18] In addition, the original structure of the SP cannot reject constant load disturbance for processes with integration.

Camacho and Smith[14] showed the design of an SMCr from an FOPDT. The design of SMCrs for dead time processes

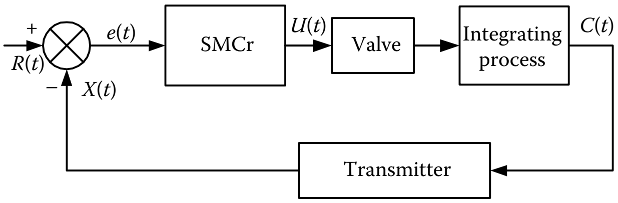

FIG. 2.30g
Modified sliding mode controller for integrating systems.

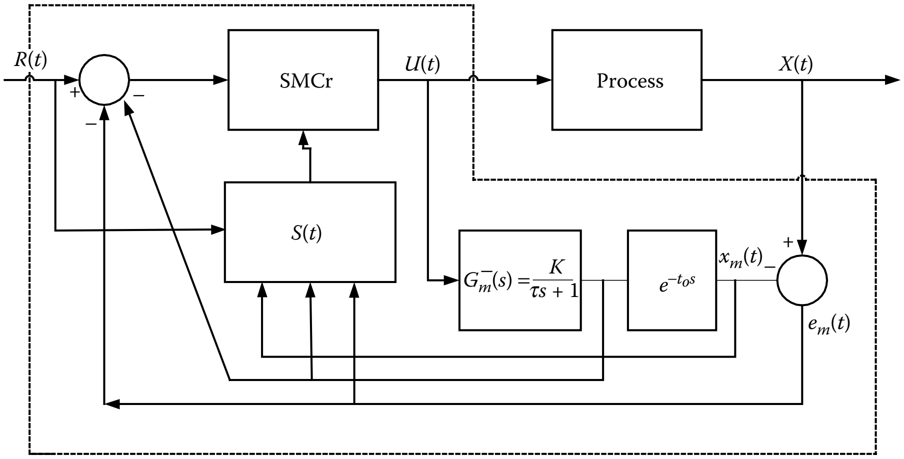

FIG. 2.30h
Robust dead time compensator scheme.

requires some assumptions,[13,14] which can be solved using the internal model approach. It was shown that by merging these two control techniques, a robust one (SMC) and a predictive one (IMC), the resulting controller will provide the benefits of both.[19] Thus, the mixing of SMC and predictive structures can produce better controllers than the original ones.[20]

The robust dead time compensator is designed in two steps: First, an invertible model of the process is chosen, and from it, the sliding surface is designed. Second, the reaching condition is satisfied, and the robustness is guaranteed. Figure 2.30h shows the proposed scheme. The nonlinear process has been modeled as an FOPDT. This model can be separated into two parts:

$$G_m^+ = e^{-t_o s} \qquad \textbf{2.30(12)}$$

$$G_m^- = \frac{K}{\tau s + 1} \qquad \textbf{2.30(13)}$$

Since $G_m^-(s)$ eliminates the dead time term from the model, this simplification facilitates the SMC design.

The controller obtained is as follows:

$$S(t) = \text{sign}(k)\left[e_m^-(t) + \lambda\int_0^t e(t)dt\right] \qquad \textbf{2.30(14)}$$

$$u(t) = \frac{\tau}{K}\left[\frac{x_m^-(t)}{\tau} + \lambda\underbrace{[R(t) - x_m(t) - e_m(t)]}_{e(t)}\right] + K_D\frac{s}{|s| + \delta} \qquad \textbf{2.30(15)}$$

$e_m^-(t)$ is the error between the reference, $R(t)$, and the model output without deadtime, $x_m^-(t)$, $x(t)$ is the controlled variable, and $e_m(t)$ is the error between the process output and the complete model output, also known as modeling error.

It is observed that this sliding surface includes a prediction term, $e_m^-(t)$, which gives a faster response to reach the set point than the original one, when processes present an elevated controllability relationship (t_0/τ). The tuning parameters for this controller are included in Table 2.30k.

SMC for MIMO Chemical Process Control

In this section, a summary is provided of the SMCr modification that should be applied when the chemical processes are multivariable[10] (see Section 2.18). The objective is to extend the applicability of the SMCrs, which were designed for SISO processes, to multivariable systems.

Industrial processes are by nature multivariable. Control of multivariable and nonlinear processes is not an easy task because of the interaction among variables (see Section 2.12) and because of the presence of dead time. The interaction results from the high probability that a manipulated variable can affect several controlled variables. This interaction among the variables degrades control quality. The proposed approach discussed below assumes that the total control system consists of multiple SMCrs acting in addition to a decoupling system (Section 2.12).

The amount of interaction between the variables can be determined by the steady-state gains K_{ij}, using the relative gain array (Section 2.25) or Bristol Array method,[11,12] which allows obtaining a dimensionless interaction index μ_{ij}. In systems with strong interaction, a common practice is to use decoupling of the interacting loops.[11,12]

Once the system is decoupled, it is possible to use a developed SMCr based on an FOPDT model. The original SMCr controller has a set of tuning equations for SISO-type processes. The idea in this part is to consider the effect of the multivariable characteristic parameters and the interaction index in the controller tuning equations.

Using the concepts of decoupling, a multivariable control system can be represented as:

$$\begin{bmatrix} C_1(s) \\ C_2(s) \\ \dots \\ C_n(s) \end{bmatrix} = \begin{bmatrix} G'_{P11}(s) & 0 & \dots & 0 \\ 0 & G'_{P22}(s) & \dots & 0 \\ \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & G'_{Pnn}(s) \end{bmatrix} \begin{bmatrix} M_1(s) \\ M_2(s) \\ \\ M_N(s) \end{bmatrix} \qquad \mathbf{2.30(16)}$$

where $C_i(s)$ represents the i-controlled variable; $M_j(s)$ is the j-manipulated variable; and $G_{pij(s)}$ is an FOPDT transfer function relating the i-controlled and j-manipulated variables, respectively. Once the system is decoupled, it is possible to use SMCr based on an FOPDT model.[13]

The parameters t_{ojj}, τ_{jj}, and K_{jj} needed to calculate the initial tuning settings of the controller are obtained from the open-loop step responses (see Section 2.22), for the *j-j pairing* of the manipulated and controlled variable pairs after decoupling. In comparison with the original SMCr tuning values, only the K_{Dj} tuning parameter has changed to include the interaction index. This provides the necessary aggressiveness to reach the sliding surface in multivariable applications (Table 2.30k).

Discussion of the Results Due to space limitations, detailed results are not included here, but they can be seen for the minimum-phase case in Camacho and Smith,[14] for the inverse response case in Reference 16 and for the integrating systems case in Reference 17.

A new control scheme, mixing the internal model approach with the SMC concept for processes with high dead time–to–time constant ratios was tested in Reference 19. Finally, the multivariable systems case can be seen in the ASME special issue.[10]

Summarizing the results, the same SMCr designed for minimum phase systems can be used with good results for a wide class of nonlinear chemical processes. These SMCrs gave robust performance on processes with dead time and in applications with modeling errors and disturbances.

SMCR IMPLEMENTATION OF PID ALGORITHM

Digital PID algorithms are widely used in distributed control systems (DCS), in programmable logic controllers (PLC), and in remote terminal unit (RTU) applications. A common PID algorithm is as follows:

$$\mathrm{MV}(t) = Kc\left[e(t) + \frac{1}{\tau_I}\int_0^t e(t)dt - \tau_D\frac{d\mathrm{CV}(t)}{dt}\right] \qquad \mathbf{2.30(17)}$$

where MV(t) is the manipulated variable, τ_I is the integral time, τ_D is the derivative term, and CV(t) is the controlled variable. Note that the derivative term is calculated using the measured controlled variable, not the error.

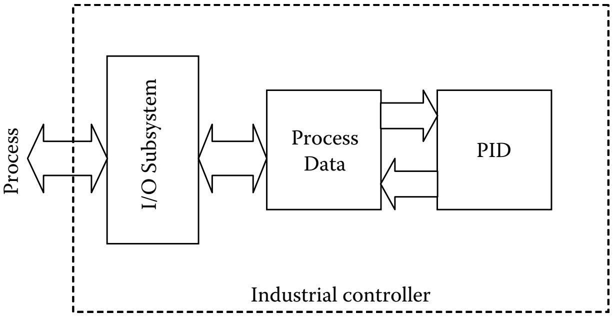

FIG. 2.30i
Implementation of PID algorithm in an industrial controller.

In this respect, Equations 2.30(6b) and 2.30(17) are similar. The discussion here will focus on implementing the SMCr based on the PID algorithms,[15] using the presently existing control devices and plant operator mentality. The PLC-based implementation of a discrete algorithm for a PID is shown in Figure 2.30f.

The term *X(t)* in Equation 2.30(6b) is the same as the term CV*(t)* in 2.30(17). The next step is to tune the PID based on the SMCr tuning equations. From Equation 2.30(6b) and Equation 2.30(17), the tuning parameters of the PID algorithm can be converted into the tuning parameters of the sliding surface $S(t)$, as follows:

$$Kc = \lambda_1 \qquad \mathbf{2.30(18)}$$

$$\tau_I = \lambda_1/\lambda_O \qquad \mathbf{2.30(19)}$$

$$\tau_D = (\lambda_1)^{-1} \qquad \mathbf{2.30(20)}$$

With the above conversions, the PID algorithm can be expressed in terms of the sliding surface term $S(t)$. The SMCr is divided in two parts—the continuous part, which is an algebraic function of the process variables and the set point, and the discontinuous part, which is also an algebraic function of $S(t)$, which is calculated from the PID algorithm that exists on the PLCs or RTUs used in industry.

Figures 2.30i and 2.30j show the implementation of this approach, where the output of the PID, which was an input

Implementation of SMCr using an industrial PID controller.

TABLE 2.30k
Summary of the Tuning Equations Used for SMCrs

	Self-Regulating	*Inverse Response*	*Integrating*	*Dead-Time Compensator*	*Multivariable*
λ_1	$\frac{t_0+\tau}{t_0\tau}$	$\frac{t_0+\tau}{t_0\tau}$	$\frac{1}{t_0}$	$\lambda \le \frac{1}{\tau+t_0}$	$\frac{t_{ojj}+\tau_{jj}}{t_{0jj}\ \tau_{jj}}$
λ_0	$\le \frac{\lambda_1^2}{4}$	$\le \frac{\lambda_1^2}{8}$	$\left(\frac{\lambda_1}{4}\right)^2$	—	$\le \frac{\lambda_{ij}^2}{4}$
K_D	$\frac{0.51}{\lvert K\rvert}\left[\frac{\tau_j}{t_{oj}}\right]^{0,76}$	$\frac{0.064}{K}\left[\frac{\tau}{t_0}\right]^{0.76}$	$\frac{0.64}{K}\left[\frac{1}{t_0}\right]^{0.76}$	$K_D \ge \frac{0.8}{\lvert K\rvert}\left(\frac{\tau}{t_0}\right)^{0.76}$	$\mu_{ij}\ \frac{0.51}{\lvert K_{jj}\rvert}\left[\frac{\tau_{jj}}{t_{0jj}}\right]^{0.76}$
δ	$0.68+0.12(KK_D\lambda_1)$	$0.68+0.12\ (KK_D\lambda_1)$	$0.68+0.12(KK_D\lambda_1)$	$0.68+0.12(KK_D\lambda)$	$0.68+0.12(K_{ij}K_{Dij}\lambda_{jj})$

to the process (manipulated variable), became an input to the discontinuous part of the SMCr.

SMCr Implementation Methodology

Three steps are required to implement the total algorithm. In each iteration, the term $S(t)$ is calculated from the PID output. The continuous and discontinuous parts of the controller algorithm are easily programmable algebraic equations. This procedure is based on the PID algorithm and already exists in most industrial controllers.

The sequence of statements summarizing the proposed algorithm is:

```
a1 = t0*tau/K
do forever
  input x
  et = x - ref
  y  = PID(et)
  st =    sign(k)*y
  ut = (x/K + a1*lambda0*et) +
          Kd*(st/(abs(st)+delta)
End
```

Table 2.30k provides a summary of the tuning equations for the SMCrs. The parameters (t_0, τ, and K) that are required to calculate the initial tuning settings of the controller are obtained from the open-loop step response (Section 2.22).

CONCLUSIONS

In the past, SMC has been an important theoretical research field. Today, it is becoming a good source of solutions to real-world problems. Its potential is limited only by the imagination of the people working in process control. Therefore, the prospects for the application for SMC in the processing industries are immense.

This section has described SMC and provided some examples of industrial applications in electromechanical systems and a practical approach for using a reduced-order model in chemical process applications. SISO and MIMO systems were also discussed.

The SMCr can be implemented from a PID algorithm, where the PID represents the sliding surface, and the rest of the controller is built using algebraic blocks. This represents an advantage from a process control engineer's point of view because the controller is of a fixed structure. This controller, having adjustable parameters, can be easily implemented in DCS.

Finally, the approach proposed for chemical industry applications has the simplicity of PID controllers and the robustness of SMCrs, and the procedure used can be easily extended to electrical and mechanical systems if reduced-order models can be obtained for those processes.

2.31 Software for Fuzzy Logic Control

D. H. F. LIU (1995) **J. ABONYI** (2005)

In 1965, Professor L. A. Zadeh of the University of California, Berkeley, presented a paper outlining fuzzy theory. In about 1970, fuzzy theory began to produce results in Japan, Europe, and China. Fuzzy control has found applications in cement kinks, papermaking machines, and polymerization reactors. Nowadays, fuzzy controllers are also used to control household appliances, such as dishwashers, washing machines, video cameras, and rice cookers, even though this fact is not always advertised. Among the main characteristics of these processes are their time-varying, nonlinear behavior and the low frequency of their measurements.

Fuzzy logic is a very human concept, potentially applicable to a wide range of processes and tasks that require human intuition and experience. Fuzzy logic control can be applied by means of software, dedicated controllers, or fuzzy microprocessors emdebbed in digital products. Application flexibility combined with inherent simplicity and wide ranges of capabilities give fuzzy logic technology great potential for growth.

INTRODUCTION

Today's manufacturing processes present many challenging control problems; among these are nonlinear dynamic behavior, uncertain and time-varying parameters, and unmeasured disturbances. In the past decade, the control of these systems has received considerable attention in both academia and industry. While advanced control strategies — coupled with cheaper and powerful computer systems — have made nonlinear process control much more practical, there is still a considerable gap between control theory and industrial practice. It is frustrating for the control theory community that elegant and comprehensive frameworks for system analysis and design are seldom applied in the process industry, which still applies the well-known PID controller (90% of control loops) and relies on manual control in complex process situations.

Conventional control theory may fall short if the model of the process is difficult to obtain, (partly) unknown, or highly nonlinear. The design of controllers for seemingly easy everyday tasks such as driving a car or grasping a fragile object continues to be a challenge for robotics, while human beings easily perform these tasks. Similarly, some industrial processes are controlled in one of the following ways:

- The process is controlled manually by experienced operators.
- The process is controlled by an automatic control system that needs manual online "trimming."

Many industrial processes operated by humans cannot be automated using conventional control techniques since the performance of these controllers is often inferior to that of the operators. One of the reasons is that linear controllers, which are commonly used in conventional control, are not appropriate for the control of nonlinear processes.

Another reason is that humans aggregate various kinds of information and combine control strategies, which cannot be integrated into a single analytic control law. The underlying principle of knowledge-based (expert) control is to capture and implement experience and knowledge available from experts (e.g., process operators).

A specific type of knowledge-based control is fuzzy rule-based control, where the control actions corresponding to particular conditions of the system are described in terms of fuzzy if–then rules.

To investigate the current application issues of advanced control techniques, a survey was made in Japan in 1995.[1] Information was obtained about the number and the evaluation of control applications, key factors for successful and failed implementations, etc. The investigated control techniques were classified as follows:

- *Advanced PID:* I-PID and two-degrees-of-freedom PID, decoupling PID, dead time compensation, gain scheduling, and auto tuning control
- *Modern Control Theory:* linear quadratic Gaussian (LQG) regulator, observer, Kalman filter, model predictive control (MPC), adaptive control, H-infinity control, repetitive control, exact linearization control, optimization control
- *FAN (Fuzzy, Artificial intelligence, Neural network):* Fuzzy control, rule-based control, neural network control

The survey showed that advanced PID-type control is widely applied, and about 30% of the 110 respondents have already used this type of control in their factories. MPC and fuzzy control are the most widely used of the modern control and FAN techniques. Slightly less than 40% of the factories have applied these solutions. Compared to a survey in 1989, the applications of decoupling PID, dead time compensation, Kalman filter, model predictive control, rule-based control, fuzzy control, and optimization have increased substantially.

Although modern control theory is rarely applied, except model-predictive control, 60 to 70% of the respondents are satisfied with the results, and the satisfaction with FAN is going up. These tendencies indicate that a huge demand exists in the industry for new fuzzy control solutions.

The objective of this section is to present the principle of fuzzy modeling and control, identify and explain the various design choices, and provide an overview of the implementation tools for engineers.

PRINCIPLE OF FUZZY SYSTEMS

Fuzzy control is a control method based on fuzzy logic. Fuzzy logic is not really "fuzzy." Just as fuzzy logic can be described simply as "computing with words rather than numbers," fuzzy control can be described simply as "control with sentences rather than equations."

For many real-world applications, a great deal of information is provided by human experts, who do not reason in terms of mathematics but instead describe the system verbally through vague or imprecise statements such as

IF The Temperature is **Up THEN** The Pressure is **High.**

Because so much human knowledge and expertise come in terms of such verbal rules, one sound engineering approach is to try to integrate such linguistic information into the modeling process. A convenient and common approach is to use fuzzy logic concepts to cast the verbal knowledge into a conventional mathematical representation.

Fuzzy logic facilitates the computerized representation of this kind of knowledge, which subsequently can be fine-tuned using process experiments (e.g., based on input/output process data). From this basis, the fuzzy system is a computation framework based on the concepts of fuzzy sets, fuzzy if–then rules, and fuzzy reasoning.

This section will introduce the reader to the structure of fuzzy models. It will not attempt to provide a broad survey of the field. For such a survey the reader is referred to *An Introduction to Fuzzy Control,* by Driankov, Helerndoorn, and Reinfrank,[2] *Fuzzy Control,* by Passino and Yurkovic,[3] or *A Course in Fuzzy Systems and Control*, by Wang.[4]

Fuzzy Sets

Conventional set theory is based on the premise that an element either belongs to or does not belong to a given set. Fuzzy set theory takes a less rigid view and allows elements to have degrees of membership of a particular set such that elements are not restricted to either being in or out of a set but are allowed to be "somewhat" in. In many cases this is a more natural approach.

For example, consider the case of a person describing the atmospheric temperature as being "hot." If one was to express this concept in conventional set theory one would be forced to designate a distinct range of temperatures, such as 25°C (77°F) and over, as belonging to the set "hot." That is, *hot* = [25;∞)°C. This seems contrived because any temperature that falls just slightly outside this range would not be a member of the set, even though a human being may not be able to distinguish between it and one that is just inside the set. In fuzzy set theory, a precise representation of imprecise knowledge is not enforced since strict limits of a set are not required to be defined; instead, a *membership function* is defined.

A membership function describes the relationship between a variable and the degree of membership of the fuzzy set that corresponds to particular values of that variable. This degree of membership is usually defined in terms of a number between 0 and 1, inclusive, where 0 implies total absence of membership, 1 implies complete membership, and any value in between implies partial membership of the fuzzy set. This may be written as follows: $A(x) = [0;\, 1]$ for $x \in U$, where $A(x)$ is the membership function and U is the universe of discourse that defines the total range of interest over which the variable x should be defined.

For example, to define membership of the fuzzy set "hot," a function that rises from 0 to 1 over the range 15 to 25°C (59 to 77°F) may be used, i.e.,

$$A(x) = \begin{cases} 0 & x < 15°\text{C} \\ \dfrac{x-15}{10} & 15 \le x \le 25° . \\ 1 & x > 25°\text{C} \end{cases} \qquad \textbf{2.31(1)}$$

This implies that 15°C (59°F) is not hot; 20°C (68°F) is a bit hot; 23°C (73.4°F) is quite hot; and 30°C (86°F) is truly hot. Specific measurable values such as 15 and 20 are often referred to as crisp values or fuzzy singletons, to distinguish them from fuzzy values, such as *hot,* which are defined by a fuzzy set. Fuzzy values are sometimes also called linguistic values. As Figure 2.31a illustrates, this definition is more reflective of human or linguistic interpretations of temperatures and hence better approximates such concepts.

While seeming imprecise to a human being, fuzzy sets are mathematically precise in that they can be fully represented by exact numbers. They can therefore be seen as a method of tying together human and machine knowledge representations. Given that such a natural method of representing information in a computer exists, information processing methods can be applied to it with the use of fuzzy systems.

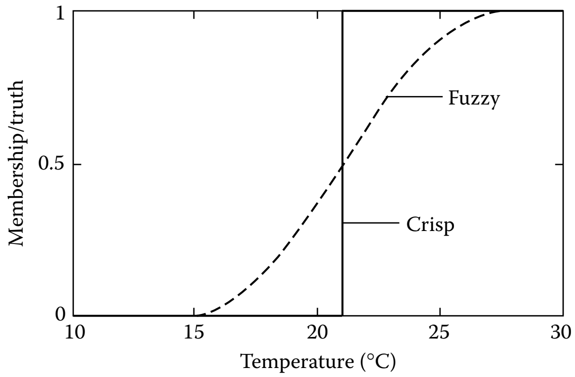

FIG. 2.31a
Representation of high temperature in terms of a "fuzzy set."

Fuzzy Systems

A fuzzy controller has a set of rules that it uses to calculate the final control action. Each rule is a linguistic expression describing the control action to be taken in response to a given set of process conditions. The rules are in the familiar if–then format, and formally the if side is called the *condition* and the then side is called the *conclusion* (more often, perhaps, the pair is called *antecedent–consequent* or *premise–conclusion*). IF (CONDITION) THEN ACTION.

Take for instance a typical fuzzy controller with two rules:

1. **IF** *error* is ***Neg*** **and** *change in error* is ***Neg*** then output is ***NB***
2. **IF** *error* is ***Neg*** **and** *change in error* is ***Zero*** then output is ***NM***

The input value "Neg" is a *linguistic term,* which is short for *Negative*; the output value "NB" stands for *Negative Big* and "NM" for *Negative Medium.* The computer is able to execute the rules and compute a control signal that depends on the measured inputs *error* and *change in error.*

The collection of such rules is called a *rule base.* The basic idea of fuzzy logic control is to formulate sets of rules for automatic operation based on practical experience and knowledge about manual control of the process. In fuzzy logic, the condition of a rule is fulfilled to a certain degree, and each rule will influence the result of the set of rules in accordance with its grade of fulfillment. To illustrate this procedure, the basic configuration of a fuzzy system is shown in Figure 2.31b.

As is depicted in this figure, a fuzzy system involves the following components:[5]

Data preprocessing processes the controller's inputs in order to obtain the inputs of the static fuzzy system. It will typically perform some of the following operations on the input signals:

- *Signal scaling.* The physical values of the input of the fuzzy system may differ significantly in magnitude. By mapping these to proper normalized (but interpretable) domains via scaling, one can instead work with signals of roughly the same magnitude. This is accomplished by normalization gains that scale the input into the normalized domain [−1, 1]. Values that fall outside the normalized domain are mapped onto the appropriate endpoint.

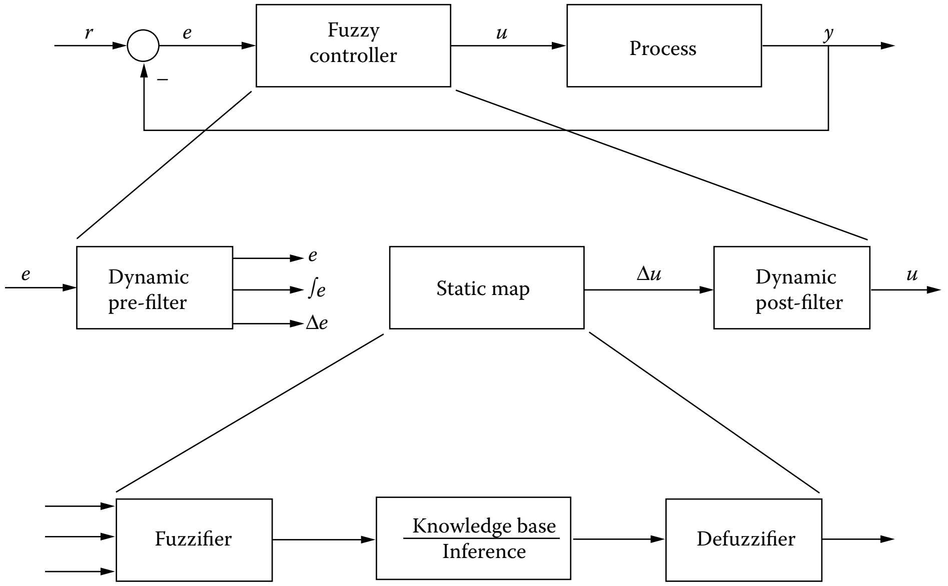

FIG. 2.31b
Fuzzy controller in a closed-loop configuration (top panel) consists of dynamic filters and a static map (middle panel). The static map is formed by the knowledge base, inference mechanism, and fuzzification and defuzzification interfaces.

- *Dynamic filtering.* In a fuzzy PID controller, for instance, linear filters are used to obtain the derivative and the integral of the control error, *e*. Nonlinear filters are found in nonlinear observers and in adaptive fuzzy control where they are used to obtain the fuzzy system parameter estimates.
- *Feature extraction.* Through the extraction of different features, numeric transformations of the controller inputs are performed. These transformations may be Fourier or wavelet transforms, coordinate transformations, or other basic operations performed on the fuzzy controller inputs.

Fuzzification maps the crisp values of the preprocessed input of the model into suitable fuzzy sets represented by membership functions.

The *rule base* is the cornerstone of the fuzzy model. The expert knowledge, which is assumed to be given as a number of if–then rules, is stored in a fuzzy rule base. According to the consequent proposition, there are three distinct classes of fuzzy models:

- *Fuzzy linguistic models* (*Mamdani models*), where both the antecedent and consequent are fuzzy propositions. Hence, a general rule of a linguistic or Mamdani fuzzy model is given by R_j: **If** x_1 is $A_{1,j}$ **and … and** x_n is $A_{n,j}$ **then** y is B_j, where R_j denotes the j-th rule, $j = 1,\ldots, N_r$, and N_r is the number of the rules. The antecedent variables represent the input of the fuzzy system, x_i. $A_{i,j}$ and B_j are fuzzy sets described by membership functions.
- *Fuzzy relational models,* which are based on fuzzy relations and relational equations.[6] These models can be considered as a generalization of the linguistic model, allowing one particular antecedent proposition to be associated with several different consequent propositions via a fuzzy relation.
- *Takagi–Sugeno* (*TS*) *fuzzy models,* where the consequent is a crisp function of the input variables, $f_j(\mathbf{x})$, rather than a fuzzy proposition.[7]

$$R_j\text{: }\mathbf{If}\quad x_1 \text{ is } A_{1,j} \quad \mathbf{and}\ldots\mathbf{and} \quad x_n \text{ is } A_{n,j}$$
$$\mathbf{then} \quad y = f_i(x) \qquad \mathbf{2.31(2)}$$

Mamdani (linguistic) fuzzy models with either fuzzy or singleton consequents are usually used as direct closed-loop controllers, while Takagi–Sugeno (TS) fuzzy systems are typically used as a supervisory controllers of fuzzy models of dynamical processes.

Inference engine. The inference mechanism or inference engine is the computational method that calculates the degree to which each rule fires for a given fuzzified input pattern by considering the rule and label sets. A rule is said to *fire* when the conditions upon which it depends occur. Since these conditions are defined by fuzzy sets which have degrees of membership, a rule will have a degree of firing or *firing strength.* The firing strength is determined by the mechanism that is used to implement the *and* in the expression. There are different methods for implementing each of the logical operators, and the reader is referred to Reference 2 for the details on these.

As can be seen in the example in Figure 2.31c, the logical product (AND connection) of a group of grades is simply the minimum value of all of the grades. Thus, in rule 5, the logical product of 1 for the control error and 0.5 for the change of the control error is 0.5. This procedure is repeated for each of the rules, as shown in Figure 2.31c. The logical sum combines the results of the rules. This is shown in the bottom of the corner of Figure 2.31c.

Defuzzification. A defuzzifier compiles the information provided by each of the rules and makes a decision from this basis. In linguistic fuzzy models the defuzzification converts the resulted fuzzy sets defined by the inference engine to the output of the model to a standard crisp signal. The centroid

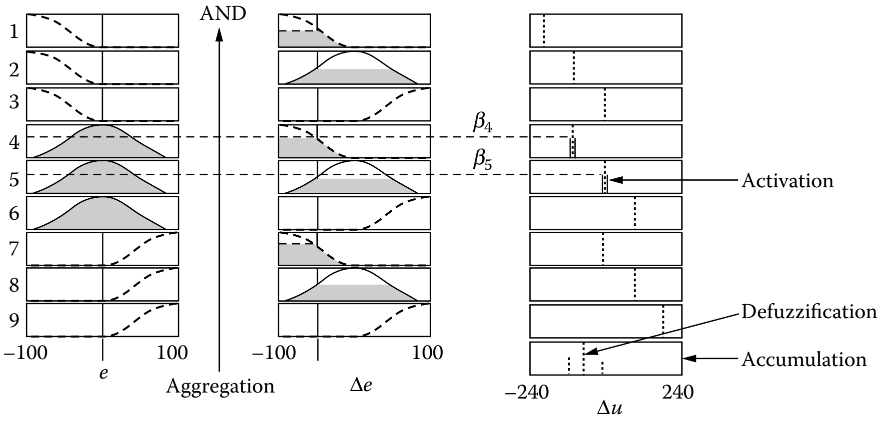

FIG. 2.31c
Example for a fuzzy inference.

method of defuzzification takes a weighted sum of the designated consequences of the rules according to the firing strengths of the rules. In the example shown in Figure 2.31c, which is the special case of Takagi–Sugeno fuzzy models, this type of defuzzification results in the following simple form:

$$y = \sum_{j=1}^{N_r} \beta_j(\mathbf{x}) f_j(\mathbf{x}) \tag{2.31(3)}$$

where $\beta_j(\mathbf{x})$ is the normalized degree of fulfillment (firing strength) of the rules:

$$\beta_j(\mathbf{x}) = \frac{\prod_{j=1}^{n} A_{i,j}(x_i)}{\sum_{i_1=1}^{N_r}\prod_{j=1}^{n} A_{i,j}(x_i)}. \tag{2.31(4)}$$

Postprocessing. The preprocessing step gives the output of the fuzzy system based on the crisp signal obtained after defuzzification. This often means the scaling of the output. Operations this post-filter may perform include:

- *Signal scaling.* A denormalization gain can be used, which scales the output of the fuzzy system to the physical domain of the actuator signal.
- *Dynamic filtering.* In some cases, the output of the fuzzy system is the increment of the control action. The actual control signal is then obtained by integrating the control increments. Of course, other forms of smoothing devices and even nonlinear filters may be considered.

EXAMPLE: FUZZY PI CONTROLLER

The previously presented decomposition of a controller to a static map and dynamic filters can be done for most classical control structures. To see this, consider a proportional–integral (PI) controller,

$$u(t) = K\left(e(t) + \frac{1}{T}\int e(t)dt\right) + \text{bias}$$

which can be expressed in discrete form by a simple difference equation: $\Delta u(k) = q_1 e(k) + q_2 \Delta e(k)$, where $\Delta e(k) = e(k) - e(k-1)$ and q_1, q_2 are the parameters of the controller that define a hyperplane shown in Figure 2.31d.

This linear form can be generalized to a nonlinear function: $\Delta u(k) = f(\mathbf{x})$, where the inputs of this static mapping are $x_1 = e(k)$ and $x_2 = \Delta e(k)$. In a fuzzy controller this nonlinear function f is represented by a fuzzy mapping.

Since the rule base represents a static mapping between the antecedent and the consequent variables, external dynamic filters must be used to obtain the desired dynamic behavior of the controller (Figure 2.31b). Furthermore, as the PI controller is defined in incremental form, signal processing is required both before and after the fuzzy mapping to obtain the control signal: $u(k) = u(k-1) + \Delta u(k)$.

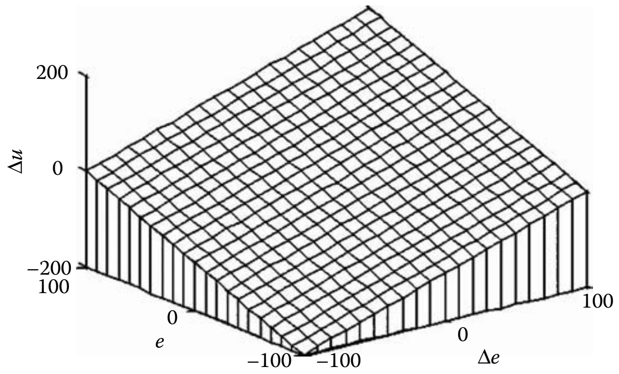

FIG. 2.31d
Control surface of a linear PI controller.

The set of rules of the PI fuzzy controller can be expressed in the following form:

$$\begin{aligned} R_j: &\text{IF} \quad e(k) \text{ is } A_{1,j} \quad \text{and} \quad \Delta e(k) \text{ is } A_{2,j} \\ &\text{THEN} \quad \Delta u_j = q_{1,j} e(k) + q_{2,j} \Delta e(k) \end{aligned} \tag{2.31(5)}$$

where Δu_j denotes the output of the j-th implication, and $q_{p,j}(p = 1, 2)$ are consequent parameters of the sub-PI controllers.

When the rule consequents are constants instead of local PI controllers, the resulted Mamdani fuzzy system can be viewed as defining a piecewise constant function with extensive interpolation.

An example of such a rule base is given in Table 2.31e. Three linguistic terms are used for each variable (N, Negative; ZE, Zero; P, Positive). Each entry of the table defines one rule, e.g., R_{11}: "**If** *e* is N **And** Δ *e* is N **then** *Δu* = –200." When the fuzzy inference shown in Figure 2.31b is used to calculate the output of the fuzzy model, the resulting control surface obtained by plotting the inferred control action for discretized values of e and Δe is shown in Figure 2.31f.

Direct and Supervisory Fuzzy Control

Since the first applications of PID-type fuzzy controllers, the application range of fuzzy systems has widened substantially. Although in most cases a fuzzy controller is used for direct feedback control, it can also be used on the supervisory level, e.g., as a self-tuning device in a conventional PID controller. Also, fuzzy control is no longer only used to directly express *a priori* process knowledge. For example, a fuzzy controller can be derived from a fuzzy model obtained through system identification. Therefore, a very general definition of fuzzy control can be given: *A fuzzy controller contains a (nonlinear) mapping that has been defined using fuzzy if–then rules.* There are four main sources for such fuzzy rules:

- *Expert experience and control engineering knowledge.* One classical example is the operator's handbook for a cement kiln.[8] The most common approach to establishing such a collection of rules of thumb is to question experts or operators using a carefully organized questionnaire.
- *Based on the operator's control actions.* Fuzzy *if–then* rules can be deduced from observations of an operator's control actions or a log book. In this case the rules express input/output relationships.
- *Based on a fuzzy model of the process.* A linguistic rule base may be viewed as an inverse model of the controlled process. Thus, the fuzzy control rules might be obtained by inverting a fuzzy model of the process. This method is restricted to relatively low-order systems, but it provides an explicit solution, assuming that fuzzy models of the open- and closed-loop systems are available.[9] Another approach is *fuzzy identification* or fuzzy model-based control (see the following subsection).
- *Based on learning (adaptive fuzzy control).* An adaptive or learning control system is used to cut down the amount of required human intervention, to increase the flexibility of the algorithm, to improve the control performance, and to reduce the initial design time and cost. Learning ability is one of the essential attributes of intelligent controllers. Being intelligent means that the controller can improve its future performance based on the information it has gained in the past.

Because of the recent surge of these techniques, one of the recent research directions is to design fuzzy systems that have learning capabilities. The first adaptive fuzzy controller was proposed by Procyk and Mamdani (1979).[10] This self-organizing algorithm was the basis of the algorithms of Árva and Nemeth (1991),[11] Renders, Saerens, and Hugues (1997),[12] and others. Nowadays, a promising approach is the combination of neural networks and fuzzy logic systems.

Artificial neural networks (ANN) are easy to train and have known convergence properties.[13] Because they are opaque, the model that results is not interpretable, and it is difficult to incorporate linguistic and/or first-principle knowledge into the identification procedure. Conversely, fuzzy models provide transparency through their linguistic interpretability. The combination of these methods resulted in neuro-fuzzy systems.[14,15]

The rule base of these neuro-fuzzy models is initialized by expert knowledge, and the model parameters are determined via similar methods that are used for the training of neural networks. As the neuro-fuzzy model can initialize and learn linguistic rules, the modeling framework can be considered as a direct transfer of knowledge. This is the powerful advantage of adaptive fuzzy systems in comparison with other nonlinear model structures (e.g., neural networks).

Classical Fuzzy Control Algorithms

The early work in fuzzy control was motivated by a desire to mimic the control actions of an experienced human operator (knowledge-based part) and obtain smooth interpolation between discrete outputs that would normally be obtained (fuzzy logic part). Hence, these fuzzy controllers perform just as well as the operators whose knowledge was used for their design. Note, this approach is not only for control applications. If the target system to be emulated is a human physician or a credit analyst, then the resulting fuzzy inference systems become fuzzy expert systems for diagnosis and credit analysis, respectively.

As is illustrated in Figure 2.31g, besides this direct control scheme, fuzzy controllers are being used in various other control schemes:

Scheme a. In this configuration, it is up to the operator to control the process in the existing (conventional) mode or to switch the controls over to a fuzzy control strategy. Often, the conventional loops represent an existing control scheme that has been controlling the

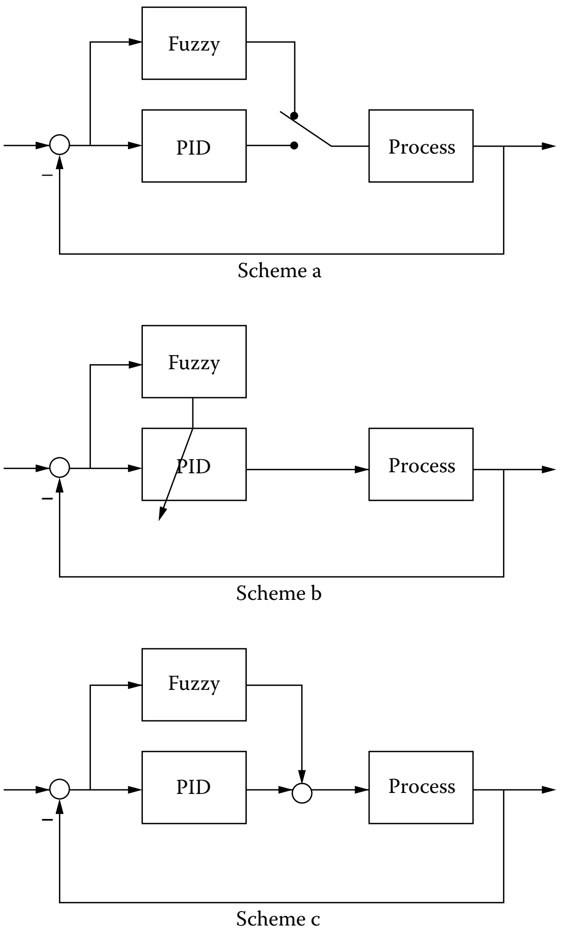

FIG. 2.31g
Fuzzy control configurations: (a) fuzzy replaces PID, (b) fuzzy adjusts PID parameters, and (c) fuzzy adds to PID output.

process before installation of a high-level strategy. The operator has to decide which of the two alternatives is the most likely to produce the best control performance.

Scheme b. In this configuration, the high-level strategy is used to adjust the tuning parameters of the conventional control loops. A common problem with linear PID controllers used for control of highly nonlinear processes is that the set of controller parameters produces satisfactory performance only when the process is within a small operational region. Outside this region, other controller settings are necessary, and these adjustments may be made automatically by a high-level strategy. This is called *gain scheduling* since such algorithms were originally used to change controller gains. A gain scheduling controller contains a linear controller whose parameters are changed as a function of the operating point in a preprogrammed way. It requires a thorough knowledge of the plant, but it is often a good way to compensate for nonlinearities and parameter variations. Additional sensor measurements can be used as *scheduling variables* that govern the change of the controller parameters, often by means of a look-up table.

Scheme c. This scheme can be viewed as a collaboration of linear and nonlinear control actions; the controller may be a linear PID controller, while the fuzzy controller is a supplementary nonlinear controller. Normally, conventional control systems using PID controllers are capable of controlling the process when the operation is steady and close to normal conditions. However, if sudden changes occur or if the process enters abnormal situations, then this configuration may be useful to bring the process back to normal operation as fast as possible. This scheme can also be interpreted as a *feedforward–feedback control,* where a measurable disturbance is being compensated. Generally, this solution requires a good model, but if a mathematical model is difficult or expensive to obtain, a fuzzy model may be useful.

These approaches have resulted in many successful applications, which are listed in Table 2.31h.

POLYMERIZATION REACTOR EXAMPLE

In this example the fuzzy control of the batch production of expanded polystyrene (EPS) is investigated. The typical unit of batch processes in polymer industries is an autoclave

Fuzzy control of a batch polymerization reactor	Abonyi, 1997[27]

with a heating–cooling system, where the reactor temperature is controlled by adjusting the temperature of the water recirculating though the jacket of the reactor. Compared to continuous processes, the control of batch processes is more difficult due to the complex sequential control tasks and the time-varying operating conditions. A further difficulty arises from the fact that vinyl polymerization is an exothermic autocatalytic reaction.

Several researchers have addressed the issue of control problems in reactor systems of this type. Juba and Hamer[28] and Berber[29] provide an excellent overview on the challenges in batch reactor control and suggest several control strategies. Davidson proposes a control algorithm that combines knowledge of the process with the logic used by the skilled operator and compares the result with standard PI controllers.[30] Examples of the application of fuzzy control to chemical reactors can also be found in the literature.[9] Here the benefits of fuzzy control schemes will be presented.

The aim of the development of fuzzy controllers was to obtain control performance better than that of the PID controller. The parameters of the designed controllers were determined based on simulation experiments. The simulator of the process has been built using MATLAB and C based on the first-principle mathematical model of the process.[31–33] During the tuning of the controller the following performance index was minimized by sequential quadratic programming

$$Q = \sum_{k=1}^{N} e(k)^2 + \lambda \sum_{k=1}^{N} \Delta u(k)^2$$

where λ is a weighting factor to maintain the dynamics of the control signal (0.2).

As we have shown in the previous example, conventional control solutions (PID algorithms, gain-scheduling) can be realized by choosing the proper fuzzy structure and can be improved by applying Takagi–Sugeno fuzzy models. The rules of the fuzzy PI controller were formulated by Equation 2.31(1). The performance of the fuzzy controller is illustrated in Figure 2.31j. As Table 2.31i demonstrates, the extension of the classical control schemes with nonlinearities defined by fuzzy systems resulted in 5 to 30% improvement in the performance index of the controllers.

TABLE 2.31i
Comparison of the Performances of Various Controllers

Control Algorithm	*Performance Index*
Optimal PI	1.883
Optimal gain-scheduled PI	1.633
Optimal PI-type fuzzy	1.579
Optimal fuzzy supervised PI controller	1.509

This example showed that fuzzy control is not only useful to handle heuristic control knowledge, but it can be a proper tool where the existing linear control algorithm should be replaced by a better, more effective nonlinear control algorithm.

MODEL-BASED FUZZY CONTROL

In spite of the practical successes, conventional fuzzy control has some drawbacks. First, fuzzy control rules are experience oriented and/or obtained after time-consuming trial-and-error experiments. Second, when a significant change in the system occurs that is outside of the operator experience, re-tuning of the fuzzy controller is necessary. Moreover, it is much easier to obtain information on how a process responds to particular inputs than to record how and why an operator responds to particular situations. These difficulties explain the recent surge of interest in model-based designs of fuzzy controllers, where fuzzy or inverse fuzzy models are used to design the controller.[34–36]

Fuzzy modeling can be effectively used in the identification of process dynamics in order to cope with nonlinear and complex systems.[9,36–38] The applicability of fuzzy models and

model-based control techniques is illustrated by several laboratory-scale or industrial examples overviewed in Table 2.31k.

Inverse Fuzzy Model-Based Control

The simplest way to control a process using a fuzzy model is to use the inverse process model as the controller. Several methods can be applied to obtain the inverse fuzzy model of a given process, but the following two are the most often used:

- Identification of the inverse model from input/output data
- Inversion of the original model

If an ideal model of the process is available, the control is perfect and the input/output relationship is stable.[51] This situation of perfect control is impossible to achieve because an exact inversion of the process can only be found in special situations, and the model is never identical to the process, resulting in a mismatch between the model and the process.

The internal model controller (IMC) structure consists of a controller, a process model, a filter, and the process itself, as shown in Figure 2.31l.

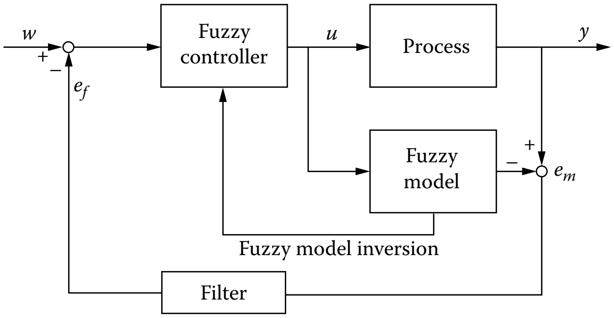

FIG. 2.31l
Fuzzy model in IMC architecture.

In this control arrangement, the process model is placed in parallel with a real process. The difference between the system and its model represents the modeling error and unmodeled process disturbances. This filtered difference is used by the controller to compensate the disturbance and the effects of the modeling error. The IMC structure provides a direct method for the design of feedback controllers. According to the above-mentioned properties of the control scheme, if a good model of the plant is available, the closed-loop system will provide good setpoint control even if unmeasured upsets or disturbances occur.

Reference 52 describes an adaptive fuzzy controller that is based on a fuzzy relational model and is applied to a laboratory-scale liquid level rig. Posthlethwaite has also applied fuzzy relational models for the identification and control of nonlinear, mainly first-order processes.[50] Contrary to these solutions, special types of Takagi–Sugeno fuzzy models can be analytically inverted. Such controllers were applied to control a radial industrial-cooling blast designed for building air conditioning[53] and for pressure control of a fermenter.[36]

When the process and control variables are subjected to level and rate constraints, and/or the system has significant time-delay or nonminimum-phase behavior, the inversion must be done for *p*-step-ahead.[54,55]

Fuzzy Model-Based Predictive Control

The *p*-step-ahead (*p*-inverse) controller can be seen as a special case of model predictive control (MPC). The nonlinear fuzzy models can be incorporated into this MPC scheme, as it is depicted in Figure 2.31m.

Among the several possible solutions of MPC, mainly the linearization-based approach has been utilized, because when a linear model is extracted from a fuzzy model, the controller can use classical linear model-based control algorithms.[56,57] Such local design techniques derived from model predictive control have been applied in References 9 and 58 through 62.

Operating Regime-Based Modeling

The modeling framework that is based on combining a number of local models, where each local model has a predefined operating region in which the model is valid, is called an *operating regime-based model.* The basic idea of operating

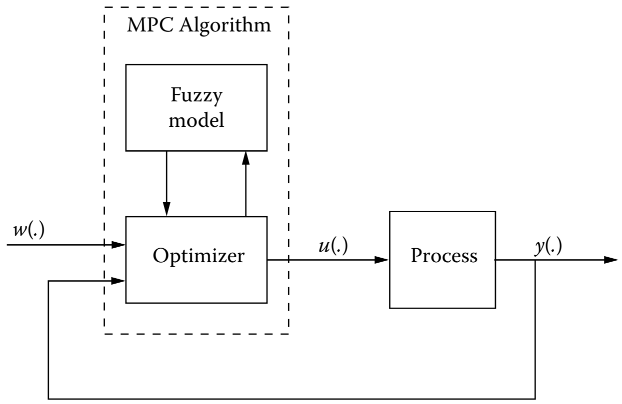

FIG. 2.31m
The role of a fuzzy model in model predictive control architecture.

regime-based modeling is that every model has a limited range of validity. This may be restricted by the modeling assumptions for a mechanistic model, or by the experimental conditions under which the identification data was obtained for an empirical model.

The model with a range of validity that is less than the operating regime of the process is called a *local model,* as opposed to a global model that is valid for the full range of the process operations. Global modeling is a complicated task because of the need to describe the interactions among a large number of phenomena that appear globally. Local modeling, on the other hand, may be considerably simpler, because locally a smaller number of phenomena may be relevant, and their interactions can be simpler. The local models can be combined into a global model using an interpolation technique.

The main advantage of this framework is its transparency. Both the concept of operating regimes and the model structure are easy to understand. This is important since the model structure can be interpreted in terms of operating regimes but also quantitatively in terms of individual local models. Furthermore, the operating regimes can be represented as a fuzzy set.[36,38] This representation is appealing because many systems change behavior smoothly as a function of the operating point, and the soft transition between the regimes introduced by the fuzzy set representation captures this feature in an elegant fashion. An example of such fuzzy models is the Takagi–Sugeno model.

Takagi–Sugeno Fuzzy Models

It is assumed that the MIMO dynamic process can be represented by the following nonlinear vector function: $\mathbf{y}(k+1) = f(\mathbf{y}(k),\ldots,\mathbf{y}(k-n_a+1), \mathbf{u}(k-n_d), \ldots, \mathbf{u}(k-n_d-n_b+1))$, where $\mathbf{y} = [y_1,\ldots y_{Ny}]^T$ is an -dimensional output vector, $\mathbf{u} = [u_1,\ldots\ u_{Nu}]^T$ is an N_u-dimensional input vector, n_a and n_b are maximum lags considered for the outputs and inputs, respectively, n_d is the minimum discrete dead time, and f represents the nonlinear model.

This MIMO Nonlinear Autoregressive with eXogenous Input (NARX) model can be represented by a Takagi–Sugeno fuzzy model,

$$R_j: \textbf{If}\quad z_1 \quad \text{is} \quad A_{1,j} \quad \textbf{and} \ldots \textbf{and} \quad z_n \quad \text{is} \quad A_{n,j} \quad \textbf{then}$$

$$\mathbf{y}^j(k+1) = \sum_{i=1}^{n_a} \mathbf{A}_i^j \mathbf{y}(k-i+1) + \sum_{i=1}^{n_b} \mathbf{B}_i^j \mathbf{u}(k-i-n_d+1) + \mathbf{c}^j \qquad \mathbf{2.31(6)}$$

where $\mathbf{A}_i^j$, $\mathbf{B}_i^j$ matrices and the $\mathbf{c}^j$ vector represent the j-th linear multivariable model, where the operating regime of this model in defined by the antecedent part of the j-th fuzzy rule. In these rule antecedents $A_{i,j}(z_i)$ represents the j-th antecedent fuzzy sets for the i-th input, where $\mathbf{z} = [z_1,\ldots z_n]$ is a “scheduling” vector, which is usually a subset of the previous process inputs and outputs,

$$\mathbf{z} = \{\mathbf{y}_1(k),\ldots,\mathbf{y}_1(k-n_a+1),\ldots,\mathbf{y}_{Ny}(k-n_a+1),\mathbf{u}_1(k-n_d),\ldots,$$
$$\mathbf{u}_1(k-n_d-n_b+1),\ldots,\mathbf{u}_{Nu}(k-n_d-n_b+1)\}$$

The proposed fuzzy model can be seen as a multivariable linear parameter varying (LPV) system model, where at the z operating point, the fuzzy model represents the following linear time-invariant (LTI) model,

$$\mathbf{y}(k+1) = \sum_{i=1}^{n_a} \mathbf{A}_i(\mathbf{z})\mathbf{y}(k-i+1)$$
$$+\sum_{i=1}^{n_b} \mathbf{B}_i(\mathbf{z})\mathbf{u}(k-i-n_d+1) + \mathbf{c}(\mathbf{z}) \qquad \mathbf{2.31(7)}$$

with

$$\mathbf{A}_i(\mathbf{z}) = \sum_{j=1}^{N_r} \beta_j(\mathbf{z})\mathbf{A}_i^j, \qquad \mathbf{B}_i(\mathbf{z}) = \sum_{j=1}^{N_r} \beta_j(\mathbf{z})\mathbf{B}_i^j,$$

$$\mathbf{c}(\mathbf{z}) = \sum_{j=1}^{N_r} \beta_j(\mathbf{z})\mathbf{c}^j,$$

where $0 \le \beta_j(\mathbf{z}) \le 1$ is the normalized truth value of the j-th rule calculated by Equation 2.31(4).

DISTILLATION COLUMN EXAMPLE

The examined process is a first-principle model of a binary distillation column. The column has 39 trays, a reboiler, and a condenser. The simulation model was developed by Skogestad.[63] The simulated system covers the most important effects for the dynamic of a real distillation column.

The studied column operates in *LV* configuration with two manipulated variables (reflux and boilup rate, $u_1 = L,V$, $u_2 = V$) and two controlled variables (top and bottom impurities, $y_1 = 1 - x_D$, $y_2 = x_B$).

The goal of this example was to improve the performance of the process by replacing the PID controller with an advanced control strategy. First, a linear model predictive controller (MPC) was designed, but it did not improve the performance of the control loop significantly. In order to obtain much better performance, the linear model of the process has been replaced by a nonlinear operating regime-based model of the distillation column.

The identified Takagi–Sugeno fuzzy model was used to represent the nonlinear dynamic system that is based on the interpolation between local linear MIMO ARX models. As the process gain varies in direct proportion with the concentrations, the fuzzy sets — the operating regions of the local models — are defined on the domain of the product impurities. This results in the MIMO Takagi–Sugeno (TS) fuzzy model structure, which was given by Equation 2.31(6).

The order of the local models is chosen to be $n_a = n_b = 2$. The process was assumed to have no time delay, $n_d = 0$. This rule base defines a grid-type partition of the operating regime. As Figure 2.31n shows, this fuzzy model consists of 16 multivariable local models.

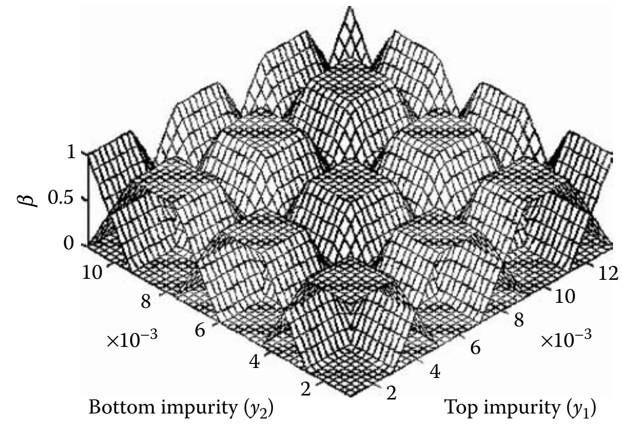

FIG. 2.31n
Operating regions of local linear models defined by fuzzy sets.

Because of the utilized nonlinear model, in the resulting MPC a nonlinear optimization problem had to be solved. To avoid this, a linear model was extracted from the nonlinear fuzzy model at each sampling time based on the linear-parameter-varying model interpretation of the Takagi–Sugeno fuzzy system. The multivariable generalized predictive controller (GPC)[64] is based on a linear ARX model extracted from the fuzzy model at each sampling time.[9]

Hence, based on the $\mathbf{y}(k)$ measured outputs, the previous values of the $\mathbf{u}$ control signal, the future set-points $\mathbf{w}$, and the $\mathbf{A}_j(\mathbf{z})$, $\mathbf{B}_j(\mathbf{z})$, $\mathbf{c}(\mathbf{z})$, parameters of the actual linear approximation of the nonlinear system (see Figure 2.31o), the multivariable general predictive controller (GPC) calculates that future control sequence vector $\{\mathbf{u}(k + j)\}$ at time k that minimizes a quadratic cost function. The results obtained are promising and hold the potential for industrial applications (Figure 2.31p).

SOFTWARE AND HARDWARE TOOLS

The development of fuzzy controllers requires intensive interaction with the user-operator of the process. Therefore, special developer tools have been introduced by various software (SW) and hardware (HW) suppliers such as Omron, Siemens, Aptronix, Inform, and National Semiconductors. Fuzzy control is also gradually becoming a standard option

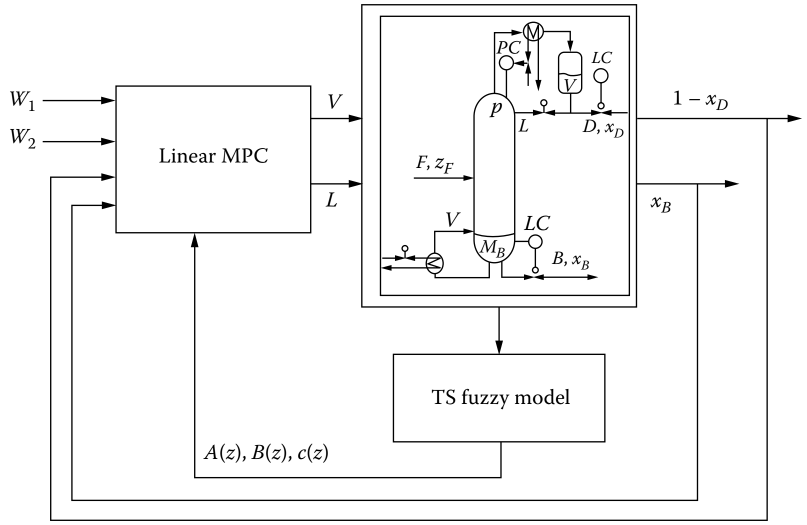

FIG. 2.31o
Fuzzy model-based predictive control of a distillation column, which is controlled in an LV-configuration.

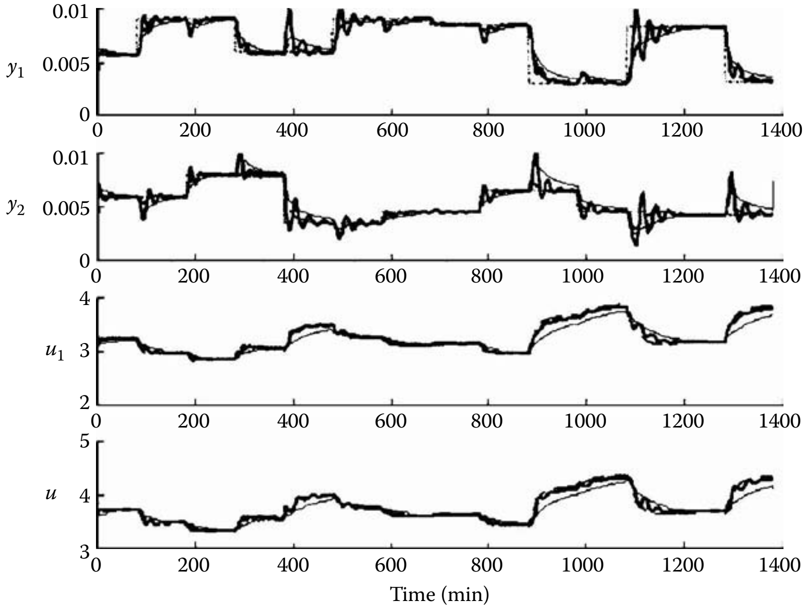

FIG. 2.31p
Performance of the constrained discrete PID (thick line), the constrained linear MPC (thin line) and the constrained nonlinear MPC (thick dashed line) for the distillation column.

in plant-wide control systems, such as the systems from Honeywell.

An extensive list of these HW and SW tools is given at www.fmt.vein.hu/softcomp/fuzzy. Although the user interfaces of these tools have been developed for different tasks, most of them consist of the following blocks.

Project Editor

The heart of the user interface is a graphical *project editor* that allows the user to build a fuzzy control system from basic blocks. An example of such an editor is given in Figure 2.31q.

	IF			THEN		THEN	
	dt_Level	Status	WaterLeve	DoS	DrainValve	DoS	FeedValve
1		TankFill	AboveNorm	1.00	Closed	1.00	Closed
2		TankFill	BelowFull	0.30	Medium	0.80	OpMax
3		TankFill		0.60	Small		
4		TankFill	StartUp	1.00	Closed	1.00	MinFlow
5		TankFill	Full	1.00	Closed	1.00	Closed
6		TankFill	CritFull	1.00	Open	1.00	Closed
7		StartPump	Full	1.00	Closed	1.00	Closed

FIG. 2.31q
Example of a project editor.

Input and output variables can be defined and connected to the fuzzy inference unit either directly or via preprocessing or postprocessing elements such as dynamic filters, integrators, and differentiators. The functions of these blocks are defined by the user, using the C language or its modification. Several fuzzy inference units can be combined to create more complicated (e.g., hierarchical or distributed) fuzzy control schemes.

Rule Base and Membership Functions

The fuzzy logic rules determine how the system reacts to input conditions. A rule-based controller is easy to understand and easy to maintain for a nonspecialist end-user. The rule base and the related fuzzy sets (membership functions) are defined using the rule base and membership function editors. This is where the designer can implement the control and optimization strategies for a solution. To best serve the needs of different applications, most of the tools provide several different rule editors.

The *spreadsheet rule editor* follows the familiar style of a table. The user can define complete rule bases just by pointing and clicking. Many experienced users prefer the *matrix rule editor* for complex rule blocks. Entering rules in FTL (Fuzzy Technology Language) format enables the rule definition in the most flexible way. Either way the rules are defined, the designer can always use any other editor to process or analyze them further.

The *membership functions editor* is a graphical environment for defining the shape and position of the membership functions. Figure 2.31q gives an example of the various interface screens.

Analysis and Simulational Tools

After the rules and membership functions have been designed, the function of the fuzzy controller can be tested using tools for *static analysis* and *dynamic simulation.*

Input values can be entered from the keyboard or read from a file in order to check whether the controller generates expected outputs. The degree of fulfillment of each rule, the adjusted output fuzzy sets, and the results of rule aggregation and defuzzification can be displayed online or logged in a file. For a selected pair of inputs and a selected output, the control surface can be examined in two or three dimensions.

Some packages also provide functions for automatic checking of completeness and redundancy of the rules in the rule base. For example, fuzzyTECH's 2D and 3D Analyzers let the designer analyze the transfer characteristics of a fuzzy logic system or its components in any possible way. Any modification of the system is immediately reflected in all analyzers. This facilitates "interactive" development of a solution.

Dynamic behavior of the closed loop system can be analyzed in simulation. While these tools comprise all simulation features for the fuzzy logic system under design, in some types of software it is also possible to use standard simulation software packages such as Matlab/Simulink™ or MatrixX™.

Code Generation and Communication Links

Once the fuzzy controller is tested using the software analysis tools, it can be used for controlling the plant either directly from the environment (via computer ports or analog inputs/outputs), or through generating a run-time code. Most of the programs generate a standard C-code and also a machine code for a specific hardware, such as microcontrollers or programmable logic controllers (PLCs). In this way, existing hardware can be also used for fuzzy control. Besides that, specialized fuzzy hardware is marketed, such as fuzzy control chips or fuzzy coprocessors for PLCs.

An example of a fuzzy processor is Motorola 68HC12 MCU. This 16-bit microcontroller family includes four fuzzy logic instructions in addition to the memory and on-chip peripheral functions. A fuzzy inference kernel on the HC12 takes one-fifth as much code space and executes more than 10 times faster compared to an HC11 general purpose MCU.

It should be noted that after the design of the fuzzy system an equivalent controller could be implemented using conventional techniques; in fact, any fuzzy controller could be represented by a classical look-up table.

CONCLUSIONS

From the control engineering perspective, a fuzzy controller is a nonlinear controller. The linguistic nature of fuzzy control makes it possible to handle expert knowledge concerning how the process should be controlled or how the process behaves. The interpolation aspect of fuzzy control has led to the viewpoint where fuzzy systems are seen as smooth function approximation schemes.

According to Michael Athans, fuzzy control methods are "parasitic"; they simply implement interpolations of control strategies obtained by other means.[65] This is partly true. Most of the fuzzy control algorithms can be interpreted as gain-scheduled controllers. Therefore, some people attack the fuzzy control community by stating that the final control and/or modeling algorithm just boils down to a nonlinear gain schedule that could be obtained by other interpolation methods, too.

Fuzzy control is a new technique that should be seen as an extension to existing control methods and not their replacement. It provides an extra set of tools which the control engineer has to learn to use where it makes sense. Nonlinear and partially known systems that pose problems to conventional control techniques can be tackled using fuzzy control. Fuzzy techniques provide a man–machine interface, which facilitates the acceptance, validation, and transparency of the process model or controller very much.[66] In this way, the control engineering is a step closer to achieving a higher level of automation in places where it has not been possible before.

2.32 Stability Analysis, Transfer Functions

C. F. MOORE (1970) **P. D. SCHNELLE, JR.** (1985) **B.G. LIPTÁK** (1995)
R. J. SMITH II (2005)

Control theory, which is the topic of this chapter, is approached differently by industry and academia. At some universities, process control courses have been treated as yet another course in mathematics, dealing with differential equations and analysis in the frequency domain. In industry, process control is discussed in the "time domain" (the domain that we understand better because we live in it) and less emphasis is given to the highly mathematical and abstract "frequency domain analysis," which makes mathematical manipulations easier to perform.

Because of this difference, even the terminology and language used in industry are different from those used in academia and in testing laboratories. This can sometimes be confusing because what the process industry calls a set point becomes a reference signal in academia, what is a controlled variable becomes process output, what is a manipulated variable becomes process input, and what is dead time becomes a time lag.

Although the frequency domain is friendly to partial differential equations, it is not so friendly to common-sense understanding and Murphy's Law-type reality. For these reasons many of the sections dealing with control loop stability in this handbook work in the time domain and use industrial terminology.

Because Chapter 2, of which this section is part, also contains a substantial amount of material on the subjects of simulation and modeling, we have used both sets of terms in the various sections. In this section, which provides an in-depth treatment to frequency domain transform theories and transfer functions used for linearization and stability analysis, it is appropriate to stay in the frequency domain.

INTRODUCTION

Most techniques used in the analysis of control problems require descriptive mathematical equations. This section describes some of the mathematical tools needed for the analysis of control problems.

One of the main topics of this section is the subject of transforms, which allow one to handle difficult problems in a simple manner. As the use of logarithms simplifies multiplication to addition, so do Laplace and z transforms perform a similar function in the solution of differential and difference equations, respectively.

State-space representation is another useful method for expressing multiple-input multiple-output (MIMO) difference and differential equations. This permits large systems to be handled as a first-order matrix system using linear algebra techniques.

Some of the other control system analysis tools discussed here are the block diagram, for signal flow representation, and linearization, which is a technique to convert nonlinear equations into linear form. Several graphical techniques are also extremely useful in the analysis of dynamic systems. These include the Bode diagram, Nyquist plot, and Nyquist array methods, which are all covered in this section.

One of the main purposes of control system analysis is to evaluate and guarantee that particular systems will be stable in their operation. Stability criteria that are discussed in this section include the Descartes, Routh's, and Nyquist criteria.

LAPLACE TRANSFORMS

One very useful tool in the analysis of differential equations is the principle of Laplace transforms. The Laplace transform concept is widely used in process control and was used to provide the basic framework upon which most automatic control theory was based.

The goal of any transform operation is to transform a difficult problem into a form that is more convenient to handle. Once the desired manipulations or results have been obtained from the transformed problem, an inverse transformation can be made to obtain the solution of the original problem.

For example, logarithms are a transform operation by which problems of multiplication and division can be transformed to problems of addition and subtraction. Laplace transforms perform a similar function in the solution of differential equations. The Laplace transform of a linear ordinary differential equation results in a linear algebraic equation. The algebraic problem is usually much simpler to solve than the corresponding differential equation would be.

Once the Laplace domain solution has been found, the corresponding time domain solution can be determined by an inverse transformation. There also exist very powerful control analysis and design techniques available for *s*-domain and frequency domain models. These include Bode and Nyquist analyses, to be discussed later.

The Laplace transform of a time domain function $f(t)$ will be noted by the symbol $F(s)$, and will be defined as follows:

$$F(s) = L[f(t)] = \int_0^\infty f(t)e^{-st}\,dt \qquad \mathbf{2.32(1)}$$

where $L[f(t)]$ is the symbol for indicating the Laplace transformation of the function in brackets. The variable s is a complex variable ($s = a + jb$) introduced by the transformation. All time-dependent functions in the time domain become functions of s in the Laplace domain (*s*-domain).

For the mathematical concept of the Laplace transformation to be meaningful, certain restrictions are placed on the function $F(s)$. However, in most practical work no such difficulties are encountered; therefore, this issue will not be considered in this treatment, and only concepts normally used in process control will be covered.

Theorems

A number of theorems exist that facilitate the use of Laplace transform techniques. The following are some of the most useful ones for causal signals.

Linearity Theorem (Superposition) This theorem holds when the result is the same if two or more "signals" are manipulated together or separately:

$$L[K\,f(t)] = KL[f(t)] = K\,F(s) \quad (K = \text{constant}) \qquad \mathbf{2.32(2)}$$

$$L[f_1(t) \pm f_2(t)] = F_1(s) \pm F_2(s) \qquad \mathbf{2.32(3)}$$

Real Differentiations Theorem First-order differential

$$L\left[\frac{d}{dt}f(t)\right] = sF(s) - f(0) \qquad \mathbf{2.32(4)}$$

General *n*th-order differential

$$L\left[\frac{d^n}{dt^n}f(t)\right] = s^nF(s) - s^{n-1}f(0) - s^{n-2}\frac{d}{dt}f(0) - s\frac{d^{n-2}}{dt^{n-2}}f(0) - \frac{d^{n-1}}{dt^{n-1}}f(0) \qquad \mathbf{2.32(5)}$$

Real Integration Theorem

$$L\left[\int f(t)dt\right] = \frac{F(s)}{s} \qquad \mathbf{2.32(6)}$$

In general,

$$L\left[\int^1\!\!\int^2 \cdots \int^n f(t)dt^n\right] = \frac{1}{s^n}F(s) \qquad \mathbf{2.32(7)}$$

Initial Value Theorem

$$f(0) = \lim_{t\to\infty} f(t) = \lim_{s\to\infty} sF(s) \qquad \mathbf{2.32(8)}$$

Final Value Theorem

$$f(\infty) = \lim_{t\to\infty} f(t) = \lim_{s\to 0} sF(s) \qquad \mathbf{2.32(9)}$$

The direct and inverse Laplace transformation of a particular function can be obtained from direct integration of Equation 2.32(1) and/or from the applications of the above theorems. Extensive tabulations of specific transform pairs are also available in most mathematical tables. A few of the more common transform pairs encountered in control analysis are tabulated in Table 2.32a.

First-Order Lag

The following two examples illustrate the solution of differential equations using the underlying principle of the Laplace transform technique. First consider a simple first-order lag described earlier:

$$\tau\frac{d}{dt}c(t) + c(t) = K\,r(t) \qquad \mathbf{2.32(10)}$$

where

$$c(0) = 0.0$$

and

$$r(t) = \begin{cases} 0 & t < 0 \\ 1 & t > 0 \end{cases} \qquad \mathbf{2.32(11)}$$

The general procedure in the solution of the above equation is to:

1. Transform the differential equation to the Laplace domain.
2. Solve the resulting algebraic equations for the system output, $C(s)$.
3. Take inverse Laplace transformation of the expression describing $C(s)$ to determine the corresponding time domain solution.

Because of the Linearity Theorem, each term in the differential equation 2.32(10) can be transformed individually:

$$L\left[\tau\frac{d}{dt}c(t)\right] + L[c(t)] = L[K\,r(t)] \qquad \mathbf{2.32(12)}$$

TABLE 2.32a
Laplace Transform Pairs

Transform, F(s)	*Function, f(t)*
1	$\delta(t)$: Unit impulse
$\frac{1}{s}$	$u(t)$: Unit Step
$\frac{1}{s^2}$	t: Unit ramp
$\frac{n!}{s^{n+1}}\ (n = 1, 2, \ldots)$	t^n: nth order ramp
$\frac{1}{s \pm a}$	$e^{\mp at}$: Exponential
$\frac{1}{s(s \pm a)}$	$\frac{1}{\pm a}(1 - e^{\mp at})$
$\frac{s}{s^2 + a^2}$	$\cos at$
$\frac{a}{s^2 + a^2}$	$\sin at$
$\frac{s}{s^2 - a^2}$	$\cosh at$
$\frac{a}{s^2 - a^2}$	$\sinh at$
$\frac{b}{(s + a)^2 + b^2}$	$e^{-at} \sin bt$: Damped sine
$\frac{s + a}{(s + a)^2 + b^2}$	$e^{-at} \cos bt$: Damped cosine
$\frac{1}{(s + a)^n}$	$\frac{1}{(n-1)!} t^{n-1} e^{-at}$
$\frac{e^{-as}}{s}$	$u(t - a)$
$\frac{e^{-as}}{s^2}$	$\begin{cases} 0 & (0 < t < a) \\ t - a & (t > a) \end{cases}$
$\frac{1 - e^{-as}}{s}$	$\begin{cases} 1 & (0 < t < a) \\ 0 & (t > a) \end{cases}$
$\log \frac{s - a}{s - b}$	$\frac{1}{t}(e^{bt} - e^{at})$
$\tan^{-1} \frac{a}{s}$	$\frac{1}{t} \sin at$

The first term can be determined by the use of the Linearity and the Real Differentiations Theorems:

$$L\left[\tau \frac{d}{dt} c(t)\right] = \tau L\left[\frac{d}{dt} c(t)\right] = \tau(sC(s) = c(\varnothing^{\circ})) \qquad \textbf{2.32(13)}$$

The second term by definition is

$$L[c(t)] = C(s) \qquad \textbf{2.32(14)}$$

The third term can be determined from the table of transform pairs in Table 2.32a.

$$L[K\, r(t)] = \frac{K}{s} \qquad \textbf{2.32(15)}$$

The entire Laplace domain equation therefore will read

$$\tau s\, C(s) + C(s) = \frac{K}{s} \qquad \textbf{2.32(16)}$$

This can be solved for $C(s)$:

$$C(s) = \frac{K}{s(1 + \tau s)} \qquad \textbf{2.32(17)}$$

For the inverse transformation, Table 2.32a provides the following transform pair:

$$L\left[\frac{1}{\pm a}(1 - e^{\pm at})\right] = \frac{1}{s(s \pm a)} \qquad \textbf{2.32(18)}$$

Therefore,

$$c(t) = K(1 - e^{-t/\tau}) \qquad t > 0 \qquad \textbf{2.32(19)}$$

Partial Fraction Expansion

Frequently the necessary inverse transformation may not be directly available in the Laplace transform tables at hand. In such cases the function must be expanded in terms of the roots of the denominator of the Laplace expression, namely,

$$F(s) = \frac{A(s)}{B(s)} = \frac{C_1}{(s + r_1)} + \frac{C_2}{(s + r_2)} + \frac{C_3}{(s + r_3)} + \cdots + \frac{C_0}{(s + r_0)} \qquad \textbf{2.32(20)}$$

where

$$B(s) = (s - r_1)(s - r_2)(s - r_3) \cdots (s - r_n)$$

$$r_1, r_2, r_3, \ldots r_n = \text{roots of } B(s) \qquad \textbf{2.32(21)}$$

$$C_1, C_2, C_3, \ldots C_n = \text{constants in partial fraction}$$

The procedure for evaluating the constants in the expansion depends on the nature of the roots, which can be:

1. Real and distinct
2. Real and repeated
3. Complex conjugates

When the roots are real and distinct, the expansion of $F(s)$ is

$$F(s) = \frac{A(s)}{(s-r_1)(s-r_2)\cdots(s-r_n)} \qquad \textbf{2.32(22)}$$

$$F(s) = \frac{C_1}{(s-r_1)} + \frac{C_2}{(s-r_2)} + \cdots + \frac{C_n}{(s-r_n)} \qquad \textbf{2.32(23)}$$

and the inverse transformation is

$$f(t) = C_1 e^{r_1 t} + C_2 e^{r_2 t} + \cdots C_n e^{r_n t} \qquad \textbf{2.32(24)}$$

where

$$\left.\begin{aligned} C_1 &= \underset{s\to r_1}{\text{limit}}\,[(s-r_1)\,F(s)] \\ C_2 &= \underset{s\to r_2}{\text{limit}}\,[(s-r_2)\,F(s)] \\ &\;\;\vdots \\ C_n &= \underset{s\to r_n}{\text{limit}}\,[(s-r_n)\,F(s)] \end{aligned}\right\} \qquad \textbf{2.32(25)}$$

For the case when the roots are real and repeated,

$$F(s) = \frac{A(s)}{(s-r_1)\cdots(s-r_j)^q\cdots(s-r_n)} \qquad \textbf{2.32(26)}$$

(The jth root is repeated q times.)

$$F(s) = \frac{C_1}{(s-r_1)} + \cdots + \left[\frac{C'_q}{(s-r_j)^q} + \frac{C'_{q-1}}{(s-r_j)^{q-1}} + \cdots + \frac{C'_1}{(s-r_j)}\right] + \cdots + \frac{C_n}{(s-r_n)} \qquad \textbf{2.32(27)}$$

The inverse transform is

$$f(t) = C_1 e^{r_1 t} + \cdots + [C'_q t^{q-1} + C'_{q-1} t^{q-2} + \cdots + C_1{}']e^{r_j t} + \cdots + C_1 e^{r_n t} \qquad \textbf{2.32(28)}$$

where

$$C'_q = \underset{s\to r_j}{\text{limit}}\,\{(s-r_j)^q\,F(s)\} \qquad \textbf{2.32(29)}$$

$$C'_{q-1} = \underset{s\to r_j}{\text{limit}}\left\{\frac{1}{1!}\frac{d}{ds}[(s-r_j)^q\,F(s)]\right\} \qquad \textbf{2.32(30)}$$

$$C_{q-k} = \underset{s\to r_j}{\text{limit}}\left\{\frac{1}{k!}\frac{d^k}{ds^k}[(s-r_j)^q\,F(s)]\right\} \qquad \textbf{2.32(31)}$$

where

$$k! = 1\cdot 2\cdot 3\cdot 4\cdot 5\cdots k.$$

For the case when the roots are complex,

$$F(s) = \frac{A(s)}{(s-r_1)\cdots(s-a-jb)\,(s-a+jb)\cdots(s-r_n)} \qquad \textbf{2.32(32)}$$

$$F(s) = \frac{C_1}{(s-r_1)} + \cdots + \frac{1}{2jb}|\pi_j|\left(\frac{e^{i\alpha}}{s-a-jb} - \frac{e^{-j\alpha}}{s-a+jb}\right) + \cdots + \frac{C_n}{(s-r_n)} \qquad \textbf{2.32(33)}$$

The inverse transformation results in

$$f(t) = C_1 e^{r_1 t} + \cdots + \frac{1}{b}|\pi_j|\,e^{at}\sin(bt+\alpha) + \cdots + C_n e^{r_n t} \qquad \textbf{2.32(34)}$$

$$\pi_j = \underset{s\to a+jb}{\text{limit}}\,[(s-a-jb)\,(s-a+jb)\,F(s)] \qquad \textbf{2.32(35)}$$

This results is a complex polynomial that can be expressed in terms of a magnitude, π_j, and an angle, α. For example,

$$\begin{aligned} F(s) &= \frac{10}{s(s^2+0.5s+0.4)} \\ &= \frac{10}{s(s+0.25-j0.58)\,(s+0.25+j0.58)} \end{aligned} \qquad \textbf{2.32(36)}$$

$$F(s) = \frac{C_1}{s} + \frac{1}{2jb}|\tau_j|\left(\frac{e^{i\alpha}}{s-a-jb} - \frac{e^{-j\alpha}}{s-a+jb}\right) \qquad \textbf{2.32(37)}$$

where $a = -0.25$; $b = 0.58$.

$$C_1 = \underset{s\to 0}{\text{limit}}\left[s\left(\frac{10}{s(s^2+0.5s+0.4}\right)\right] = 25 \qquad \textbf{2.32(38)}$$

$$\pi_j = \underset{s\to 0.25-j\,0.58}{\text{limit}} \left[(s^2+0.5s+0.4)\left(-\frac{10}{s(s^2+0.5s+0.4}\right)\right] = \frac{10}{-0.25+j0.58} \qquad \textbf{2.32(39)}$$

$$|\pi_j| = \frac{10}{\sqrt{(0.25)^2+(0.58)^2}} = \frac{10}{0.63} = 15.9 \qquad \textbf{2.32(40)}$$

$$\alpha = \text{angle of } \pi_j = 0 - \tan^{-1}\frac{0.58}{-0.25} = -113.5 \qquad \textbf{2.32(41)}$$

Therefore,

$$c(t) = 25 + \left(\frac{15.9}{0.58}\right) e^{-0.25t} \sin(0.58t - 113.5°) \quad \textbf{2.32(42)}$$

Z TRANSFORMS

Laplace transformation is a powerful tool for the solution of linear *differential* equations and is particularly useful when these equations represent the dynamic behavior of continuous systems. For certain kinds of discontinuous systems, whose dynamic behavior can be defined by linear *difference* equations, there exists another kind of transformation calculus, the *z*-transformation. It is particularly applicable to the study and design of sampled data control.

Let us suppose that we have a continuous function, $f(t)$, such as that shown at the top in Figure 2.32b by curve (1) and that this signal is to be fed into a sampling device such as that shown in Figure 2.32b(2).

At fixed intervals of time of period T, the switch closes briefly, allowing the signal $f(t)$ to be transmitted. If the length of time the switch is closed is infinitesimally short, the switch or sampler may be treated as an impulse modulator. That is to say, the sampler puts out a train of impulses $I(t)$, spaced from one another by the time interval T (Figure 2.32b (3)). The intermittent function at the switch output is designated as $f^*(t)$.

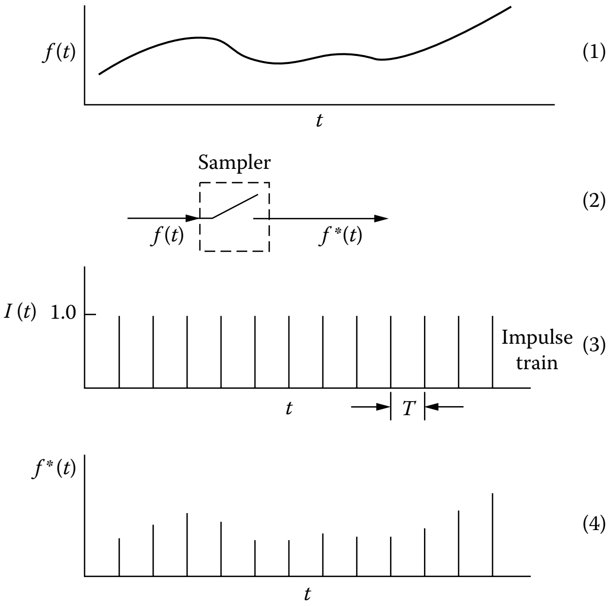

FIG. 2.32b
Sampling of continuous signals.

The sampling is represented mathematically as

$$\begin{aligned} I(t) &= U'(t-T) + U'(t-2T) + U'(t-3T) + \cdots \\ &\quad + U'(t-kT) + \cdots \end{aligned} \quad \textbf{2.32(43)}$$

$$= \sum_{n=0}^{+\infty} U'(t-nT) \quad \textbf{2.32(44)}$$

where U' is the unit impulse. We may now define $f^*(t)$ as the product of the input signal and the switching function:

$$f^*(t) = f(t)I(t) \quad \textbf{2.32(45)}$$

Substituting Equation 2.32(44) into Equation 2.32(45) we obtain

$$f^*t = \sum_{n=0}^{\infty} f(nT)U'(t-nT) \quad \textbf{2.32(46)}$$

The Laplace transformation of both sides leads to

$$f^*(s) = \sum_{n=0}^{\infty} f(nT)e^{-nTs} \quad \textbf{2.32(47)}$$

The form of this equation is not particularly convenient for the study of sampled data control systems. Let us therefore introduce a new variable z, which is defined as

$$z = e^{Ts} \quad \textbf{2.32(48)}$$

Then by substitution into Equation 2.32(47) we obtain the z transform:

$$f^*(s) = \sum_{n=0}^{\infty} f(nT)z^{-n} \quad \textbf{2.32(49)}$$

$$= F(z) \quad \textbf{2.32(50)}$$

$F(z)$ is seen to be an infinite series in powers of z^{-1}.

The following three theorems are useful in z transforms:

1. The shifting theorem: If $z[f(t)] = F(z)$ then

$$z[f(t+T)] = z[F(Z) - f(0)] \quad \textbf{2.32(51)}$$

2. The initial value theorem:

$$\lim_{t\to 0} f^*(t) = \lim_{z\to\infty} f(z) \quad \textbf{2.32(52)}$$

3. The final value theorem:

$$\lim_{t\to 0} f^*(t) = \lim_{z\to 1}\left(\frac{z-1}{z}\right)F(z) \quad \textbf{2.32(53)}$$

If the sampling frequency is at least twice as high as the highest frequency of interest in the continuous input signal, the information contained in the *z* transform of the sampler output is equivalent to that contained in the Laplace transform of the sampler output.

To put it another way, if *T* is the sampling period, then a complete reconstruction of the input signal can be obtained from the sampler output signal for input sinusoidal frequencies up to $\omega = (2\pi/T)1/2 = \pi/T$ radians/unit time.

As was done with the Laplace transform pairs in Table 2.32a, a partial list of the *z* transforms and inverse *z* transform pairs is tabulated in Table 2.32c.

First-Order Lag

Solve the following first-order linear difference equation, given $w(0) = -1$:

$$w^*(t+T) + 2w^*(t) = t^* \qquad \textbf{2.32(54)}$$

Taking the *z* transformation of Equation 2.32(54) one obtains

$$z[W(z)+1] + 2W(z) = \frac{Tz}{(z-1)^2}$$

or

$$(z+2)\,W(z) = \frac{Tz}{(z-1)^2} - z$$

from which $W(z)$ can be solved:

$$W(z) = \frac{Tz}{(z+2)(z-1)^2} - \frac{z}{z+2} \qquad \textbf{2.32(55)}$$

To find the inverse transform of the first term, it is expanded (without the constants and the *z* in the numerator) in partial fractions:

$$\frac{1}{(z+2)\,(z-1)^2} = \frac{K_1}{z+2} + \frac{K_{22}}{(z-1)^2} + \frac{K_{21}}{z-1} \qquad \textbf{2.32(56)}$$

Using the previously applied method one finds

$$K_1 = \left.\frac{1}{(z-1)^2}\right|_{z=-2} = \frac{1}{9},$$

$$K_{22} = \left.\frac{1}{z+2}\right|_{z=1} = \frac{1}{3},$$

$$K_{21} = \left[\frac{d}{dz}\left(\frac{1}{z+2}\right)\right]_{z=1} = -\frac{1}{9}$$

Substituting these constants in Equation 2.32(56), one can now write Equation 2.32(55) in its partial-fraction form:

$$W(z) = \frac{T}{9}\left[\frac{z}{z+2} + \frac{3z}{(z-1)^2} - \frac{z}{z-1}\right] - \frac{z}{z+2} \qquad \textbf{2.32(57)}$$

Finally, one obtains, using transform Table 2.32c:

$$w^*(t) = \frac{T}{9}\left[\left(1-\frac{9}{T}\right)(-2)^{t/T} + 3\frac{t}{T} - 1\right]^*$$

$$= \frac{T}{9}\sum_{n=0}^{\infty}\left[\left(1-\frac{9}{T}\right)(-2)^n + 3n - 1\right]\delta(t-nT) \qquad \textbf{2.32(58)}$$

The solution in Equation 2.32(58) is given in the form of a train of impulses of varying strength.

TABLE 2.32c
z Transform Pairs

Transform F(z)	*Transform f(t)*
1	$\delta(t)$: Unit impulse
$\frac{z}{z-1}$	$u(t)$: Unit Step
$\frac{Tz}{(z-1)^2}$	t: Unit Ramp
$\frac{T^2 z(z+1)}{(z-1)^3}$	t^2
$\frac{z}{z-e^{aT}}$	e^{at} : Exponential
$F(e^{aT}z)$	$e^{-at}f(t)$
$\frac{z \sin bT}{z^2 - 2z\cos bT + 1}$	$\sin bt$
$\frac{z(z-\cos bT)}{z^2 - 2z\cos bT + 1}$	$\cos bt$
$\frac{z \sinh bT}{z^2 - 2z\cosh bT + 1}$	$\sinh bt$
$\frac{z(z-\cosh bT)}{z^2 - 2z\cosh bT + 1}$	$\cosh bt$
$z[F(z) - f(0)]$	$f(t+T)$
$z^2[F(z) - f(0)] - zf(T)$	$f(t+2T)$
$z^{-n}F(z)$	$f(t-nT)U(t-nT)$

Inverse *z* Transform

There are two basic ways of performing the inverse *z* transformation. The first of these is analogous to the inverse Laplace transformation (i.e., partial fractions). The *z* transform, $F(z)$, is expressed in partial-fraction terms, each sufficiently simple that it may be found in transform tables.

The other method involves expressing $F(z)$ as a sequence of z^{-1}, by dividing the denominator of $F(z)$ into the numerator. Then

$$F(z) = a_0 + \frac{a_1}{z} + \frac{a_2}{z^2} + \frac{a_3}{z^3} + \frac{a_4}{z^4} + \cdots \frac{a_n}{z^n} + \cdots \qquad \textbf{2.32(59)}$$

$$\frac{1}{z^k} = e^{-kTs} \qquad \textbf{2.32(60)}$$

$$L^{-1}\left(\frac{1}{z^k}\right) = U'(t - kT) \qquad \textbf{2.32(61)}$$

$$\begin{aligned} f^*(t) &= a_0 U'(0) + a_1 U'(t - T) \\ &\quad + a_2 U'(t - 2T) + \cdots \end{aligned} \qquad \textbf{2.32(62)}$$

This method therefore leads to an intermittent function, a series of impulses at the sampling instants. $f^*(t)$ may therefore be written $f^*(nT)$. Note that the sequence $f^*(t)$ or $f^*(nT)$ may or may not be convergent and that the coefficients a_1, a_2, … a_n are the amplitudes of $f(t)$ at $t = 0$, t, $2T$, …, nT.

As an example, find

$$Z^{-1}\left[\frac{Tz}{(z-1)^2}\right]$$

Before we perform the long division, it is advantageous to arrange both the numerator and the denominator in ascending powers of z^{-1}:

$$\begin{aligned} \frac{Tz}{(z-1)^2} &= T\frac{z^{-1}}{(1 - z^{-1})^2} = T\frac{z^{-1}}{1 - 2z^{-1} + z^{-2}} \\ &= T(z^{-1} + 2z^{-2} + 3z^{-3} + \cdots + kz^{-k} + \cdots) = \sum_{n=0}^{\infty}(nT)z^{-n} \end{aligned} \qquad \textbf{2.32(63)}$$

Hence

$$f^*(t) = Z^{-1}\left[\frac{Tz}{(z-1)^2}\right] = \sum_{n=0}^{\infty}(nT)\,\delta(t - nT) \qquad \textbf{2.32(64)}$$

STATE SPACE REPRESENTATION

Application and design of control systems are predicated on the description of the "process" by means of difference and/or differential equations. Here, state space notation (discussed further in Section 2.33) is introduced as a conventional formulation for representing these mathematical systems.

State space notation allows nth-order difference/differential equations and coupled sets of difference/differential equations to be expressed as vector–matrix equations. This then enables these dynamic systems to be manipulated, transformed, and studied by means of simple linear algebraic procedures. State space representations for simple second-order systems and for 2 × 2 (two inputs, two outputs) multivariable systems will also be developed and demonstrated in the following paragraphs.

Vector and Matrix Operations

The reader with no background in this area is referred to Reference 1 because the material presented here requires an understanding of definitions and operations pertinent to the application of vector and matrix methods in modern control. In the equations below, the vector quantities are underscored and matrices are designated by capital letters.

Second-Order Model

A general continuous state space model is described by a system of linear differential equations of the first order.

$$\text{state equation } \underline{\dot{x}}(t) = A\underline{x}(t) + B\underline{u}(t) \qquad \textbf{2.32(65)}$$

$$\text{output equation } \underline{y}(t) = C\underline{x}(t) \qquad \textbf{2.32(66)}$$

$\underline{x}(t) - n \times l$ state variables

$\underline{u}(t) - m \times l$ manipulated variables

$\underline{y}(t) - j \times 1$ output variables

$A - n \times n$ state parameter matrix

$B - m \times m$ input parameter matrix

$C - j \times j$ output parameter matrix

The discrete state space formulation is completely analogous.

$$\text{state equation } \underline{x}(n+1) = A\underline{x}(n) + B\underline{u}(n) \qquad \textbf{2.32(67)}$$

$$\text{output equation } \underline{y}(n) = C\underline{x}(n) \qquad \textbf{2.32(68)}$$

These are very simple state space models intended for explanation. Various segmented forms are of more practical use in general application.[2]

The $\underline{u}(t)$ vector is the manipulated or disturbance input. It can be thought of as a list of variables that are used to control or disturb the dynamic process. The $\underline{y}(t)$ vector is the output or measured variable vector. It can be thought of as a list of things one can see or measure about the process.

The $\underline{x}(t)$ vector is the state vector. The state vector is of a dimension consistent with the order of the dynamic process. It can be thought of as the output of the integrators or delay elements in a dynamic block diagram or signal flow diagram. The conversion of a simple second-order difference equation into a discrete state space representation will help illustrate this concept. Consider the following second-order linear difference equation:

$$w(n+2) + b_1 w(n+1) + b_0 w(n) = e(n) \qquad \textbf{2.32(69)}$$

Rearranging Equation 2.32(69):

$$w(n+2) = -b_1 w(n+1) - b_0 w(n) + e(n) \qquad \mathbf{2.32(70)}$$

It is also true from the definition of the time delay that

$$w(n+1) = w(n) \qquad \mathbf{2.32(71)}$$

If one defines the state vector $\underline{x}(n)$ as

$$\underline{x}(n) = \begin{bmatrix} w(n) \\ w(n+1) \end{bmatrix} \qquad \mathbf{2.32(72)}$$

From Equation 2.32(72) it is apparent that

$$\underline{x}(n+1) = \begin{bmatrix} w(n+1) \\ w(n+2) \end{bmatrix} \qquad \mathbf{2.32(73)}$$

If one defines the input vector $\underline{u}(n)$ as

$$\underline{u}(n) = \begin{bmatrix} 0 \\ e(n) \end{bmatrix} \qquad \mathbf{2.32(74)}$$

and defines the output vector $\underline{y}(n)$ as

$$\underline{y}(n) = \begin{bmatrix} w(r+2) \\ 0 \end{bmatrix} \qquad \mathbf{2.32(75)}$$

The state system can now be represented as

$$\underline{x}(n+1) = A\,\underline{x}(n) + \underline{b}\,\underline{u}(n) \qquad \mathbf{2.32(76)}$$

$$\underline{y}(n) = \underline{c}x(n) \qquad \mathbf{2.32(77)}$$

or combining Equations 2.32(70) to 2.32(73):

$$x_1(n+1) = w(\underline{n}+1) = w(\cancelto{x_1(n)}{n}) \qquad \mathbf{2.32(78)}$$

$$x_2(n+1) = w(n+2) = -b_1 w(n \cancelto{x_2(n)}{+} 1) - b_0 w(\cancel{n}) + e(n) \qquad \mathbf{2.32(79)}$$

$$y_1(n) = x_2(n) \qquad \mathbf{2.32(80)}$$

Rewriting yields

$$x_1(n+1) = x_1(n) + 0\,x_2(n) + 0\,e(n) \qquad \mathbf{2.32(81)}$$

$$x_2(n+1) = -b_0 x_1(n) - b_1 x_2(n) + 1\,e(n) \qquad \mathbf{2.32(82)}$$

$$y_1(n) = 0\,x_1(n) + 1\,x_2(n) + 0\,e(n) \qquad \mathbf{2.32(83)}$$

Putting in vector–matrix notation gives the following expression:

$$\underline{x}(n+1) = \underbrace{\begin{bmatrix} 1 & 0 \\ -b_0 & -b_1 \end{bmatrix}}_{A} \underline{x}(n) + \underbrace{\begin{bmatrix} 0 \\ 1 \end{bmatrix}}_{\underline{b}} \underline{e}(n) \qquad \mathbf{2.32(84)}$$

$$\underline{y}(n) = \underbrace{\begin{bmatrix} 1 \\ 0 \end{bmatrix}}_{\underline{c}} x(n) \qquad \mathbf{2.32(85)}$$

The second-order difference Equation 2.32(79) is now a first-order matrix difference equation of dimension two. This state space formulation is convenient for use in many control analysis methods.

Multiple-Input Multiple-Output

State space notation is particularly useful in representing multivariable dynamic systems. Multivariable implies that the system under consideration has more than one input (disturbance and/or manipulated) and more than one output (measured and/or control). Multiple-input multiple-output systems are typically described by sets of coupled difference or differential equations. Consider the following set of equations:

$$\frac{dL_1}{dt} = f_1(w_1) - f_2(w_2, L_1, L_2) \qquad \mathbf{2.32(86)}$$

$$\frac{dL_2}{dt} = f_3(w_1) - f_4(L_2) \qquad \mathbf{2.32(87)}$$

These equations are coupled because L_2 affects L_1 through f_2 of Equation 2.32(86) and L_1 affects both L_1 and L_2 through f_1 and f_3.

Assume that this coupled set of equations can be linearized (see discussion later on linearization). The linearized versions of Equations 2.32(86) and 2.32(87) are given below.

$$\frac{dL_1}{dt} = a_1 L_1 + a_2 L_2 + b_1 w_1 + b_2 w_2 \qquad \mathbf{2.32(88)}$$

$$\frac{dL_2}{dt} = a_3 L_1 + a_4 L_2 + b_3 w_1 + b_4 w_2 \qquad \mathbf{2.32(89)}$$

Define

$$\underline{x} = \begin{bmatrix} L_1 \\ L_2 \end{bmatrix}, \quad \underline{u} = \begin{bmatrix} w_1 \\ w_2 \end{bmatrix}, \quad \dot{\underline{x}} = \begin{bmatrix} \frac{dL}{dt}1 \\ \frac{dL}{dt}2 \end{bmatrix} \qquad \mathbf{2.32(90)}$$

Assume one can measure L_1 and L_2 so that

$$\underline{y} = \begin{bmatrix} L_1 \\ L_2 \end{bmatrix} \qquad \mathbf{2.32(91)}$$

The multiple-input multiple-output state space vector–matrix formulation of Equations 2.32(88) and 2.32(89) is

$$\dot{\underline{x}} = \underbrace{\begin{bmatrix} a_1 & a_2 \\ a_3 & a_4 \end{bmatrix}}_{A} \underline{x} + \underbrace{\begin{bmatrix} b_1 & b_2 \\ b_3 & b_4 \end{bmatrix}}_{B} \underline{u} \qquad \textbf{2.32(92)}$$

$$\underline{y} = \underbrace{\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}}_{C=I} \underline{x} \qquad \textbf{2.32(93)}$$

TRANSFER FUNCTIONS

A notation used to describe the dynamics of a particular process or system is the transfer function. For a system with an input $r(t)$ and an output $c(t)$, the transfer function $G(s)$ is defined as the ratio of the Laplace transform of the output of the system $C(s)$ divided by the Laplace transform of the input to the system $R(s)$.

$$G(s) = \frac{C(s)}{R(s)} \qquad \textbf{2.32(94)}$$

An inherent assumption in applying the transfer function is that the process is initially at steady state, meaning that

$$\frac{d}{dt}c(0) = \frac{d^2}{dt^2}c(0) = \cdots = \frac{d^n}{dt^n}c(0) = 0.0 \qquad \textbf{2.32(95)}$$

$$\frac{d}{dt}r(0) = \frac{d^2}{dt^2}r(0) = \cdots = \frac{d^n}{dt^n}r(0) = 0.0 \qquad \textbf{2.32(96)}$$

and

$$c(0) = K\,r(0) \qquad \textbf{2.32(97)}$$

where K is the steady-state gain of the process. Under such conditions the Laplace transform of a particular differential equation can be obtained by substituting

$$s \leftrightarrow d/dt(\ ) \qquad \textbf{2.32(98)}$$

$$s^2 \leftrightarrow d^2/dt^2(\ ) \qquad \textbf{2.32(99)}$$

$$s^n \leftrightarrow d^n/dt^n(\ ) \qquad \textbf{2.32(100)}$$

$$1/s \leftrightarrow \int (\ )\,dt \qquad \textbf{2.32(101)}$$

$$1/s^2 \leftrightarrow \int\int (\ )\,dt^2 \qquad \textbf{2.32(102)}$$

$$1/s^n \leftrightarrow \int\int\cdots\int^n (\ )\,dt^n \qquad \textbf{2.32(103)}$$

$$C(s) \leftrightarrow c(t) \qquad \textbf{2.32(104)}$$

$$R(s) \leftrightarrow r(t) \qquad \textbf{2.32(105)}$$

The transfer function can then be determined by solving for $C(s)/R(s)$. Consider the three examples described below.

Second-Order Lag

Consider the following second-order equation:

$$\frac{d^2}{dt^2}c(t) + 2\xi\omega_n\frac{d}{dt}c(t) + \omega_n^2 c(t) = K\,\omega_n^2\,r(t) \qquad \textbf{2.32(106)}$$

After the substitutions:

$$s^2C(s) + 2\xi\omega_n sC(s) + \omega_n^2 C(s) = K\omega_n^2 R(s) \qquad \textbf{2.32(107)}$$

Therefore,

$$\frac{C(s)}{R(s)} = \frac{K\omega_n^2}{s^2 + 2\xi\omega_n s + \omega_n^2} \qquad \textbf{2.32(108)}$$

PID Controllers

A typical proportional, integral, and derivative (PID) controller is given by

$$m(t) = K_c\left(e(t) + \frac{1}{T_i}\int e(t)\,dt + T_d\frac{d}{dt}e(t)\right) \qquad \textbf{2.32(109)}$$

After the substitutions:

$$M(s) = K_c\left(E(s) + \frac{1}{T_i s}E(s) + T_d s\,E(s)\right) \qquad \textbf{2.32(110)}$$

Therefore,

$$\frac{M(s)}{E(s)} = K_c\left(1 + \frac{1}{T_i s} + T_d s\right) \qquad \textbf{2.32(111)}$$

When using a particlar manufacturer's PID algorithm, it is advisable to review the specification on how the algorithm is implemented. (See Section 2.21.)

Multiple-Input Multiple-Output

Multivariable state space representations can also be provided by transfer functions. They are referred to as *transfer function matrices.* Consider the following state space system:

$$\dot{\underline{x}} = A\underline{x} + B\underline{u} \qquad \textbf{2.32(112)}$$
$$\underline{y} = C\underline{x}$$

Taking the Laplace transform of both equations yields

$$s\underline{x}(s) - \underline{x}(0) = A\underline{x}(s) + B\underline{u}(s) \qquad \textbf{2.32(113)}$$

$$\underline{y}(s) = C\underline{x}(s) \qquad \textbf{2.32(114)}$$

Rearranging gives

$$\underline{x}(s) = (sI - A)^{-1}\,\underline{x}\,(0) + (sI - A)^{-1}\,B\,\underline{u}(s) \qquad \textbf{2.32(115)}$$

and

$$\underline{y}(s) = C(sI - A)^{-1}\,\underline{x}\,(0) + C(sI - A)^{-1}\,B\,\underline{u}(s) \qquad \textbf{2.32(116)}$$

The transfer function matrix is defined as

$$G(s) = C(sI - A)^{-1}\,B \qquad \textbf{2.32(117)}$$

Consider the 2 × 2 state space system in Equations 2.32(92) and 2.32(93).

$$(sI - A) = \begin{bmatrix} s & o \\ o & s \end{bmatrix} - \begin{bmatrix} a_1 & a_2 \\ a_3 & a_4 \end{bmatrix} = \begin{bmatrix} s - a_1 & -a_2 \\ -a_3 & s - a_4 \end{bmatrix} \qquad \textbf{2.32(118)}$$

$$(sI - A)^{-1} = \begin{bmatrix} s - a_4 & a_2 \\ a_3 & s - a_1 \end{bmatrix} \Big/ \text{C.E.} \qquad \textbf{2.32(119)}$$

$$\underbrace{S^2 - (a_1 + a_4)s + (a_1 a_4 - a_2 a_3)}_{\text{Characteristic Equation (C.E.)}} \qquad \textbf{2.32(120)}$$

if $C = I$ then

$$G(s) = C(sI - A)^{-1}\,B =$$

$$= \begin{bmatrix} \dfrac{(s - a_4)b_1 - a_2 b_3}{\text{C.E.}} & \dfrac{(s - a_4)b_2 - a_2 b_4}{\text{C.E.}} \\[2ex] \dfrac{(s - a_1)b_3 - a_3 b_1}{\text{C.E.}} & \dfrac{(s - a_1)b_4 - a_3 b_2}{\text{C.E.}} \end{bmatrix} \qquad \textbf{2.32(121)}$$

Consider element 1,1 of $G(s)$:

$$G_{11}(s) = \frac{b_1(s - (a_4 b_1 + a_2 b_3))}{s^2 - (a_1 + a_4)s + (a_1 a_4 - a_2 a_3)}\;\frac{x_1(s)}{u_1(s)} \qquad \textbf{2.32(122)}$$

This is the transfer function that relates $x_1(s)$ and $u_1(s)$ in the single-input single-output case. It has a second-order denominator (or two poles) and a first-order numerator (or one zero), as discussed later in this section in connection with stability.

BLOCK DIAGRAMS

In control system analysis, it is not convenient to use the various mathematical equations, while a block diagram format of representation can give further insight. Such diagrams not only provide an organized description of the flow of information and energy, but they also, in the framework of the transfer function notation, facilitate the simultaneous solution of the differential equations that describe the system.

TABLE 2.32d
Symbols Used in Block Diagrams

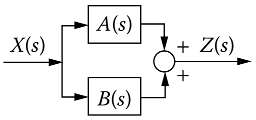
Symbol	*Interpretation*
	Input or output signal; arrow gives direction.
	Branch point. Division of a signal to give two or more paths without modification.
	Summing point. $Z(s) = \pm X(s) \pm Y(s)$
	System element. $Y(s) = G(s)X(s)$

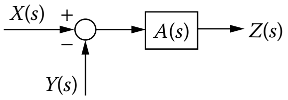
The standard symbols used in the construction of block diagrams are listed in Table 2.32d. The two main symbols are a circle, which indicates summation of two signals, and a rectangle, which indicates multiplication of a signal by a constant K or by a transfer function $G(s)$. It is important to note that both symbols indicate linear operations.

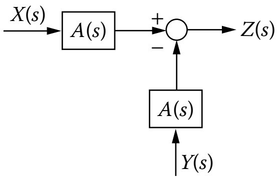
In using block diagrams to analyze control problems it is important to be able to convert from one form to another. Such manipulations are termed block diagram algebra. Table 2.32e lists some examples of conversions.

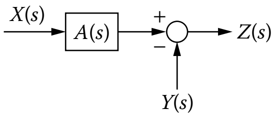
TABLE 2.32e
Conversions Used in Block Diagrams

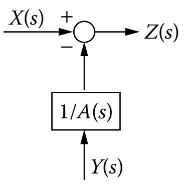
Original Form	*Converted Form*
					

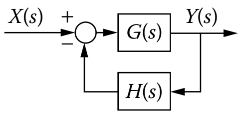


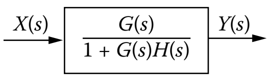












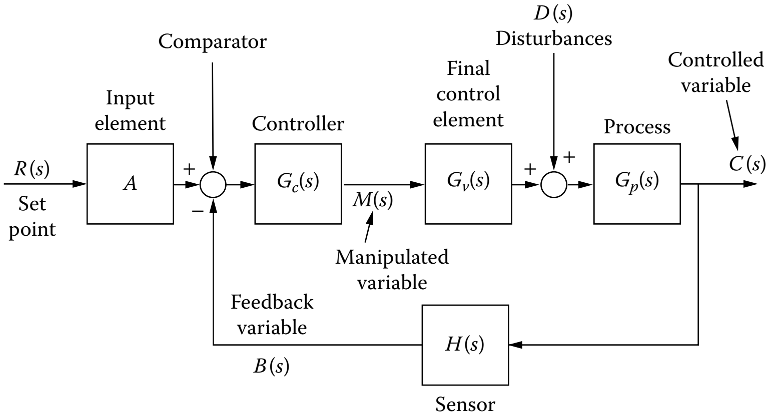


FIG. 2.32f
The block diagram of a typical control loop.

In control analysis the most frequent block diagram manipulations involve feedback loops of some sort. The rules for reducing such systems into a single transfer function can be summarized as follows.

$$\text{Output} = \frac{(\text{Input})\begin{pmatrix}\text{Product of blocks in the forward}\\ \text{path between input signal}\\ \text{and output signal}\end{pmatrix}}{1+\begin{pmatrix}\text{Product of blocks in the}\\ \text{control loop}\end{pmatrix}} \qquad \textbf{2.32(123)}$$

For systems with more than one input, Equation 2.32(123) becomes

$$\text{Output} = \sum_{i=1}^{N} \frac{(\text{Input-}i)\begin{pmatrix}\text{Product of blocks in the forward}\\ \text{path between input-}i\\ \text{and output signal}\end{pmatrix}}{1+\begin{pmatrix}\text{Product of blocks in the}\\ \text{control loop}\end{pmatrix}} \qquad \textbf{2.32(124)}$$

For example, consider the feedback-type control system in Figure 2.32f, where

$$G_c(s) = K_c \text{ (proportional control)} \qquad \textbf{2.32(125)}$$

$$G_p(s) = \frac{K}{1+\tau s} \text{ (first-order feedback)} \qquad \textbf{2.32(126)}$$

$$H(s) = \frac{K_H}{1+\tau_H s} \text{ (first-order feedback)} \qquad \textbf{2.32(127)}$$

Substituting,

$$c(s) = \frac{\dfrac{AK_cK}{1+\tau s}}{1+K_c\left(\dfrac{K}{1+\tau s}\right)\left(\dfrac{K_H}{1+\tau_H s}\right)}R(s) + \frac{B\left(\dfrac{K}{1+\tau s}\right)}{1+K_c\left(\dfrac{K}{1+\tau s}\right)\left(\dfrac{K_H}{1+\tau_H s}\right)}D(s) \qquad \textbf{2.32(128)}$$

or

$$c(s) = \frac{AK_cK(1+\tau_H s)}{(1+\tau s)(1+\tau_H s)+K_cKK_H}R(s) + \frac{BK(1+\tau_H s)}{(1+\tau s)(1+\tau_H s)+K_cKK_H}D(s) \qquad \textbf{2.32(129)}$$

LINEARIZATION

The great majority of techniques used in the analysis of control problems, including block diagrams, are dependent on the existence of mathematical equations in a linear form. By their very nature, most systems are nonlinear to one degree or another and therefore must be approximated by some linear equation. The technique used to linearize a nonlinear function can best be illustrated by considering a nonlinear equation such as

$$Y = \phi(X_1, X_2, X_3, \ldots) \qquad \textbf{2.32(130)}$$

where Y = dependent variable; X = independent variables; and ϕ = nonlinear function.

The equation can be expanded about a point $(X_{1i}, X_{2i}, X_{3i}, \ldots)$ using a Taylor's series expansion in which the higher-order terms are ignored.

$$Y = Y_i + \left.\frac{\delta Y}{\delta X_1}\right|_i (X_1 - X_{1i}) + \left.\frac{\delta Y}{\delta X_2}\right|_i (X_2 - X_{2i}) + \left.\frac{\delta Y}{\delta X_3}\right|_i (X_3 - X_{3i}) + \cdots \tag{2.32(131)}$$

or

$$y = K_1 x_1 + K_2 x_2 + K_3 x_3 + \cdots \tag{2.32(132)}$$

where

$$y = Y - Y_i \tag{2.32(133)}$$

$$x = X - X_i \tag{2.32(134)}$$

$$K_1 = \left.\frac{\delta Y}{\delta X_1}\right|_i = \text{constant} \tag{2.32(135)}$$

$$K_2 = \left.\frac{\delta Y}{\delta X_2}\right|_i = \text{constant} \tag{2.32(136)}$$

$$K_3 = \left.\frac{\delta Y}{\delta X_3}\right|_i = \text{constant} \tag{2.32(137)}$$

For example, consider the development of the transfer function representation for the water tank shown in Figure 2.32g. A material balance on the tank yields

$$\rho Q_{\text{in}} - \rho Q_{\text{out}} = \frac{d}{dt}(\rho H K_s) \tag{2.32(138)}$$

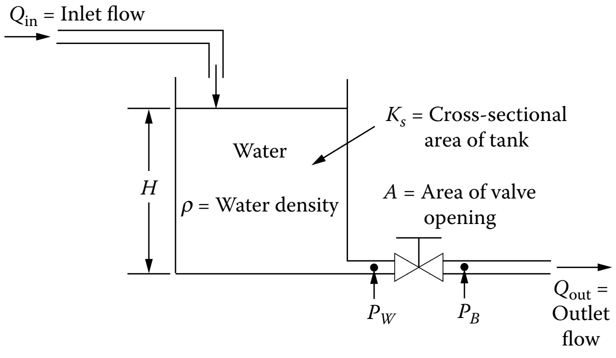

FIG. 2.32g
The operation of a water tank illustrates a nonlinear process.

Flow out of the tank is a function of the area of the valve opening and of the pressure drop across the valve, which can be determined by the following equation:

$$Q_{\text{out}} = C_d A \sqrt{(2g_c/\rho)(P_w - P_B)} \tag{2.32(139)}$$

where ρ = water density; C_d = orifice discharge coefficient (constant); P_B = backpressure (constant); P_w = water pressure at valve; and A = area of valve opening.

The pressure at the valve is caused by the height of water column in the tank:

$$P_w = \rho \frac{g}{g_c} H \tag{2.32(140)}$$

Therefore the valve equation is

$$Q_{\text{out}} = C_d A \sqrt{\frac{2g_c}{\rho}\left(\rho \frac{g}{g_c} H - P_B\right)} \tag{2.32(141)}$$

Substituting into the material balance yields

$$Q_{\text{in}} - C_d A \sqrt{\frac{2g_c}{\rho}\left(\rho \frac{g}{g_c} H - P_B\right)} = \rho K_3 \frac{d}{dt}(H) \tag{2.32(142)}$$

which equation is nonlinear and must be linearized before a Laplace transform can be determined. Using the linearization technique described earlier, the nonlinear equation can be expressed as a linear function about a normal operating point $(Q_{\text{out}i}, Q_{\text{in}i}, A_i, H_i)$ as follows:

$$q_{\text{out}} = K_1 a + K_2 h \tag{2.32(143)}$$

where

$$q_{\text{out}} = (Q_{\text{out}} - Q_{\text{out}i}) \tag{2.32(144)}$$

$$a = (A - A_i) \tag{2.32(145)}$$

$$h = (H - H_i) \tag{2.32(146)}$$

$$K_1 = \left.\frac{\delta Q_{\text{out}}}{\delta A}\right|_i = C_d \sqrt{\frac{2g_c}{\rho}\left(H_i \rho \frac{g}{g_c} - P_B\right)} \tag{2.32(147)}$$

$$K_2 = \left.\frac{\delta Q_{\text{out}}}{\delta H}\right|_i = C_d A_i \sqrt{\frac{2g_c/\rho}{H_i \rho \frac{g}{g_c} - P_B}\left(\rho \frac{g}{g_c}\right)} \tag{2.32(148)}$$

Expressing Q_{in} as a deviation from a reference operating condition, $Q_{\text{in}i}$, the linearized process differential equation is

$$q_{\text{in}} - K_1 a - K_2 h = K_3 \frac{dh}{dt} \tag{2.32(149)}$$

The Laplace transformation of this equation yields:

$$Q_{\text{in}}(s) - K_1 A(s) - K_2 H(s) = K_3 s H(s) \qquad \textbf{2.32(150)}$$

or

$$H(s) = \frac{Q_{\text{in}}(s)}{K_2 + K_3 s} - \frac{K_1 A(s)}{K_2 + K_3 s} \qquad \textbf{2.32(151)}$$

Therefore the two transfer functions that describe the water tank process are

$$\frac{H(s)}{Q_{\text{in}}(s)} = \frac{1}{K_2 + K_3 s} \qquad \textbf{2.32(152)}$$

$$\frac{H(s)}{Q_{\text{in}}(s)} = \frac{K_1}{K_2 + K_3 s} \qquad \textbf{2.32(153)}$$

GRAPHIC REPRESENTATIONS

Analytical solutions to dynamic control problems are typically very tedious. In practice these systems of equations are analyzed using computer-aided graphical techniques. Two of these graphic methods will be discussed here—Bode plots and Nyquist plots. In the subsequent paragraph where stability is discussed, these plotting techniques will prove valuable.

Bode Plots

Bode plots are useful graphical techniques for the analysis of dynamic systems. The Bode plot correlates certain parameters as functions of frequency. Consider the closed-loop equation based on Figure 2.32h.

$$\frac{C(s)}{R(s)} = \frac{G(s)}{1 + G(s)\,H(s)} \qquad \textbf{2.32(154)}$$

If the $r(t)$ input to this system is a sine wave, the steady-state output $c(t)$ will be a sine wave of different amplitude and shifted in phase. If this change in amplitude and phase shift were recorded versus various different frequency $r(t)$ inputs and plotted on rectangular coordinates, these would be the magnitude and phase Bode plots, respectively.

Equation 2.32(154) can be examined in the frequency domain by substituting $s = j\omega$.

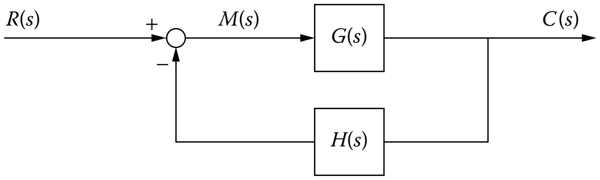

FIG. 2.32h
Feedback control loop.

The frequency response, magnitude versus frequency, for the control ratio

$$\frac{C(j\omega)}{R(j\omega)} = \frac{G(j\omega)}{1 + G(j\omega)H(j\omega)} \qquad \textbf{2.32(155)}$$

can be determined for any given frequency. For each value of frequency, Equation 2.32(155) yields a phasor quantity (see "Nyquist Plots," below) whose magnitude is $C(j\omega)/R(j\omega)$ and whose phase angle α is the angle between $C(j\omega)$ and $R(j\omega)$.

For a given sinusoidal input signal, the input and steady-state output are of the following forms:

$$r(t) = R \sin \omega t \qquad \textbf{2.32(156)}$$

$$c(t) = C \sin(\omega t + \alpha) \qquad \textbf{2.32(157)}$$

An ideal system may be one in which

$$\alpha = 0^\circ$$

$$R = C \qquad \textbf{2.32(158)}$$

for $0 < \omega < \infty$. Curves 1 in Figure 2.32i represent the ideal system. If the above equations are analyzed, it is found that an instant transfer of energy must occur from the input to the output in zero time. This is a prerequisite for faithful reproduction of a step input signal. In reality, this generally cannot be achieved, since in any physical system there is energy dissipation and there are energy-storage elements. Curves 2 and 3 in Figure 2.32i represent actual systems.

The Bode plot provides significant information concerning the time response of the system. Two features of the frequency plot are the maximum value M_m and resonant frequency ω_m. The time response is qualitatively related to these values M_m and ω_m, which can be determined from the frequency response plots.

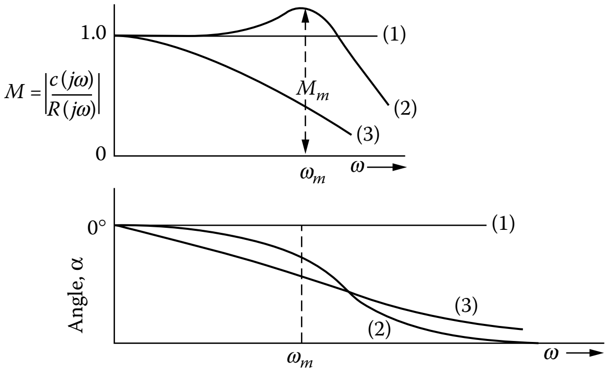

FIG. 2.32i
Bode plots [frequency response characteristic of C(jω)/R(jω) . . in rectangular coordinates].

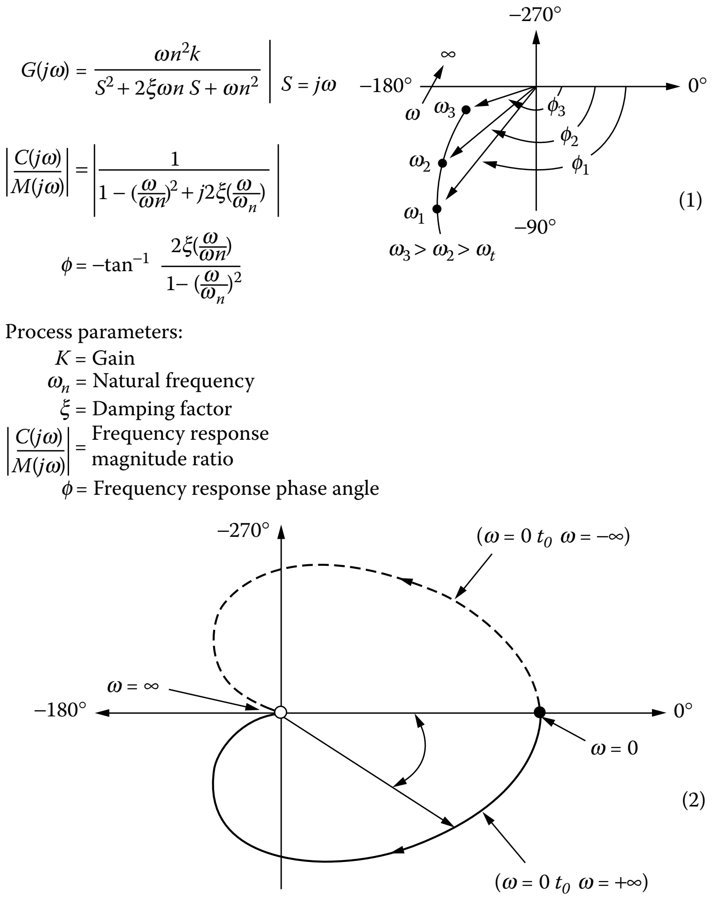

FIG. 2.32j
(1) Phasor-locus development in the complex plane. (2) The direct Nyquist plot.

The magnitude and phase versus frequency information is generated from the phasor quantity. A transfer function can be shown to equal the complex quantity.

$$G(j\omega) = \alpha + j\omega = |G(j\omega)|\, e^{i\theta(\omega)} \qquad \textbf{2.32(159)}$$

$$|G(j\omega)| = \sqrt{\alpha^2 + \omega^2}, \qquad \text{magnitude} \qquad \textbf{2.32(160)}$$

$$\theta(\omega) = \tan^{-1}(\omega/\alpha), \qquad \text{phase} \qquad \textbf{2.32(161)}$$

The quantity typically plotted on the magnitude Bode plot is the decibel, defined as

$$20 \log |G(j\omega)| \qquad \textbf{2.32(162)}$$

Techniques for generating Bode plots vary from quick asymptotic approximation to relatively simple computer packages.

Nyquist Plots

Another method of representing the open-loop steady-state sinusoidal response is the polar plot or Nyquist plot. From this plot, the stability and the frequency response of the closed-loop system can be obtained (see discussion later on stability), and the closed-loop time response of the system can be predicted.

Consider the forward transfer function:

$$|G(j\omega)| = \frac{C(j\omega)}{M(j\omega)} \qquad \textbf{2.32(163)}$$

For a given frequency, $G(j\omega)$ is a phasor quantity whose magnitude is $|C(j\omega)/M(j\omega)|$ and whose phase angle is $\phi(\omega)$. Representing this quantity in polar coordinates can be done by a phasor whose length corresponds to the magnitude vector $|C(j\omega)/R(j\omega)|$ and whose angle with respect to the positive real axis corresponds to $\phi(\omega)$, as shown in Figure 2.32j(1).

Thus a set of values of $G(j\omega)$ for frequencies between 0 and ∞ yields a set of phasors whose tips are connected by a smooth curve, as shown in Figure 2.32j(2). The polar plot in Figure 2.32j(2) contains all the necessary information and is of this form.

Transfer Function Matrix The reader has now been introduced to several forms of graphical representations employed in synthesis work. These techniques, whether computer generated or done by hand, can be very useful in analyzing dynamic systems.

An extension of the Nyquist plot is also very useful in analyzing interactions in multivariable systems. As defined earlier, the transfer function matrix is a matrix of single-input single-output transfer functions representing a multiple-input multiple-output system.

It is possible to take this matrix of transfer functions and plot a matrix of Nyquist plots. Figure 2.32k(1) shows such a matrix for a possible dynamic system described by Equation 2.32(121). This plot alone allows the designer to study the stability and frequency response characteristics of the individual single-input single-output transfer functions.

Another very useful property that can be calculated and displayed graphically is the row dominance property. The dominant transfer function of a given row of a transfer function matrix is the element whose time behavior would dominate (i.e., faster response within a given frequency range). Diagonal row dominance has the following definition for $Q(s)$ [$Q(s) = G(s)^{-1}$ or the inverse transfer function matrix].

$$|q_{ii}(s)| \sum_{\substack{j=1 \\ j \neq 1}}^{m} |q_{ij}(s)| > 0 \qquad \textbf{2.32(164)}$$

This implies that for any s, the modulus of each element on the diagonal of $Q(s)$ exceeds the sum of the moduli of the off-diagonal elements. The row dominance can be graphically illustrated. For each Nyquist plot, at specified frequencies, the modulus of all other same-row elements is calculated. This number is used as the radius for a circle drawn on the Nyquist contours with circle center on the Nyquist contours at the frequency specified [refer to Figure 2.32k(2)]. These circles are called Gershgorin circles.

When this is done for a range of frequencies, the circles sweep out a band called a Gershgorin band. If the origin does not lie within the Gershgorin band, the element is said to be dominant on that row. For example, in Figure 2.32k(2), the g_{11} and g_{21} plots do not have Gershgorin bands that circle the origin; therefore, they are dominant on their respective rows. This matrix is then column 1 dominant, not diagonally dominant as we would like from a decoupling standpoint. Later, compensation will be designed to achieve this dominance.

Multiple-input multiple-output Nyquist arrays bigger than 2 × 2 are very cumbersome to calculate by hand. Computer methods are typically necessary for these systems (see Section 2.38).

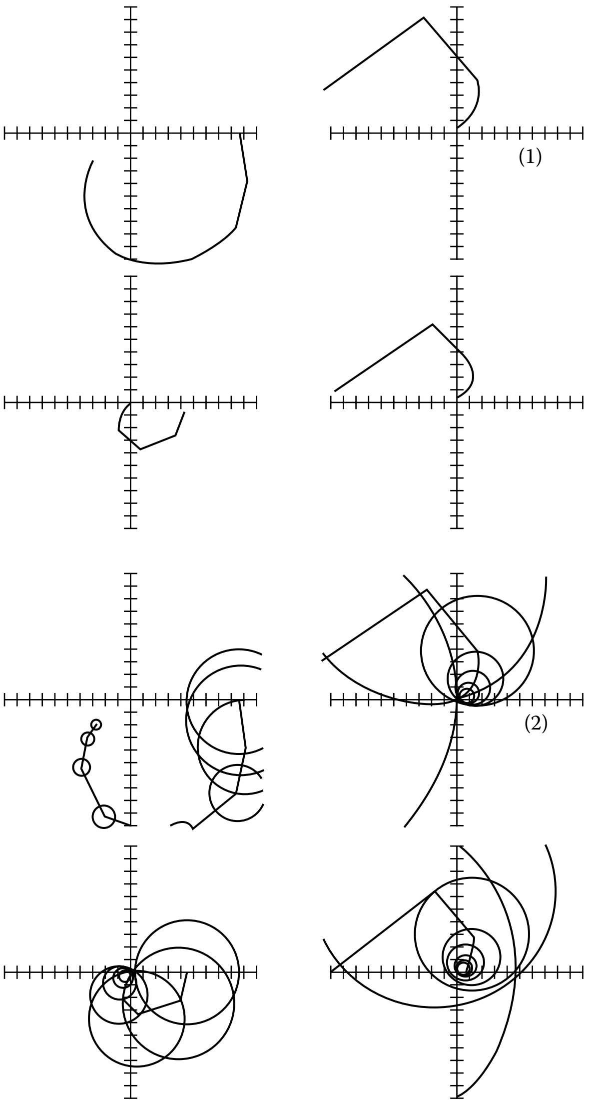

FIG. 2.32k
(1) Nyquist array plot. (2) Nyquist array plot with Gershgorin bands.

STABILITY

A stable linear time-invariant system or element is one in which the system response is always bounded. Any bounded system input is called a BIBO (bounded-input, bounded-output).

While most processes encountered in the process industries (with the exception of a few chemical reactors) are inherently stable, a feedback system employed to control the process can lead to a potentially unstable system. Mathematically, the stability of a linear time-invariant system can be determined by an analysis of the roots of the *characteristic equation* from the differential equation describing the process (which corresponds to the roots of the denominator of the transfer function).

The characteristic equation can be written as follows:

$$\sum_{i=0}^{n} a_i p^i = a_n(s-p_1)(s-p_2)\ldots(s-p_n) = 0 \qquad \textbf{2.32(165)}$$

Consider Figure 2.32l(1). Here the roots of the characteristic equation (for a given K) are on the imaginary axis, and the system is oscillating. In Figure 2.32l(2,3), the roots are to the right of the imaginary axis (i.e., the real part of the root is positive). Both systems are unstable. Their time responses are growing in amplitude. However, in many situations it may not be necessary to actually obtain the exact position of the roots in order to learn the nature of these roots.

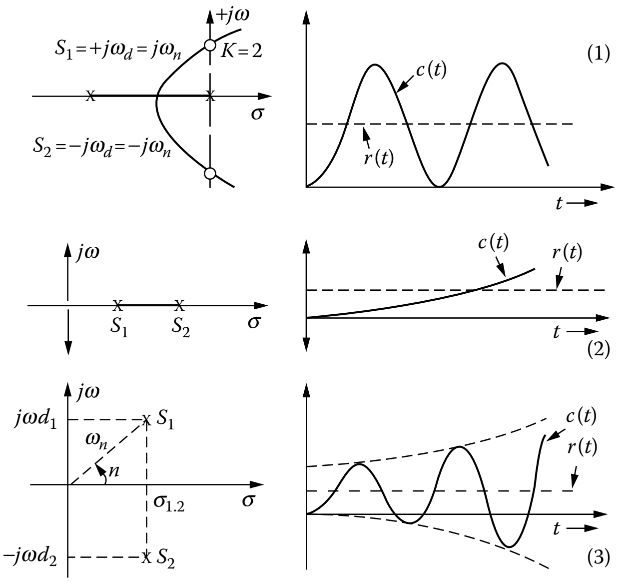

FIG. 2.32l
Roots plotted and associated time response showing (1) continuous oscillations, (2) real root unstable condition, (3) underdamped unstable pole placement.

Descartes' Rule of Signs

A simple rule-of-thumb analysis that can provide much insight into the nature of roots is Descartes' rule of signs:

$$\text{Let } f(s) = a_n s^n + a_{n-1}s^{n-1} + \cdots + a_2 s^2 + a_1 s^1 + a_0 \qquad \textbf{2.32(166)}$$

be a polynomial with real coefficients and $a_0 \neq 0$:

1. The number of positive real zeros of f is either to the number of variations in sign of $f(s)$ or is less than that number by an even integer.
2. The number of negative real zeros of f is either to the number of variations in sign of $f(-s)$ or is less than that number by an even integer.

If the terms in the denominator are arranged in descending powers of s, Descartes' rule of signs states that the number of positive *real* roots cannot exceed the number of variations in sign from term to term.

Therefore a simple *necessary* but *not sufficient* condition of stability that can be immediately assessed for any transfer function is that all the coefficients of each term in the denominator must be the same sign. If any variations in sign exist, the system is unstable. If no variations in sign exist, the system is potentially stable; however, instabilities could result from complex roots in the right-hand plane that Descartes' rule is unable to predict.

For example, for the transfer function

$$F(s) = \frac{3}{(s+3)(s+4)} \qquad \textbf{2.32(167)}$$

the characteristic equation is given by $Q(s) = (s + 3)(s + 4) = 0$, and the roots of the equation, −3, and −4, are in the left half plane. This transfer function is stable. For instance, if one of the roots would have been positive then the system would have been unstable. For complex systems that are stable, the characteristic equation roots would have to be in the imaginary axis and the left half plane.

Routh's Criterion

One absolute method of determining whether complex or real roots lie in the right-hand plane is by the use of Routh's criterion. The method entails systematically generating a column of numbers that are then analyzed for sign variations. The characteristic equation of the polynomial is set to zero. If a transport lag exists, Routh's Criterion cannot be used.

The first step is to arrange the denominator of the transfer function into descending powers of s. All terms including those that are zero should be included.

$$A(s) = a_n s^n + a_{n-1}s^{n-1} + a_{n-2}s^{n-2} + \cdots + a_0 \qquad \textbf{2.32(168)}$$

Next, arrange the coefficients of s according to the following schedule:

$$\begin{array}{ccccc} a_n & a_{n-2} & a_{n-4} & a_{n-6} & \cdots \\ a_{n-1} & a_{n-3} & a_{n-5} & a_{n-7} & \cdots \end{array} \qquad \textbf{2.32(169)}$$

Now, expand according to the following manner:

$$\begin{array}{c|ccccc} s^n & a_n & a_{n-2} & a_{n-4} & a_{n-6} & \cdots \\ s^{n-1} & a_{n-1} & a_{n-3} & a_{n-5} & a_{n-7} & \cdots \\ s^{n-2} & b_1 & b_2 & b_3 & b_4 & \cdots \\ s^{n-3} & c_1 & c_2 & c_3 & \cdots & \\ \vdots & : & & & & \\ s^2 & g_1 & g_2 & & & \\ s^1 & h_1 & & & & \\ s^0 & i_1 & & & & \end{array} \qquad \textbf{2.32(170)}$$

The power of s (left of bar) is included to help keep track of were one is located in the array. The equations for the coefficients in the additional rows of above array 2.32(170) are as follows:

$$b_1 = -\frac{1}{a_{n-1}}\begin{vmatrix} a_n & a_{n-2} \\ a_{n-1} & a_{n-3} \end{vmatrix} \qquad b_2 = -\frac{1}{a_{n-1}}\begin{vmatrix} a_n & a_{n-4} \\ a_{n-1} & a_{n-5} \end{vmatrix}, \ldots$$

$$c_1 = -\frac{1}{b_1}\begin{vmatrix} a_{n-1} & a_{n-1} \\ b_1 & b_2 \end{vmatrix} \qquad c_2 = -\frac{1}{b_1}\begin{vmatrix} a_{n-1} & a_{n-5} \\ b_1 & b_3 \end{vmatrix}, \ldots$$

2.32(171)

This process is continued until all new terms are zero. Routh's criterion says that the number of roots (real or complex) of the denominator of the transfer function that lie in the right-hand plane is equal to the number of changes of sign in the leftmost column of the array shown in Equation 2.32(170). If any zeros appear in the first element of any of the nth rows, the transfer function is marginal or instable.

As an example, consider a system described by the following transfer function:

$$g(s) = \frac{s+1}{s^3 + 2s^2 + 5s + 24} \qquad \textbf{2.32(172)}$$

An initial analysis made using Descartes' rule of thumb indicates that, since all the signs of the denominator are the same, the system appears to be stable; however, Routh's criterion must be applied in order to determine this conclusively. The Routh array is

$$\begin{array}{c|ccc} s^3 & 1 & 5 & 0 \\ s^2 & 2 & 24 & 0 \\ s^1 & -7 & 0 & \\ s^0 & 24 & 0 & \end{array} \qquad \textbf{2.32(173)}$$

An inspection of the leftmost column indicates two sign changes (one from +2 to –7 and the other from –7 to +24); therefore, there are two roots in the right-half plane, resulting in an unstable system.

Nyquist Criterion

In the process industries, the Routh criterion has the limitation of not being applicable to systems containing dead time. Another more general stability criterion is the Nyquist criterion. This is based on the "frequency response" of a process and can be easily applied to dead time or to other distributed parameter effects.

To demonstrate the use of the Nyquist criterion, consider the Nyquist plot diagram of Figure 2.32j(2). From this plot the stability can be determined by an investigation of the $s = -1$ point in the complex plane. The Nyquist stability criterion: Let $G(s)H(s)$ be the ratio of two polynomials in s. If $G(s)H(s)$ is within and on C, and if there are no poles or zeros on C, then

$$N = z - P \qquad \textbf{2.32(174)}$$

where N = net number of encirclements of point $s = -1$ in a clockwise direction; z = number of zeros of $G(s)H(s)$ that lie in the right-hand plane; and P = number of poles of $G(s)H(s)$ that lie in the right-hand plane.

The system is unstable if the contour either encircles or passes through the (–1, 0) point in a clockwise direction.

CONCLUSIONS

While the analysis of transfer functions seems to be a mathematics course for process control systems, the possession of the knowledge to deal with systems in both the time and frequency domain allows one to understand what is happening in those systems. Using the stability analysis techniques described in this section will allow the reader to design stable control systems.

2.33 State Space Control

I. VAJK (2005)

Please note that in this section the language of control system is used, which differs somewhat from the terminology used by engineers working in the process industries. Therefore it might be of value to note that when the term *system* appears in this text, it refers to the process; when *system output* is used, that term refers to the controlled variable $y(t)$; when *system input* is referred to, that term is equivalent to the manipulated variable $u(t)$; and when the term *reference signal* is used, it, in the everyday PID terminology, means set point.

INTRODUCTION

Using state space control, the poles of the system to be controlled can be placed to arbitrary positions. To achieve a satisfactory dynamic system behavior, the roots of the closed-loop characteristic equations are to be assigned properly. The predefined system behavior can be achieved by applying proportional feedback for all the state variables of the system.

The controller given by state variable feedback is realizable if and only if the system is controllable. The control strategy requires access to all the state variables of the system. In practice, however, this condition is rarely satisfied by most systems. This implies that the unmeasured state variables are supposed to be estimated. This is achievable if and only if the system is observable.

Consequently, the complete control strategy will turn out to be a combination of a state observer and a state feedback, where the unmeasured state variables will be substituted by their estimated values. The state space control techniques using both state variable estimation and feedback can be converted to traditional feedback control schemes realized by transfer functions.

STATE SPACE DESCRIPTION

Linear dynamic systems can be described in a number of mathematical forms. One of these is the *impulse response* description. Assuming that the impulse response is available, the system output [in process control, the controlled variable $y(t)$] at an arbitrary time can be determined, if up to that time the history of the system input [in process control, the manipulated variable $u(t)$] is known. [The controlled variable $y(t)$—system output—can be calculated by evaluating a convolution integral.]

Another way to describe a linear dynamic process is to introduce the use of state variables. In this case there is no need to know how the system developed to arrive to a certain state at a given time instant; the system output can be calculated by using the instantaneous value of the state variables and that of the system input. When selecting state variables in a system, it is reasonable to choose variables that are unable to exhibit abrupt changes.

Consider the state space model (or in short, *state model*) of a system given by

$$\begin{aligned}\dot{\mathbf{x}}(t) &= \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t)\\ \mathbf{y}(t) &= \mathbf{C}\mathbf{x}(t) + \mathbf{D}\mathbf{u}(t)\end{aligned} \qquad \mathbf{2.33(1)}$$

where $\mathbf{x}(t)$ is the state vector with n entries, while $\mathbf{u}(t)$ and $\mathbf{y}(t)$ are the system input and output signals, respectively.

In the case of single-input single-output (SISO) systems both $\mathbf{u}(t)$ and $\mathbf{y}(t)$ are scalar quantities. The $\mathbf{A}$(n by n) and $\mathbf{B}$(n by 1) matrices in Equations 2.33(1) will determine how the state variables develop from an initial state if a given input is applied to the system. The matrices $\mathbf{C}$(1 by n) and $\mathbf{D}$(1 by 1) tell how to find the system output once the state variables and the input signal are available for the calculations.

The evaluation of Equations 2.33(1) suggests that the system dynamics is described by n first-order differential equations. Note that Equations 2.33(1) represent an appropriate way to uniformly describe linear systems with multiple inputs and multiple outputs (MIMO systems). Finally observe that the $\mathbf{D}$ matrix allows a direct contribution from the input $\mathbf{u}(t)$ to the output $\mathbf{y}(t)$. In all real processes it takes some time for a change in the manipulated variable to have an effect on the controlled variable. This delay between the input and the output results in $\mathbf{D} = \mathbf{0}$.

A state model is not unique in the sense that several sets of $\{\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathbf{D}\}$ exist to ensure input/output equivalence. Equivalent state models can be linked together by using a simple linear transformation, called similarity transformation. Assume that $\mathbf{T}$ (n by n) is an arbitrary nonsingular matrix, then $\mathbf{x}(t)$ can be transformed to a new state representation $\mathbf{z}(t)$ by

$$\mathbf{z}(t) = \mathbf{T}\mathbf{x}(t). \qquad \mathbf{2.33(2)}$$

The transformed state model can simply be derived as

$$\begin{aligned}\dot{\mathbf{z}}(t) &= \mathbf{TAT}^{-1}\mathbf{z}(t) + \mathbf{TBu}(t)\\ \mathbf{y}(t) &= \mathbf{CT}^{-1}\mathbf{z}(t) + \mathbf{Du}(t)\end{aligned} \qquad \mathbf{2.33(3)}$$

Among the state models several canonical forms exist (e.g., controllability, observability, diagonal forms). System controllability and observability are important features attached to state models:

- A system is controllable if there exists a finite control input to govern the system from an arbitrary initial state to an arbitrary final state within a finite time horizon. The ability to control (controllability) can be checked by considering the rank of the controllability matrix

  $$\mathbf{Q} = [\mathbf{B} \quad \mathbf{AB} \quad \mathbf{A}^2\mathbf{B} \quad \ldots \quad \mathbf{A}^{n-1}\mathbf{B}] \qquad \mathbf{2.33(4)}$$

  The system is controllable if and only if the controllability matrix is of full rank (rank is n). In case of MIMO systems the controllability matrix is not a square matrix, so one way to check if the rank of **Q** is n is to consider $\mathbf{QQ}^T$, which is an $n \times n$ matrix. If $\mathbf{QQ}^T$ is not singular it indicates that **Q** is of full rank and the system is controllable.
- A system is observable if from knowing the input and output records of a system for a finite time period the initial value of the state variables can be calculated. A system is observable if and only if the observability matrix

  $$\mathbf{M} = \begin{bmatrix}\mathbf{C}\\ \mathbf{CA}\\ \ldots\\ \mathbf{CA}^{n-1}\end{bmatrix} \qquad \mathbf{2.33(5)}$$

  is of full rank (n). Again, for MIMO systems the singularity of $\mathbf{M}^T\mathbf{M}$ can alternatively be checked.

Equations 2.33(1) exhibit the fundamental description of SISO time-invariant linear dynamic systems. Using the Laplace transformation we obtain:

$$\begin{aligned}s\mathbf{x}(s) - \mathbf{x}(t_0) &= \mathbf{Ax}(s) + \mathbf{Bu}(s)\\ \mathbf{y}(s) &= \mathbf{Cx}(s) + \mathbf{Du}(s)\end{aligned} \qquad \mathbf{2.33(6)}$$

where $\mathbf{x}(t_0)$ is the initial value of the state vector and s stands for the Laplace operator. Rearranging Equations 2.33(6), the Laplace transform of the output signal can be expressed as follows:

$$\mathbf{y}(s) = (\mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D})\mathbf{u}(s) + \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{x}(t_0) \qquad \mathbf{2.33(7)}$$

Observe the term

$$H(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D} \qquad \mathbf{2.33(8)}$$

establishing the relation between the input and output signals. $H(s)$ is the well-known *transfer function* of the system. Some algebra leads to

$$H(s) = \frac{\mathbf{C}\,\mathrm{adj}(s\mathbf{I} - \mathbf{A})\mathbf{B}}{\det(s\mathbf{I} - \mathbf{A})} + \mathbf{D} = \frac{B(s)}{A(s)} \qquad \mathbf{2.33(9)}$$

where $B(s)$ and $A(s)$ are both polynomials. It can be shown that for systems that are controllable *and* observable, $B(s)$ and $A(s)$ are relatively prime (often called coprime) polynomials, i.e., polynomials having no common roots. Note that if $\mathbf{D} = \mathbf{0}$ holds, then the order of $B(s)$ is less than the order of $A(s)$. Systems with $\mathbf{D} = \mathbf{0}$ are also called strictly proper systems. The rest of this section is devoted to strictly proper systems.

CONTROL LAW DESIGN

As it was indicated earlier, state variable feedback can ensure arbitrary pole locations for the closed-loop system. In other words, using state variable feedback, the poles of the original system (i.e., the poles of the system with no state variable feedback) can be moved to arbitrarily assigned positions in the complex plane. The question here is how to find the gains along the feedback path to achieve the required pole locations. Assume first that all the state variables are directly available (measured) for feedback. Later on, this condition will be relaxed.

State Variable Feedback

Assume that the feedback is applied around the state model

$$\begin{aligned}\dot{\mathbf{x}}(t) &= \mathbf{Ax}(t) + \mathbf{Bu}(t)\\ \mathbf{y}(t) &= \mathbf{Cx}(t)\end{aligned} \qquad \mathbf{2.33(10)}$$

by using the linear combination of the state variables according to

$$\mathbf{u}(t) = -\mathbf{K}\,\mathbf{x}(t) + \mathbf{u}_r(t) \qquad \mathbf{2.33(11)}$$

where $\mathbf{u}_r(t)$ is the set point (scalar value in case of SISO systems) of the system and **K** is the gain matrix (essentially a row vector in case of SISO systems). The block diagram of the closed-loop system is shown in Figure 2.33a. Designing a controller is after all a procedure to find appropriate values for the gain matrix. Substituting Equation 2.33(11) back to Equation 2.33(10) results in the following differential equation for the closed-loop system:

$$\dot{\mathbf{x}}(t) = (\mathbf{A} - \mathbf{B}\mathbf{K})\mathbf{x}(t) + \mathbf{B}\,\mathbf{u}_r(t) \qquad \mathbf{2.33(12)}$$

Using the Laplace transforms, we obtain:

$$y(s) = \mathbf{C}(s\mathbf{I}_n - \mathbf{A} + \mathbf{BK})^{-1}\mathbf{B}u_r(s) + \mathbf{C}(s\mathbf{I}_n - \mathbf{A} + \mathbf{BK})^{-1}\mathbf{x}(t_0) \qquad \mathbf{2.33(13)}$$

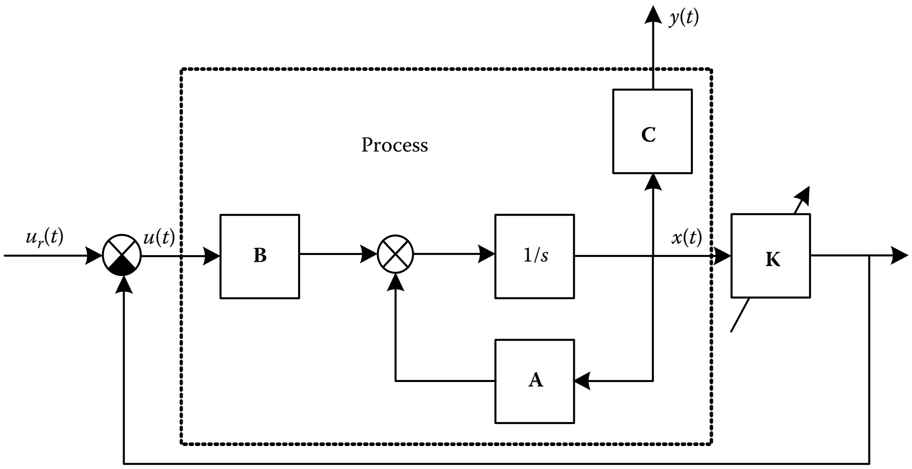

FIG. 2.33a
Controlled process with state variable feedback.

or

$$y(s)=\frac{\mathbf{C}\,\mathrm{adj}(s\mathbf{I}_n-\mathbf{A}+\mathbf{BK})}{\det(s\mathbf{I}_n-\mathbf{A}+\mathbf{BK})}(\mathbf{B}u_r(s)+\mathbf{x}(t_0)) \qquad \mathbf{2.33(14)}$$

The above relation clearly shows that the closed-loop behavior is determined by the closed-loop characteristic polynomial:

$$\alpha(s)=\det(s\mathbf{I}_n-\mathbf{A}+\mathbf{BK}) \qquad \mathbf{2.33(15)}$$

Also, the overall relation between the set point and the output can be expressed by

$$\frac{y(s)}{u_r(s)}=\mathbf{C}(s\mathbf{I}_n-\mathbf{A}+\mathbf{BK})^{-1}\mathbf{B}=\frac{B(s)}{\alpha(s)} \qquad \mathbf{2.33(16)}$$

Ignoring the effect of the nonzero initial value $\mathbf{x}(t_0)$, Equation 2.33(16) shows that the state variable feedback just applied is equivalent to applying a series term $A(s)/\alpha(s)$ directly for the system given by the transfer function $B(s)/A(s)$.

Next, the elements of the **K** gain matrix will be determined such that the roots of the closed-loop characteristic equation are $\{-s_1, -s_2, \ldots -s_n\}$. Using Equation 2.33(15) results in

$$\det(s\mathbf{I}_n-\mathbf{A}+\mathbf{BK})=(s+s_1)(s+s_2)\ldots(s+s_n) \qquad \mathbf{2.33(17)}$$

Then the entries of **K** can be determined by matching the coefficients of the identical powers of s in the polynomials of the two sides in Equation 2.33(17).

Ackermann derived a nice compact algorithm to find **K** directly. Introduce the polynomial

$$\alpha(s)=(s+s_1)(s+s_2)\ldots(s+s_n)=s^n+\alpha_{n-1}s^{n-1}+\cdots+\alpha_0 \qquad \mathbf{2.33(18)}$$

and the matrix polynomial

$$\alpha(\mathbf{A})=\mathbf{A}^n+\alpha_{n-1}\mathbf{A}^{n-1}+\cdots+\alpha_0\mathbf{I} \qquad \mathbf{2.33(19)}$$

The Ackermann formula presents the gain matrix by

$$\mathbf{K}=[0 \quad 0 \quad \ldots \quad 1]\mathbf{Q}^{-1}\alpha(\mathbf{A}) \qquad \mathbf{2.33(20)}$$

where **Q** denotes the controllability matrix. The Ackermann formula shows why the inverse of the controllability matrix should be nonsingular to get a gain matrix. If **Q** is nonsingular the gain matrix obtained by the Ackermann formula is unique.

An even simpler way to determine the coefficients of the gain matrix can be obtained if the state model is assumed to be available in controllability form. Denoting the gain vector associated with the controllability form by $\mathbf{K}_c$, consider a polynomial $K(s)$ with coefficients delivered by $\mathbf{K}_c$. Then, the characteristic polynomial of the closed-loop system simply becomes

$$\alpha(s)=A(s)+K(s) \qquad \mathbf{2.33(21)}$$

Equation 2.33(21) offers a direct way to determine the feedback gain matrix; namely, $K(s)$ can be calculated knowing the goal of the design, i.e., the location of the closed-loop poles.

The presented state variable feedback can also be considered as a generalization of the traditional PD compensation. The generalization is accomplished in the sense that all the closed-loop poles are moved to desired positions. Consequently, all the components of the system response transients are under control. At the same time, according to the fundamental property of the PD compensation, the steady-state error will not go to zero if the system is disturbed by additive constant noise. This becomes only achievable by inserting integrator(s) into the loop.

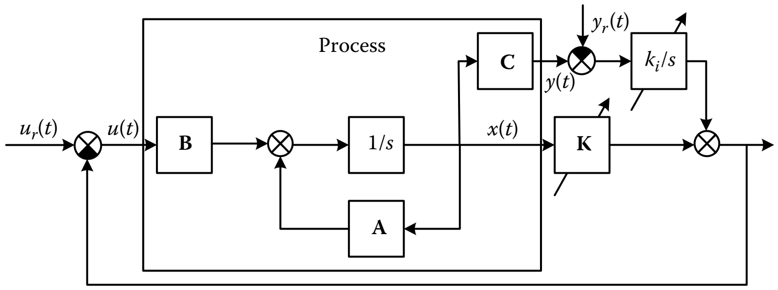

FIG. 2.33b
State feedback with PI action.

State Feedback with PI Control

The state variable feedback concept outlined in the previous section represents a certain generalization of the PD compensation technique. To ensure zero steady-state error, an additional integrator should be inserted into the loop. This can easily be done by augmenting the size of the state vector by one more entry. Denoting the new state variable by $z(t)$ we have

$$\dot{z}(t) = y(t) - y_r(t) \tag{2.33(22)}$$

where $y_r(t)$ denotes the reference signal. The description of the augmented system becomes:

$$\begin{aligned} \dot{\bar{\mathbf{x}}}(t) &= \bar{\mathbf{A}}\bar{\mathbf{x}}(t) + \bar{\mathbf{B}}u(t) + \bar{\mathbf{B}}_r y_r(t) \\ y(t) &= \bar{\mathbf{C}}\bar{\mathbf{x}}(t) \end{aligned} \tag{2.33(23)}$$

where

$$\begin{aligned} &\bar{\mathbf{x}}(t) = \begin{bmatrix} \mathbf{x}(t) \\ z(t) \end{bmatrix} \quad \bar{\mathbf{A}} = \begin{bmatrix} \mathbf{A} & 0 \\ \mathbf{C} & 0 \end{bmatrix} \quad \bar{\mathbf{B}} = \begin{bmatrix} \mathbf{B} \\ 0 \end{bmatrix} \\ &\bar{\mathbf{B}}_r = \begin{bmatrix} 0 \\ -1 \end{bmatrix} \quad \bar{\mathbf{C}} = [\mathbf{C} \quad 0] \end{aligned} \tag{2.33(24)}$$

The state variable feedback will be realized by using the augmented state vector for feedback, according to

$$u(t) = -\bar{\mathbf{K}}\bar{\mathbf{x}}(t) = -\mathbf{K}\mathbf{x}(t) - k_i z(t) = -\begin{bmatrix} \mathbf{K} & k_i \end{bmatrix} \begin{bmatrix} \mathbf{x}(t) \\ z(t) \end{bmatrix} \tag{2.33(25)}$$

Applying the above feedback, the characteristic polynomial of the closed-loop system can be written as

$$\begin{aligned} \bar{\alpha}(s) &= \det(s\mathbf{I}_{n+1} - \bar{\mathbf{A}} + \bar{\mathbf{B}}\bar{\mathbf{K}}) = \det\begin{bmatrix} s\mathbf{I}_n - \mathbf{A} + \mathbf{BK} & \mathbf{B}k_i \\ \mathbf{C} & s \end{bmatrix} \\ &= s\det(s\mathbf{I}_n - \mathbf{A} + \mathbf{BK}) + \mathbf{C}\operatorname{adj}(s\mathbf{I}_n - \mathbf{A} + \mathbf{BK})\mathbf{B}k_i \end{aligned} \tag{2.33(26)}$$

Using the transfer functions introduced earlier, Equation 2.33(26) leads to

$$\bar{\alpha}(s) = s(A(s) + K(s)) + B(s)k_i \tag{2.33(27)}$$

Relation to Equation 2.23(21) is clearly seen from the above form. Given $\bar{\alpha}(s)$, $A(s)$, and $B(s)$, the feedback polynomial $K(s)$ and the k_i coefficient can both be determined.

The block scheme of the state variable feedback extended by the integrator is shown in Figure 2.33b. The augmented system is capable of rejecting nonzero steady-state error. Note that the closed-loop system exhibits identical operational performance for following the reference signal (servo property), as well as for rejecting additive disturbances acting on the system output.

A final remark here relates to the size of the feedback gain matrix. For SISO systems **K** is a vector with n entries, while for MIMO systems **K** is an $m \times n$ matrix, where m denotes the number of inputs. The entries of the gain matrix are adjusted to locate the closed-loop poles; however, there are only n poles to be located, resulting in n equations to determine $m \times n$ coefficients in the gain matrix. Consequently, there exist several gain matrices resulting in identical closed-loop characteristic equations.

OBSERVER DESIGN

So far a state variable feedback technique has been studied assuming that all the state variables are available for the feedback. This condition is rarely met in practice. In the following, how to modify the control strategy derived so far to be able to incorporate the unavailable state variables into the feedback structure will be discussed. The procedure developed to estimate the state variables based on the input/output records of the system is called state estimation or state reconstruction, and the related functional unit is called an *observer.*

Full Order Observer

The state variables are to be estimated by the following linear model

$$\dot{\hat{\mathbf{x}}}(t) = \mathbf{Q}\hat{\mathbf{x}}(t) + \mathbf{R}\mathbf{u}(t) + \mathbf{S}\mathbf{y}(t) \qquad \mathbf{2.33(28)}$$

where $\hat{\mathbf{x}}(t)$ denotes the estimated state vector. Formally, designing an observer is equivalent to determining the **Q**, **R**, and **S** matrices. One classical solution of this problem is to use a feedback in the observer itself driven by the deviation between the measured and estimated system outputs:

$$\begin{aligned}\dot{\hat{\mathbf{x}}}(t) &= \mathbf{A}\hat{\mathbf{x}}(t) + \mathbf{B}\mathbf{u}(t) + \mathbf{L}(\mathbf{y}(t) - \hat{\mathbf{y}}(t)) \\ \hat{\mathbf{y}}(t) &= \mathbf{C}\hat{\mathbf{x}}(t)\end{aligned} \qquad \mathbf{2.33(29)}$$

The above expression clearly shows how the estimated system output is derived from the estimated state vector. The related block scheme, also called the *asymptotic state observer,* is shown in Figure 2.33c. The error in the state estimation can be expressed by

$$\tilde{\mathbf{x}}(t) = \hat{\mathbf{x}}(t) - \mathbf{x}(t), \qquad \mathbf{2.33(30)}$$

whose development is described by the following differential equation:

$$\dot{\tilde{\mathbf{x}}}(t) = (\mathbf{A} - \mathbf{L}\mathbf{C})\tilde{\mathbf{x}}(t) + \mathbf{L}\mathbf{y}(t) \qquad \mathbf{2.33(31)}$$

The error in the state estimation develops according to the characteristic polynomial

$$\beta(s) = \det(s\mathbf{I}_n - \mathbf{A} + \mathbf{L}\mathbf{C}) \qquad \mathbf{2.33(32)}$$

Various choices for the gain matrix **L** allow locating the poles of the above characteristic polynomial.

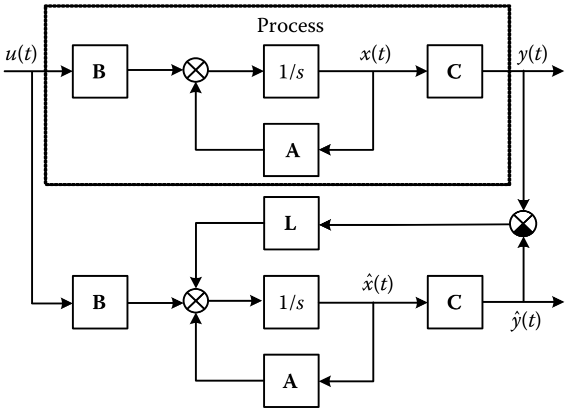

FIG. 2.33c
Block scheme of the full order observer.

Assume working with single output systems. To design the way as the error in the state estimation decays, the poles of the characteristic Equation 2.33(32) should be located to predefined $-s_1, -s_2, \ldots -s_n$ values. To determine the entries of the vector **L**, polynomial equation

$$\det(s\mathbf{I}_n - \mathbf{A} + \mathbf{L}\mathbf{C}) = (s + s_1)(s + s_2)\ldots(s + s_n) \qquad \mathbf{2.33(33)}$$

should be solved. Again, this can be done by matching the coefficients of the left-side and right-side polynomials in a very similar way as the feedback gain vector was determined by Equation 2.33(17) earlier. Introducing the polynomial

$$\beta(s) = (s + s_1)(s + s_2)\ldots(s + s_n) = s^n + \beta_{n-1}s^{n-1} + \cdots + \beta_0 \qquad \mathbf{2.33(34)}$$

and the matrix polynomial

$$\beta(\mathbf{A}) = \mathbf{A}^n + \beta_{n-1}\mathbf{A}^{n-1} + \cdots + \beta_0\mathbf{I} \qquad \mathbf{2.33(35)}$$

the related Ackermann formula takes the following form:

$$\mathbf{L} = \beta(\mathbf{A})\mathbf{M}^{-1}[0 \quad 0 \quad \ldots \quad 1]^T \qquad \mathbf{2.33(36)}$$

where **M** still denotes the observability matrix. Equation 2.33(36) shows that the observer feedback gain vector **L** exists if and only if **M** is invertible. In other words, to be able to apply the Ackermann formula and to have a unique solution for the observer gain vector **L**, the system should be observable.

The structure of the observer shown in Figure 2.33c can be transferred to an equivalent form shown in Figure 2.33d. According to this structure, the observer itself can be interpreted as a servo controller with a reference signal represented by the system output and a controlled signal represented by the estimated output signal. Further on the system parameters are stored in **A**, **B**, and **C**, while the system state variables are the estimated states.

Comparing Figures 2.33a and 2.33d, it is seen that the structure of the state variable control and that of the full order

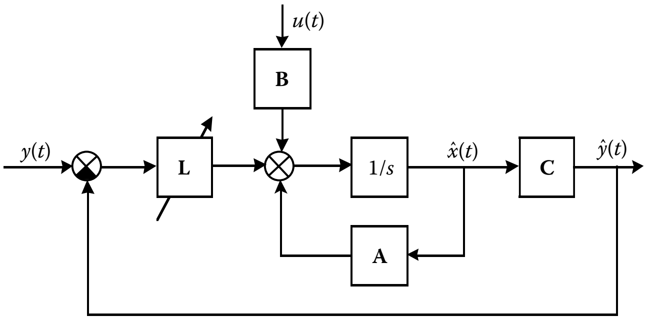

FIG. 2.33d
Full order observer as a servo problem.

observer resemble each other to a large extent. The output signal, as well as the **L** and **C** matrices, play an identical role in the observer as the control signal, as well as the **B** and **K** matrices do in the state variable control. Parameters in matrix **L** and parameters in matrix **K** are to be freely adjusted for the observer and for the state variable control, respectively. In a sense, calculating the controller and observer feedback gain matrices represents dual problems. In this case, duality means that any one of the structures shown in Figures 2.33a and 2.33d can be turned to its dual form by reversing the direction of the signal propagation, interchanging the input and output signals ($u \leftrightarrow y$), and transforming the summation points to signal nodes and vice versa.

The function realized by the observer can also be expressed in the form of a transfer function. Assuming zero initial state variable conditions, the solution of Equation 2.33(29) results in

$$\hat{y}(s) = \mathbf{C}(s\mathbf{I}_n - \mathbf{A} + \mathbf{LC})^{-1}(\mathbf{B}u(s) + \mathbf{L}y(s)) \qquad \mathbf{2.33(37)}$$

Elementary matrix operations used for Equation 2.33(32) lead to a polynomial separation:

$$\beta(s) = \det(s\mathbf{I}_n - \mathbf{A} + \mathbf{LC}) = A(s) + L(s) \qquad \mathbf{2.33(38)}$$

where

$$A(s) = \det(s\mathbf{I}_n - \mathbf{A}) \qquad \mathbf{2.33(39)}$$

and

$$L(s) = \mathbf{C}\mathrm{adj}(s\mathbf{I}_n - \mathbf{A})\mathbf{L} \qquad \mathbf{2.33(40)}$$

Using the observability form for the state model studied, coefficients of the $L(s)$ polynomial are identical to the entries of matrix **L**. Then using the above polynomials, Equation 2.33(37) turns to

$$\beta(s)\hat{y}(s) = (A(s) + L(s))\hat{y}(s) = B(s)u(s) + L(s)y(s) \qquad \mathbf{2.33(41)}$$

For MIMO systems the **L** matrix consists of $n \times p$ entries, where p denotes the number of the system outputs. However, the required location of the observer poles defines only n equations, thus the problem—just as when designing a MIMO state variable feedback control—is underdetermined.

Full Order Observer for Constant Error

It is a well-known fact from classical control theory that the application of proportional controllers ensures finite, nonzero control error when constant set points or constant disturbances are applied. Not surprisingly at all, if the output signal the observer intends to follow contains a constant, nondecaying, nonzero component (typically derived from constant disturbance acting on the input), the state estimation will be biased. The concept of duality suggests that this bias can be eliminated by adding an integrator to the observer circuit.

Consider a system together with an unknown constant additive noise (augmented system):

$$\begin{aligned} \dot{\mathbf{x}}(t) &= \mathbf{A}\mathbf{x}(t) + \mathbf{B}(u(t) + w(t)) \\ \dot{w}(t) &= 0 \\ y(t) &= \mathbf{C}\mathbf{x}(t) \end{aligned} \qquad \mathbf{2.33(42)}$$

Following the technique applied earlier, the state variables of the augmented system can be estimated along the following equations:

$$\begin{aligned} \dot{\hat{\mathbf{x}}}(t) &= \mathbf{A}\hat{\mathbf{x}}(t) + \mathbf{B}(u(t) + \hat{w}(t)) + \mathbf{L}(y(t) - \hat{y}(t)) \\ \dot{\hat{w}}(t) &= l_i(y(t) - \hat{y}(t)) \\ \hat{y}(t) &= \mathbf{C}\hat{x}(t) \end{aligned} \qquad \mathbf{2.33(43)}$$

The characteristic polynomial of the augmented system is

$$\bar{\beta}(s) = \det\begin{bmatrix} s\mathbf{I}_n - \mathbf{A} + \mathbf{LC} & -\mathbf{B} \\ l_i\mathbf{C} & s \end{bmatrix} \qquad \mathbf{2.33(44)}$$

The roots of the characteristic equation can be affected via the feedback elements in **L** and l_i. Using equivalent transformations for the above determinant, Equation 2.33(44) can be separated by

$$\bar{\beta}(s) = s(A(s) + L(s)) + B(s)l_i \qquad \mathbf{2.33(45)}$$

Then in the knowledge of $\bar{\beta}(s)$, $A(s)$, and $B(s)$, the coefficients in $L(s)$, and l_i itself, can be calculated.

Reduced Order Observer

If no significant disturbance is acting on the system output, there is no need to construct an observer providing an error in the estimated output signal converging to zero only asymptotically, rather than having an error in the estimated output signal being constantly zero. It is seen in Figure 2.33d that the feedback is utilizing the error in the estimated output signal and the state estimation is influenced by this error via the linear gain **L**. The error in the estimated output signal is forced to be constantly zero if the state estimation provides

$$\mathbf{y}(t) = \mathbf{C}\hat{\mathbf{x}}(t) \qquad \mathbf{2.33(46)}$$

If the output signals of the system are linearly independent from each other, they can be considered as state variables. Introduce the state vector such that all the output variables show up in the state vector. Then the state vector can be separated according to

$$\mathbf{z}(t) = \begin{bmatrix} \mathbf{y}(t) \\ \mathbf{z}_r(t) \end{bmatrix} \qquad \mathbf{2.33(47)}$$

where $\mathbf{z}_r(t)$ contains the state variables not measured directly. The transformation leading to the state vector by Equation 2.33(47) can be found by

$$\mathbf{z}(t) = \begin{bmatrix} \mathbf{y}(t) \\ \mathbf{z}_r(t) \end{bmatrix} = T\mathbf{x}(t) = \begin{bmatrix} \mathbf{C} \\ \mathbf{T} \end{bmatrix} \mathbf{x}(t) = \begin{bmatrix} \mathbf{y}(t) \\ \mathbf{Tx}(t) \end{bmatrix} \qquad \mathbf{2.33(48)}$$

The goal now is to find an estimation for the inaccessible $\mathbf{z}_r(t)$ component of the state vector as the state vector of the following linear state model:

$$\dot{\hat{\mathbf{z}}}_r(t) = \mathbf{Q}\hat{\mathbf{z}}_r(t) + \mathbf{Ru}(t) + \mathbf{Sy}(t) \qquad \mathbf{2.33(49)}$$

Find the matrices **Q**, **R**, and **S** in Equation 2.33(49) such that the estimation error

$$\tilde{\mathbf{z}}_r(t) = \hat{\mathbf{z}}_r(t) - \mathbf{z}_r(t) \qquad \mathbf{2.33(50)}$$

asymptotically converges to zero.

The state model using the new (transformed) state vector takes the following form:

$$\begin{aligned} \begin{bmatrix} \dot{\mathbf{y}}(t) \\ \dot{\mathbf{z}}_r(t) \end{bmatrix} &= \begin{bmatrix} \mathbf{C} \\ \mathbf{T} \end{bmatrix} \mathbf{A} \begin{bmatrix} \mathbf{H} & \mathbf{F} \end{bmatrix} \begin{bmatrix} \mathbf{y}(t) \\ \mathbf{z}_r(t) \end{bmatrix} + \begin{bmatrix} \mathbf{C} \\ \mathbf{T} \end{bmatrix} \mathbf{Bu}(t) \\ \mathbf{y}(t) &= \mathbf{C}\begin{bmatrix} \mathbf{H} & \mathbf{F} \end{bmatrix} \begin{bmatrix} \mathbf{y}(t) \\ \mathbf{z}_r(t) \end{bmatrix} \end{aligned} \qquad \mathbf{2.33(51)}$$

where the notation by

$$\begin{bmatrix} \mathbf{C} \\ \mathbf{T} \end{bmatrix}^{-1} = \begin{bmatrix} \mathbf{H} & \mathbf{F} \end{bmatrix} \qquad \mathbf{2.33(52)}$$

has been applied. Performing the above operations, Equation 2.33(51) becomes

$$\begin{aligned} \dot{\mathbf{z}}_r(t) &= \mathbf{TAFz}_r(t) + \mathbf{TAHy}(t) + \mathbf{TBu}(t) \\ \dot{\mathbf{y}}(t) &= \mathbf{CAFz}_r(t) + \mathbf{CAHy}(t) + \mathbf{CBu}(t) \\ \mathbf{y}(t) &= \mathbf{CFz}_r(t) + \mathbf{CHy}(t) = \mathbf{y}(t) \end{aligned} \qquad \mathbf{2.33(53)}$$

Then, using Equation 2.33(53), the following relation is derived

$$\begin{aligned} \dot{\hat{\mathbf{z}}}_r(t) &= \mathbf{TAF}\hat{\mathbf{z}}_r(t) + \mathbf{TAHy}(t) + \mathbf{TBu}(t) \\ \hat{\mathbf{x}}(t) &= \mathbf{F}\hat{\mathbf{z}}_r(t) + \mathbf{Hy}(t) \end{aligned} \qquad \mathbf{2.33(54)}$$

to estimate the state variables. The functional unit realizing the above state estimation algorithm is called reduced order observer; see Figure 2.33e for the block diagram. The error related to the estimation of the inaccessible state variables can be expressed by

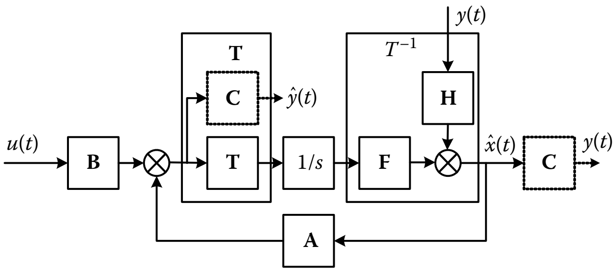

FIG. 2.33e
Block scheme of the reduced order observer.

$$\dot{\tilde{\mathbf{z}}}_r(t) = \mathbf{TAF}\dot{\tilde{\mathbf{z}}}_r(t), \qquad \mathbf{2.33(55)}$$

while the error related to the original state vector can be written as

$$\dot{\tilde{\mathbf{x}}}(t) = \mathbf{FTA}\tilde{\mathbf{x}}(t) = (\mathbf{I}_n - \mathbf{HC})\tilde{\mathbf{x}}(t) \qquad \mathbf{2.33(56)}$$

The initial condition of the original state vector can be calculated by $\tilde{\mathbf{x}}(t_0) = \mathbf{F}\tilde{\mathbf{z}}_r(t_0)$. Selecting appropriate values in **H**—keeping in mind that $\mathbf{CH} = \mathbf{I}_p$ holds—the error by Equation 2.33(56) can arbitrarily be reduced. Note that here *p* denotes the number of the system outputs.

Using the constraint by

$$\mathbf{HC} + \mathbf{FT} = \mathbf{I}_n \qquad \mathbf{2.33(57)}$$

(see Equation 2.33[52]), the reduced order observer shown in Figure 2.33e can equivalently be transformed to the form shown in Figure 2.33f. Note that the observer is using one single matrix (**H**) to reconstruct the state vector. Selecting the elements in matrix **H**, the constraint by $\mathbf{CH} = \mathbf{I}_p$ should be taken into account. The number of the state variables involved in the observer shown in Figure 2.33f is *not* minimal; however, it is operating as a reduced order observer.

Assuming one single output signal and a state model where this single output is one of the state variables, we have

$$\mathbf{C} = \begin{bmatrix} 1 & 0 & \dots & 0 \end{bmatrix}, \qquad \mathbf{2.33(58)}$$

as well as a matrix **H**

$$\mathbf{H} = [1 \quad h_1 \quad \dots \quad h_{n-1}]^T = [1 \quad \tilde{\mathbf{H}}^T]^T \qquad \mathbf{2.33(59)}$$

of special structure. Separating the states as before leads to

$$\mathbf{A} = \begin{bmatrix} \mathbf{A}_{11} & \mathbf{A}_{12} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{bmatrix} \quad \text{and} \quad \mathbf{B} = \begin{bmatrix} \mathbf{B}_1 \\ \mathbf{B}_2 \end{bmatrix} \qquad \mathbf{2.33(60)}$$

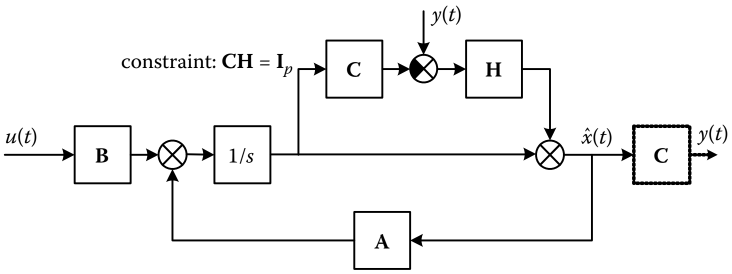

FIG. 2.33f
Reduced order observer with extra state variables.

and the form of the reduced order observer is

$$\dot{\hat{\mathbf{z}}}_r(t) = (\mathbf{A}_{22} - \tilde{\mathbf{H}}\mathbf{A}_{12})(\hat{\mathbf{z}}_r(t) + \tilde{\mathbf{H}}y(t)) + (\mathbf{A}_{21} - \tilde{\mathbf{H}}\mathbf{A}_{11})y(t) + (\mathbf{B}_2 - \tilde{\mathbf{H}}\mathbf{B}_1)\mathbf{u}(t)$$

$$\hat{\mathbf{x}}(t) = \begin{bmatrix} y(t) \\ \hat{\mathbf{z}}_r(t) + \tilde{\mathbf{H}}y(t) \end{bmatrix} \qquad \mathbf{2.33(61)}$$

Further on, the error in the state estimation is expressed by

$$\dot{\tilde{\mathbf{z}}}(t) = (\mathbf{A}_{22} - \tilde{\mathbf{H}}\mathbf{A}_{12})\tilde{\mathbf{z}}(t) \qquad \mathbf{2.33(62)}$$

Based on Equation 2.33(62), the disturbance rejection property of the closed-loop system equipped with the reduced order observer will be determined by the roots of the

$$\tilde{\beta}(s) = \det(s\mathbf{I}_{n-1} - \mathbf{A}_{22} + \tilde{\mathbf{H}}\mathbf{A}_{12}) \qquad \mathbf{2.33(63)}$$

characteristic equation. Note that the coefficients in $\tilde{\mathbf{H}}$ represent the freedom to locate the roots of the closed-loop characteristic equation. To be able to complete the design in that way, the subsystem belonging to the states in the reduced observer must be observable.

In case of constant disturbances, even reduced order observers need special treatment. Assume a constant additive disturbance signal acting on the input:

$$\dot{w} = 0 \qquad \mathbf{2.33(64)}$$

Augmenting the state equation by the above relation, the number of the state variables will be increased, and an additional integrator will be part of the observer. The augmented reduced order observer is capable of rejecting disturbances of unknown constant values.

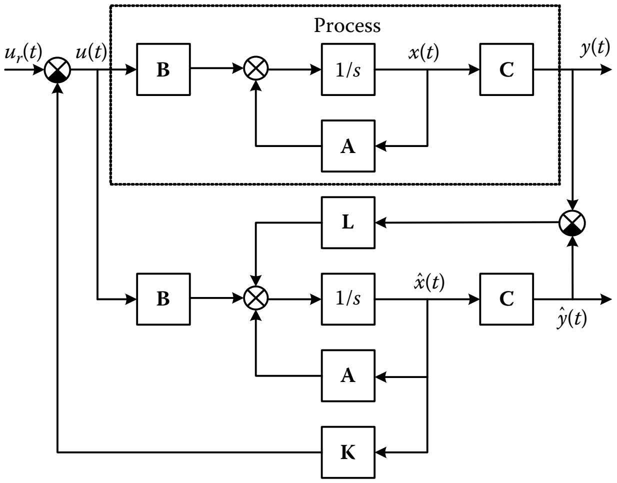

FIG. 2.33g
Block scheme of the combined observer-controller.

COMBINED OBSERVER–CONTROLLER

The state variable feedback and observer strategies discussed in the previous sections can be applied *simultaneously,* as well. The state variable feedback driven by the reconstructed states can be considered as a complete controller (see Figure 2.33g). State reconstruction is realized using the measured variables. In the above part of this chapter, two state variable feedback strategies (a proportional and an extended one by an integrator), as well as four state reconstruction strategies (full order and reduced order observers with or without handling constant input disturbance) were presented. Any pair combined by a selected state variable feedback strategy and a selected observer strategy is applicable.

Combined Observer-Controller Behavior

First consider a closed-loop system with state variable feedback using a full order observer to reconstruct the unmeasured state variables. Again, the system is described by

$$\begin{aligned}\dot{\mathbf{x}}(t) &= \mathbf{A}\mathbf{x}(t) + \mathbf{B}\mathbf{u}(t)\\ \mathbf{y}(t) &= \mathbf{C}\mathbf{x}(t)\end{aligned} \qquad \mathbf{2.33(65)}$$

while the full order observer is given by

$$\dot{\hat{\mathbf{x}}}(t) = \mathbf{A}\hat{\mathbf{x}}(t) + \mathbf{B}\mathbf{u}(t) + \mathbf{L}(\mathbf{y}(t) - \mathbf{C}\hat{\mathbf{x}}(t)) \qquad \mathbf{2.33(66)}$$

Applying the control strategy of

$$\mathbf{u}(t) = -\mathbf{K}\hat{\mathbf{x}}(t) + \mathbf{u}_r(t) \qquad \textbf{2.33(67)}$$

Equations 2.33(65) through 2.33(67) allow deriving the following state equation for the closed-loop system:

$$\begin{bmatrix} \dot{\mathbf{x}}(t) \\ \dot{\hat{\mathbf{x}}}(t) \end{bmatrix} = \begin{bmatrix} \mathbf{A} & -\mathbf{BK} \\ \mathbf{HC} & \mathbf{A}-\mathbf{BK}-\mathbf{HC} \end{bmatrix} \begin{bmatrix} \mathbf{x}(t) \\ \hat{\mathbf{x}}(t) \end{bmatrix} + \begin{bmatrix} \mathbf{B} \\ \mathbf{B} \end{bmatrix} \mathbf{u}_\mathbf{r}(t) \qquad \textbf{2.33(68)}$$

where the system state vector and the observer state vector together form the complete state vector of the closed-loop system.

Selecting the state estimation error $\breve{\mathbf{x}}(t) = \hat{\mathbf{x}}(t) - \mathbf{x}(t)$ to replace the estimated state vector in the complete state vector, the following form can be obtained:

$$\begin{bmatrix} \dot{\mathbf{x}}(t) \\ \dot{\breve{\mathbf{x}}}(t) \end{bmatrix} = \begin{bmatrix} \mathbf{A}-\mathbf{BK} & -\mathbf{BK} \\ \mathbf{0} & \mathbf{A}-\mathbf{HC} \end{bmatrix} \begin{bmatrix} \mathbf{x}(t) \\ \breve{\mathbf{x}}(t) \end{bmatrix} + \begin{bmatrix} \mathbf{B} \\ \mathbf{0} \end{bmatrix} \mathbf{u}_\mathbf{r}(t) \qquad \textbf{2.33(69)}$$

The above form allows the derivation of the characteristic polynomial of the closed-loop system in an easy way:

$$\det\left(\begin{bmatrix} s\mathbf{I}_n - \mathbf{A} + \mathbf{BK} & \mathbf{BK} \\ \mathbf{0} & s\mathbf{I}_n - \mathbf{A} + \mathbf{LC} \end{bmatrix}\right)$$
$$= \det(s\mathbf{I}_n - \mathbf{A} + \mathbf{BK})\det(s\mathbf{I}_n - \mathbf{A} + \mathbf{LC}) \qquad \textbf{2.33(70)}$$

Equation 2.33(70) shows that the roots of the closed-loop characteristic equation contain roots determined by the state variable feedback law and roots introduced by the observer. It is also seen that the state variable feedback and the observer can be designed independently from each other. In other words, the setting of the coefficients in the feedback gain vector does not depend on whether the feedback is using the state vector itself or its reconstructed value. In the literature, this property is referred to as the *separation property* or *separation theory.* As far as the concept of setting the dynamics of the state variable feedback and that of the observer, it is reasonable to design fast enough transient dynamics for the observer to force the error in the state vector reconstruction to converge quickly to zero. "Fast enough transient" means here that the observer dynamics are to be designed faster than the dynamics of the system being observed. Assigning too-short time constants for the observer may lead to unwanted closed-loop behavior; specifically, the state estimation may become extremely sensitive, especially in cases of noisy measurements.

Considering SISO systems, find the transfer functions between the reference signal and the control input, as well as between the system output and the control input, respectively. Based on Equations 2.33(66) and 2.33(67), the control input can be written by

$$u(s) = -\mathbf{K}(s\mathbf{I}_n - \mathbf{A} + \mathbf{LC} + \mathbf{BK})^{-1}\mathbf{L}(y(s) - y_r(s)) \qquad \textbf{2.33(71)}$$

For the sake of simplicity, assume zero initial conditions for the state vectors involved. Also, selecting a special reference signal, a closed-loop system exhibiting identical servo and disturbance rejection properties will be designed. Equation 2.33(71) can be expressed in the form of a rational transfer function:

$$u(s) = -\frac{F(s)}{G(s)}(y(s) - y_r(s)) \qquad \textbf{2.33(72)}$$

where the nth order denominator polynomial above can be expressed by

$$G(s) = \det(s\mathbf{I}_n - \mathbf{A} + \mathbf{LC} + \mathbf{BK}), \qquad \textbf{2.33(73)}$$

while the numerator polynomial $F(s)$ is given by

$$F(s) = \mathbf{K}\operatorname{adj}(s\mathbf{I}_n - \mathbf{A} + \mathbf{LC} + \mathbf{BK})\mathbf{L}. \qquad \textbf{2.33(74)}$$

Using the above polynomials the characteristic equation of the closed-loop system is

$$P(s) = G(s)A(s) + F(s)B(s) \qquad \textbf{2.33(75)}$$

In harmony with Equation 2.33(70), it is seen that the closed-loop characteristic equation can be derived by multiplying the characteristic equations represented by the state variable feedback and the observer, respectively:

$$P(s) = \alpha(s)\beta(s) = G(s)A(s) + F(s)B(s) \qquad \textbf{2.33(76)}$$

Studying the behavior of the closed-loop system, no distinction can be made between the poles of the state variable feedback and the observer. Theoretically, all the poles of the closed-loop system can be assigned for the design procedure. Given a system with $A(s)$ and $B(s)$ and a design goal specified by $P(s)$, the polynomials $F(s)$ and $G(s)$ are to be determined to complete the closed-loop control. Assuming that controllability and observability both hold, as well as $ord(P(s)) = 2n$, solving the Diophantine Equation 2.33(76), a unique solution is obtained for $F(s)$ and $G(s)$. The controller derived is strictly proper.

For stable systems the presented control structure can also be transformed into an IMC (internal model control) form (see Figure 2.33h). In this structure a parallel process model is applied, preceded by a serial compensator. The overall transfer function becomes

$$\frac{y(s)}{y_r(s)} = \frac{F(s)B(s)}{\alpha(s)\beta(s)} \qquad \textbf{2.33(77)}$$

Note that the number of state variables realizing the IMC structure is *3n,* while the characteristic equation of the system remains as $\alpha(s)\beta(s)$ after eliminating the common terms.

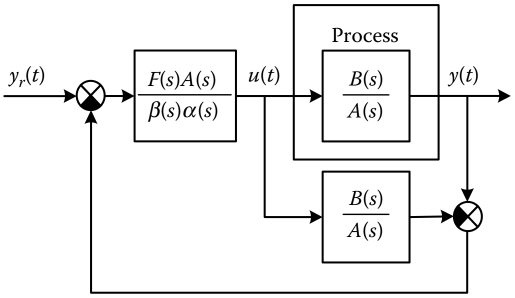

FIG. 2.33h
Observer-controller as internal model controller.

If the measured control input is available for realizing the control strategy, it is reasonable to derive another form of the controller utilizing the control signal. Assume that $\mathbf{u}(t)$ is the control input directly driving the process and $\mathbf{u}_0(t)$ is the control signal released by the controller (see Figure 2.33i). The actual feedback and observer relations can be written as

$$\begin{aligned}\dot{\hat{\mathbf{x}}}(t) &= (\mathbf{A}-\mathbf{LC})\hat{\mathbf{x}}(t)+\mathbf{Bu}(t)+\mathbf{L}(\mathbf{y}(t)-\mathbf{y}_r(t))\\ \mathbf{u}_0(t) &= -\mathbf{K}\hat{\mathbf{x}}(t)\end{aligned} \qquad \textbf{2.33(78)}$$

or for SISO systems in the form of transfer functions:

$$u_0(s) = -\mathbf{K}(s\mathbf{I}_n - \mathbf{A}+\mathbf{LC})^{-1}(\mathbf{B}u(s)+\mathbf{L}(y(s)-y_r(s))) \qquad \textbf{2.33(79)}$$

With some straightforward manipulations:

$$\beta(s)u_0(s) = -F(s)(y(s)-y_r(s))-(G(s)-\beta(s))u(s). \qquad \textbf{2.33(80)}$$

In the above expression

$$\frac{F(s)}{\beta(s)}$$

and

$$\frac{G(s)-\beta(s)}{\beta(s)}$$

are strictly proper transfer functions. The transfer function form of the combined observer–controller is shown in Figure 2.33i.

The presented versions require various amounts of computing power but result in identical control actions for a stable, linear, disturbance-free process. At the same time, for practical applications with slightly nonlinear behavior or input saturation, the exact calculations may lead to different closed-loop behavior.

Note that the polynomial approach shown above can accomplish even more complex control strategies. The state variable feedback technique followed so far required the polynomial $P(s)$ to be separable according to $P(s) = \alpha(s)\beta(s)$. A possible generalization may assume $P(s)$ to be freely selectable. The control problem then is set up as follows: given $A(s)$, $B(s)$, $P(s)$, and $\beta(s)$ find the polynomials $F(s)$ and $G(s)$ such that

$$\frac{F(s)}{\beta(s)}$$

and

$$\frac{G(s)-\beta(s)}{\beta(s)}$$

are both strictly proper. The control strategy derived in that way is more general than the state variable feedback control supported by an observer.

Due to the limited available space, not all the eight versions (two feedback solutions and four observers) will be discussed here. In general, each additional integrator or constant input disturbance estimation will increase the order of the controller by one. Applying a reduced order observer will reduce the order of the controller. The resulting $F(s)/\beta(s)$ and $F(s)/G(s)$ blocks will be just proper, not strictly proper transfer functions.

Transfer-Function Interpretation

A general controller is driven by the reference signal, the output signal, and the control signal. Assuming that the controller is linear and the number of the states used by the

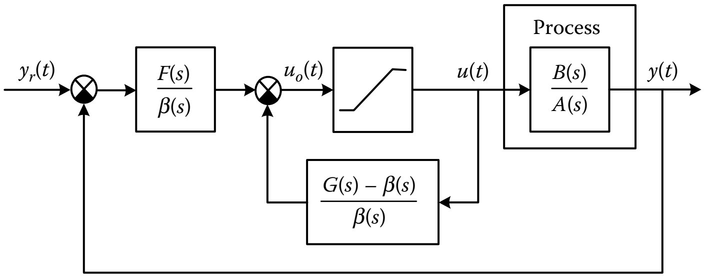

FIG. 2.33i
Transfer function form of the combined observer-controller.

TABLE 2.33j
Orders of the Transfer-Function Polynomials Equivalent to the Combined Observer–Controller

Feedback	*Observer*	*ord* $\alpha(s)$	*ord* $\beta(s)$	*No. States*	*No. Integr.*	*ord* $G(s)$	*ord* $F(s)$
P	O	n	n	n	0	n	$n-1$
PI	O	$n+1$	n	$n+1$	1	n	n
P	EO	n	$n+1$	$n+1$	1	n	n
PI	EO	$n+1$	$n+1$	$n+2$	2	n	$n+1$
P	R	n	$n-1$	$n-1$	0	$n-1$	$n-1$
PI	R	$n+1$	$n-1$	n	1	$n-1$	n
P	ER	n	n	n	1	$n-1$	n
PI	ER	$n+1$	n	$n+1$	2	$n-1$	$n+1$

controller is q, the most complicated possible controller can be described by

$$p_f(s)u(s) = p_{\mathrm{yr}}(s)y_r(s) - p_y(s)y(s) - p_u(s)u(s) \qquad \mathbf{2.33(81)}$$

The above controller is realizable if and only if ord($p_f(s)$) ≥ ord($p_{\mathrm{yr}}(s)$), ord($p_f(s)$) ≥ ord($p_y(s)$) and ord($p_f(s)$) > ord($p_u(s)$) are held for the polynomials involved. Designing identical servo and disturbance rejection properties we have $p_{yr}(s) = p_y(s)$. Then the control law by Equation 2.33(81) simplifies to

$$p_f(s)u(s) = p_y(s)(y_r(s) - y(s)) - p_u(s)u(s) \qquad \mathbf{2.33(82)}$$

resulting in

$$u(s) = \frac{p_y(s)}{p_f(s) + p_u(s)}(y_r(s) - y(s)) \qquad \mathbf{2.33(83)}$$

On the other hand, the general form of the controller design using the state variable feedback technique is based on the following form (i is the number of pure integrators in the controller to be designed):

$$P(s) = \alpha(s)\beta(s) = G(s)A(s)s^i + F(s)B(s) \qquad \mathbf{2.33(84)}$$

Solution of the above Diophantine equation results in the controller polynomials. The control law itself turns out to be

$$u(s) = \frac{F(s)}{s^i G(s)}(y_r(s) - y(s)). \qquad \mathbf{2.33(85)}$$

Comparing Equations 2.33(83) and 2.33(85), it is seen that the state variable feedback control is equivalent to a polynomial-based controller with $p_y(s) = F(s)$ and $p_f(s) + p_u(s) = s^i G(s)$.

If the control input is available and used for the control law calculations, the integrators included in the controller should be separated. In the case of state variable feedback control, the control input can be calculated by

$$\beta(s)u(s) = \frac{F(s)}{s^i}(y_r(s) - y(s)) - (G(s)s^c - \beta(s))u(s) \qquad \mathbf{2.33(86)}$$

In other words, the control input calculations are always filtered according to the characteristic polynomial of the observer.

Table 2.33j summarizes the state variable feedback and observer methods discussed in this section. It contains the order of the polynomials in the Diophantine equations and the number of the state variables involved for various control strategies. The following notations are used:

P	State variable feedback (proportional feedback from the state variables)
PI	State variable feedback plus extra integral feedback from the output
O	Basic full order asymptotic observer
EO	Extended asymptotic observer (observer with constant disturbance)
R	Reduced order observer
ER	Extended reduced order observer (reduced order observer with constant disturbance)
No. states	Number of the state variables in the controller
No. integr.	Number of the integrators in the controller

The table shows that the state variable feedback extended by an integrator and the proportional state variable feedback with an observer extended by constant disturbance estimation result in identical control actions. Although these control configurations are associated with identical $F(s)$ and $G(s)$ polynomials, under practical conditions (e.g., control signal saturation, handling slight nonlinearities) they will exhibit different closed-loop behavior because the detailed realizations of the algorithms are different.

CONCLUSIONS

This section overviewed the state variable feedback control of continuous-time linear dynamic processes. Using static gain coefficients for the state variables, the location of the closed-loop poles can be assigned in an arbitrary way. In order to improve both the servo and disturbance rejection properties of the closed-loop system, it is reasonable to extend this basic feedback structure by a term integrating the output signal.

State variables that are not directly accessible but are needed to obtain the feedback signal can be replaced by their estimates. The state estimate can be obtained by full order or reduced order observers.

It has been shown how the state variable control together with an observer can be interpreted in the form of transfer functions. Though only continuous-time problems have been discussed, all the control methods and control algorithms that were discussed can also be transformed to handle discrete-time systems.

Instead of describing the design criterion by the desired location of the roots of the closed-loop characteristic equation, the feedback gain matrix can be found as a result of optimizing a loss function (LQ problem). In that case the feedback gain matrix will be calculated as the solution of a Riccati equation.

The estimated states can be found not only by assigning the poles of the observer characteristic polynomial, but also by a well-elaborated solution based on stochastic considerations and assumptions related to the disturbances (Kalman filter technique). The two approaches are based on different assumptions; however, they lead to identical control actions for SISO systems.

INTRODUCTION

The goal of statistical process control (SPC) is to detect whether a process has undergone statistical abnormality — that is, a shift from its normal statistical behavior. The use of statistical techniques to detect variations in product quality and consistency dates back to Walter Shewhart's work at Bell Laboratories in the early 1900s. His work resulted in the development of statistical quality charts (Shewhart charts). These charts are still used for analyzing patterns in product variability. In the 1940s and 1950s, W. Edwards Deming's work in statistical quality control (SQC) methodology evolved into a 14-point management program for quality improvement. His approach emphasized the application of statistical principles to control the production process.

As with most other applications of statistics, different statistical methods operate under certain assumptions. These methods are subject to significant abuse and misuse when the assumptions are not understood and the methods are applied to data sets that they should not be used on. Most of these assumptions have to do with the nature of the data set (homogeneous, randomness, distribution shape, data collection techniques, etc.). A number of different charting techniques are available. This allows the user to select the one(s) that are most appropriate for their data set. Before going into the specifics, some general comments are appropriate.

SPC and Process Control

Just as a proportional-integral-derivative (PID) controller needs to be tuned to properly control individual loops, so an SPC process can be thought of as a means of tuning the overall process. SPC might not be considered by process control engineers as part of process control. It is a powerful statistical tool to help verify whether a process is performing properly and to help troubleshoot the process if a correction or improvement is desired.

We usually think of control in terms of a direct correction applied to the process in response to a change in the control variable. This is the case with both the open-loop control configuration (where a human manually initiates the correction) and the closed-loop (where an automatic controller initiates it).

One might think of SPC as an extreme form of open-loop control. SPC uses statistical process monitoring techniques to determine the status of the process, a combination of statistical and troubleshooting techniques to identify the cause(s) of upsets and the process area(s) requiring improvement/adjustment, and verification techniques to ensure that the adjustment(s) have resulted in the desired change.

Because of the open-loop decision-making nature of SPC, many believe that SPC charting should be done manually. This view is based at least partially on the assumption that a human observer will pay closer attention during periods of upsets and therefore will be better prepared for the troubleshooting and problem-solving phases of the process. Those sharing this view prefer to keep the observer actively involved in the SPC process.

In the name of productivity and to make better use of our powerful computing tools, many organizations have implemented forms of automated SPC charting and monitoring. When automated, the SPC calculations and charting are usually implemented in a Plant Information Data Base and may be displayed either in that system and/or a process control computer. Most of those who have automated the first phase are still performing the nonmonitoring portions of the SPC process manually. A few of the more aggressive automation types are attempting to implement diagnostic and process adjustment activities with artificial intelligence or other computer models.

Continuous Processes

It needs to be emphasized that all statistical techniques are not valid for all data sets. SPC tools that were developed for discrete manufacturing need to be adapted and/or interpreted differently when applied to a continuous process environment. Many statistical techniques involve assumptions that are not valid on all data sets. These may include issues such as the randomness of the data, the shape of the distribution, and data collection technique issues. It should also be noted that choosing an appropriate chart(s) for the data set and/or problem can greatly simplify the SPC process. Different charting techniques can offer a different view of the same data set.

SPC techniques are the heart and soul of today's Six Sigma quality programs. Six Sigma is a very popular and powerful process improvement tool, which is implemented by a team. The team is usually led by operations people and includes process control engineers and operations, quality, or middle-management personnel. It is normally targeted at measuring the Process Capability of both manufacturing and nonmanufacturing processes and then focuses on improving those processes.

What Is Statistical Control?

All processes exhibit variation. There is no cause for adjusting the total process unless the variation exceeds statistically acceptable limits. If the process is within acceptable statistical limits, changes would only introduce instability. Just as a PID controller needs to be tuned to properly control a loop, so the SPC process can be thought of as a procedure to help determine the tuning parameters for the total process. In other words with SPC, the control is usually on a process scale and not for individual loops.

What does it mean for a process to be in statistical control? A process is considered in control if it is experiencing only normal upsets and variation that have often occurred in the past. A process is out of statistical control when the change is sustained and it brings the controlled variable outside the limits of its normal range of variation. In that case one should try to identify the cause of the change in order to decide how to respond to it.

Understanding the types of variation allows one to predict the performance of a stable process. If an "in-control" process is making large quantities of out-of-specification product, the control limits need to be changed. Process control limits are not design specifications but are values that describe past performance of the process. Therefore, in order to change the SPC limits, one needs to change the process.

SPC TOOLS AND TECHNIQUES

SPC problem-solving techniques include:

- Analysis of processes for stability and the effects of process modifications (control charts and capability indices)
- Defining problems and setting priorities (Pareto charts)
- Identifying causes for good and bad performance (cause and effect diagrams—fishbone charts/diagrams)
- Quantifying relationships between process or product variables and other variables (scatter plots or other correlation tools)

Control Charts

The most widely used SPC tools are control charts. On these charts, the measurements of product samples are plotted to show their centering (XBar chart) and dispersion values (R chart). The centering value is the average of the samples. The dispersion value is the frequency distribution from that average. These charts are used to distinguish random, uncontrollable variations in measured parameters from variations that are controllable and should be corrected. To control product quality, the aim is to keep the product variation within the random pattern.

Figure 2.34a shows a centering and a dispersion chart. Both charts have similar components: centerline, upper limit, lower limit, and sample size. The centerline, also called the average, is shown with a solid line. The average of all the samples should be at this value. The upper and lower limits are shown by dotted lines. If the average is achieved, the averages of n samples should be less than the upper limit and greater than the lower limit. Variations within the limits are

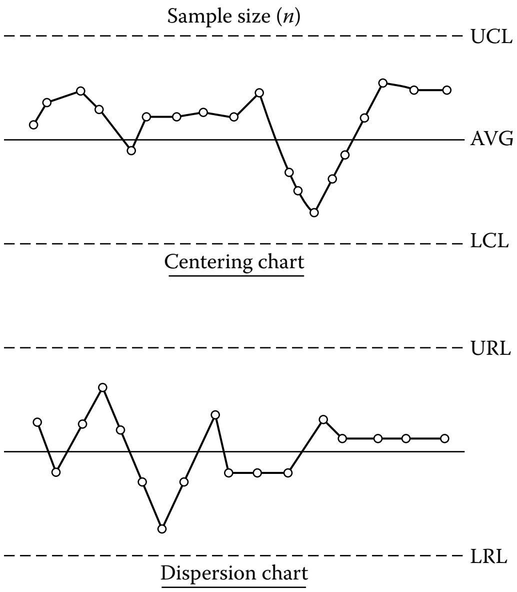

FIG. 2.34a
Shewhart chart for a subgroup sampling method. The centering (XBar) chart helps determine whether the centering of the process is stable. The Dispersion (R) chart helps determine whether the spread of the process is stable.

considered to be normal. Variations outside the limits are considered to be abnormal.

Charts and Tables

Tables 2.34b, 2.34c, and 2.34d show various control strategies for both the single point sampling method and for the subgroup sampling method. Also described are points to be stored for various types of centering charts. Tables 2.34e, 2.34f, and 2.34g give the equations for single point centering chart limits and

TABLE 2.34b
Control Chart Types for a Single Point Sampling Method

Chart Family	*Chart Type*	*Description*
Centering Chart	Individual	Uses individual point values to provide a trend.
	Geometric Mean	Uses the geometric mean to provide exponential smoothing.
	Moving Average	Uses the moving average to remove noise and indicate an overall trend.
Dispersion Chart	Range (R chart)	Commonly called an R chart. Plots the range which is the difference between the highest and lowest sample in the range. The number of samples for calculating the range is configured by the user.

TABLE 2.34d
Control Chart Types for a Subgroup Sampling Method

Chart Family	*Chart Type*	*Description*
Centering Chart	Average (XBar)	Commonly called an XBar chart. Plots the average of data in the specified range. All subgroup samples are saved until the specified size is met. The average is then calculated, and the value written to disk.
	Median	Plots the median value in the same manner as the average chart plots the average value.
Dispersion Chart	Range (R chart)	Commonly called an R chart. Plots the range which is the difference between the highest and lowest sample in the subgroup. Samples are collected until the subgroup is complete, then sorted in order of size. The average or median is determined for the centering chart, and then the range is calculated.
	Range with Sigma	Plots the R values in the same manner as in the range chart, but the limits are calculated using a derivation value (sigma) that was entered during configuration.
	Root Mean Squared	Used for subgroups of 12 to 25 points. Uses the root mean square (RMS) to calculate the limits and centerline.
	Root Mean Squared with Sigma	Plots points in the same manner as the RMS chart, but the limits and the centerline are calculated using a deviation value (sigma) that was entered during configuration.
	Standard Deviation	Plots the standard deviation of the subgroup points.

single point dispersion chart values. Tables 2.34h, 2.34i, 2.34j, and 2.34k give the equations for subgroup centering chart values and chart limits.

Interpretation of Charts

The XBar chart (Table 2.34d) or Shewhart chart is used in combination with rule-based checks. It can detect whether a process output has undergone statistical abnormality—that is, a shift from its normal statistical behavior. On noisy processes, a simple time trend does not make this kind of deviation visually obvious, but simple rule checks can.

Centering charts generated from single point measurements (Table 2.34b) indicate that a process is not in statistical control if any one of the following is true:

1. One or more points fall outside the control limits.
2. Seven or more consecutive points fall on the same side of the centerline.
3. Ten of 11 consecutive points fall on the same side of the centerline.
4. Three or more consecutive points fall on the same side of the centerline and all are located closer to the control limit than to the centerline.

Centering charts generated from the subgroup sampling method indicate abnormal fluctuations when:

1. Any single subgroup value is more than three standard deviations away from the centerline (or set point).
2. Two consecutive subgroup values are more than two standard deviations away from the centerline, on the same side of the centerline.
3. Three consecutive subgroup values are more than one standard deviation away from the centerline, on the same side of the centerline.

4. Two out of three consecutive subgroup values are more than two standard deviations away from the centerline, with all three values on the same side of the centerline.
5. Five consecutive subgroup values are on the same side of the centerline.

Another process violation detection chart, called the moving range chart, differs from an Xbar chart in that each datum is an actual scanned data point rather than a subgroup average of several samples.

The Purpose of the Charts

When utilizing SPC charts one needs to remember their purpose and choose them accordingly. The purpose of a good chart is to give information about the data that is not self-evident.

Graphs can help make recognition of data patterns and features much easier than most tables or lists. Shewhart's first principle for understanding data is that no data have meaning apart from their context. Shewart also provided two rules for the presentation of data:

1. Data should always be presented in a way that preserves the evidence in the data for all the predictions that might be made from them.
2. Whenever average, range, or histogram charts are used to summarize data, the summary should not mislead the user into taking any action that the user would not take if the data were presented in a time series.

With all of the charting techniques that are available, one needs to be careful of which to use and when. These are powerful techniques that can be helpful but if misapplied can be misleading.

Figures 2.34l and 2.34m depict histograms of a relatively large (500-data point) data set that is in statistical control. Histograms tend to obscure (at a minimum) the sequential information in the data.

Using Charts

Utilizing an average verses an X-plane histogram could lead one to differing conclusions regarding a process/data set.

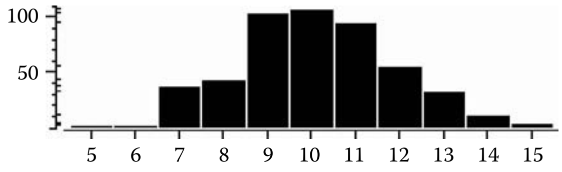

FIG. 2.34l
Histogram of 500 observations in the "X-Plane." (Courtesy of SPC Press Inc.)

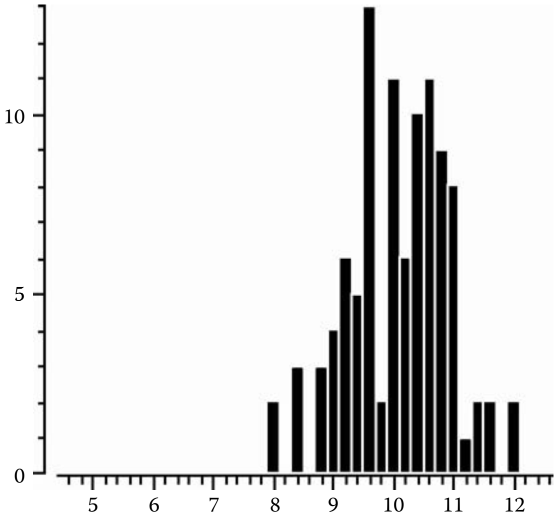

FIG. 2.34m
Histogram of the data provided in Figure 2.34l. Data set in the "Average Plane." (Courtesy of SPC Press Inc.)

Averaged charts tend to hide the frequency and magnitude of outliers. If only a simple glance is made at these charts (which represent the same process, which is in control), it could lead one to think that the first depicted a process in tighter control (it appears to have a very smooth normal distribution shape) and the second appears to be only generally normal in shape.

A quick glance could also lead one to think that the first indicated a process with a wider control limit (data range from 7 to 15) than the second (data range of 8 to 12). Also, the smooth-appearing normal distribution of the first as compared to the more jagged-appearing normal distribution of the second could mislead one to assume that the first represents a process that is in better control.

This comparison of two very similar charts of the same data is meant to encourage the review of data in many different forms, using many types of charts. This can help one to see different features in the data and better understand one's process. Patterns within the data may contribute more to understanding the process than a macro statistical overview of the data would. This is especially true for distributions that exhibit highly nonnormal tendencies (single tails, bimodal, etc.).

PROCESS CAPABILITY

An unstable, out-of-statistical-control process cannot be evaluated for its capability. Process Capability is the heart of the famed Six Sigma program. The Six Sigma program is intended to answer the following question: "Is the process capable of producing a product within the specifications to the statistical Six Sigma (Standard Deviations)?" If it is not, the Six Sigma program is to assist the user to identify the weak points that are keeping it from achieving this level of performance.

Upon achieving a state of statistical control, a process can be evaluated to determine whether it is capable of meeting the desired specification(s) or requirement(s). Usually a minimum of 20 to 25 subgroups is desirable to get a representative picture of the process. In order to characterize the capability of the process, its natural deviation is compared to the width of the specifications. This includes the evaluation of both the upper specification limit (USL) and the lower specification limit (LSL) independently to account for the location of the average process reading relative to the specifications. If there is only one limiting specification (LSL or USL), then the capability only needs to be calculated on that side.

The standard deviation ($\hat{\sigma}$) is used to evaluate the common level of process variation and is calculated by

$$\hat{\sigma} = \frac{\bar{R}}{d_2} \qquad 2.34(1)$$

where $\hat{\sigma}$ indicates that the value is an estimate, d_2 is a scaling factor, which is based on n samples in the subgroup, and $\bar{R}$ is the average range. The values of d_2 for 5, 10, 15, 20, and 25 samples (n) are, respectively, 2.326, 3.078, 3.472, 3.735, and 3.931.

A common technique for reporting process capability is the use of a ratio called the C_p index. The C_p index is the ratio that is obtained by dividing the distance to specification by the distance to the common cause variation. The C_p index is calculated as follows:

$$C_p \text{ for the upper side: } C_{pu} = \frac{\text{USL} - \bar{X}}{3\hat{\sigma}} \qquad 2.34(2)$$

where $\bar{X}$ is the subgroup average.

$$C_p \text{ for the lower side: } C_{pl} = \frac{\bar{X} - \text{LSL}}{3\hat{\sigma}} \qquad 2.34(3)$$

The minimum of these two values will be the worst of the two cases and is reported as the C_p or C_{pk} index.

A C_p value over 1.33 would indicate a capable (acceptable, saying that 99.73% of individual readings are within specification) process, while a C_p index of less than 1.0 would indicate a "noncapable" process. A C_p index between 1.0 and 1.33 would indicate a marginal process. C_{pu} values for four different process states are shown in Figure 2.34n. For the latter cases, the next step is to improve the process.

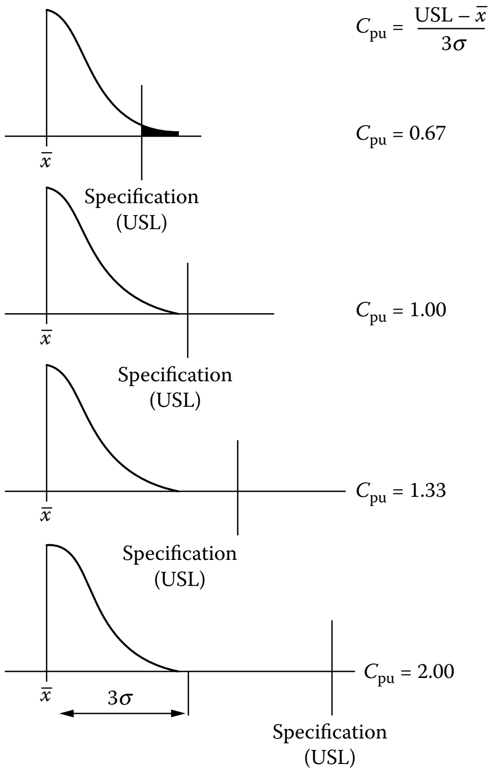

FIG. 2.34n
C_{pu} values for four different process states: C_{pu} less than 1.0, a noncapable process; C_{pu} between 1.0 and 1.33, a marginal process; C_{pu} equal to 1.33 or greater, a capable process.

There are three general ways to increase the values of the C_p index:

1. Move the specifications or set points (if they have not been properly established).
2. Move the process average, if the specification has only one limit (unilateral), or center the process average if the process has two limits (bilateral).
3. Reduce the common cause variation.

Identifying Causes

The goal of all SPC techniques is to first determine that the process behavior is not normal and next to identify/diagnose the cause(s) of unusual (good or bad but not normal) performance. One of the cause-and-effect tools used in SPC is the Ishikawa cause-and-effect diagram (also called the fishbone diagram).

Figure 2.34o depicts an Ishikawa fishbone diagram. This diagram is actually a thought process flow diagram (sort of a cause-and-effect checklist/map), which helps the user to systematically determine the root causes of problems. It begins with the major potential causes and assists/guides the user to work backwards through the listed causes to determine a root cause.

The user must first identify all the potential causes that can affect the process/product problem being studied. This diagnostics process can be lengthy and involve the use of designed experiments and many other techniques to study the process. The goal of this diagnostics process is to obtain a process that is in control. If the abnormal performance was bad, the goal is to eliminate its cause. If the abnormal performance was favorable, the goal is to incorporate it into the new normal process (process improvement).

Implementing SPC Concepts

The implementation of real-time SPC increases the demands on instrumentation, communication networks, and computer technology. Developments in microchip technology offer improved accuracy and stability for primary sensors. The use of digital transmitters eliminates the error contribution of

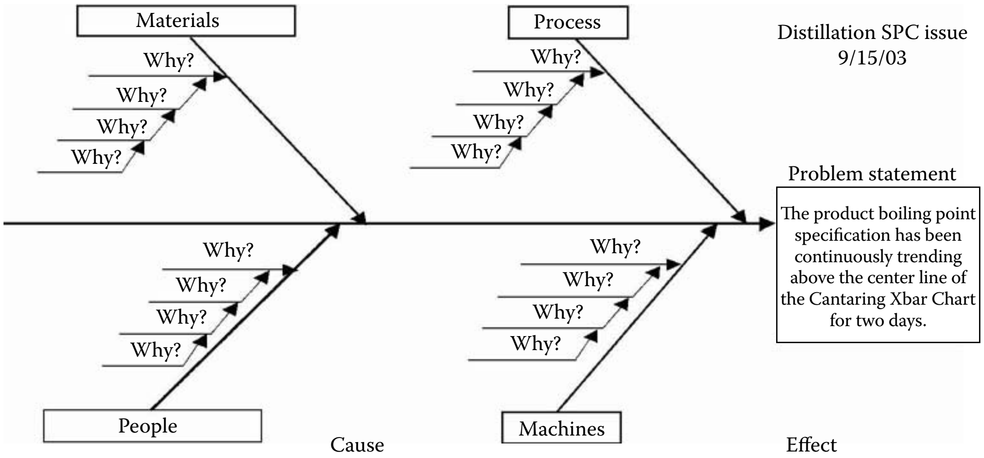

Fig. 2.34o
A fishbone diagram is a powerful diagnostic tool to help identify and define problems. (Created with QI Macros for Excel SPC Software.)

analog-to-digital conversion. Microprocessor-based “smart” transmitters contribute to better accuracy and higher reliability by their improved rangeability. Automatic pressure and temperature compensation, remote calibration, and self-diagnostics also contribute to better data quality.

The range of process variables that can be measured has also increased. Advances in online analytical instrumentation have made it possible to measure a variety of physical properties and chemical compositions that could not be directly detected in the past. (For more information, refer to Volume 1 of this handbook, titled *Process Measurement and Analysis*.)

Good quality data input (measurement) is useful for online SPC only if the control system network can transfer the process information rapidly enough for real-time data manipulation. The use of MAP (Manufacturing Automation Protocol) for integration of different vendors’ products into a common communications network facilitates streamlined data transmission. The MAP OSI (Open System Interconnection) model defines communication network functions in seven layers, allowing software programs to be utilized over different networks.

Although most of these techniques predate the computer, the ability to interface a personal computer with the control system also increases the feasibility of adding real-time SPC to existing plants. Intelligence at the I/O interface level enables routine operating functions to be handled locally, while conserving higher-level processing capability for SPC-type applications.

It is not necessary to implement any or all phases of an SPC program in a real-time mode. One only needs to automate those portions of an SPC program that one feels comfortable with, and the nonautomated SPC techniques can still be performed on a non-real-time basis. Many of those who have automated the data collection and monitoring phases are still performing the nonmonitoring portions of the SPC process manually. Others are implementing diagnostic and process adjustment activities with artificial intelligence or other computer models.

DATA STORAGE, COMPUTATION, AND DISPLAY

The ability to store statistical records of individual process data points is essential for generating and analyzing SPC control charts. Historical information is particularly useful for statistical analysis of cause-and-effect relationships using fishbone diagrams. Figure 2.34p shows the Pareto chart that enables diagnosis of the most likely causes of off-spec production runs at the component level by searching the historical database.

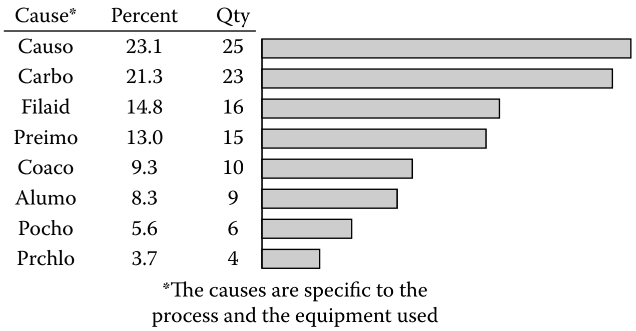

FIG. 2.34p
A historical data search, presented in the form of a Pareto chart, can help identify the most likely causes of off-spec production runs.

The desirability of performing identical mathematical studies as well as providing real-time data points warrants a dedicated SPC computer for many chemical process industry applications. Figure 2.34q is a scatter plot showing the use of a linear regression algorithm to explore the relationship between a selected product property (particle size) and an input variable (mixing time). Knowing this relationship, the operator can adjust the problem variable (mixing time) to restore the product (particle size) to meet specifications.

Statistical calculations translate into practical control results through the interpretation of statistical control charts. Configurable CRT displays are prerequisites to maximizing the use of online SPC charting capabilities. Automatic SPC alarm notifications and summary displays can isolate the problem input variables.

A computerized technique called online diagnostics is used to determine and anticipate the causes of plant operating problems before they actually occur. This diagnostic technique is basically a mix of SPC and fault-diagnostic principles that are programmed into an expert system that operates online. Thereby, process operators can anticipate and react to potential problems before they occur.

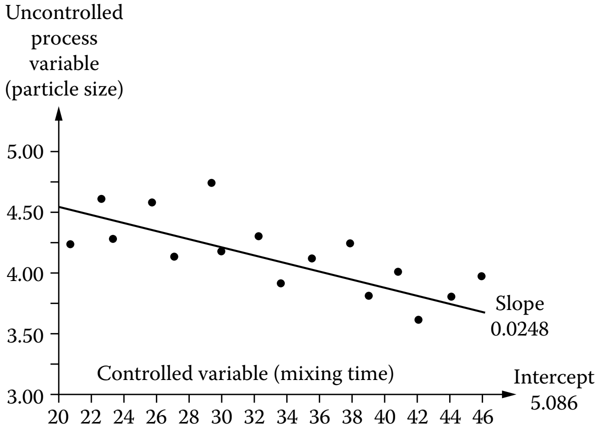

FIG 2.34q
Scatter plots can be used to investigate relationships between process variables and can indicate how much a controlled variable (mixing time) should be adjusted to bring an uncontrolled variable (particle size) within specifications.

2.35 Tuning PID Controllers

P. W. MURRILL (1970) **P. D. SCHNELLE, JR.** (1985) **B. G. LIPTÁK** (1995)
J. GERRY, M. RUEL, F. G. SHINSKEY (2005)

In order for the reader to fully understand the content and concepts of this section, it is advisable to first become familiar with some basic topics. These include gains, time lags and reaction curves (Section 2.22), the PID control modes (Section 2.3), feedback and feedforward control (Section 2.9), and relative gain calculations (Section 2.25).

Controllers are designed to eliminate the need for continuous operator attention when controlling a process. In the automatic mode, the goal is to keep the controlled variable (or process variable) on set point. The controller tuning parameters determine how well the controller achieves this goal when in automatic mode.

DISTURBANCES

The purpose of a controller is to keep the controlled variable as close as possible to its set point at all times. How well it achieves this objective depends on the responsiveness of the process, its control modes and their tuning, and the size of the disturbances and their frequency distribution.

Sources

Disturbances arise from three different sources: set point, load, and noise. Noise is defined as a random disturbance whose frequency distribution exceeds the bandwidth of the control loop. As such, the controller has no impact on it, other than possibly amplifying it and passing it on to the final actuator, which can cause excessive wear and ultimate failure.

Set point and load changes affect the behavior of the control loop quite differently, owing to the dynamics in their path. A controller tuned to follow set point changes tends to respond sluggishly to load variations, and conversely a controller tuned to correct disturbances tends to overshoot when its set point is changed.

Set Point The set point is the desired value of the controlled variable and is subject to adjustment by the operator. In a continuous process plant, most of the control loops operate as regulators, having a set point that remains unchanged for days and even months at a time.

Examples of variables held at constant set points are drum-level and steam temperature of a boiler, most pressure and level variables, pH of process and effluent streams, most product-quality variables, and most temperature loops. Set-point response is of no importance to these loops, but they must contend with load upsets minute by minute. In fact, the only loops in a continuous plant that must follow set-point changes are flow loops.

Batch plants have frequent transitions between steady states, some of which require rapid response to set-point changes with minimal overshoot. However, some of these changes are large enough to saturate the controller, particularly at startup. This can cause integral windup, which requires special means of prevention to overcome.

The Load Only pure-batch processes — where no flow into or out of the process takes place — operate at constant load, and that load is zero. All other processes can expect to encounter variations in load, which are principally changing flow rates entering and leaving vessels. A liquid-level controller, for example, manipulates the flow of one liquid stream, while other streams represent the load. Feedwater flow to a boiler is manipulated to control drum level and must balance the combined flows of steam and blowdown leaving to keep level at set point. The load changes frequently and often unpredictably, but the set point may never change.

In a typical temperature control loop, the load is the flow of heat required to keep temperature constant. Liquid entering a heat exchanger will require a certain flow of steam to reach a controlled exit temperature. Variations in liquid flow and inlet temperature will change the demand for steam flow manipulated to keep exit temperature at set point.

Dynamics

The term *process dynamics* can refer to capacitance, inertia, resistance, time constant, dead time or their combinations. There is no dynamics involved with changing the set point, unless intentionally placed there for the purpose of filtering the set point.

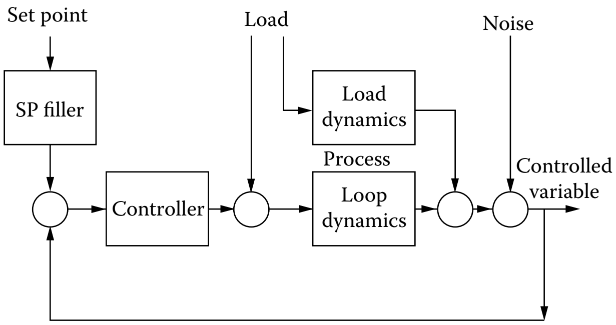

FIG. 2.35a
Load variables always pass through the dominant dynamic elements.

However, there is *always* dynamics in the load path. Load variables are principally the flow rates of streams similar to those manipulated by the controller. Therefore the dynamics in their path to the controlled variable are similar — and in most cases identical — to the dynamics in the loop itself.

Figure 2.35a presents all the essential elements of a control loop, showing its disturbance sources and dynamics. Most frequently, the dynamics are common to both the load disturbance and the controller output, meaning that the load and manipulated streams enter the process at the same point. An example would be the control of composition of a liquid at the exit of a blender, where both the manipulated and load streams making up that blend are introduced at a common entry point.

Less often encountered is the process where the dynamics in these two paths differ. An example of this is a shell-and-tube heat exchanger, wherein the temperature of a liquid leaving the tube bundle is controlled by manipulating the flow of steam to the shell. The shell may have more heat capacity than the tubes, causing the temperature to respond more slowly to a change in steam flow than to a change in liquid flow. Nonetheless, these two dominant lags will typically not differ greatly.

Step Responses

Step testing is recommended for all control loops where the frequency content of the disturbance variables is not specified. There are cases of periodic disturbances, and they can pose special problems for control loops that themselves are capable of resonating at a particular period. They are found principally in cascade loops and in process interactions where controllers manipulate valves in series or in parallel. These are considered in other sections of this work. Another period disturbance is the cyclic operation of such cleaning devices as soot-blowers.

For the general case, the step disturbance is the most difficult test for the controller in that it contains all frequencies, including zero. In fact, the frequency content of the step is identical to that of integrated white noise — therefore, it is an excellent test for loops subject to random disturbances.

Steps are also quite common in industry, representing conditions caused by sudden startup and shutdown of equipment; starting and stopping of multiple burners, pumps and compressors; and capacity changes of reciprocating compressors. If a control loop can respond adequately to a step disturbance, then a ramp or exponential disturbance will have less of an impact on it.

The step is also the easiest test to apply, requiring only a size estimate, and can be administered manually. Pulses require duration estimates, and doublet pulses require balancing. Step changes in set point are the usual disturbance applied to test or tune a loop, even for loops that operate at constant set point. Figure 2.35b illustrates a step response with 1/4 decay ratio.

The usual result of tuning a controller for set point response is to reduce its performance to variations in load. Therefore, the effectiveness of a controller and its tuning as a load regulator need to be determined by simulating a step load change.

Simulating a Load Change

Some controllers have an adjustable output bias. An acceptable simulation of load change, when the controller is in automatic and at steady state, is a step change in the value of this bias. The value of the controller output prior to the step is an indication of the current plant load because the loop was in a steady state. The step in bias in that case moves the controller output to another value, which disturbs the controlled variable and causes the controller to integrate back to its previous steady-state output.

Alternatively, controllers that can be transferred "bumplessly" between manual and automatic modes (most do — all

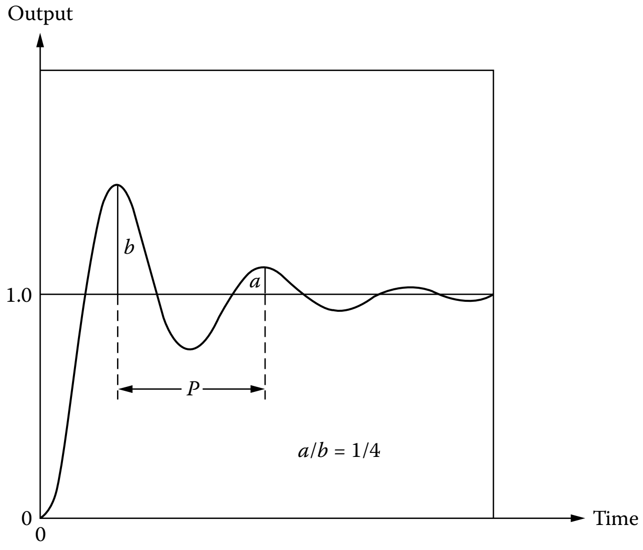

FIG. 2.35b
Step response curve of a control loop tuned for 1/4 decay ratio.

should) allow simulating a load change by using that feature. This is done by waiting until the loop is at steady state and on set point (zero deviation). At that point switching to the *manual* mode and stepping the output by the desired amount in the desired direction, and immediately (before a deviation develops) transferring back to the *automatic* mode.

This procedure can be followed for all but the fastest loops, such as flow loops. For them, a step in set point is acceptable, both because flow loops must follow set-point changes, and because for them, set-point tuning gives acceptable load response.

Comparing Set-Point and Load Responses

The steady-state process gain of a flow loop is typically between 1 and 2, as indicated by the controller output being between 50 and 100% when the flow measurement is at full scale. The proportional gain of a typical flow controller is in the range of 0.3 to 1.0, with the higher number associated with the process that has the lower steady-state gain. Therefore, the proportional loop gain for a typical flow loop is in range of 0.6 to 1.0. As a result, a step change in set point will move the controller output approximately the correct amount to produce the same change in flow, by proportional action alone, that gives excellent set-point response.

This is not the case for other loops. Level has the opposite behavior. To maintain a constant level, the controller must match the vessel's inflow and outflow precisely. Changing the set point will cause the controller to change the manipulated flow, but only temporarily — when the level reaches the new set point, the manipulated flow must return to its original steady-state value.

Therefore, *no* steady-state change in output is required for a level controller to respond to a set-point change. The Integrated Error (IE) sustained by a controller following a disturbance varies directly with the change in output between its initial and final steady states. In response to a set-point change, the level controller has the same initial and final steady-state output values and hence sustains zero integrated error.

As a result, the error that is integrated while the level is approaching the new set point will be matched exactly by an equal area of overshoot. In other words, set-point overshoot is unavoidable in a level loop unless set-point filtering is provided.

Most other processes, such as temperature, pressure, and composition, have steady-state gains higher than those of a flow process. But more importantly, they are also dominated by lags, which allows the use of a higher controller proportional gain for tight load regulation. When this high proportional gain is multiplied by the process steady-state gain, the resulting loop gain can be as high as 5 to 10 or more.

A set-point step then moves the controller output far more than required to drive the controlled variable to the new set point, producing a large overshoot. To minimize set-point overshoot, the controller must be detuned, with lower gain and longer integral time than is optimum for load regulation, or a filter must be applied to the set point.

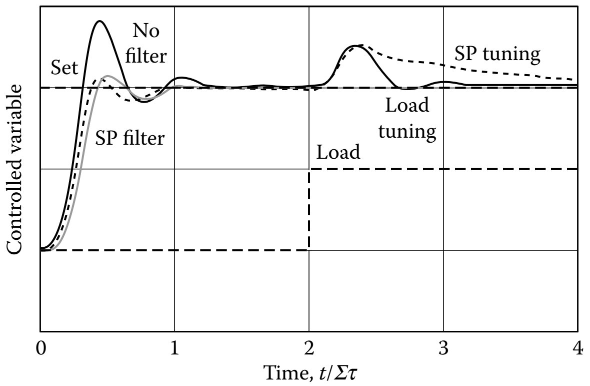

FIG. 2.35c
Set-point tuning slows load recovery for lag-dominant processes.

Figure 2.35c compares responses to steps in set point and load for a process with distributed lag such as a dashed exchanger, distillation column, or stirred tank. The time scale is normalized to $\Sigma\tau$, which is the time required for the distributed lag to reach 63.2% of the full response to a step input in the open loop. It is also the residence time of liquid in a stirred tank.

If the PID settings are adjusted to minimize the Integrated Absolute Error (IAE) to the set point change, the dashed response curve is produced (SP tuning). Note that following a step change in load, the return to set point is sluggish. This is commonly observed with lag-dominant processes. The PID settings that produce the minimum-IAE load response, shown in black (no filter), result in a large set-point overshoot, however.

Set-Point Filtering

If optimum load rejection is desired, without the large set-point overshoot that it produces on lag-dominant processes, the proportional response to set-point changes needs to be reduced.

Some PID controllers have the option to eliminate proportional action on the set point altogether. This tends to produce a set-point undershoot, which can significantly dashed the controller response, and it should never be used in the secondary controller of a cascade system. (Incidentally, derivative action should never be applied to the set point, as this always produces overshoot.)

Some controllers can reduce the controller's proportional gain when it acts on set point changes, either through the use of a lead-lag filter, or by the use of a specially structured algorithm. This adjustment allows separate optimization of set-point response, after the PID settings have been tuned to optimize the controller's load response. The filter used for the loop whose response is shown in Figure 2.35c has applied only half the controller's proportional gain to the set point.

OPEN-LOOP TUNING

Applying a step to the process is simple and can be used to tune the loop and to obtain a simple model for the process. Two methods are widely used. The first is the “process reaction curve,” which is not used to calculate the process model but is used to obtain the tuning parameters for rejecting the upsets caused by load changes.

The second method uses the “process model” by obtaining a simple process model; the tuning parameters are calculated from this model based on either a load rejection or a set point change criterion.

Process Reaction Curve

When a process is at steady state and it is upset by a step change, it usually starts to react after a period of time called the dead time (Figure 2.35d). After the dead time, most processes will reach a maximum speed (reaction rate), then the speed will drop (self-regulating process) or the speed will remain constant (integrating process).

When tuning a loop to remove disturbances caused by load changes, the controller must react at its maximum rate of reaction, and the strength of the reaction will correspond to the maximum speed. Hence, to tune the loop, it is not necessary to know the process model. It is sufficient to know the dead time and the maximum speed to calculate the tuning parameters.

Figure 2.35e illustrates the response of a temperature loop after a step change in the controller output. This example will be used throughout this section to illustrate the differences between the recommended settings arrived at by using the various tuning techniques.

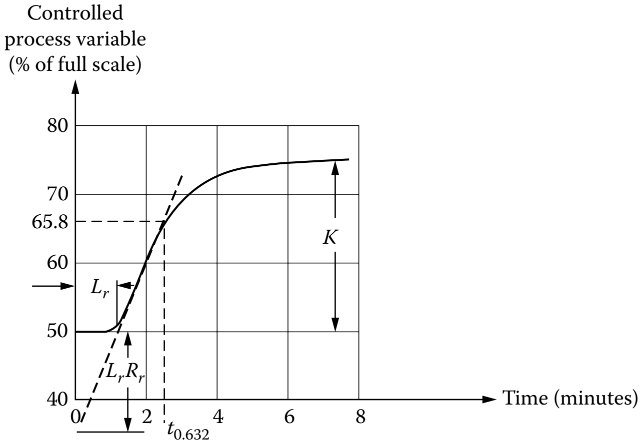

FIG. 2.35d
Reaction curve of a self-regulating process, caused by a step change of one unit in the controller output. $L_r = t_d$ is dead time, R_r is reaction rate, and K is process gain.

From this curve, it is not possible to determine the process model since the curve is too short to tell whether the reaction rate remains constant (integrating process) or goes down (self-regulating process). From such a test, the model cannot be found but the tuning parameters for load rejection can be estimated.

As can be seen from Figure 2.35e, a 10% change in CO was applied at 10 s and the temperature started to increase

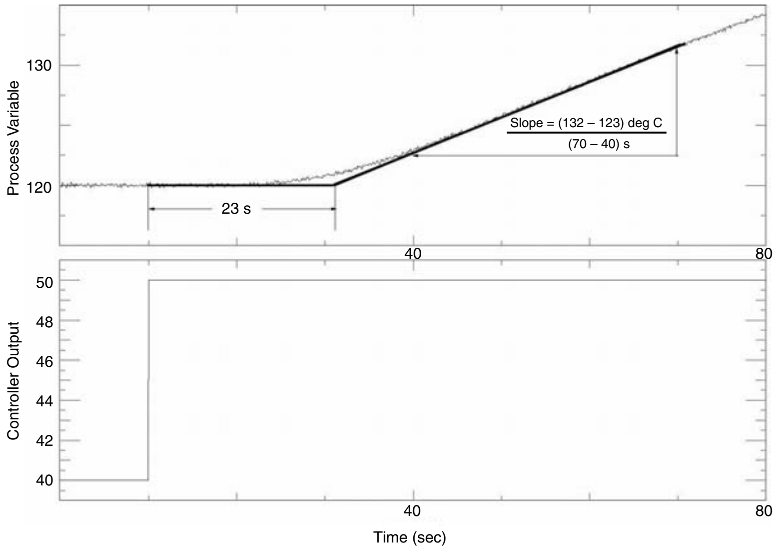

FIG. 2.35e
Process reaction curve in response of a change in controller output (CO). The process variable (PV) range is 0 to 300 degC and the CO range is 0 to 100%.

TABLE 2.35f
Equations for Calculating the Ziegler–Nichols Tuning Parameters for an Interacting Controller

Type of Controller	*P (gain)*	*I (minutes/repeat)*	*D (minutes)*
P	$\frac{\Delta \mathrm{CO}}{R_r * \mathrm{td}}$	—	—
PI	$0.9 * \frac{\Delta \mathrm{CO}}{R_r * td}$	3.33 t_d	—
PID	$1.2 \frac{\Delta \mathrm{CO}}{R_r * td}$	2 t_d	0.5 t_d

23 s seconds later at 33 s. Hence the dead time (t_d) is 23 s and the reaction rate (speed) is

$$R_r = \frac{\Delta \mathrm{PV}}{\Delta t} \qquad \textbf{2.35(1)}$$

The slope is:

$$\frac{\Delta \mathrm{PV}}{\Delta t} = \frac{132\,\mathrm{deg\,C} - 123\,\mathrm{deg\,C}}{70\ \mathrm{s} - 40\ \mathrm{s}} = \frac{9\,\mathrm{deg\,C}}{30\ \mathrm{s}} = \frac{\frac{9\,\mathrm{deg\,C}}{300\,\mathrm{deg\,C}} * 100}{30\ \mathrm{s}}$$
$$= \frac{3\%}{30\ \mathrm{s}} = 0.1\%/\mathrm{s} = 6.0\%/\mathrm{min}$$

After the dead time (t_d) and the reaction rate (R_r) have been determined, the controller settings are calculated by using the equations in Table 2.35f.

If a PI controller is to be used for the process that was tested in Figure 2.35e, the values are:

P = 0.9*10%/(0.1%/s X 23 s) = 3.9

I = 3.33 * 23 s = 76.6 s = 1.28 minutes.

Ziegler and Nichols recommend using the ratio of the controller output divided by the product of the slope and the dead time to calculate the proportional gain. The ideal process has a small dead time and a small slope, so that the controller can aggressively manipulate the controller output to bring the process back to set point.

The integral and derivative are calculated using the dead time. The proportional is calculated using the slope and the dead time. If the slope is high, then the controller gain must be small because the process is sensitive; it reacts quickly. If the dead time is long, the controller gain must be small because the process response is delayed and therefore the controller cannot be aggressive. If one can reduce the slope and the dead time of any process, it will be easier to control.

One of the advantages of open-loop tuning over the closed-loop tuning technique is its speed because one does not need to wait for several periods of oscillation during several trial-and-error attempts. The other advantage is that one does not introduce oscillations into the process with unpredictable amplitudes. In open-loop tuning, the user selects the upset that is introduced, and it can be small. Yet another advantage is that this test can be performed prior to the installation of the control system.

The disadvantages are also multiple. The open-loop test is not as accurate as the closed-loop one because it disregards the dynamics of the controller. Another disadvantage is that the S-shaped reaction curve and its inflection point are difficult to identify when the measurement is noisy and/or if a small step change was used.

Because of the above considerations, a good approach is to use the open-loop method of tuning in order to obtain the first set of initial tuning constants for a loop during startup. Then, refine these settings once the system is operating by retuning the loop using the closed-loop method.

Process Model

There are many ways to use and interpret the dead time (t_d) and reaction rate (R_r) values obtained from the open-loop tuning method. Most open-loop methods are based on approximating the process reaction curve by a simpler system. Several techniques are available to obtain a model.

The most common approximation by far is a pure time delay (dead time) plus a first-order lag. One reason for the popularity of this approximation is that a real-time delay of any duration can only be represented by a pure time delay because there is yet no other simple and adequate approximation. Theoretically, it is possible to use higher-than-first-order lags plus dead time, but accurate approximations are difficult to obtain. Thus the real process lag is usually approximated by a pure time delay plus a first-order lag. This approximation is easy to obtain, and it is sufficiently accurate for most purposes.

The process's dead time is the time period following an upset during which the controlled variable is not yet responding. The time constant is a period between the time when a response is first detected and the time when the response has reached 63.2% of its final (new steady-state) value. The time constant is also the time it would take for the controlled variable to reach its final value if the initial speed were maintained.

Bump Tests Figure 2.35g shows the Ziegler–Nichols procedure to approximate that process reaction curve with a first-order lag plus a time delay. The first step is to draw a straight-line tangent to the process reaction curve at its point of maximum rate of ascent (point of infection).

Although this is easy to visualize, it is quite difficult to do in practice. This is one of the main difficulties in this procedure, and a considerable number of errors can be introduced at this point. The slope of this line is termed the reaction rate R_r. The time between the instant when the bump was applied and the time at which this line intersects the initial value of the controlled variable prior to the test is the dead time, or transport time delay t_d.

Figure 2.35g illustrates the determination of these values for a one-unit step change (ΔCO) in the controller output

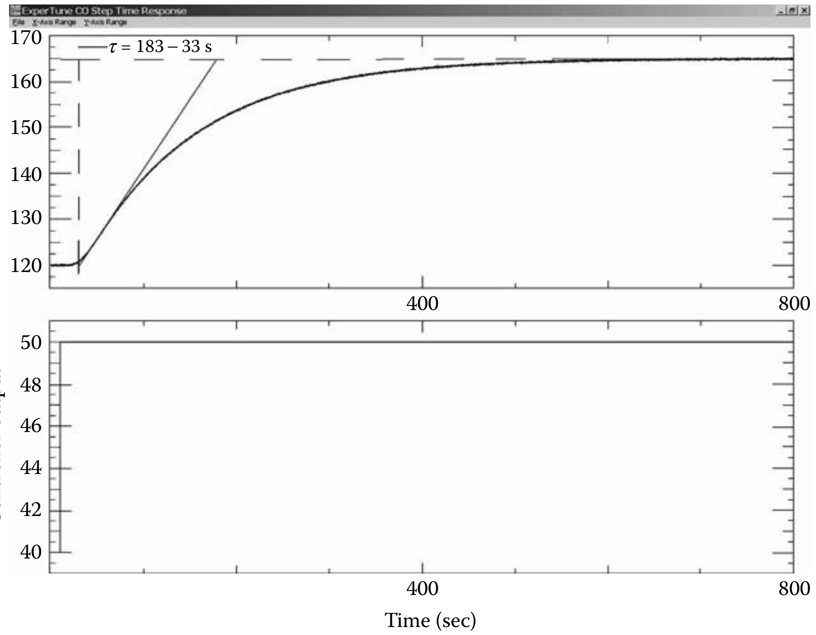

FIG. 2.35g
Maximum slope curve, Fit 1.

(manipulated variable) to a process. If a different-size step change in controller output was applied, the value of τ_d would not change significantly.

However, the value of R_r is essentially directly proportional to the magnitude of the change in controller output. Therefore, if a two-unit change in output was used instead of a one-unit change, the value of R_r would be approximately twice as large. For this reason the value of R_r used in Equation 2.35(2) or any other must be the value that would be obtained for a one-unit change in controller output.

In addition to the dead time and reaction rate, the value of the process gain K must also be determined as follows:

$$K = \frac{\text{final steady-state change in controlled variable (\%)}}{\text{change in controller ouput (control unit)}} \qquad \mathbf{2.35(2)}$$

There is a second method to determine the pure time delay plus the first-order lag approximation. In order to distinguish between these two methods, they will be called Fit 1 (described in Figure 2.35g) and Fit 2 (described in Figure 2.35h). The only difference between these two is in how the first-order time constant is obtained. In case of Fit 2, the time constant of the process is determined as the difference between the time when the dead time ends and the time when the controlled variable has covered 63.2% of the distance between the pre-test steady state and the new one. The dead time determination by both fits is the same and was already described.

Another method to determine the dead time is to measure the time when the PV moves by 2% of the total change.

The first-order lag time constants are given by:

$$\text{Fit1: } \tau_{F1} = K/R_r = 1.5/0.1\%/\text{s} = 150 \text{ s}$$
$$\text{(same slope as previous section)} \qquad \mathbf{2.35(3)}$$

$$\text{Fit 2: } \tau_{F1} = t_{63.2\%} - t_0 = 155 \text{ s} - 33 \text{ s} = 122 \text{ s} \qquad \mathbf{2.35(4)}$$

In Equation 2.35(4), $t_{63.2\%}$ is the time necessary to reach 63.2% of the final value, and t_0 is the time elapsed between the CO change and the beginning of the PV change. Note that the parameters for Fit 1 are based on a single point on the response curve, which is the point of maximum rate of ascent. However, the parameters obtained with Fit 2 are based on two separate points.

Studies[3] indicate that the open-loop response based on Fit 2 always provides an approximation that is as good or better than the Fit 1 approximation. A typical curve resulting from the above procedure is shown in Figure 2.35i.

The response shown in Figure 2.35i resulted from a ten-unit change in controller output. For different step changes, K and R_r must be adjusted accordingly. From a curve such as in Figure 2.35i, a number of parameters can be determined. The controller settings are calculated from the equations in Table 2.23j:

Table 2.35k compares the results obtained in terms of process gain (K), time constant ($\tau(s)$), dead time ($t_d(s)$), and the resulting controller gain (K_c) and integral time setting (T_i(min)) of a PI controller.

In the following discussion, the process model determined by the second fit will be used to compare against a variety of tuning criteria.

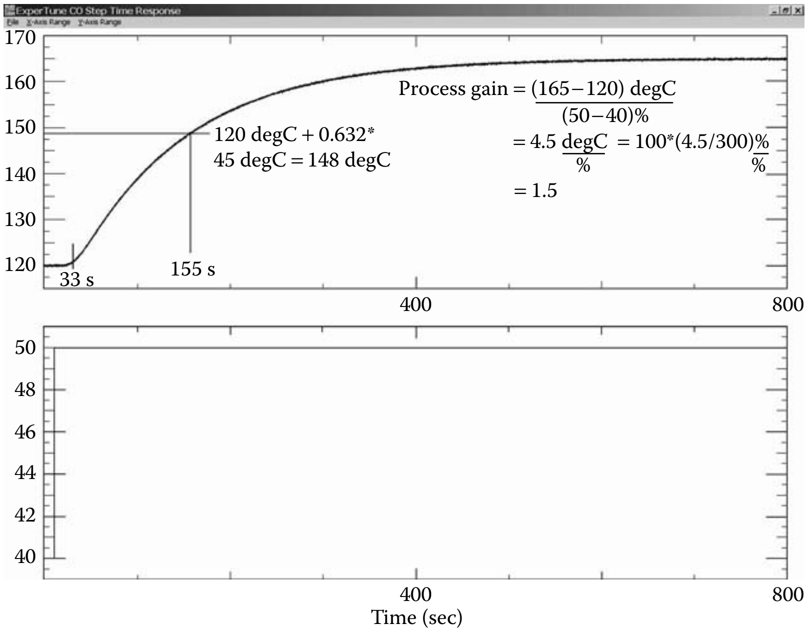

FIG. 2.35h
Bump test, Fit 2 curve.

Comparing the Tuning Methods One of the earliest methods for using the process reaction curve was proposed by Ziegler and Nichols. When using their process reaction curve method, which was described in connection with Figure 2.35e, only R_r and t_d or t_0 must be determined. Using these parameters, the empirical equations to be used to predict controller settings to obtain a decay ratio of 1/4 are given in Table 2.35j in terms of K, t_d, and τ.

In developing their equations, Ziegler and Nichols considered processes that were not "self-regulating." To illustrate,

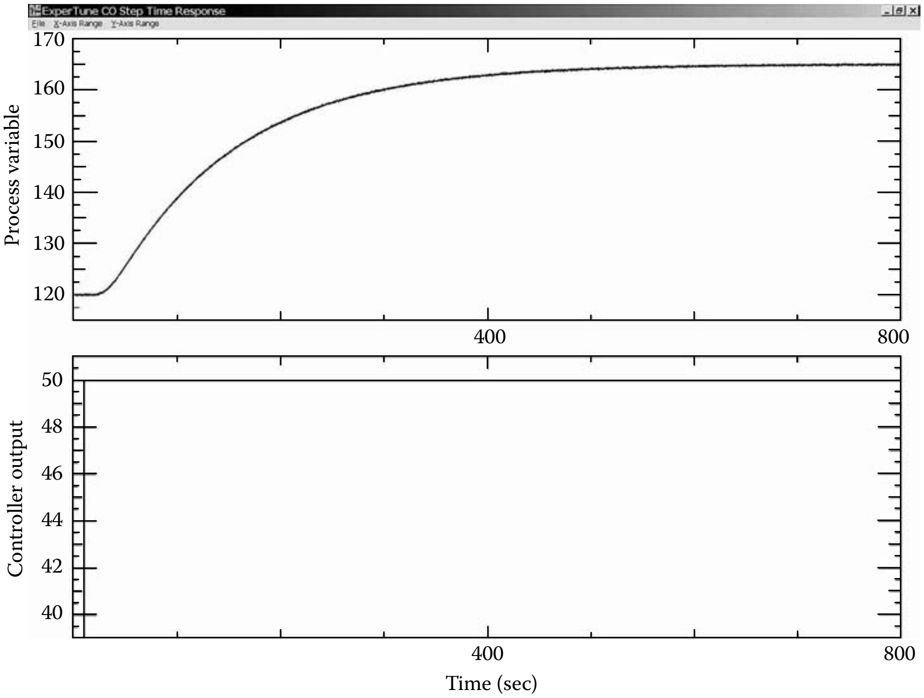

FIG. 2.35i
A typical reaction curve using the dead time and time constant obtained by a bump test.

TABLE 2.35j

Ziegler–Nichols' Recommendations to Obtain the Tuning Parameters for an Interacting Controller Based on the Readings Calculated from a Model

Type of Controller	*P (gain)*	*I (minutes/repeat)*	*D (minutes)*
P	$\frac{\tau}{K*t_d}$	—	—
PI	$0.9*\frac{\tau}{K*t_d}$	3.33 t_d	—
PID	$1.2\frac{\tau}{K*t_d}$	2 t_d	0.5 t_d

consider the level control of a tank with a constant rate of liquid outflow. Assume that the tank is initially operating at constant level. If a step change is made in the inlet liquid flow, the level in the tank will rise until it overflows. This process is not "self-regulating."

On the other hand, if the outlet valve opening and outlet backpressure are constant, the rate of liquid removal increases as the liquid level increases. Hence, in this case, the level in the tank will rise to some new position but will not increase indefinitely, and therefore system will be self-regulating. To account for self-regulation, Cohen and Coon[4] introduced an index of self-regulation μ defined as:

$$\mu = R_r L_r / K \qquad \textbf{2.35(5)}$$

TABLE 2.35k

The Tuning Setting Recommendations for a PI Controller Resulting from the Three Methods of Testing Described

Testing Method Used	*K*	τ *(s)*	t_d *(s)*	K_c	T_i *(min)*
Reaction curve				3.91	1.28
Process model Fit1, ZN	1.5	150	23	3.91	1.28
Process model Fit 2, ZN	1.5	122	23	3.18	1.28

Note that this term can also be determined from the process reaction curve. For processes originally considered by Ziegler and Nichols, μ equals zero and therefore there is no self-regulation. To account for variations in μ, Cohen and Coon suggested the equations given in Table 2.35l in terms of t_d and τ.

In case of a proportional control, the requirement that the decay ratio be 1/4 is sufficient to ensure a unique solution, but for the case of proportional-plus-reset control, this restraint is not sufficient.

Another constraint in addition to the 1/4 decay ratio can be placed on the response to determine the unique values of K_c and T_i. This second constraint can be to require that the control area of the response be at its minimum, meaning that the area between the response curve and the set point be the smallest. This area is called the error integral or the integral of the error with respect to time.

With the proportional-plus-reset-plus-rate controller (PID), the same problem of not having a unique solution exists even when the 1/4 decay ratio and the minimum error integral constraints are applied. Therefore, a third constraint must be chosen to obtain a unique solution. Based on the work of Cohen and Coon, it has been suggested that this new constraint could have a value of 0.5 for the dimensionless group $K_c K t_d / \tau$. The tuning relations that will result from applying these three constraints are given in Table 2.35l. This method has been referred to as the 3C method.[5–7]

Greg Shinskey suggested a variation to the above, where the proportional gain and the integral time are increased.

TABLE 2.35l

Comparison of Equations Recommended by Ziegler–Nichols, Shinskey, Cohen–Coon, and 3C for the Determination of the Tuning Settings for PID Controllers

	Ziegler–Nichols	*Shinskey*	*Cohen–Coon*	*3C*
P	$KK_c = (t_d/\tau)^{-1.0}$	$(t_d/\tau)^{-1.0}$	$(t_d/\tau)^{-1.0} + 0.333$	$1.208(t_d/\tau)^{-0.956}$
P	$KK_c = 0.9(t_d/\tau)^{-1.0}$	$0.95(t_d/\tau)^{-1.0}$	$0.9(t_d/\tau)^{-1.0} + 0.082$	$0.928(t_d/\tau)^{-0.946}$
I	$\frac{T_i}{\tau} = 3.33(t_d/\tau)$	$4.0(t_d/\tau)$	$\frac{3.33(t_d/\tau)[1+(t_d/\tau)/11]}{1+2.2+(t_d/\tau)}$	$0.928(t_d/\tau)^{-0.583}$
P	$KK_c = 1.2(t_d/\tau)^{-1.0}$	$0.855(t_d/\tau)^{-1.0}$	$1.35(t_d/\tau)^{-1.0}+0.270$	$1.370(t_d/\tau)^{-0.950}$
I	$\frac{T_i}{\tau} = 2.0(t_d/\tau)$	$1.6(t_d/\tau)$	$\frac{2.50(t_d/\tau)[1+(t_d/\tau)/5]}{1+0.6(t_d/\tau)}$	$0.740(t_d/\tau)^{0.738}$
D	$\frac{Td}{\tau} = 0.5(t_d/\tau)$	$0.6(t_d/\tau)$	$\frac{0.37(t_d/\tau)}{1+0.2(t_d/\tau)}$	$0.365(t_d/\tau)^{0.950}$

Integral Criteria Tuning[8]

Table 2.35m provides the controller settings that minimize the respective integral criteria to the ratio t_d/τ. The settings differ if tuning is based on load (disturbance) changes as opposed to set point changes. Settings based on load changes will generally be much tighter than those based on set point changes. When loops tuned to load changes are subjected to a set point change, a more oscillatory response is observed.

Which Disturbance to Tune for

With tuning parameters calculated for load rejection, the integral time (T_i) and derivative time (T_d) will depend mostly on the dead time (t_d) of the process.

In contrast, if the tuning parameters are calculated for a set-point change, the integral time will be longer and the derivative time will be shorter, and they will depend mostly on the time constant of the process.

The relationship between the controller settings based on integral criteria and the ratio t_0/τ is expressed by the tuning relationship given in Equation 2.35(6).

$$Y = A\left(\frac{t_0}{\tau}\right)^B \qquad \textbf{2.35(6)}$$

where $Y = KK_c$ for proportional mode, τ/T_i for reset mode, T_d/τ for rate mode; A, B = constant for given controller and mode; t_0, τ = pure delay time and first-order lag time constant.

Hence, using these equations,

$$K_c = \frac{A}{K}\left(\frac{t_0}{\tau}\right)^B \qquad \textbf{2.35(7)}$$

$$\frac{1}{T_i} = \frac{A}{\tau}\left(\frac{t_0}{\tau}\right)^B \qquad \textbf{2.35(8)}$$

$$T_d = \tau * A\left(\frac{t_0}{\tau}\right)^B \qquad \textbf{2.35(9)}$$

Lambda Tuning

Lambda tuning originated from Dahlin in 1968; it is based on the same IMC theory as MPC,[4,5] is model-based, and uses a model inverse and pole-zero cancellation to achieve the desired closed-loop performance.

Lambda tuning is a method to tune loops based on pole placement. This method ensures a defined response after a set-point change but is generally too sluggish to properly reject disturbances. Promoters for this method often claim that all loops should be tuned on the basis of Lambda tuning. Doing so, the controllers are almost in "idling mode" and

TABLE 2.35m

	D	0.420	1.000	0.500	1.000

when the process load changes or other disturbance occurs, the time to eliminate this disturbance is quite long for most processes, because the integral time selected equals the process time constant.

The promoters also suggest the use of a closed-loop time constant, which is three times the process time constant. Doing so, the response time in the automatic mode will be three times longer than in manual. Therefore, the response time will be slower in automatic. This is adequate if no disturbance occurs but if no disturbance occurs, the control loop is not needed.

"Lambda tuning" refers to all tuning methods where the control loop speed of response is a selectable tuning parameter. The closed loop time constant is referred to as "Lambda" (λ). Therefore, following a set-point change, the PV will reach set point as a first-order system (same type of response as in the manual mode when the CO is changed).

Lambda tuning has been widely used in the pulp and paper industry, but control specialists are starting to realize that it is often too sluggish to handle disturbances. For a first-order plus dead time model

$$T_i = \tau \tag{2.35(10)}$$

$$K_c = \frac{1}{K} * \frac{T_i}{\lambda + t_d} \tag{2.35(11)}$$

where λ = closed loop time constant; it is recommended to use $\lambda = 3\tau$.

TABLE 2.35n

The Tuning Setting Recommendations for a PI Controller Resulting from the Criteria Listed

Criteria	*Tuning*	K_c	T_i *(min)*
Load change criteria	Ziegler–Nichols	3.18	1.28
	CCC	3.00	0.71
	Shinskey	3.37	1.53
	IAE	3.40	1.03
SP change criteria	IAE	2.13	1.16
	Lambda	0.21	2.03

The performance of lambda tuning is unacceptable for correcting upsets caused by load changes if the process time constant is larger than the dead time. This is the case with pressure, level, and temperature control applications. With flow loops, the results are similar to other methods since the time constant is in the same order of magnitude as the dead time.

In Table 2.35n, Fit 2 (Figure 2.35h) will be used as the reference to compare the process models found using the different tuning criteria. For load and set-point responses of the different tuning techniques, see Figures 2.35o, p, and q.

Adjusting Robustness To remove oscillations in a control loop, hence to increase the robustness, it is necessary to give

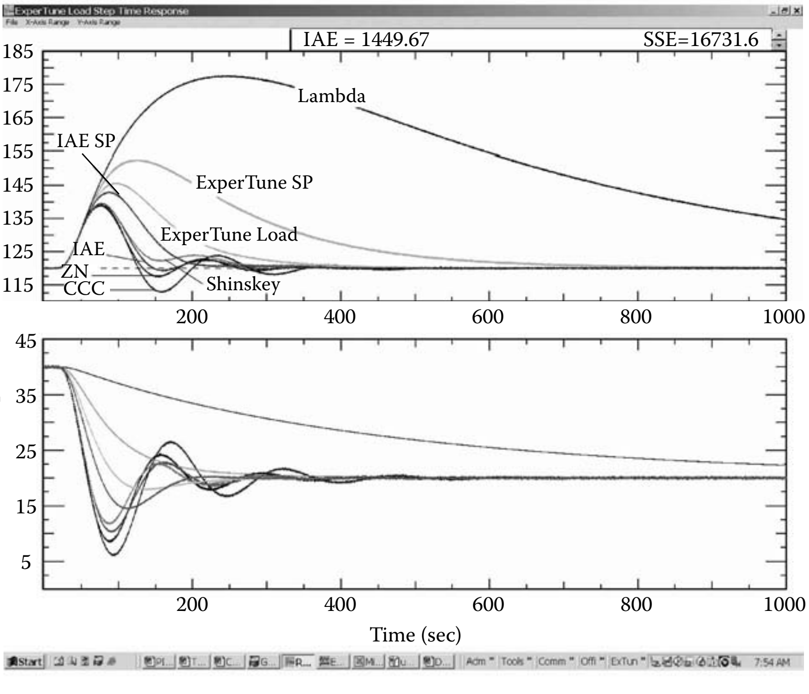

FIG. 2.35o

Load responses of the different tuning techniques (example).

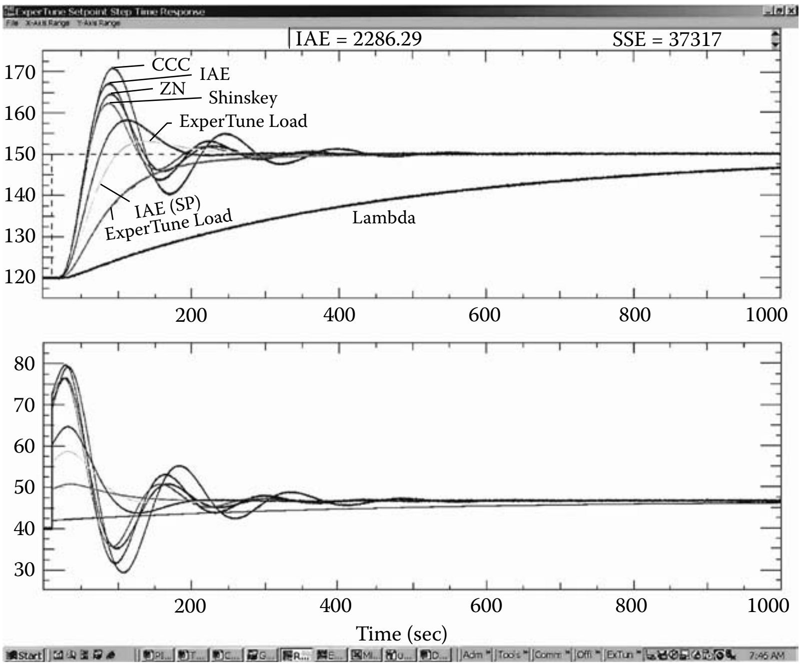

FIG. 2.35p
Set-point responses of the different tuning techniques (example).

up some performance. By reducing the proportional gain in a control loop, the robustness will be increased and the oscillations will be reduced or removed.

As a rule of thumb, dividing the proportional gain by a factor of two will eliminate the oscillations; dividing again the proportional gain by a factor of two will remove most of the overshoot. (For more on robustness, see Section 2.26.)

Digital Control Loops

Digital control loops differ from continuous control loops by having the continuous controller replaced by a sampler, a discrete control algorithm calculated by the computer, and a hold device (usually a zero-order hold). In such cases Moore et al. have shown that the open-loop tuning methods presented

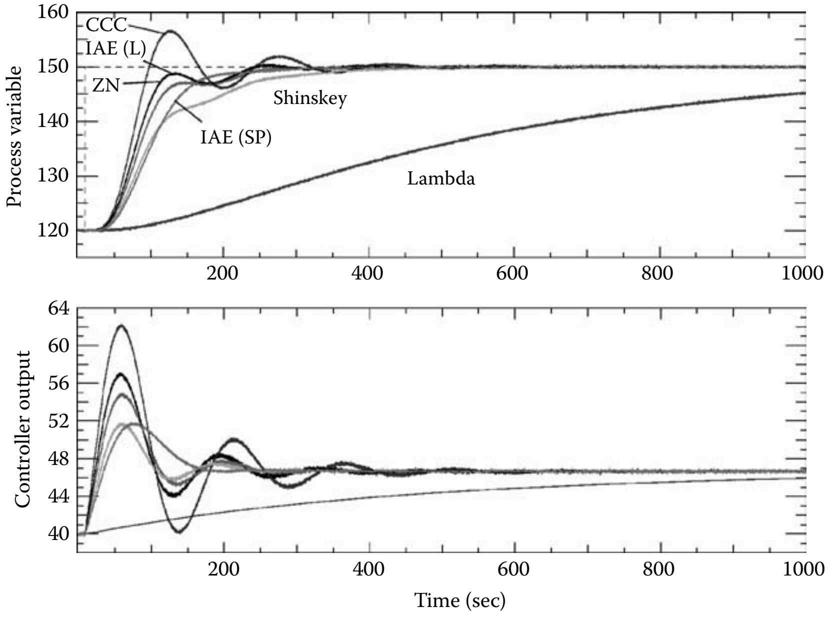

FIG. 2.35q
Set-point responses of the different tuning techniques (example) with a controller where the P is applied only on PV changes.

previously may be used, considering that the dead time used is the sum of the true process dead time and one-half of the sampling time, as expressed by Equation 2.35(12):

$$t_0' = t_0 + T/2 \qquad \textbf{2.35(12)}$$

where T is the sampling time. t_0' is used in the tuning relationships instead of t_0. (Section 2.38 deals with the subject of controller tuning by computer.)

CLOSED-LOOP RESPONSE METHODS

As has been discussed previously, in the open-loop method of tuning, the controller does not even have to be installed in order for the controller settings to be determined. When the closed-loop method is used, the controller is in automatic. Described below are the two most common closed-loop methods of tuning, the ultimate method and the damped oscillation method.

Ultimate Method

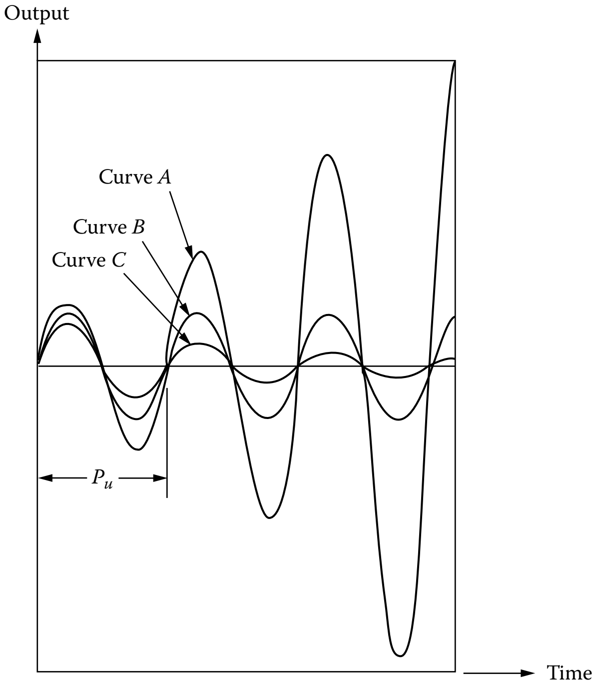
One of the first methods proposed for tuning controllers was the ultimate method, reported by Ziegler and Nichols[1] in 1942. This method is called "the ultimate method" because its use requires the determination of the ultimate gain (sensitivity) and the ultimate period. The ultimate gain K_u is the maximum allowable value of gain (for a controller with only a proportional mode) for which the system is stable. The ultimate period is the response's period with the gain set at its ultimate value (Figure 2.35r).

In order for a closed loop to display a quarter of the amplitude damping (Figure 2.35b), its loop gain must be at 0.5. This means that the *product* of the gains of all the components in the loop — composed by the process gain (G_p), the sensor gain (K_s), the transmitter gain (K_t), the controller gain (K_c = 100/PB), and the control valve gain (K_v) — must be at 0.5. When the loop is in sustained, undampened oscillation, the gain product of the loop is 1.0 and the amplitude of cycling is constant (Curve B in Figure 2.35r).

The period when the closed loops oscillate depends mostly on the amount of dead time in the loop. The period of oscillation in flow loops is 1 to 3 seconds; for level loops, it is 3 to 30 seconds (sometimes minutes); for pressure loops, 5 to 100 seconds, for temperature loops; 0.5 to 20 minutes; and for analytical loops, from 2 minutes to several hours.

When controlled by analog controllers (no dead time added by sampling), plain proportional loops oscillate at periods ranging from two to five dead times, PI loops oscillate at periods of three to five dead times, and PID loops at around three dead time periods.

The settings determined by this method will be based on load disturbance rejection and will not be suitable for set-point changes. The tuning parameters are in fact calculated on the basis of the distance where the loop will operate from instability. Settings for load rejection are not too far from instability, but tuning parameters for set-point change are different, and the process model is needed for their determination.



Curve A: unstable, runaway oscillation
Curve B: continuous cycling, marginal stability
Curve C: stable, damped oscillation

FIG. 2.35r
Ultimate gain is the gain that causes continuous cycling (Curve B) and ultimate period (Pu) is the period of that cycling.

The optimum integral and derivative settings of controllers vary with the number of modes in the controller (P = 1, PI = 2 mode, PID = 3 mode) and with the amount of dead times in the loop. For noninteracting PI controllers with no noticeable dead time, one would set the integral (T_i) for about 75% of the period of oscillation.

As the dead time-to-time constant ratio rises, the integral setting becomes a smaller percentage of the oscillation period — around 60% when the dead time equals 20% of the time constant, about 50% when their ratio is at 50%, about 33% when they are equal, and about 25% when the dead time exceeds the time constant.

For noninteracting PID loops with no dead time, one would set the integral minutes/repeat (I) to a value equal to 50% of the period of oscillation and the derivative time (D) to about 18% of the period. As dead time rises to 20% of the time constant, (I) drops to 45% and (D) to 17% of the period. At 50% dead time, (I) = 40% and (D) = 16%. When the dead time equals the time constant, (I) = 33% and (D) = 13%; finally, if dead time is twice the time constant, (I) = 25% and (D) = 12%.

Tuning Example The same example as was used earlier will be used to illustrate the "ultimate" closed-loop tuning method. The aim of this tuning process is to determine the controller gain or proportional band that would cause sustained, undampened oscillation (K_u) and to measure the corresponding period of oscillation, called the ultimate period (P_u). The steps in this tuning sequence are as follows:

1. Set all controller dynamics to zero. In other words, set the integral to infinite (or maximum) minutes per repeat or zero (or minimum) repeats per minute and set derivative to zero (or minimum) minutes.
2. Set the gain or proportional band to some arbitrary value near the expected setting (if known) or at $K_c = 1$ (PB = 100%) if no better information is available.
3. Let the process stabilize. Once the PV is stable, introduce an upset. The simplest way to do that is to move the set point up or down by a safe amount (for example, move it by 2% for half a minute) and then return it to its original value.

The result will be an upset in the PV resembling the characteristics of curve A, B, or C in Figure 2.35r. If the response is undampened (curve A), the gain (or proportional) setting is too high (proportional narrow); inversely, if the response is damped (curve C), the gain (or proportional) setting is too low (proportional wide). Therefore, if the response resembles curve A, the controller gain is increased; if it resembles curve C, the gain is reduced, and the test is repeated until curve B is obtained.

After one or more trials, the state of sustained, undampened oscillation will be obtained (curve B), and at that point the test is finished. (Make sure that the oscillation is a sinusoidal and not a limit cycle.) Next, read the proportional gain that caused the sustained oscillation. This is called the "ultimate gain" (K_u), and the corresponding period is the ultimate period of oscillation (P_u).

Once the values of K_u and P_u are known, one might use the recommendations of Ziegler–Nichols (Table 2.35s) or the recommendations that were described earlier, which also consider the dead time-to-time constant ratio. No one tuning is perfect, and experienced process control engineers do come up with their own "fudge factors" based on experience.

TABLE 2.35s

Tuning Parameters Based on the Measurement of K_u and P_u Recommended by Ziegler–Nichols for a Noninteracting Controller

Type of Controller	*P (gain)*	*I (minutes/repeat)*	*D (minutes)*
P	0.5 K_u	—	—
PI	0.45 K_u	$P_u/1.2$	—
PID	0.6 K_u	$P_u/2$	$P_u/8$

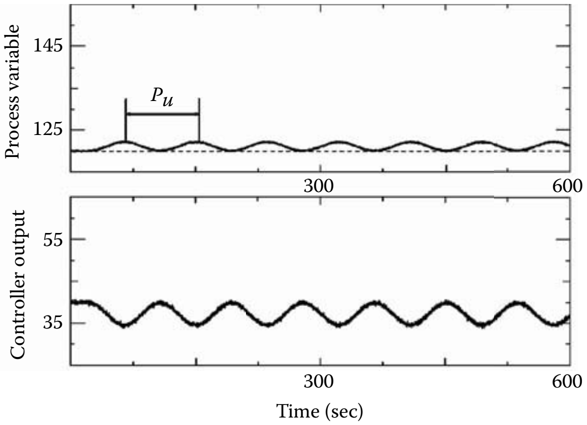


FIG. 2.35t

Ultimate cycling response of the same process that was tested in Figure 2.35e.

In order to use the ultimate gain and the ultimate period to obtain the controller settings for proportional controllers, Ziegler and Nichols correlated the decay ratio vs. gain expressed as a fraction of the ultimate gain for several systems. From the results they concluded that if the controller gain is set to equal one-half of the ultimate gain, it will often give a decay ratio of 1/4, i.e.,

$$K_c = 0.5K_u \text{ (PB} = 2\text{PB}u) \qquad \textbf{2.35(13)}$$

By analogous reasoning and testing, the equations in Table 2.35s were found to also give reasonably good settings for noninteracting two- and three-mode controllers. Again it should be noted that these equations are empirical and exceptions abound. For the same example as before, Figure 2.35t illustrates the ultimate cycling response.

The ultimate gain and period obtained from Figure 2.35t are: $K_u = 7.75$ and $P_u = 87$ s.

Hence the recommended tuning settings for the process that was used in the example are: $K_p = 3.49$ and $T_i = 1.21$ minutes.

There are a few exceptions to the tuning procedure described here because in some cases, decreasing the gain makes the process more unstable. In these cases, the "ultimate" method will not give good settings. Usually in cases of this type, the system is stable at high and low values of gain but unstable at intermediate values. Thus, the ultimate gain for systems of this type has a different meaning. To use the ultimate method for these cases, the lower value of the ultimate gain is sought.

Advantages and Disadvantages The main advantage of the closed-loop tuning method is that it considers the dynamics of all system components and therefore gives accurate results at the load where the test is performed. Another advantage is that the readings of K_u and P_u are easy to read and the period of oscillation can be accurately read even if the measurement is noisy.

TABLE 2.35u
Harriott Tuning Parameters for a Noninteracting Controller Calculated from $K_{c1/4}$ Obtained to Reach a Quarter-of-Amplitude Decay

Type of Controller	*P (gain)*	*I (minutes/repeat)*	*D (minutes)*
P	$K_{c1/4}$	—	—
PID	adjusted	$P/1.5$	$P/6$

The disadvantages of the closed-loop tuning method are that when tuning unknown processes, the amplitudes of undampened oscillations can become excessive (unsafe) and the test can take a long time to perform. One can see that when tuning a slow process (period of oscillation of over an hour), it can take a long time before a state of sustained, undampened oscillation is achieved through this trial-and-error technique. For these reasons, other tuning techniques have also been developed and some of them are described below.

Damped Oscillation Method

Harriott has proposed a slight modification of the previous procedure. For some processes, it is not feasible to allow sustained oscillations and therefore, the ultimate method cannot be used. In this modification of the ultimate method, the gain (proportional control only) is adjusted, using steps analogous to those used in the ultimate method, until a response curve with 1/4 of the decay ratio is obtained. However, with this tuning method, it is necessary to note only the period P of the response.

Again it should be noted that the equations in Table 2.35u are empirical and exceptions abound.

Example for Damped Cycling From Figure 2.35v the gain and period are found to be $K_{c1/4} = 7.75$ and $P = 87$ s. Hence the recommended tuning settings for the PI controller are $K_p = 3.49$ and $T_i = 1.21$ minutes.

After these modes are set, the sensitivity is again adjusted until a response curve with 1/4 of a decay ratio is obtained.

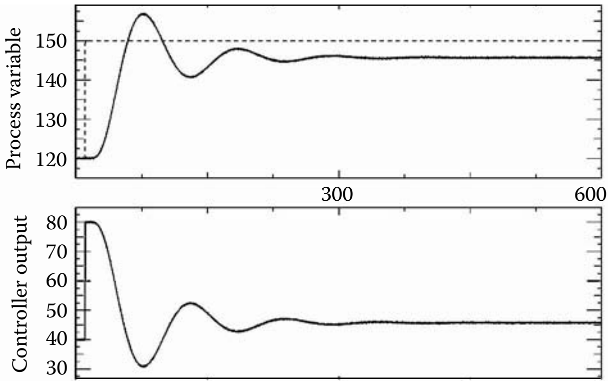

FIG. 2.35v
Damped cycling for the example.

This method usually requires about the same amount of work as the ultimate method since it is often necessary to experimentally adjust the value of the gain to obtain a decay ratio of 1/4. It is also possible to use this method to use a different decay ratio criterion.

Advantages and Disadvantages In general, there are two major disadvantages to the ultimate and damped oscillation methods. First, both are essentially trial-and-error methods, since several values of gain must be tested before the ultimate gain or the gain to give a 1/4 decay ratio are to be determined. To make one test, especially at values near the desired gain, it is often necessary to wait for the completion of several oscillations before it can be determined whether the trial value of gain is the desired one.

Second, while one loop is being tested in this manner, its output may affect several other loops, thus possibly upsetting an entire unit. While all tuning methods require that some changes be made in the control loop, other techniques require only one and not several tests, unlike the closed-loop methods.

Also, if the tuning parameters are too aggressive, the expected response can be obtained by increasing the proportional band (or decreasing the proportional gain). The integral and derivative settings probably need to be modified. The proportional gain has to be reduced to 3.5 to have a quarter-of-amplitude decay.

COMPARISON OF CLOSED AND OPEN LOOP

Table 2.35w provides a comparison of open-loop and closed-loop results for the process example used in Figure 2.35e.

FREQUENCY RESPONSE METHODS

Frequency response methods for tuning controllers involve first determining the frequency response of the process, which is a process characteristic. From this, tuning can be developed. Frequency response methods (FRM) may have several advantages over other methods: These are:

1. FRM require only one process bump to identify the process. The bump can be a change in automatic or manual,

TABLE 2.35w
Comparison of Closed and Open Loop Test Results

	Type of Tuning Test	K_c	T_i *(min)*
Open loop	Reaction curve	3.91	1.28
	Model Fit 2	3.18	1.28
Closed loop	Closed loop, ultimate cycling	3.49	1.21
	Closed loop, damped cycling	3.5	1.20

and be either a pulse, step, or other type of bump. A setpoint change provides excellent data from FRM.

2. FRM do not require any prior knowledge of the process dead time or time constant. With the other time response methods, one often needs a dead time estimate and a time constant estimate.
3. FRM do not require any prior knowledge of the process structure. Time response methods often require the user to have such model structure knowledge, i.e., whether it is first or second order or whether it is an integrator. For FRM-based tuning none of this is required; only the process data are needed.

Obtaining the Frequency Response

The process frequency response is a graph of amplitude ratio and phase vs. oscillation or sine wave frequency. If one injects a sine wave into a linear process at the controller output, the PV will also display a sine wave. The output (PV) sine wave will probably be of smaller height relative to the input and will be shifted in time.

The ratio of the heights is the amplitude ratio at the frequency of the input sine wave. The shift in time is the phase shift or phase lag. A time shift resulting in the trough of the output when aligned with the crest of the input is generally thought to be 180 degrees out of phase or 180 degrees of phase lag.

By applying a variety of sine wave inputs to a process, one can obtain a table of amplitude ratios and phase lags dependent on the sine wave frequency. If one plots these, the result will be the frequency response of the process.

Using Fourier analysis computer software programs one can calculate the process frequency response from a bump, pulse, or any other signal that applies sufficient excitation to the controller output. In the evaluation both the CO and PV trends are used. The data provided for these programs should start from a settled state, experience a quick change, and end settled.

Any one of the responses in Figures 2.35e, g, h, i, o, p, q, and v would provide adequate data for frequency response–based testing. Figure 2.35x shows the typical frequency response arrived at by the use of computer software.

PID Tuning Based on Frequency Response

In most processes, both the amplitude ratio and the phase angle will decrease with increasing frequencies. Assuming

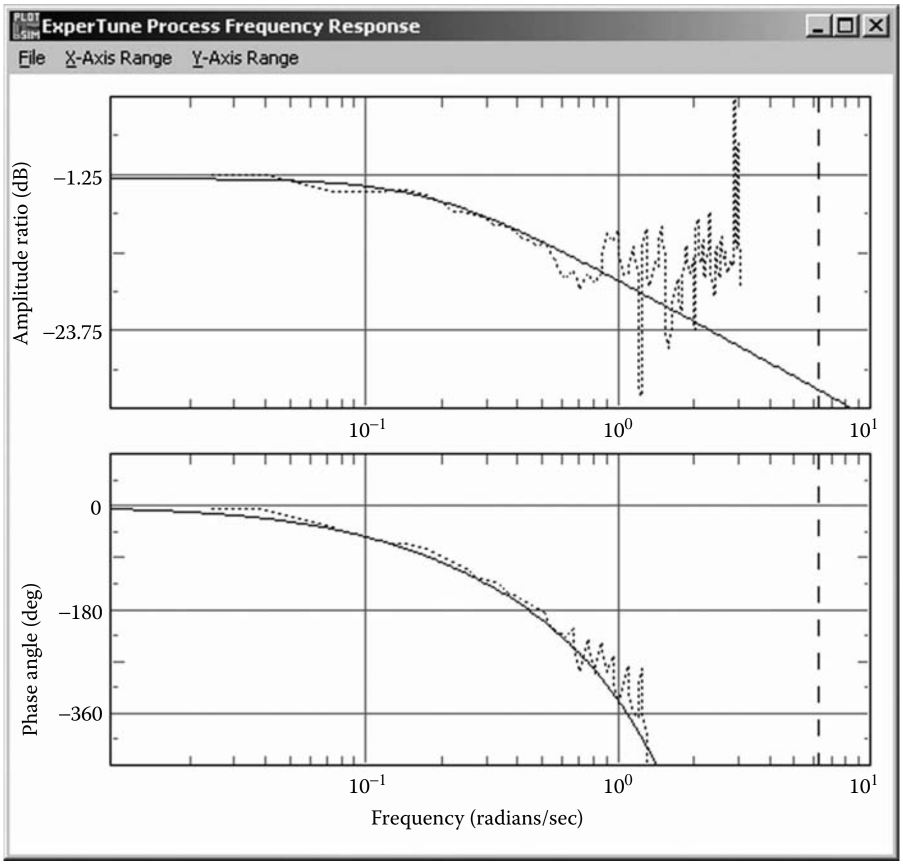

FIG. 2.35x
Typical model (solid line) and actual (dash line) process frequency response.

that the combined phase and amplitude ratio decreases with frequency when the process and the controller frequency responses are combined, the following general stability rule applies: A control system will be unstable if the open-loop frequency response has an amplitude ratio that is larger than one when the phase lag is 180 degrees.

To provide proper tuning, a margin of safety in the gain and phase is desired. Tuning constants are therefore adjusted to result in the highest gain at all frequencies and yet achieve a certain margin of safety or stability. This is best accomplished using computer software.

FINE TUNING

The performance of a controller can be tested by simulating a load change in the closed loop as described at the beginning of this section. This can be especially useful if the initial tuning is not satisfactory or if the process characteristics have changed. It is simply a trial-and-error method of recognizing and approaching an optimum — or otherwise desirable — load response.

Optimum Load Response

As described earlier, the optimum load response is generally considered to be that which has a minimum IAE, in that it combines minimum peak deviation with low integrated error and short settling time. The second curve from the bottom in each of Figures 2.35y and z represents a minimum-IAE load response for a distributed lag under PI control.

This second curve from the bottom has a symmetrical first peak, low overshoot, and effective damping. The time scale of these curves is normalized to the 63.2% open-loop step response of the distributed lag, identified as $\Sigma\tau$. On either side of the optimum curve in both figures are other response curves, which were produced by changing one of the controller settings.

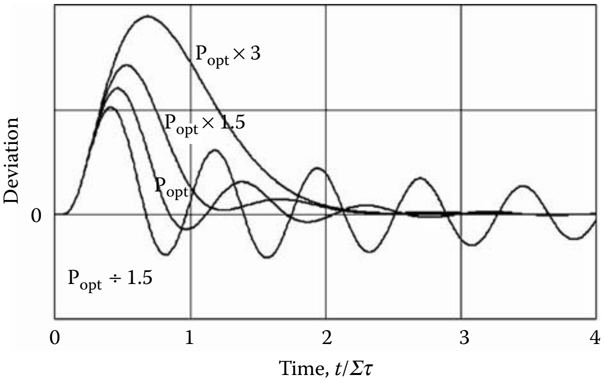

FIG. 2.35y
The proportional setting affects the height of the first peak and its symmetry.

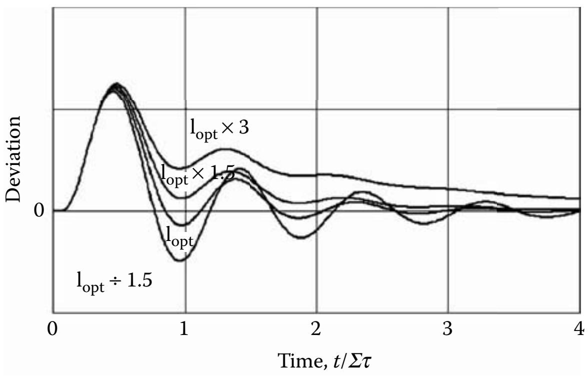

FIG. 2.35z
The integral setting primarily affects the location of the second peak.

In Figure 2.35y, the proportional band of the controller is the parameter being adjusted. Note that increasing the proportional band increases the height of the first peak and also its damping; but along with the increased damping comes a loss of symmetry. In Figure 2.35z, it is the integral time of the controller that is being adjusted. Note that it has no effect at all on the first peak but determines the location of the second, i.e., the overshoot or undershoot of the process variable's deviation.

The integrated error IE of a standard PID controller varies directly with the product of its proportional band and integral time. While increasing either of these settings improves damping, it also increases IE in direct proportion, and therefore it costs performance. Increasing both settings above their optimum compounds this effect.

Effect of Load Dynamics

All of the tuning rules described in this section to optimize load regulation will apply only to loops in which the dynamics in the load path are identical to those in the path of the controller output. Yet Figure 2.35a shows the possibility that the dynamics are different in the two paths, for example in the case of heat exchangers.

Any dead time in the load path, or variation thereof, will have no effect on the load response curve, simply delaying it by more or less time. The dominant lag in the load path is what determines the shape of the leading edge of the response curve.

As a demonstration, a distributed lag in a PI control loop was simulated to assess the effects of variations in load dynamics. Three different load-response curves appear in Figure. 2.35aa representing ratios of $\Sigma\tau_q/\Sigma\tau_m$ varying from 0.5 to 2, where subscripts q and m identify the load and manipulated-variable paths, respectively.

In all three cases, the PI controller has been tuned to minimize IAE following a simulated load change, simulated by stepping the controller output, which produces the center curve represented by $\Sigma\tau_q/\Sigma\tau_m = 1$. However, when a true load step

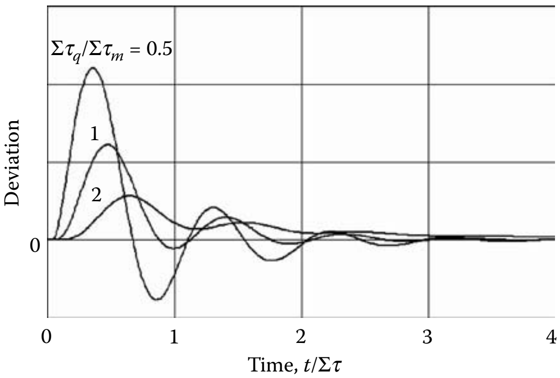

FIG. 2.35aa
Load dynamics affect the shape of the response curve.

passes through different dynamics than in the controller-output path, the resulting response curve is no longer minimum-IAE.

As might be expected, faster dynamics in the load path produce a faster rising deviation, which therefore peaks at a higher value before the controller can overcome it. The larger peak is then followed by a large overshoot. By contrast, slower dynamics in the load path reduce the peak deviation, followed by an undershoot. The IAE for the curve where $\Sigma\tau_q/\Sigma\tau_m = 0.5$ is actually only 6% higher than the minimum, but for the case where $\Sigma\tau_q/\Sigma\tau_m = 2$, the IAE is actually 53% above the minimum, indicating substantial need for correction. The appearance of the exaggerated overshoot and the undershoot indicate that those responses are no longer minimum-IAE, and that the integral time needs adjusting. Retuning the controllers for minimum-IAE response in the presence of different load dynamics resulted in the development of the correction factors plotted in Figure 2.3bb.

To use these factors, one should first tune the controller to minimize IAE following a load change simulated by stepping the controller output. After that the appropriate correction factors should be found for the expected ratio of load-to-manipulated lag $\Sigma\tau_q/\Sigma\tau_m$.

The integral time will need correcting regardless of the controller used—it must be multiplied by a factor represented by the top curve for a PID controller and the middle curve for a PI controller. If the controller is a noninteracting (ideal, parallel) PID, then its proportional band should be multiplied by the correction factor, which is indicated by the dashed line. PI and interacting (series) PID controllers do not require a correction to the proportional setting, and no correction to the derivative setting is required for any controller.

Symbols, Abbreviations

CO	Controller output
FRM	Frequency response method
G_p	Process gain
IAE	Integral of absolute error
IE	Integral error
ISE	Integral of squared error
ITAE	Integral of absolute error × time
ITSE	Integral of squared error × time
K_p	Proportional gain for a PID controller
K_u	Ultimate controller gain
PV	Process variable or measurement
R_r	Reaction rate, slope
RRT	Relative response time, the time to remove most of a disturbance
SP	Set point
τ (Tau)	Process time constant (seconds)

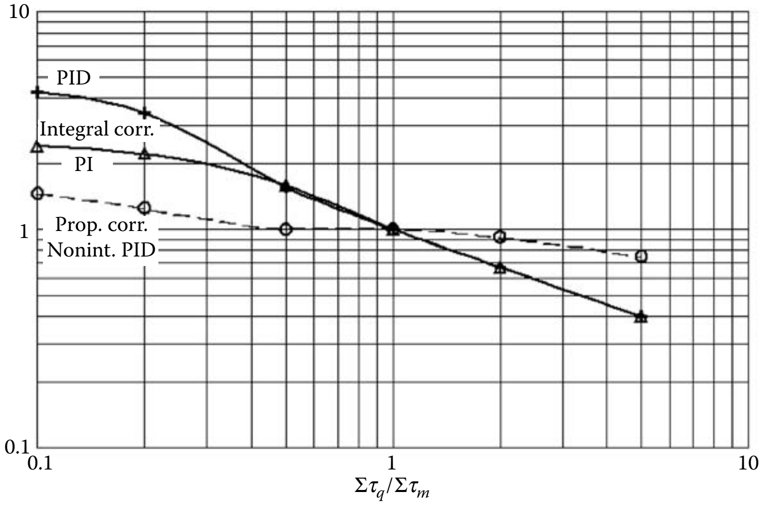

FIG. 2.35bb
To obtain minimum-IAE response, integral time and possibly the proportional band may require correction for load dynamics.

$t_0(t_d)$ Process dead time (seconds)

T_i Integral time (s) -for a PID controller

T_d Derivative time (s) for a PID controller

τ_F PV filter time constant

t_u Ultimate period

2.36 Tuning Level Control Loops

H. L. WADE (2005)

INTRODUCTION

Liquid level control loops, while among the most common control loops, have some unique and very distinctive characteristics:

- Liquid level is usually not a self-regulating process, but an integrating one.
- Intuitive general rules of thumb used for tuning, such as "If it's cycling, reduce the gain." do not apply and will often produce the opposite effect.
- Liquid level control loops, if once properly tuned, do not usually need retuning, although they may *appear* to go out of tune due to the onset of valve sticking.

This section first presents an approach to level control tuning, which is based on an idealized process model. Many actual level control loops can be approximated by this idealized process model. Later in the section, some of the characteristics of nonidealized level control systems are considered.

Most processes require extensive testing to obtain even their approximate process models. Most liquid level control loops, however, readily yield to an analytical approach because their process models can be formulated, desired performance parameters established, and from this their controller tuning parameters can be calculated. Once this is done, other attributes of the control loop such as the period of oscillation can be predicted.

The counterintuitive nature of level controllers makes their tuning by trial-and-error techniques difficult. On the other hand, the determination of their tuning parameters by analytical means is a natural choice and for that reason liquid level control loops should be engineered, not tuned.

In the following paragraphs, the discussion will start with an ideal model. After that, some of the nonideal characteristics of real installations and worst-case conditions (even if they are very unlikely to occur) will be discussed.

IDEALIZED MODEL

An idealized liquid level control system is shown in Figure 2.36a. Attributes of this idealized system are:

- The tank has constant cross-sectional area.
- The level controller is cascaded to a flow controller.
- A valve positioner is installed on the flow control valve.
- All inflow goes to outflow; the tank is merely a buffer storage tank.
- The maximum outflow is the same as the maximum inflow.
- The tank is of significant size relative to the flow rates.
- There is no thermal effect such as in the case of boiler drum level control.
- The level controller set point is constant.

The consequences of the above attributes are:

- The level process is linear.
- Up- or downstream pressure, line loss, or pump curve have no effect on loop behavior.

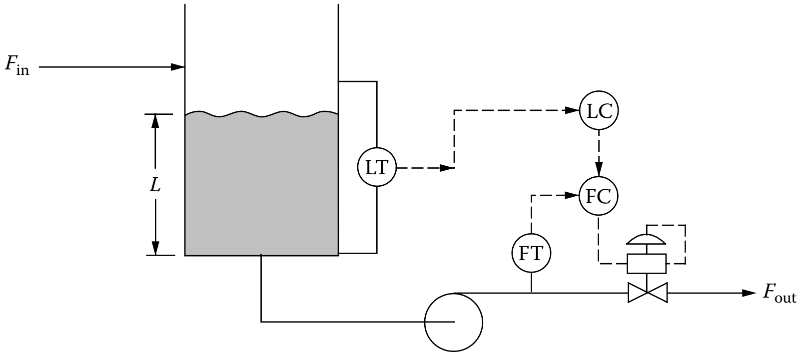

FIG. 2.36a
Liquid level control of an ideal process.

- The control loop performance is not affected by valve size.
- There is no dead time in the loop.
- The speed of response of the flow loop is significantly faster than that of the level in the tank; therefore, the dynamics can be ignored.
- Response to set-point change need not be considered because set-point changes are rarely made. The critical consideration is the response of the loop to load disturbances.

Figure 2.36a describes a common installation where the level controller manipulates the outflow from the tank in response to changes in inflow. The level controller can also manipulate the inflow in response to varying demands for the outflow. The discussion in the following paragraphs is applicable to both cases.

Time Constant of the Tank

A key parameter for the analysis of this process is the tank holdup time, also called the *tank time constant.* If the tank geometry (diameter and distance between the level taps) and maximum outflow rate (flow rate corresponding to 100% of the level measurement span) are known, then the tank time constant can be calculated as

$$T_L = \frac{Q}{F} \qquad \mathbf{2.36(1)}$$

where T_L = tank time constant; Q = tank hold up quantity, between upper- and lower-level sensor taps; and F = maximum flow rate. Q and F should be in compatible units, such as "gallons" and "gallons per minute," in which case the time constant will be in minutes.

A block diagram of the control loop with a PI controller is shown in Figure 2.36b. If the loop operates at constant set point, then the response to a load disturbance (i.e., to a change in the inflow F_{in}) is of more interest, and the set-point response can be neglected. However, in addition to the response of the level to a change in F_{in}, there is also interest in the response of the outflow, F_{out}, to a change in. F_{in}. The transfer functions of these two responses can be derived from Figure 2.36b:

$$\frac{L(s)}{F_{\text{in}}(s)} = \frac{\frac{s}{T_L}}{s^2 + \frac{K_C}{T_L}s + \frac{K_C}{T_I T_L}} \qquad \mathbf{2.36(2)}$$

$$\frac{F_{\text{out}}(s)}{F_{\text{in}}(s)} = \frac{\frac{K_C}{T_L}s + \frac{K_C}{T_I T_L}}{s^2 + \frac{K_C}{T_L}s + \frac{K_C}{T_I T_L}} \qquad \mathbf{2.36(3)}$$

where K_C is the controller gain; T_I is the integral time of the controller in minutes per repeat; and T_L is the time constant of the tank in minutes.

According to these equations, the loop acts as a second-order system. These transfer functions can also be written using the traditional servo-mechanism terminology as

$$\frac{L(s)}{F_{\text{in}}(s)} = \frac{\frac{s}{T_L}}{s^2 + 2\zeta\omega_n s + \omega_n^2} \qquad \mathbf{2.36(4)}$$

$$\frac{F_{\text{out}}(s)}{F_{\text{in}}(s)} = \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \qquad \mathbf{2.36(5)}$$

where ζ, the damping factor, and ω_n, the natural frequency, are given by

$$\zeta = \frac{1}{2}\sqrt{\frac{K_C T_I}{T_L}} \qquad \mathbf{2.36(6)}$$

$$\omega_n = \sqrt{\frac{K_C}{T_I T_L}} \qquad \mathbf{2.36(7)}$$

The damping factor is a dimensionless number; the natural frequency is in radians per minute, if T_I is in minutes per repeat and T_L is in minutes.

Many practicing engineers may be more familiar with the term decay ratio (DR), rather than the damping

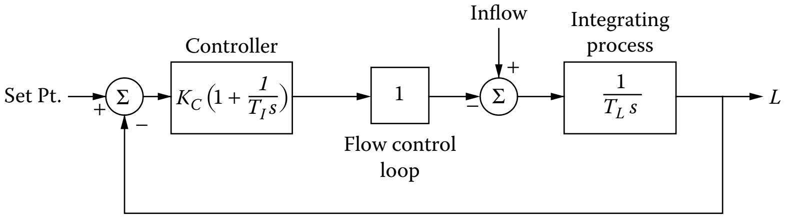

FIG. 2.36b
Block diagram of a liquid level control loop for an ideal process.

TABLE 2.36c
Equations for Calculating the Tuning Parameters of a PI Level Controller for an Ideal Level Process

Tuning Parameter	Underdamped ζ < 1		*Critically Damped* ζ = 1
	Rigorous	*Simplified*	
K_C	$2\zeta e^{-\zeta f(\zeta)}\left(\frac{\Delta F_{\text{in}}}{\Delta L_{\max}}\right)$	$2\zeta e^{-\zeta f(\zeta)}\left(\frac{\Delta F_{\text{in}}}{\Delta L_{\max}}\right)$	$\frac{2}{e}\left(\frac{\Delta F_{\text{in}}}{\Delta L_{\max}}\right)$ $(e = 2.71828\cdots)$
T_I	$2\zeta e^{\zeta f(\zeta)}\left(\frac{T_L\,\Delta L_{\max}}{\Delta F_{\text{in}}}\right)$	$4\zeta^2\left(\frac{T_L}{K_C}\right)$	$4\left(\frac{T_L}{K_C}\right)$

factor, ζ. The damping factor and decay ratio are related as follows:

$$\zeta = \frac{-\ln(\text{DR})}{\sqrt{4\pi^2 + (\ln(\text{DR}))^2}} \qquad \textbf{2.36(8)}$$

$$DR = \exp\left(\frac{-2\pi\zeta}{\sqrt{1-\zeta^2}}\right) \qquad \textbf{2.36(9)}$$

For example, the familiar quarter-amplitude decay ratio in terms of damping factor is $\zeta = 0.215$.

Determining Tuning Parameters

In addition to knowing the tank hold-up time, T_L (see Equation 2.36[1]), the analytical determination of tuning parameters requires choosing values for three design parameters:

1. ΔF_{in}—The maximum anticipated step change in disturbance (inflow) that can be expected, in percent of full scale measurement of the inflow
2. $\Delta L_{\max}$—The maximum allowable deviation from set point, in percent of full scale level measurement, resulting from a step disturbance of size ΔF_{in}
3. DR—the desired decay ratio after such a step disturbance

Once the above three values have been determined, a value for T_L can be obtained and Equation 2.36(8) can be used to convert decay ratio to damping factor. This will then permit one to derive the equations tabulated in Tables 2.36c, 2.36d, and 2.36e.

Table 2.36c provides equations to calculate tuning parameters, while Tables 2.36d and 2.36e give equations for the calculation of various characteristics of the level in the tank and of the response to a step change in inflow. In Tables 2.36c, 2.36d, and 2.36e:

$$f(\zeta) = \frac{1}{\sqrt{1-\zeta^2}}\tan^{-1}\frac{\sqrt{1-\zeta^2}}{\zeta} \qquad \textbf{2.36(10)}$$

TABLE 2.36d
Equations for Calculating Some of the Predicted Behavior Attributes of Control on an Ideal Level Process

Behavior Attribute	Underdamped ζ < 1		*Critically Damped* ζ = 1
	Rigorous	*Simplified*	
Arrest time—T_{aL}	$f(\zeta)e^{\zeta f(\zeta)}\left(\frac{T_L\,\Delta L_{\max}}{\Delta F_{\text{in}}}\right)$	$\frac{f(\zeta)}{2\zeta}T_I$	$\frac{T_I}{2}$
Period—P	$\frac{2\pi}{\sqrt{1-\zeta^2}}e^{\zeta f(\zeta)}\left(\frac{T_L\,\Delta L_{\max}}{\Delta F_{\text{in}}}\right)$	$\frac{\pi}{\zeta\sqrt{1-\zeta^2}}T_I$	N/A
IAE	$\left(\frac{1+e^{\frac{-\zeta\pi}{\sqrt{1-\zeta^2}}}}{1-e^{\frac{-\zeta\pi}{\sqrt{1-\zeta^2}}}}\right)e^{2\zeta f(\zeta)}\left(\frac{T_L(\Delta L_{\max})^2}{\Delta F_{\text{in}}}\right)$	Same as ←	$e^2\left(\frac{T_L(\Delta L_{\max})^2}{\Delta F_{\text{in}}}\right)$

TABLE 2.36e

Equations for Calculating the Predicted Behavior Attributes of Level Controls

Behavior Attribute	*Underdamped* $\zeta < 1$ *Rigorous*	*Underdamped* $\zeta < 1$ *Simplified*	*Critically Damped* $\zeta = 1$
Maximum change in outflow $\Delta F_{\text{out-max}}$	$(1+e^{-2\zeta f(\zeta)})\Delta F_{\text{in}}$	$(1+e^{-2\zeta f(\zeta)})\Delta F_{\text{in}}$	$(1+e^{-2})\Delta F_{\text{in}}$
Arrest time—T_{aF}	$2f(\zeta)e^{\zeta f(\zeta)}\left(\dfrac{T_L\,\Delta L_{\max}}{\Delta F_{\text{in}}}\right)$	$2T_{\text{aL}}$	$2T_{\text{aL}}$
Max rate of change of outflow $\left(\dfrac{dF_{\text{out}}}{dt}\right)_{\max}$	$\zeta \le \frac{1}{2}$ $\left[\exp\left(-\zeta f(\zeta)-\dfrac{1}{\sqrt{1-\zeta^2}}\tan^{-1}\left(\dfrac{(1-4\zeta^2)\sqrt{1-\zeta^2}}{\zeta(3-4\zeta^2)}\right)\right)\right]\left(\dfrac{(\Delta F_{\text{in}})^2}{T_L\,\Delta L_{\max}}\right)$	$\zeta \le \frac{1}{2}$ Same as ←	
	$\frac{1}{2} < \zeta < 1$ $2\zeta\, e^{-\zeta f(\zeta)}\left(\dfrac{(\Delta F_{\text{in}})^2}{T_L\,\Delta L_{\max}}\right)$	$\frac{1}{2} < \zeta < 1$ Same as ←	$\dfrac{2}{e}\left(\dfrac{(\Delta F_{\text{in}})^2}{T_L\,\Delta L_{\max}}\right)$

In the three tables, the columns labeled "rigorous" provide equations that are entirely a function of the following four fixed or chosen parameters—T_L, ζ (as determined from the chosen decay ratio), ΔF_{in}, and $\Delta L_{\max}$. The column labeled "simplified" produces the same results, calculated in terms of a previously calculated quantity.

Once the tuning parameters have been calculated, the predicted behavior of the level and the outflow can be calculated from Tables 2.36d and 2.36e. In Table 2.36d, the level arrest time, T_{aL}, is the time period beginning at the disturbance and ending when the maximum deviation from set point is reached.

In Table 2.36e, the outflow arrest time, T_{aF}, is the time period that begins with the disturbance and ends when the maximum change in outflow is reached. The maximum rate of change of outflow is provided because it is this quantity, rather than the size of the outflow change itself, that can be the maximum disturbance to a downstream process unit.

The equations given in Tables 2.36c, 2.36d, and 2.36e describe this tuning technique, but they are not very useful due to the large amount of computation required. For three specific decay ratios, Tables 2.36g and 2.36h provide equations for calculating tuning settings, level and outflow parameters. The three decay ratios chosen are: 1) critically damped, 2) quarter-decay ratio and 3) 1/20 decay ratio.

The critically damped decay ratio is chosen because it is a recognized basis for tuning. Quarter amplitude damping is chosen because of its familiarity. The third response, although less familiar, is chosen because it provides both the minimum IAE and the lowest maximum rate of change in outflow. Figure 2.36f depicts the level responses when the level controllers are tuned on the basis of these three forms of responses with equal values of maximum deviation.

Tables 2.36g and 2.36h also provide correction factors to account for two real-world phenomena:

1. The use of non-cascade control
2. The presence of dead time in the control loop

In the equations, θ is the ratio,

$$\frac{\text{Dead time}}{T_L}$$

and K_V is the valve gain. The correction factors were determined as a "best fit" to simulation results, for the values of θ between 0.0 and 0.5.

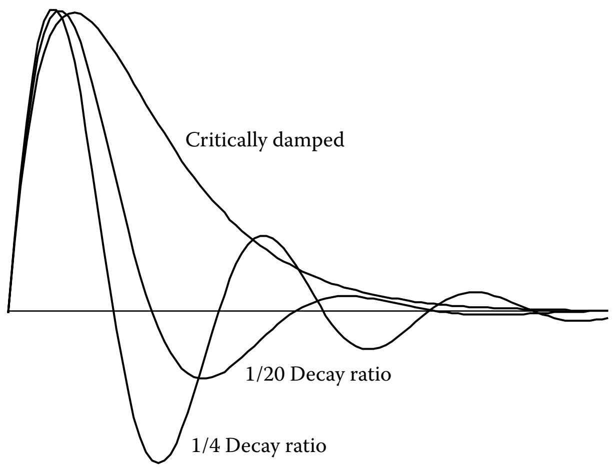

FIG. 2.36f

Response of the levels to equal maximum deviation when the controllers are tuned for the noted three decay ratios.

TABLE 2.36g

Working Equations for Calculating Tuning Parameters for a PI Level Controller for a Process with Dead Time and Non-Cascade Control

ΔF_{in} = max. step change in disturbance

$L_{\max}$ = max. allowable deviation of level from set point

T_L = hold up time, minutes

$\theta = \dfrac{\text{Date Time}}{T_L} \quad (0 \le \theta \le 0.5)$

K_V = Valve Gain, if non-cascade = 1.0 if level is cascaded to flow

Decay Ratio DR	*Damping Factor* ζ	*Gain* K_C	*Integral Time* T_I
Critically damped	1.0	$\dfrac{0.74\,\Delta F_{\text{in}}}{(1-\theta)^{0.5}\,K_V\,\Delta L_{\max}}$	$\dfrac{4.0\,T_L}{(1-\theta)^{0.5}\,K_V K_C}$
0.05	0.430	$\dfrac{0.5\,\Delta F_{\text{in}}}{(1-\theta)\,K_V\,\Delta L_{\max}}$	$\dfrac{0.74\,T_L}{(1-\theta)^{1.25}\,K_V K_C}$
0.25	0.215	$\dfrac{0.32\,\Delta F_{\text{in}}}{(1-\theta)^{1.5}\,K_V\,\Delta L_{\max}}$	$\dfrac{0.19\,T_L}{(1-\theta)^{2.4}\,K_V K_C}$

Example

Assume that a tank has the following specifications:

Tank diameter 5.0 feet
Distance between level transmitter taps 8.0 feet
Maximum outflow (upper end of outflow transmitter span) 250 gpm

Assume also that the level controller is the cascade master of a flow controller (valve gain $K_V = 1.0$), and that there is no dead time in the loop (the dead-time/T_L ratio = $\theta = 0$). The tank holdup time is calculated by:

$$\text{Surge volume} = \frac{\pi}{4} \times 5^2 \times 8 = 157.3 \text{ ft}^3$$

$$\text{Surge quantity} = Q = 157.3 \text{ ft}^3 \times 7.48 \frac{\text{gal}}{\text{ft}^3} = 1176.6 \text{ gal}$$

$$\text{Hold up time} = T_L = \frac{1176.6}{250} = 4.7 \text{ min}$$

Also, assume that the worst-case disturbance is anticipated to be a step change in inflow of 10%. In the event of this disturbance, the maximum level deviation should not exceed 5% (about 5 inches) and the system should settle out rapidly, so a decay ratio of 0.05 is chosen.

$$\Delta F_{\text{in}} = 10\%$$

$$\Delta L_{\max} = 5\%$$

With these data, Table 2.36g can be used to calculate tuning parameters:

$$K_C = \frac{0.50 \times 10}{5} = 1.0$$

$$T_I = \frac{0.74 \times 4.7}{1.0} = 3.45 \text{ min/repeat}$$

Tables 2.36h and 2.36i can be used to predict the level and outflow response:

TABLE 2.36h

Working Equations for Calculating Predicted Behavior Attributes of Level Response to a Step Change in Inflow, Level Control Loop with Dead Time and Non-Cascade Control

Decay Ratio DR	*Level Arrest Time* T_{aL}	*Period* P	*IAE*
Critically Damped	$0.5(1-\theta)^{0.96}T_I$	Not Applicable	$7.39(1-\theta)^{0.52} \times T_L \dfrac{\Delta L^2_{\max}}{\Delta F_{\text{in}}}$
0.05	$1.45(1-\theta)^{0.70}T_I$	$8.09(1-\theta)^{1.13}T_I$	$4.61(1-\theta) \times T_L \dfrac{\Delta L^2_{\max}}{\Delta F_{\text{in}}}$
0.25	$3.22(1-\theta)^{0.47}T_I$	$14.93(1-\theta)^{1.56}T_I$	$5.45(1-\theta)^{0.54} \times T_L \dfrac{\Delta L^2_{\max}}{\Delta F_{\text{in}}}$

TABLE 2.36i

Working Equations for Calculating Predicted Behavior Attributes of Outflow Response to a Step Change in Inflow; Level Control Loop with Dead Time and Non-Cascade Control

Decay Ratio *DR*	*Outflow* $\Delta F_{out\text{-}max}$	*Outflow Arrest Time* T_{aF}	*Outflow* *Max Rate of Change*
Critically Damped	$\dfrac{1.14\Delta F_{\text{in}}}{(1-\theta)^{0.1}}$	$1.0\ (1-\theta)^{1.26}T_I$	$\dfrac{0.74}{(1-\theta)^{0.70}}\times\dfrac{\Delta F_{\text{in}}^2}{T_L\Delta L_{\max}}$
0.05	$\dfrac{1.34\Delta F_{\text{in}}}{(1-\theta)^{0.22}}$	$2.50(1-\theta)^{1.36}T_I$	$\dfrac{0.52}{(1-\theta)^{1.37}}\times\dfrac{\Delta F_{\text{in}}^2}{T_L\Delta L_{\max}}$
0.25	$\dfrac{1.55\Delta F_{\text{in}}}{(1-\theta)^{0.25}}$	$6.43(1-\theta)^{1.75}T_I$	$\dfrac{0.61}{(1-\theta)^{1.16}}\times\dfrac{\Delta F_{\text{in}}^2}{T_L\Delta L_{\max}}$

Level arrest time (from time of disturbance to time when maximum deviation is reached):

$$T_{\text{aL}} = 1.45 \times 3.45 = 5.0 \text{ minutes}$$

$$\text{Period } P = 8.09 \times 3.45 = 27.9 \text{ minutes}$$

The period may seem to be excessive; however, since a fast settling behavior was selected (decay ratio of 0.05), the maximum deviation during the second half-cycle will be about 1.1 inches, during the third half-cycle about 0.25 inches, and so on.

NONIDEAL PROCESSES

The discussion so far has been based on an idealized process model. Many real applications will deviate from the idealized model. In the following paragraphs some commonly encountered situations will be described, along with suggested procedures for coping with them.

Irregular Vessel Shapes

For irregularly shaped vessels, such as horizontal or spherical tanks, the direct use of the level measurement signal as the input to the level controller may result in highly nonlinear process characteristics and undesirable control loop behavior. In this case, the loop can be linearized by converting the level measurement into the volumetric holdup in the vessel, which can be computed from the vessel geometry and the actual level. In this case, the converted measurement signal should be scaled in 0 to 100% of maximum volumetric holdup.

No Cascade Loop

If the slave flow control loop shown in Figure 2.36a is not provided, then the holdup time cannot be calculated from Equation 2.36(1), because the maximum outflow cannot be related to the maximum setting of a secondary controller.

To attempt to determine the maximum outflow rate when the outlet valve is wide open would probably be futile because of the unknown variables such as line loss, pump curve effects, and hydrostatic head effects in the tank. In addition, because the process response is nonlinear, the maximum outflow rate with a wide-open valve will vary with the level in the tank.

In this case, what needs to be determined is the apparent holdup time at the nominal operating point and the valve gain. The corresponding block diagram is shown in Figure 2.36j, and the required test is illustrated in Figure 2.36k.

To determine the apparent holdup time and the valve gain at the actual operating point, the operation must be stable, the inflow and the level at the normal set point must be constant, and the controller must be in the automatic mode. In addition, the controller output should be within its extreme limits. It is necessary for inflow to remain constant during the test. The control valve modulating the outflow should have a positioner or at least be as "sticktion free" as possible.

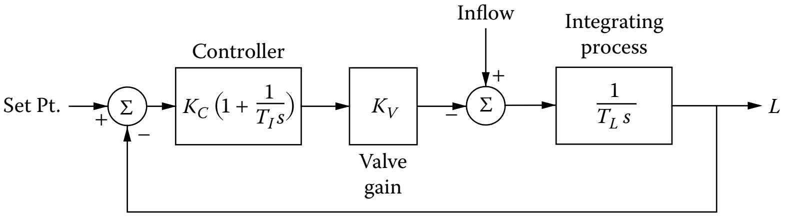

FIG. 2.36j

Block diagram of a conventional liquid level control loop, where there is no cascade slave controller and the level controller directly throttles the valve of an ideal process.

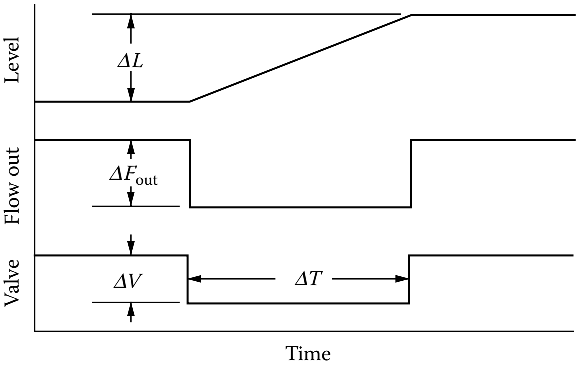

FIG. 2.36k
Illustration of a test to estimate the apparent holdup time and valve gain for noncascade level control.

The testing is done in the following sequence: First, switch the controller to manual and change the previously constant output signal by a small amount, say, $\Delta V\%$ (see Figure 2.36k). In response, the outflow will change by an amount ΔF and the level will start changing. After a certain period of time, say Δt, move the controller output back to where it was before the test. As a consequence, the level should stop changing. Once the level has stabilized, determine the change in level, ΔL, that occurred during the test.

Convert the readings for ΔL, ΔF_{out}, and ΔV into percent of full scale. The equation for estimating the apparent holdup time is

$$T_L = \frac{\Delta F_{\text{out}}\,\Delta t}{\Delta L} \qquad \textbf{2.36(11)}$$

and the valve gain is

$$K_V = \frac{\Delta F_{\text{out}}}{\Delta V} \qquad \textbf{2.36(12)}$$

Dead Time

The ideal level process has neither dead time nor lag time, but real processes can have either or both. For example, in case of the level-flow cascade loop in Figure 2.36a, the flow control loop may have a finite response time. If there is a dead time in the loop, θ, the ratio of dead time to holdup time should be calculated and used in the equations listed in Tables 2.36g, 2.36h, and 2.36i. Similarly, the actual valve gain (K_V) should be used in Table 2.36g (for cascade loops, $K_V = 1.0$).

Unequal In- and Outflows

When determining step changes in the inflow to a vessel, it should always be the actual flow that enters the tank. Hence the change in feed rate, ΔF_{in}, can be due to any cause, such as actual change in vessel feed rate, change in the liquid/vapor ration of the feed, change in reboiler heat, or change in liquid load on the trays in the distillation tower.

Flashing Liquids

There are cases where flashing liquids result in a false indication of level. An example is the “shrink and swell” effect in a boiler drum. The shrink and swell effect can be approximated as dead time; hence, the dead time correction factors in Tables 2.36g, 2.36h, and 2.36i may be used.

Sinusoidal Disturbance

If a sinusoidal variation in inflow is anticipated (for instance, due to cycling of a process controller at an upstream process unit), then the maximum variation in level and the amplitude of variation of outflow should be investigated. If the frequency of the sinusoidal variation is not known in advance, then a worst case condition could be assumed for the investigation, where the frequency of inflow disturbance in the same as the natural frequency of the level control loop.

An oscillating input will cause both the level and the outflow to oscillate with the same period. If the process can be approximated by the ideal model, which was defined at the beginning of this section, and if the inflow oscillates with a known amplitude and period (P_{in}), then Figures 2.36l and 2.36m can be used to determine the amplitude of both the level and of the outflow oscillations.

The undamped natural frequency, ω_n, is calculated from the damping factor, ζ, which is obtained from Table 2.36g, based on the chosen response (decay ratio) to a step disturbance and from the tuning parameters. If the process fits the ideal process model, Equation 2.36(7) can be used to calculate ω_n. Otherwise, the period, P, given by Table 2.36h, should be used to calculate ω_n from the equation below:

$$\begin{aligned}\omega_n &= \frac{2\pi}{P\sqrt{1-\zeta^2}} && \text{if DR} = 1/20 \text{ or } 1/4 \\ &= \frac{2}{T_I} && \text{if Critically Damped}\end{aligned} \qquad \textbf{2.36(13)}$$

From the period of oscillation of the input, P_{in}, the frequency in radians per minute can be calculated from:

$$\omega = \frac{2\pi}{P_{\text{in}}} \qquad \textbf{2.36(14)}$$

The frequency ratio $\frac{\omega}{\omega_n}$ in Figure 2.36l should be used to calculate $K_C \frac{L(\omega)}{F_{\text{in}}(\omega)}$. (If the frequency of the disturbance is unknown, then for a worst case analysis, use a frequency ratio of 1.0.) From this and from the amplitude of the disturbance oscillation, $F_{\text{in}}(\omega)$, one can calculate the predicted amplitude of oscillation of level about the set point, $L(\omega)$.

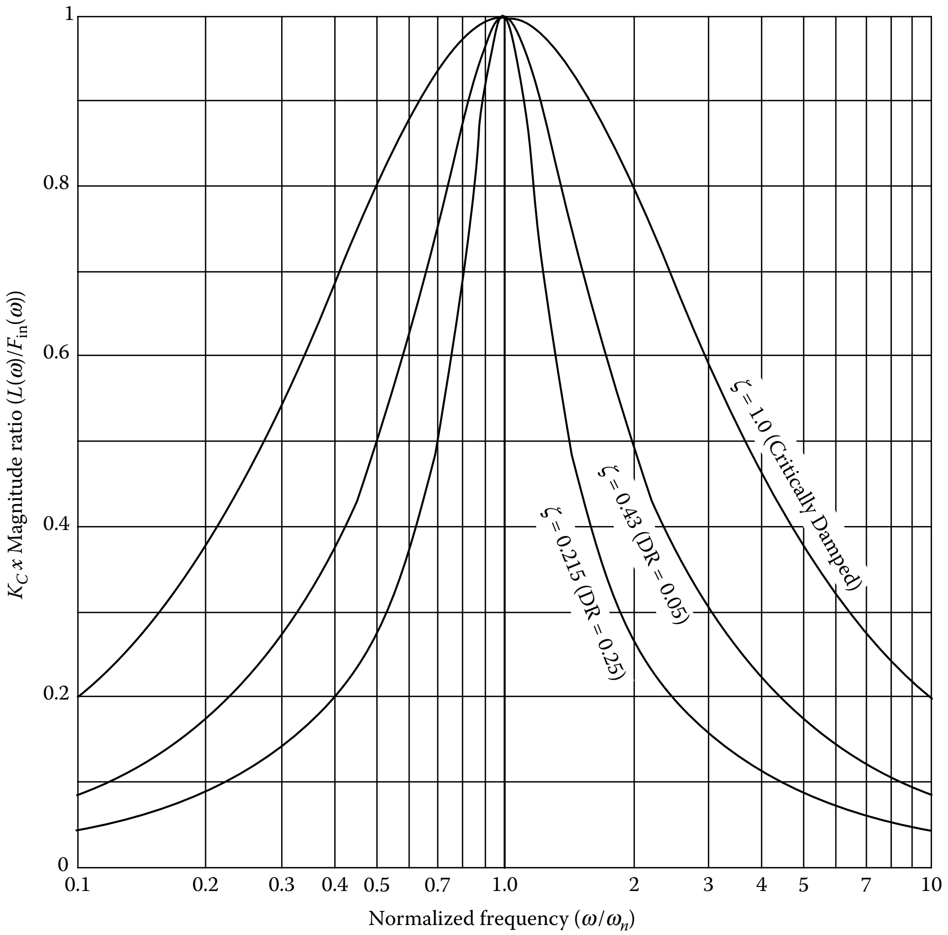

FIG. 2.36l

Magnitude ratio of changes in level to sinusoidal changes to inflow.

If the peak deviation from set point (one half the amplitude of oscillation) exceeds the allowable maximum deviation, then K_C should be increased by the relation:

$$K_{C\text{-new}} = \frac{0.5\,L(\omega)}{\Delta L_{\max}} \qquad \mathbf{2.36(15)}$$

After this, one can return to Tables 2.36g, 2.36h, and 2.36i and calculate T_I and the predicted attributes of the response.

If the magnitude and period of oscillation of the input are assumed or known, use Figure 2.36m to calculate the magnitude ratio of oscillations of outflow to inflow,

$$\frac{F_{\text{out}}(\omega)}{F_{\text{in}}(\omega)}$$

then calculate the amplitude of oscillation of the outflow.

As a final check, if there are level control loops in series, such as in case of a train of distillation towers, it is necessary to check the natural frequency of each tower. Ideally, the natural frequency of each tower should be no more than half the natural frequency of the preceding tower. Since the size of the towers (holdup time) cannot be changed, the best "handle" for adjusting the ratio of the natural frequencies is to increase $\Delta L_{\max}$ for the downstream tower or to decrease $\Delta L_{\max}$ for the tower upstream.

OTHER APPROACHES TO TUNING

Averaging Level Control

Many liquid level loops are not critical and one can tolerate fluctuation, even offset in levels, if it smooths out the flow to a downstream process unit. This can be accomplished by using a proportional-only controller. This technique is called "averaging liquid level control."[1] Assuming that the allowable excursions above and below set point are equal, then the controller gain should be set according to the equation

$$K_C = \frac{100}{2\,\Delta L_{\max}} \qquad \mathbf{2.36(16)}$$

or the proportional band should equal $2 \times \Delta L_{\max}$ and the bias (manual reset) should be set to 50%. With this arrangement, if the disturbance is such that a controller output of 50% is

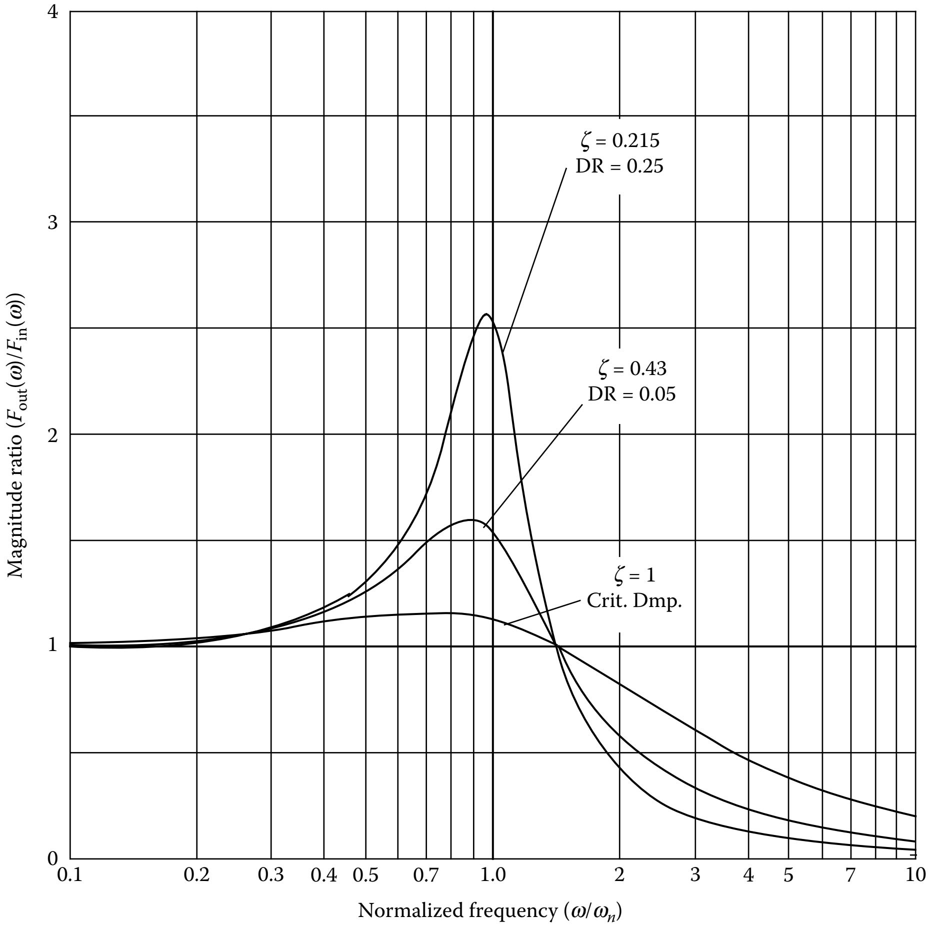

FIG. 2.36m
Magnitude ratio of changes in outflow to sinusoidal changes in inflow.

required, the level will be on set point. Otherwise, there will be a steady-state offset between set point and level measurement. When a step change in inflow occurs, the level will respond as a first-order lag with a time constant equal to the holdup time divided by the controller gain.

This technique ensures that the level never exceeds the limits because at the limits, the outflow is either at 0 or 100%. This technique also provides the lowest rate of change of the outflow, hence the minimum disturbance to a downstream processing unit. The disadvantage of this method is the fact that the level is rarely at set point. This is probably more of a disadvantage from the operator's acceptance point of view than any other.

It might appear that one could achieve the advantages of averaging level control and still maintain the level at the set point by using Equation 2.36(16) to determine the controller gain and then by using a slow reset action. Equation 2.36(6) shows, however, that a large value for T_I will produce a larger damping factor or even an overdamped response. If the response is underdamped, the loop will have a very long period; if overdamped, the return to set point will be excessive. Furthermore, with the reset action causing an effective shift of the proportional band, the positive protection of knowing exactly where the level will be when the controller output is at maximum or minimum is lost.

Controller Gain and Resonance

If it is desired to stay closer to the set point, the controller gain can be increased. Although there is no theoretical upper limit for the gain of a proportional-only controller used on an integrating process, in practice the gain will be limited by resonance that may occur within the loop.

If the level sensor is of the external cage type, then there may be a manometer effect between the liquid in the vessel and the liquid within the level sensor cage. This will appear as an oscillation within the control loop even when the total mass holdup is unchanging. If there is a large surface area of the liquid, this may result in a resonant sloshing, with a period proportional to the cross-sectional areas.

For a probe or a point-source sensor, this will also show up as an oscillation within the loop. Furthermore, splashing, such as from upper trays in a distillation tower, may result in the appearance of noise on the level measurement. Thus there will be a practical limit to the controller gain. With a high gain, any measurement noise present will cause excessive valve action. Therefore, the gain may be reduced, and some integral action is added within the controller.

Nonlinear Gain

Some manufacturers provide a nonlinear control algorithm that has the effect of increasing the controller gain as the measurement gets further away from set point. An example is the "error-squared algorithm," in which a modified error, ê, is calculated as:

$$\hat{e} = e|e|. \qquad \textbf{2.36(17)}$$

When the level is on set point, this algorithm gives a very low gain, which increases as the measurement gets further away from set point. Other manufacturers accomplish a similar operation by linear characterization of the error signal. Sometimes the nonlinear behavior is applied to only one of the controller modes, such as to the proportional mode, with the other controller mode seeing the normal error signal.

2.37 Tuning Interacting Loops, Synchronizing Loops

M. RUEL (2005)

INTRODUCTION

The reader is advised to also read Sections 2.6, 2.12, and 2.22. This is desirable to gain a full understanding of the phenomenon of interaction and decoupling; the methods discussed in this section cannot be used in all cases, and a full understanding of the other options for overcoming interactions between control loops can be helpful.

MULTILOOP SYSTEMS

When a unit process is controlled by several control loops, there is no magic formula that can tell whether one loop will affect another. This information will only come through an in-depth understanding of the process. If one loop directly interacts with another, oscillation in the first loop will cause oscillation in the second and possibly in other downstream loops. If the same pump feeds two flow loops, oscillation in one loop can cause oscillation in the second.

When a loop is cycling, it is essential to determine whether the process is causing cycling, or whether the cycling is attributable to other loops or possibly to the loop itself. To check the cause, one can switch the particular loop to manual mode; if the cycling continues, it is probable that the cycling is being caused by an external source.

There is also hidden cycling, which occurs if a cycle is present but is hidden by noise. To uncover a hidden cycle, the readings should be collected in the manual mode, and power spectral density analysis should be used on the data collected. In that case, the hidden cycles will show up as peaks.

In some installations the problem is not that the loops interact, but it is imperative that they respond with the same speed. In either case, one should be knowledgeable about the tools that are available to determine loop health and performance:

Control Loop Analysis

The following criteria should be met for a control system to perform in an optimal manner:

- The power spectral density should be flat, no cycling present.
- Cumulative power spectral density should be continuous.
- Statistical analysis: Data distribution should be a bell curve, variability should be small, valve movements should be minimized.
- Development of a process model is desirable to validate the process and to find tuning parameters.
- Robustness analysis is recommended to validate tuning parameters.
- The process should be analyzed to check for hysteresis and backlash, stiction, noise, process model inaccuracy, hidden cycling, and nonlinearities.
- Oscillation should be evaluated by determining the area under the curve, which is a good indicator of control quality.
- Cross-correlation and multivariate techniques can be used to measure interaction between signals and loops They can also help to determine whether multivariable control should be considered.
- Performance indexes, such as variability, IAE, and Harris index, should all be monitored.

INTERACTING LOOPS

An example of a control system with potentially interacting multiple loops is illustrated in Figure 2.37a. Here two liquids

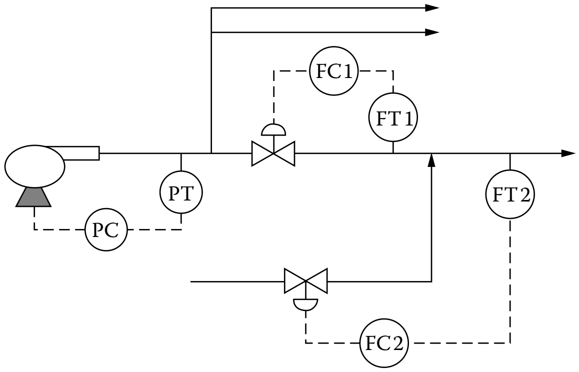

FIG. 2.37a
Illustration of potentially interacting control loops.

are being mixed. The expensive process fluid is controlled by FC1 at a flow rate of 100 GPM. The second flow controller (FC2) adds water to dilute the process fluid by maintaining the total flow between 200 and 400 GPM.

All three of these loops have the potential to be fast. A response time of less than 30 seconds is attainable on all three loops, but which loop should be the fastest? What is the logic behind this decision and why should one be faster than the others in the first place?

The reason why the speeds should be different is because if they are not, the loops can oscillate whenever an upset occurs because the correction generated by one loop upsets the others and this generates cycling. As to which loop should be the fastest, one should evaluate the process to determine which controlled variable needs to be constant in order for the other loop(s) to operate properly.

In Figure 2.37a, by observing the process we would conclude that in order for the flow loop (FC1) to function properly, the upstream pressure to its control valve has to be constant. Because that upstream pressure has to be constant regardless what the flow is, therefore, the pressure loop must be faster than flow loop #1.

If this was not the case, if the pressure loop and the #1 flow loop were tuned to have the same speed of response, they may work for a while, but eventually, when a disturbance occurs, it will cause the two loops to oscillate. For example the following sequence of events could cause oscillation in this control configuration:

1. Another user valve is suddenly closed and this disturbance causes the line pressure to increase.
2. If the pressure control loop is not faster than the flow loop, the flow through FC1 will increase.
3. To correct for the flow increase, FC1 will close down its valve, which in turn will cause the pressure to rise.
4. Eventually the pressure loop will slow down the pump, which will cause the flow to decrease.
5. As the flow drops, FC1 will open its valve to compensate, which will cause the pressure to decrease.
6. In response to the drop in pressure, the PC will speed up the pump, causing the flow to increase again.

In this configuration, if PC is not faster than FC1, steps 3, 4, 5, and 6 will repeat continuously and the two loops will oscillate and potentially resonate.

Likewise, since FC1 controls the process fluid feed to the flow loop controlled by FC2, flow loop 1 must be faster than 2. If this is not the case, a disturbance in flow 1 could cause both flow controllers to react, and oscillation would result.

Tuning to Eliminate the Interaction

When loops interact, it is necessary to make sure that their response speeds are not the same and not even similar because speeds that differ but are close also have the potential to oscillate. To be on the safe side, one should select response speeds that differ by a factor of three to five. If speeds are closer than 3:1, loops may one day start to oscillate. In case of loops that are highly interactive, a speed ratio of up to 10:1 may be required to fully decouple them.

For the control system described in Figure 2.37a, this means that the response time of the pressure loop will determine the response time of flow loop #1, and the response time of flow loop #1 will determine the response time of flow loop #2. In tuning interacting loops, one would do that by placing the downstream loop in manual while tuning the upstream loop; once the upstream loop's speed of response is determined, use a multiple of that to set the downstream controller.

So, for the control system in Figure 2.37a, one would place FC1 and FC2 in manual, while aggressively tuning the pressure controller to provide a high speed of response. The response time of the pressure control loop will determine the system response time. Once the PC is tuned, one would place the pressure loop in automatic so that to the rest of the control system, it would seem as if it were part of the process.

Flow controller FC1 is tuned next, while FC2 is still in manual. FC1 must be tuned for a response time that is at least three times slower than that of the pressure loop response time. For ideal separation it should be 5 to 10 times slower. Once FC1 is tuned, both the PC and FC1 are left in automatic, while FC2 is being tuned. Again, FC2 should be tuned for a response time which is at least 3 times (ideally 5 to 10 times) slower than flow loop FC1.

Therefore, one can sum up the tuning of the three interacting loops into the following three steps:

Step 1. Tune PC for quick response, while other loops are in manual mode. For the purposes of an example, assume that the settling time of this fastest loop turns out to be 30 seconds (Figure 2.37b).

Step 2. Tune FC1 for moderate response, while PC remains in automatic and FC2 in manual mode. Tune FC1 for a settling time of at least three times that of the PC, or at least 90 seconds (Figure 2.37c).

Step 3. Tune FC2 for a slow response while PC and FC1 both remain in the automatic mode. The settling time of FC2 should be at least three times that of the FC1, or at least 270 seconds (Figure 2.37d) .

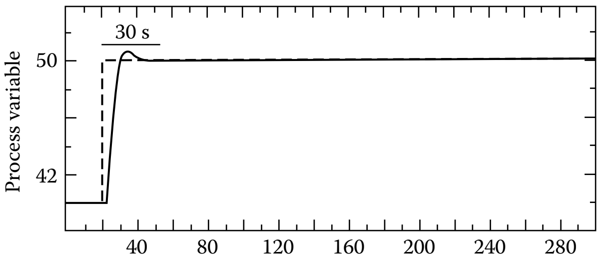

FIG. 2.37b
After the fastest loop is tuned, measuring its response time (settling time), which in this case is 30 seconds.

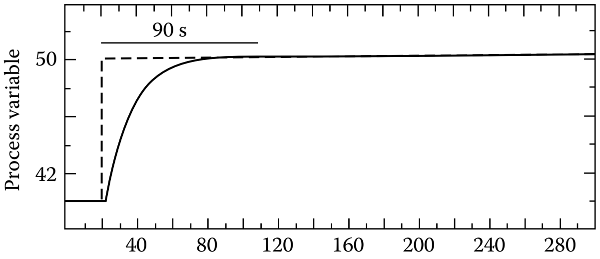

FIG. 2.37c
Tuning the less fast loop for a response time (settling time) that is three times that of the fastest loop or in this case is 90 seconds.

For a summary of the steps required in tuning any number of interacting loops, refer to Table 2.37e.

The method of removing interaction by reducing the speed of response has disadvantages because this can cause the control loops to become sluggish and unable to effectively correct upsets and disturbances. If this is the case the use of more sophisticated techniques of decoupling is recommended, as discussed in Section 2.12.

Cascade loops is another case of interacting loops. Hopefully, in a cascade system, the inner loop has to be faster than the outer loop. (See Section 2.6.)

SYNCHRONIZING LOOPS

In some control systems, the loops do not interact but they do work together. Such configurations are called synchronized loops, and it is desirable for such loops to have the same response time. It is important to note that synchronized loops should be so designed that there is no physical link between them that could cause interaction.

Batch mixing is one example of a control system that should be synchronized. Figure 2.37f illustrates a control system for mixing three ingredients in a mix tank. The goal of such a control system is to maintain the required ratio of the ingredients even during startup or shutdown or when the rate of production changes.

Because the control valves and pipe volumes associated with the three flow control loops are substantially different, it is probable that their process gains, dead times, and time constants also differ. In such cases, if all three loops were tuned for 10% overshoot (or any other criterion), the response times of the loops would not be the same. Therefore, when the rate of production rises and the level controller calls for increased flows, the recipe flow ratios will be out of balance until all three flows reach their new set points and regain stability.

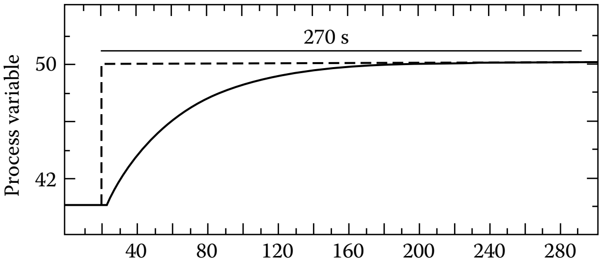

FIG. 2.37d
Tuning the least fast loop for a response time (settling time), which is three times that of the less fast loop or in this case is 270 seconds.

TABLE 2.37e
The Sequence of Steps to be Used in Tuning Any Number of Interacting Control Loops

	Fast →				**Slow**
Steps	**Loop$_1$**	**Loop$_2$**	**Loop$_3$**	...	**Loop$_n$**
1	**Tune**	Manual	Manual	Manual	Manual
2	Automatic	**Tune**	Manual	Manual	Manual
3	Automatic	Automatic	**Tune**	Manual	Manual
	...	...	...	...	...
n	Automatic	Automatic	Automatic	Automatic	**Tune**
n + 1	Automatic	Automatic	Automatic	Automatic	Automatic

To ensure that all three loops move at the same speed, one should determine the response time of the slowest loop and match the response times of the others to it. Normally, the slowest loop is also the one with the largest dead time. The steps involved in tuning synchronizing loops are:

1. Apply an upset (bump test) to each loop. This can be a temporary change of set point.

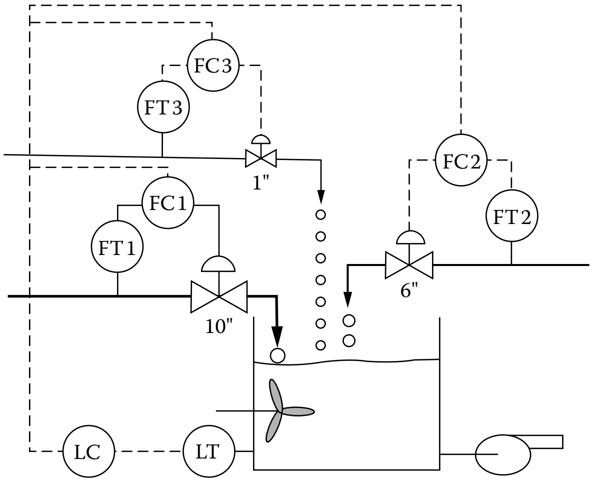

FIG. 2.37f
In order to keep the ratio of ingredients constant during load changes, the loops have to be synchronized (their speed of response has to be the same).

TABLE 2.37g
Summary of Steps Required in Tuning to Synchronize Control Loops

Steps	**Loop$_1$**	**Loop$_2$**	**Loop$_3$**	...	**Loop$_n$**
1	**Test**	**Test**	**Test**	**Test**	**Test**
2	Slowest →				
3					**Tune at maximum speed**
4	Tune at same speed				
5	Automatic	Automatic	Automatic	Automatic	Automatic

2. From the responses of the loops, determine which is slowest.
3. Tune the slowest loop for maximum speed of response and measure the response time that results.
4. Adjust the tuning parameters of the other loops so that they will also have approximately the same response time.

When tuning loops that need to work in harmony, select tuning parameters that give similar response times. If this is done using software, the expected speed can be specified. If done by hand, techniques such as pole placement, Internal Model Control, or Lambda tuning should be used.

The tuning steps that were described in Section 2.35 can all be performed automatically under computer control. The pattern recognition type self-tuning controllers do this by applying the "open-loop" method of tuning during their "pretune phase" (step change in manual mode) and by using the "closed-loop" method to evaluate the loop performance during upsets.

Computers can also perform "model-based" tuning. In that case, the performance of the proposed tuning constants is first checked on a mathematical model of the process, and only if they perform well on the model are they used on the real process. Because of the overlap between some of the earlier sections in this chapter and this one, it is suggested that the reader also read those to gain a complete understanding of the tuning capabilities of computers and of digital systems.

INTRODUCTION

Computer programs that were developed to aid in the *design* of process control systems are gaining general popularity and acceptance. Several good commercially available packages exist. These computer programs include nonlinear simulation tools, linearizing routines, predictor and estimation techniques, linear quadratic Gaussian methods, time series, and frequency response techniques. This section will discuss the approach to a design problem using such methods.

The *maintenance* of control systems is equally important as is a good workable design. Many good control schemes fall into disuse because of a lack of proper fine-tuning, failure to adapt to changing process requirements, or poor maintenance. As time progresses and the operating processes change in the plant, some controllers might have to be detuned to prevent cycling or switched to a manual mode of operation. Good maintenance cannot be substituted by tuning. If equipment fails, the loop should not be re-tuned; the piece of equipment should be repaired.

Computer-aided control analysis tools can be thought of in two categories. First there are the techniques that are useful in control system design. These are typically used in the design of new plants or new control systems. The nature of such tools is most often offline because that is the safest mode for investigating new control methods.

Maintenance-related software is the second category of the computer-aided tools of control analysis required in maintenance of existing systems. The nature of these techniques is frequently online. They involve trying to identify the process dynamics while the plant is operating. They use step testing techniques and/or recursive estimation methods for adaptive tuning. After the process model is updated, these techniques can be used to calculate new control system parameters.

In addition to keeping the controllers tuned, other methods are available to improve the quality and reliability of process measurements. Overall process balance calculations and the use of predictor/estimator filters (i.e., Kálmán filters) can help to improve the quality of measurements. These better-quality measurements are contributing to better control performance, which will be discussed in more detail in the following paragraphs.

PROCESS MODELING

A good control system can only be designed, if the process is well understood, so that it can be mathematically modeled (Sections 2.13 to 2.17). Some control systems are less sensitive to model errors than others. However, as the requirements for improved control performance increase, so does the need for model accuracy.

Process control engineers use many types of process models. Each type of model is preferred for some group of applications. Table 2.38a provides a list of some of these computer models and of their typical applications.

Time and Frequency Domains

Software packages that are available to tune loops and to optimize a process can use either time series or frequency analysis techniques. To obtain the best PID tuning settings and the best process model, frequency response methods have several advantages over other methods. These are:

- Frequency response methods require only one bump to identify the dynamics of the process.
- The bump can be made in manual mode or can be a set-point change in the automatic mode.
- The change can be a pulse, a step, or bumps of other characteristics.
- Frequency response methods do not require prior knowledge of the dead time or time constant of the process.
- In contrast, when using time response methods, one often needs an estimate of both the dead time and the time constant.
- In addition, when using time response methods, the type of the process model has to be known.

TABLE 2.38a
Types of Computer Models Used in Various Control Applications

Computer Model Type	*Typical Application*
Large-scale nonlinear dynamic simulation	Used for offline investigation of process, process dynamics, and control application; large effort required to generate models
Frequency response models, single-input single-output (SISO)	Used to investigate open-loop behavior and specify closed-loop feedback control
Frequency response models, multiple-input multiple-output (MIMO)	MIMO models are used to study interaction; model typically generated from state space models or plant testing
State space models, MIMO Continuous and discrete linear models	Used for control system design with methods such as linear quadratic optimal and pole placement control; used for estimate/predictor models; models typically generated from linearization of simulation models or plant tests
Time series models, SISO Difference equations	Used for adaptive control and state parameter estimation
Simple low order models SISO continuous time	Used for quick time domain model fits to plant tests for control-loop tuning

Currently the main tool employed for control system design is dynamic process simulation using basic physical laws such as time-dependent balance relationships of mass, heat, momentum, etc. This type of simulation effort is very time consuming and requires an in-depth understanding of the process and the availability of large dynamic modeling software packages, which are available commercially. Many of these packages have several common features.

First, the simulation models require the input of many differential equations representing the process. The packages usually handle the numerical integration and output of the desired time variables with very little effort on the part of the user.

Once the process has been adequately modeled, the control system is tuned by dynamic simulation. The time behavior of the closed-loop system is studied and is changed in order to try new intuitively devised schemes or control designs that are recommended by other computer design methods such as the linear quadratic optimal or the frequency response methods.

Single-input single-output transfer function models allow control systems to be analyzed in the frequency domain. Computer-generated graphics are used by many control analysis packages to draw root locus, Bode plots, Nichols charts, and Nyquist plots. The individual transfer function models are typically generated from linearized differential equations, plant pulse or step testing, or transformed state space models (see Section 2.33). All of these procedures have been computerized, which makes the analysis more convenient, and are very helpful in control system design and specification in the offline mode.

State Space Models

State space models are nothing more than linearized matrix representations of multiple-input multiple-output or high-order differential or difference equations. The convenient matrix formulation of the state space models makes them great candidates for manipulation and study by computer. These linear models can be used for time simulation (over the range where the linearization is valid). They can be transformed to transfer function matrix representations. They can be used to formulate linear quadratic optimal controllers. They can also be used to build predictor/estimators (i.e., Kálmán filters).

State space control models are very flexible and are a common starting point for many computer-aided control analysis packages. The state space model is useful for offline design and online analysis and recursive study.

The above techniques are basically design tools used offline. One popular online use for state space models is the estimator/predictor configuration. Here the computer evaluates the state space model of the process alongside with the real process. The measurable information about the process is fed into the computer model. The model predicts or estimates those states of the process that cannot be measured. This information is then used for the control of the process.

The methods used for estimating unmeasured states vary. One popular method is Kálmán filtering. In this method the estimated states are updated with information from the process model and measure their inputs on the basis of the statistical properties of the measurement noise. Details about Kálmán filtering and other estimation/prediction techniques can be found in References 1 and 2.

These filtering techniques improve measurement quality and utility, thus improving the entire control system. Certain modeling applications can be used to signal instrument problems by monitoring the deviation between the output that is predicted by the model and the output of the actual process. If this deviation becomes too large, it is possible that sensor maintenance is required.

Time Series Models

Time series models are also useful in adaptive control applications. Discrete time models are used to represent single-input single-output systems processes. The parameters of the time series models are estimated using recursive techniques. The updated model resets the online controller to keep the loop adequately tuned. This again is an online computer application that is primarily aimed at improving control quality.

The low-order single-input single-output continuous model consists of a series of time lags associated with loop elements (valve, process, transmitter, etc.). Usually, the controlled processes also have transport delay (pure dead time) resulting, for example, from transport lag in pipes. Unlike nuclear reactors and modern missiles, these processes are usually stable without feedback controllers, just operating in the open loop.

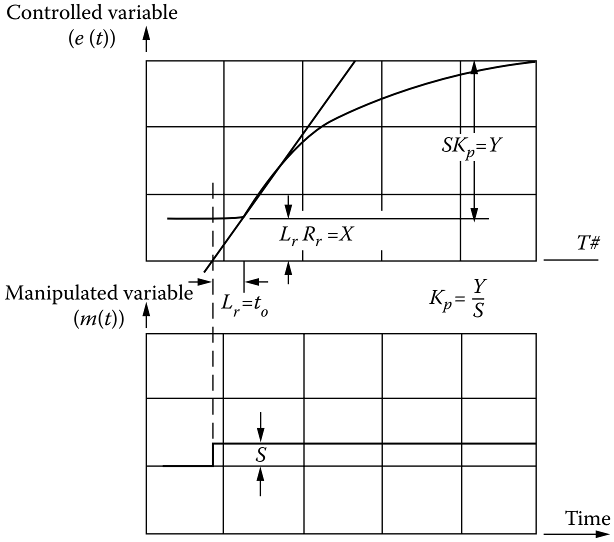
A general mathematical structure for these simple processes is composed of a first-order lag and dead time, as described in Equation 2.38(1). This model has three parameters: gain, time constant, and dead time.

$$\frac{dc(t)}{dt} = \frac{1}{\tau}[Km(t - t_0) - c(t)] \qquad \textbf{2.38(1)}$$

where t = variable time; $\frac{dc(t)}{dt}$ = derivative of the controlled variable with respect to time; $c(t)$ = controlled process variable, the output of the process; m = manipulated process variable; K = process gain; τ = process time constant; and $t_0 = t_d = L_r$ apparent process dead time.

This mathematical structure has the advantage of constrained dimensionality. Dead time in the model conveniently lumps the higher-order process time delays and the actual processes' dead time into a single parameter.

This model is used to tune a simple feedback loop by fitting the model to the process. This fitting is done by control loop tunings to achieve the desired response.



Processes that drift during the conventional step response test will invalidate the measured parameters X, Y and L_r.

FIG. 2.38b

First-order response to a step change in manipulated variable, while the controller is in manual, can determine the process gain (Kp) and dead time (Lr).

FITTING SIMPLE MODELS

Step Response

The conventional step response test (Figure 2.38b), which is performed while the controller is in manual, is probably the most popular method for fitting the three-term process model. This method works well for process loops that, after an upset, will achieve a new steady state. In addition, the common characteristics of these processes is that their time constant τ is small and that they do not appreciably drift during the test.

However, if the process gain ($K_p = Y/S$) is unknown, which is often the case, this technique has the disadvantage that the step size (S) must be selected by trial and error. This is because too small a step might provide a reaction curve that is hard to read, and too large a step might result is an unacceptable upset.

To fit this three-parameter model to the process while using this test, the following measurements have to be made manually or automatically:

1. Step size of the manipulated variable (S)
2. The apparent dead time ($L_r = t_0$)
3. The total change in the controlled variable ($X = L_r R_r$) over the period of the apparent dead time ($L_r = t_0$), if the controlled variable is changing at its maximum rate of change (R_r)
4. The final value controlled variable's response (Y)

After these four values have been obtained, the following parameters can be determined:

$$R_r = \frac{X}{SL_r} \tag{2.38(2)}$$

$$K_p = \frac{Y}{S} \tag{2.38(3)}$$

$$\tau = \frac{K_p}{R_r} \tag{2.38(4)}$$

Modified Step Response

The conventional step response test is not practical in loops with large time constants. Furthermore, it does not provide a check on the accuracy in performing the test itself unless repeated. Even if the test is repeated, errors can still occur in unit conversion.

A combination of a modified step response and an ultimate sensitivity test overcomes the above limitations (Figure 2.38c). When performing the modified step response, the operator retains the step just long enough to be certain that the process

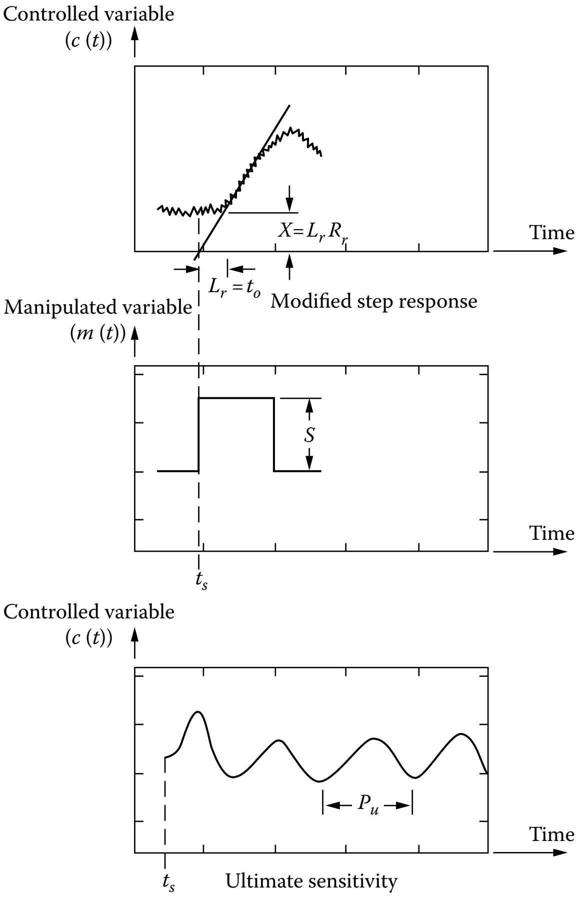


FIG. 2.38c

The combination of the modified step response test and the ultimate sensitivity test is better suited for processes with dead time.

response reaches the maximum rate of change and then returns the manipulated variable to its initial value. Because in this test the controlled variable does not have to achieve a new steady state, the selection of step size *S* is not critical. The maximum rate of rise in this case too is obtained by Equation 2.38(2).

This technique should not be confused with pulse testing, which requires analysis of the total pulse response curve.

Ultimate Gain Test

The ultimate gain (K_u) test calls for increasing the gain of a proportional controller until the process cycles at constant amplitude, without convergence or divergence. The following equations describe the behavior of the system:

$$\frac{K_u K_p}{\sqrt{\left(\frac{2\pi\tau}{P_u}\right)^2 + 1}} = 1 \qquad \textbf{2.38(5)}$$

$$\tan^{-2}\left(\frac{2\pi\tau}{P_u}\right) + \frac{2\pi L_r}{P_u} = \pi \qquad \textbf{2.38(6)}$$

where K_u is the ultimate gain of the controller and P_u is the ultimate cycle period. These equations hold true if proportional-only control is continuously applied or if sampling is used at such a rate that it is apparently continuous with respect to either the dead time (L_r) or the time constant (τ). Equations 2.38(5) and 2.38(6) can be reduced to determine the process time constant and the gain:

$$\tau = \frac{P_u}{2\pi}\left[\tan\left(\pi - \frac{2\pi L_r}{P_u}\right)\right] \qquad \textbf{2.38(7)}$$

$$K_p = \frac{1}{K_u}\sqrt{\left(\frac{2\pi\tau}{P_u}\right)^2 + 1} \qquad \textbf{2.38(8)}$$

With τ calculated from Equation 2.38(7) and the gain from Equation 2.38(8), Equation 2.38(4) can be used to give a cross-check on the accuracy of the test and on the validity of the model structure.

Discrete Cycling

The process gain can be determined by another equation by discrete cycling of the loop while using a sample rate, which equals the dead time ($L_r = t_0$). If the gain required to reach ultimate sensitivity is K_{ud}, then the conditions of stability are defined by:

$$K_{\mathrm{ud}} K_p [1 - e^{t_0/\tau}] = 1 \qquad \textbf{2.38(9)}$$

Process gain can be computed from this test by

$$K_p = \frac{1}{K_{\mathrm{ud}}} \frac{e^{t_0/\tau}}{e^{t_0/\tau} - 1} \qquad \textbf{2.38(10)}$$

The amplitude of cycling obtained with the discrete test will be different from that of the continuous test, which provides an additional means of checking whether the gain is linear. The degree to which this test can be automated is strictly a function of available hardware and software.

If a valid model cannot be obtained, the instrument engineer should tune a controller by trial and error, or, if a more scientific approach is desired, then more general model structures and identification approaches should be tried. If the process gain is nonlinear, frequent adjustment or online adaptation should be considered.

The reader should also refer to the tables provided in Section 2.35, which provide equations to calculate the tuning parameters for a variety of tuning objectives. The tests described can be automated by the use of software packages, which not only perform these tests but also can analyze some of the results.

TUNING CRITERIA AND FORMULAS

For those processes that fit the first-order plus dead time model, a variety of approaches are described in the literature for computing the tuning settings. With conventional control applications, the techniques that have been developed were found to work well. A set of equations are provided below to give guidance in the tuning of controllers. These transfer function equations allow the calculation of the manipulated variables $M(s)$ (where s is the Laplace operator), for the control modes P, PI, and PID, as a function of the process error $E(s)$:

Control Mode: P $\quad M(s) = K_c E(s) \qquad$ **2.38(11)**

Control Modes: PI $\quad M(s) = K_c(1 + 1/T_i s)E(s) \qquad$ **2.38(12)**

Control Modes: PID $\quad M(s) = K_c(1 + 1/T_i s + T_d S)E(s) \qquad$ **2.38(13)**

In the following, a number of tables are provided that contain some traditional tuning criteria and the corresponding tuning equations for P, PI, and PID controllers, when they are tuned to correct for load disturbances in the process. Table 2.38d lists a variety of tuning criteria that have been discussed in earlier sections. Tables 2.38e, 2.38f, and 2.38g list the equations to be used in determining the proportional, integral, and derivative settings for the various criteria listed in Table 2.38d. Depending on which performance criterion is selected from Table 2.38d and on the number of control modes, the formulas can be selected manually or automatically (per-programming) from the next three tables.

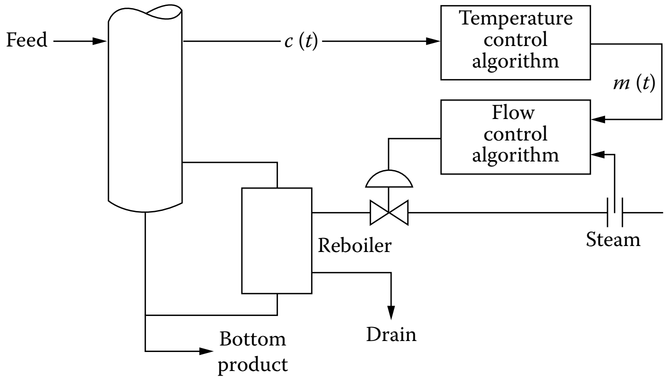

FIG. 2.38h
The tuning example is based on the temperature cascade loop shown in this figure.

Example

In this example the previously outlined tuning method will be applied to a pilot plant distillation unit under the direct digital control of a time-shared computer. Figure 2.38h illustrates the unit process on which the process operator in cooperation with a computer tunes the cascade loop, which controls the temperature of this unit.

Figure 2.38i shows the modified step response method of testing, where the upper two plots show how the operator applies a step in the open loop and obtains a response of the controlled variable, which allows for the determination of the ultimate sensitivity. This is then followed by the closed-loop portion of the test, which is shown in the lower two plots. Here the ultimate gain of the process is obtained.

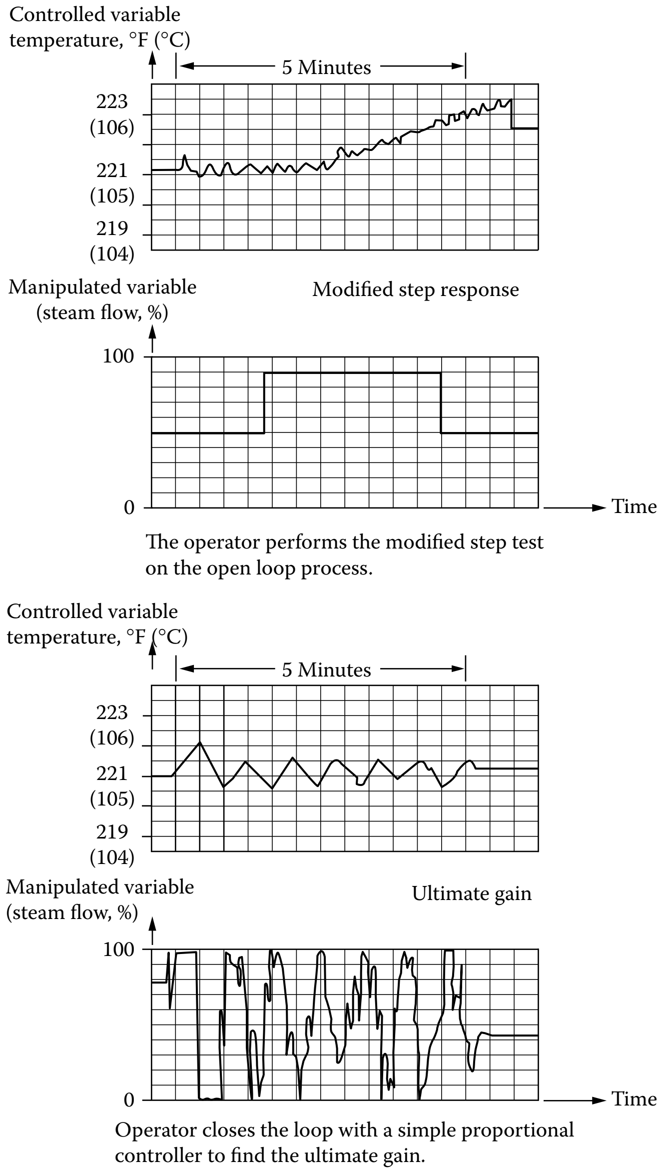
Once the data are collected, Equation 2.38(8) is used to calculate the process gain (K_p = 74%) This can than be verified by using Equation 2.38(4) to also calculate K_p = (time constant – T)(maximum rate of rise – R_r), which is considered to be adequate verification.

Tuning and Diagnostic Software

Some software packages include a variety of automatic means for obtaining better process models and improved tuning settings and also provide data for better maintenance.[2] The information below is taken from Section 5.6 of Volume 3 of this handbook, where the topic is treated in more detail.

Some of these software packages can perform a variety of analyses (auto-correlation, cross-correlation, power spectral density, statistical, linearity, etc.) They can also identify a variety of process models (integrator, dead time, first-order and higher orders, etc.); measure signal and valve noise; evaluate valve hysteresis, stiction, and nonlinearity; and evaluate the time and frequency response of the loop. In addition, they can evaluate and recommend control algorithm variations (error, reset, filtering, and sampling).

These advanced software packages can also provide performance analysis (IAE, ISE, response time, robustness, variability, statistics) and can suggest multivariable control strategies (cascade, feed forward, Smith predictor).



The operator performs the modified step test on the open loop process.

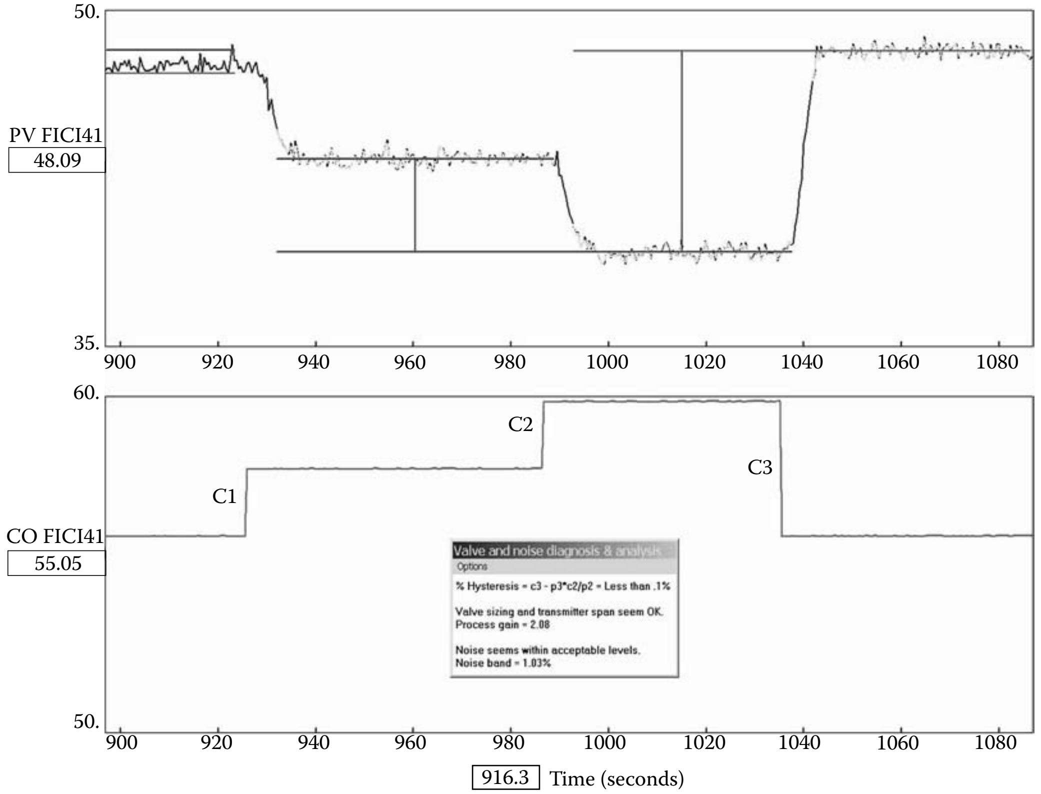
Operator closes the loop with a simple proportional controller to find the ultimate gain.

FIG. 2.38i
The modified test response (top two plots) is obtained in the open loops as a step response, while the ultimate gain is determined (bottom two plots) in the closed-loop mode.

Example

A flow loop in a refinery was analyzed and tuned using such a software package. Figure 2.38j illustrates the test for valve hysteresis, which was completed in the manual mode in less than 3 minutes.

Software tools were used to analyze the data collected. It was found that the gain of this flow process varied from 1.3 to 2.4, which gives a linearity (maximum gain over



% Hysteresis = c3 - p3*c2/p2 = Less than .1%

Valve sizing and transmitter span seem OK.
Process gain = 2.08

Noise seems within acceptable levels.
Noise band = 1.03%

FIG. 2.38j
Valve hysteresis test results, which were obtained in less than 3 minutes of manual testing.

minimum gain) of 1.8; the response time of the loop exceeded 1 minute; hysteresis was under 0.1%; and stiction (the sticking of the valve) was 1.1%. Based on the data collected, it was found that the process gain is 2.3, the dead time of the process is 3.6 seconds, and the time constant is 2.4 seconds.

As a consequence of this evaluation, the sticking valve was repaired, and then the loop was re-tuned.[3] Figure 2.38k provides a tabulation of the performance statistics of this flow loop before (left) and after (right) of the tuning. Figure 2.38l provides a visual indication of the valve sticking (left) before maintenance was performed

> on it. As can be seen, the controller output (*CO*) had to change over 1% (from about 55 to 56%) before the valve would respond. The improvement in loop performance can be seen by comparing the fluctuation of flow between 46.5 and 49.5% (left) to about half as much (right), achieved by the fixing of the valve and the re-tuning of the loop.

CONCLUSIONS

With the various techniques described in this section, the operator can check the controller tuning and the process model accuracy periodically or when operating conditions change. Up-to-date modeling and tuning should greatly improve process performance and safety because most of these techniques maintain process safety by allowing the operators to remain in the loop during the critical testing phase.

In addition, cost reductions are also realized when reducing the amount of trial-and-error tuning because the operator need not wait to bring the process to a final value in the step response test. This saves time when dealing with slow processes. Test signal size is not critical, reducing trial-and-error selection.

Time-shared systems with DCS or supervisory control have greater scaling and sensitivity capabilities than conventional industrial instruments. Also, it can perform unit conversion and can be easily programmed to abort the tests automatically and set off alarms if necessary.

In general, the computer can be a very valuable tool for control system analysis and design in both online and offline testing. Offline techniques range from full-blown computer simulations of process and the associated control system to simple linear first-order plus dead time type models generated from step testing. Online techniques can involve state space optimal control (Section 2.33) and Kálmán filtering techniques,[4] or they can be as simple as some of the automated tuning procedures that were discussed in this section.

The computer has become a very important tool, and software is widely available for the process control and instrument engineer to use to implement a variety of offline techniques of testing. Online techniques are also becoming more popular as the process control computer is becoming part of most control system installations.

Testing, modeling, and tuning improve process performance and result in cost reductions by reducing the amount of trial-and-error tuning. Time-shared systems with DCS, PLC, or supervisory control offer a convenient vehicle to assist operators in tuning, while data acquisition can be done automatically. In minutes a loop can be analyzed and re-tuned.

Flow sheet symbols

Types:	Receiver controllers: Indicating, recording, miniature, high-density miniature, and large case
Direct-connected controllers:	Blind, indicating, or recording, in large or medium case for field or panel mounting.
Application:	Receiver controllers: Control of any variable that can be measured and translated into an air pressure by a pneumatic transmitter; includes automatic and manual control and set point adjustment.
Direct-connected controllers:	Have own measuring element in contact with the process; measuring elements available include pressure, differential pressure, temperature, level, pH, thermocouple, radiation pyrometer, and humidity.
Typical Front Panel Size:	Miniature: 6 in. × 6 in. (150 mm × 150 mm)
High-density miniature:	3 in. × 6 in. (75 mm × 150 mm)
Large case:	15 in. × 20 in. (375 mm × 500 mm)
Minimum Response Level:	Less than 0.01% of full scale
Input Range (measurement):	3 to 15 PSIG (0.2 to 1.0 bar) or direct-connected
Output Range (signal to valve):	3 to 15 PSIG (0.2 to 1.0 bar)
Repeatability:	± 0.2% of span
Inaccuracy:	± 0.25 to 2% of span
Displays:	Set point, process variable (measurement), controlled variable (output to control valve), deviation, and balance
Maximum Frequency Response:	Flat to 30 Hz
Maximum Zero Frequency Gain:	750
Control Modes:	Manual, on-off, proportional (P), integral (I-reset), derivative (D-rate), floating, differential gap, follow-up, cascade
Costs:	Direct-connected, indicating, field-mounted controller costs range from $500 to $2000; miniature indicating controller costs $1000 to $2500; miniature high-density indicating controller indicating $1500 to $2500; miniature recording controller costs

$2000 to $3000; large-case indicating controller costs $1500 to $2500; and large-case recording controller costs $2000 to $3000

HISTORY AND DEVELOPMENT

Pneumatic controllers were first introduced at the turn of the twentieth century. They logically followed the development of diaphragm-actuated valves in the 1890s. Early types were all direct connected, local mounting, indicating, or blind types. Large-case indicating and circular chart recording controllers appeared around 1915. All early models incorporated two-position, on/off action or proportional action. It was not until 1929 that reset action was introduced. Rate action followed in 1935.

Until the late 1930s, all controllers were direct connected and therefore had to be located close to the process. Pneumatic transmitters were not introduced until the later 1930s. To make them compatible, the large-case pressure recording and indicating controllers were easily converted into receiver controllers. This made remote mounting practicable, and centralized control rooms became a reality. Because of the inherent advantages, the combination of pneumatic transmitters and receiver controllers quickly became popular. Since the recording and indicating receiver controllers were quite large, control rooms and panel boards were likewise spacious. Additionally, all control boards had a monotonous look and usually came in one color—black.

A revolution in design occurred in 1948 with the introduction of miniature instruments. Here the concept of the controller evolved into a combination of a small, approximately 6 in. × 6 in. (150 mm × 150 mm), panel front indicating and recording control station and a blind receiver controller. The station permitted the operator to monitor the measured variable (process variable), set point, and valve output; it allowed the operator to switch between, and operate in, either the automatic or manual control modes.

Miniature controllers ushered in the era of the graphic panel, in which the instruments are inserted into graphic symbols representing the attendant process apparatus. Control rooms became more compact, control boards more meaningful and colorful, and because operators quickly developed a "feel" for the process, training time was considerably reduced.

Nevertheless, graphic panels were also wasteful of space and presented major modification problems each time the process was changed. This led to the evolution of the semi-graphic panel, in which a graphic symbol diagram of the process appeared above the miniature instruments mounted in neatly spaced rows and columns.

In 1965, miniature, high-density mounting style stations appeared. The new lines brought with them the most advanced ideas in displays, operating safety and simplicity, packaging, installation simplicity, and servicing facility. Along with some of the standard miniature controllers, they offered computer compatibility along with some unique control capabilities that had previously been impractical.

The early 1980s saw some important new entries in the pneumatic controller market. These included pneumatic controllers using RTD and thermocouple type sensors and pneumatic controllers with microprocessor-based serial communication modules for tie-in to distributed control systems.

As first analog (Section 3.2), and later digital electronic (Section 4.4) and DCS-based software controllers (Chapter 4) became available, they gradually took over the controller marketplace, but pneumatic units are still used in many existing plants and in locations where intrinsic safety is essential.

OPERATING PRINCIPLES

There are both force and motion balance pneumatic controllers. A receiver-type pneumatic controller based on the force balance principle (moment-balance) is shown schematically in Figure 3.1a. A process transmitter (lower left) senses the measured variable (i.e., process variable, e.g., pressure, temperature, flow) and transmits a proportional air pressure to the measured variable (MV) bellows of the controller.

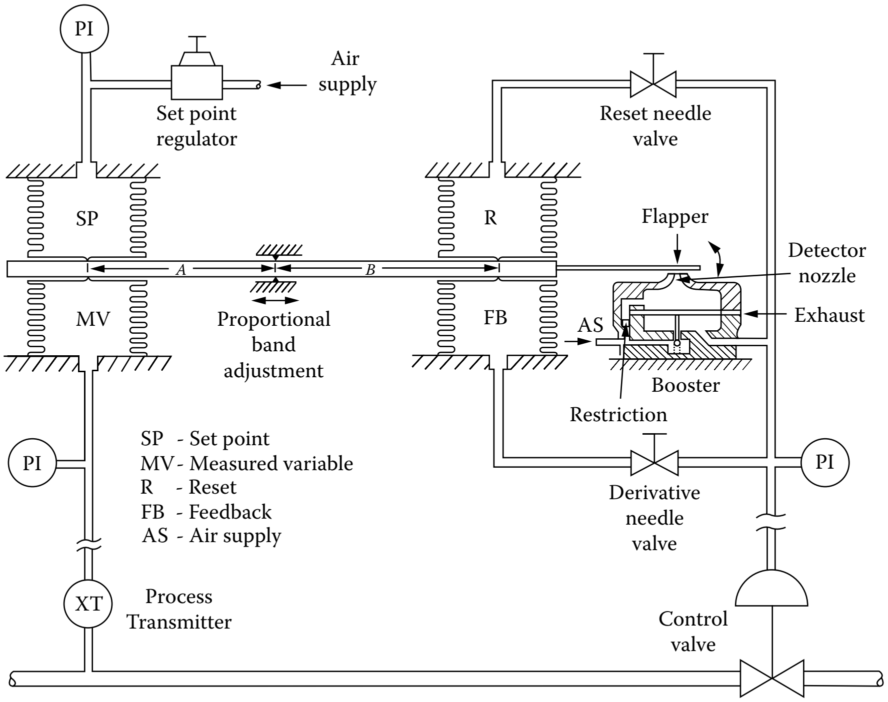

FIG. 3.1a

Moment-balance controller.

The controller compares the measured variable against the set point (SP) and sends a corrective air signal (error or deviation) to manipulate the control valve, thereby completing the feedback control loop.

Figure 3.1a depicts a so-called direct acting controller; the output of the controller increases when the measured variable increases. The controller action is selected as a function of the failure position of the control valve and the relationship between the controlled and manipulated variables. To illustrate this relation with an example, visualize a process cooler. The purpose of the control loop on that cooler is to maintain the temperature at the outlet of the cooler. If the cooling water valve fails closed, a *rise* in the detected temperature will require further opening of the coolant valve, which means that the air signal to the valve should *drop* and therefore the controller has to be reverse acting.

In Figure 3.1a, the controller consists of two sets of opposed bellows of equal area, acting at opposite ends of a force beam that rotates about a movable pivot. Extending from the right end of the beam is a flapper that baffles the detector nozzle of the booster relay.

Booster Circuit

Supply air connects to the pilot valve of the booster and flows through a fixed restriction into the top housing and out the detector nozzle. The flapper is effective in changing the backpressure on the nozzle as long as the clearance is within one-fourth of the nozzle diameter. The restriction size is selected on the basis that the continuous air consumption will be reasonable and that it will be large enough not to clog with typical instrument air. The nozzle, on the other hand, must be large enough that when the flapper has a clearance of one-fourth nozzle diameter, nozzle backpressure drops practically to atmospheric. It must not be so large, however, that the seating of the flapper becomes too critical.

A typical size of restriction is 0.012 in. ID (0.3 mm) while the nozzle would be 0.050 in. ID (1.3 mm). The nozzle backpressure is a function of flapper position. (For a more detailed discussion of circuits, refer to Section 1.4, “Electronic versus Pneumatic Instruments.”)

The exhaust diaphragm senses nozzle backpressure and acts on the pilot valve. If the backpressure increases, it pushes down on the valve, opening the supply port to build up the underside pressure on the diaphragm until it balances the nozzle backpressure. If the backpressure decreases, the diaphragm assembly moves upward, allowing the valve to close off the supply seat while opening an exhaust seat in the center of the diaphragm. This allows the underside pressure to exhaust through the center mesh material of the diaphragm assembly until the pressures balance.

Proportional Response

Since a pressure range of 3 to 15 PSIG (0.2 to 1.0 bar) is an almost universal standard for representing 0 to 100% of the range of a measured variable, a set point, and the output of receiver controllers, this description will assume the operation to be in this range.

To understand the proportional response, first assume that the derivative needle valve is wide open and that the reset needle valve is closed with 9 PSIG (0.6 bar) mid-scale pressure, trapped in the reset bellows R (Figure 3.1a). If the set point is adjusted to 9 PSIG (0.6 bar), when the measured variable equals set point, the flapper will automatically be positioned so that the booster output, acting on the feedback bellows (FB), will be equal to the reset pressure, namely 9 PSIG (0.6 bar). The reason for this is that the force beam will only come to equilibrium when all of the moments cause a rotation of the beam with attendant repositioning of the flapper and change in feedback pressure until the moment balance is restored.

If the pivot is positioned centrally, where moment arm A equals B, then for every 1 PSI (0.067 bar) difference between set point and measured variable there will be a 1 PSI (0.067 bar) difference between reset and controller output, or feedback. This represents a 100% proportional band setting, or a gain of one. Percent proportional band is defined as the input change divided by the output change times 100. Proportional bands are typically adjustable from 5 to 500%. Gain equals the ratio of output change to input change. For a description of both the proportional band and of controller action, refer to Figure 3.1b.

$$\text{PB}\,\% = \frac{\text{change in input}}{\text{change in output}} \times 100 \qquad \textbf{3.1(1)}$$

$$\text{gain} = \frac{\text{output change}}{\text{input change}} = 100/\text{PB} \qquad \textbf{3.1(2)}$$

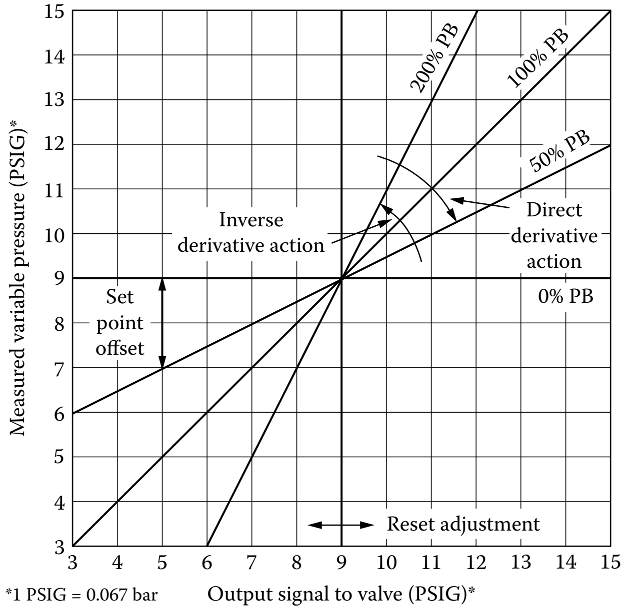

FIG. 3.1b
Graphic representation of control functions.

If the pivot in Figure 3.1a is shifted to the right, to the point where moment arm A is four times greater than moment arm B, then every 1-PSI (0.067-bar) change in the measured (also called controlled) variable results in a 4-PSI (0.27-bar) change in the output (also called manipulated) variable. This gives a proportional band of 25%, or a gain of four.

If the pivot is moved to the left, the ratio is reversed and the proportional band would be 400%, which corresponds to a gain of 0.25. If the pivot could be moved to the right to coincide with the center of the R and FB bellows, the most sensitive setting would be achieved, i.e., approaching 0% band or infinite gain. In this state, the slightest difference between MV and SP would rotate the flapper to change the output to 0 PSI (0 bar) or full supply pressure, depending upon the action of the error (on/off control).

Reset or Integral Response

If it were practical to use a 1 or 2% proportional band on all processes, proportional action alone would be sufficient for most processes. However, most process loops become unstable at such or even wider bands. Flow control loops, for example, usually require more than a 200% band for stability. Assuming that the process cannot tolerate a band narrower than 50%, in that case (Figure 3.1b), the controller can maintain the measured variable on set point only when valve pressure is 9 PSIG (0.6 bar).

If the valve pressure has to be 5 PSIG (0.3 bar), it can only occur when the measured variable deviates from set point by 2 PSI (0.14 bar) (a 16.7% of full scale error). In most cases this amount of error, more correctly termed offset, is intolerable. Nevertheless, in real control systems the valve pressure must change as the load changes.

If the load is such as to require a 5-PSIG (35-kPa) valve pressure, one way of eliminating the offset would be to *manually* change the reset pressure R to 5 PSIG. The output or valve pressure would then be 5 PSIG when the error is zero. Initially, when proportional-only controllers were used, such manual reset was used, but that is totally unacceptable today.

It is a simple matter to make this reset action automatic. It only requires that the reset bellows be able to communicate with the controller output pressure through some adjustable restriction such as a needle valve. The reset action must be tuned to the process in such a way as to allow the process sufficient time to respond. Too fast a reset speed, in effect, makes the controller "impatient" and results in instability. Too slow a speed results in stable operation, but the offset is permitted to persist for a longer period than necessary.

To describe the automatic reset action, assume that set point is at 9 PSIG (0.6 bar) and the reset is trapped at 9 PSIG, while valve pressure feedback, because of load change, must be at 5 PSIG (0.3 bar). According to Figure 3.1b, with the proportional band at 50%, the measured variable will be controlled at 7 PSIG (0.46 bar).

If the reset needle valve is then opened slightly, the pressure in the reset bellows will gradually decrease. As it drops from 9 to 7 PSIG (0.6 to 0.46 bar), the measured variable pressure will rise from 7 to 8 PSIG (0.46 to 0.5 bar). The reset pressure will continue to drop until it exactly equals output, i.e., 5 PSIG (0.3 bar). At this point, the measured variable will exactly equal set point, 9 PSIG (0.6 bar). With this configuration, regardless of where the valve pressure must be, the controller will ultimately provide the correct valve pressure with no offset between set point and measured variable.

Reset action can also be understood by looking at it from the controller design perspective. We can see that the controller cannot come to equilibrium as long as there is any difference in pressure between reset and feedback. This is because if there is, the open communication through the reset needle valve will cause the reset to continue to change, which in turn directly reinforces the feedback pressure.

Reset and feedback, in turn, cannot be equal unless the set point and the measured variable are equal to each other. This fact alone ensures that the controller will maintain corrective action until it makes the measured variable exactly equal to set point regardless of where feedback must be. Referring to Figure 3.1b, reset in effect shifts the proportional band lines along a horizontal axis at set-point level. It makes the middle of the band coincide with the required valve pressure.

Reset time is the time required for the reset action to produce the same change in output that the proportional action would if the error remained constant (the available integral time settings range from 0.01 to 60 minutes per repeat). For example, if the response to an error of a plain proportional controller is a 1-PSI (0.067-bar) change in its output and the error is sustained, the integral mode with a 1 minute/repeat reset setting will require 1 minute to eliminate that offset. The integral setting can have the units of either time/repeat or repeats/unit of time.

Derivative Response

If a needle valve is inserted between the booster output and the feedback bellows as in Figure 3.1a, it delays the rebalancing action of the feedback bellows and causes the controller to give an exaggerated response to changes in the measured variable. The degree of exaggeration is in proportion to the speed or rate at which the measured variable is changing. (The term derivative action refers to the slope or the rate of change.)

Derivative or rate action is particularly effective in the control of slow processes, such as in temperature control loops. It compensates for lag or inertia. For a sudden change of even small magnitude, it provides an extra "kick" to the control valve. This is because the derivative mode assumes that upsets will continue at the rate they are occurring and corrects right away for the error that would evolve one derivative time later. Conversely, when the error is dropping as the controlled process variable is returning to set point, the rate action anticipates that the inertia of the process will carry it below the set point and begins cutting back the valve response accordingly.

The method shown in Figure 3.1a for adding derivative action to the has some serious limitations. If the derivative needle valve is located as shown, the derivative action will interact with both the proportional and the integral responses and, in fact, will follow the proportional response. This design therefore is useless in preventing overshoot on startup or when large upsets occur, and this derivative also interacts with set point changes. Therefore an independent derivative unit is needed, as shown in Figure 3.1e and described later.

Derivative action can be viewed as if it temporarily changed the proportional band and therefore temporarily changed the slope of the lines in Figure 3.1b. If the error is rising, the change is clockwise; if it is dropping, the change is counterclockwise; if the error is constant, no change occurs. Derivative time is the amount of time (usually in minutes) by which the rate action anticipates into the future and leads the feedback pressure during a steady ramp input change. (Derivative settings can usually be adjusted from 0.01 to 60 minutes.)

MINIATURE CONTROLLER DESIGNS

Two designs of force-balance receiver controllers are shown in Figures 3.1c and 3.1d. The controller in Figure 3.1c closely resembles that of Figure 3.1a, except that the bellows all act from one side against a pivoted "wobble plate." The wobble plate acts as the nozzle's baffle. Rotating the pivot axis

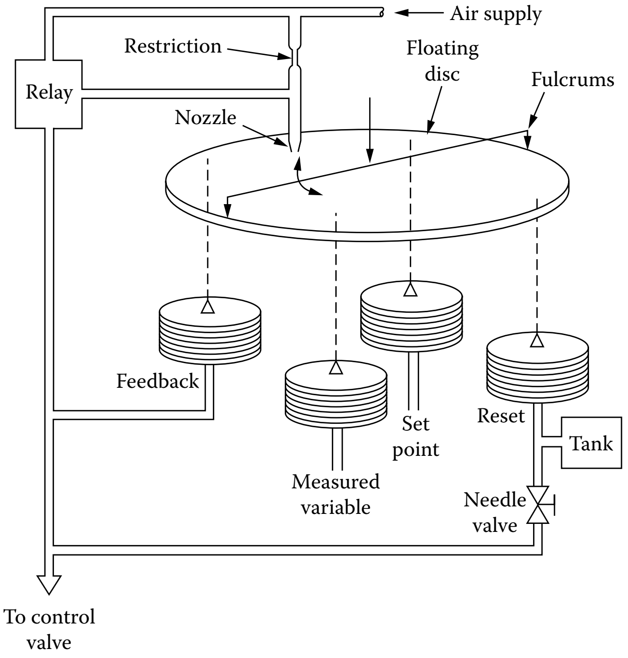

FIG. 3.1c
Typical moment-balance controller.

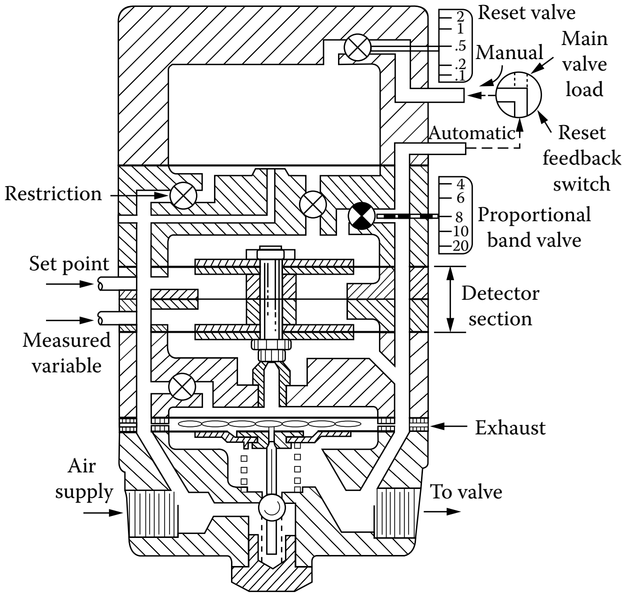

FIG. 3.1d
Force-balance controller.

changes the proportional band. When the pivot axis coincides with the reset and feedback bellows, 0% proportional band results; when it coincides with the measured variable and set point bellows, infinite band results. When the axis bisects the two bellows' axis, 100% proportional band results. Otherwise, the operation is the same as described for Figure 3.1a.

The controller in Figure 3.1d is constructed of machined aluminum rings, which are separated by rubber diaphragms with bolts holding the assembly together. The lower portion of the controller forms the booster section. This is quite similar to the booster in Figure 3.1a.

The detector section consists of three diaphragms. The upper and lower diaphragms have equal areas, while the center diaphragm has half the effective area of the other two. Reset pressure acts in the top chamber. Assume this pressure is at mid-scale and that the reset needle valve is closed. The reset pressure acts on the top diaphragm, which is part of a 1:1 repeating relay. Supply air passes through a restriction and out the exhaust nozzle. The diaphragm baffles the nozzle to make the backpressure equal to the reset pressure.

Assume further that the proportional band needle valve is closed. The pressure then acting on top of the detector section will be the reset pressure as reproduced by the 1:1 relay since the two chambers are connected via a restriction. If the measured variable signal equals the set point, the detector diaphragm assembly, with its integral nozzle seat, will baffle off the nozzle so as to make the controller output, or valve pressure, equal to the reset pressure, thus balancing all of the forces acting on the detector.

If the measured variable is then increased by 1 PSI (0.067 bar), the increase in pressure acts downward on the lower diaphragm as well as upward on the center diaphragm. The net effect is the same as having the pressure act downward on a diaphragm of half the area of the lower diaphragm. Since the output pressure acts upward on the full area of the lower diaphragm, it needs to increase only 1/2 PSI (0.03 bar) to bring the forces to balance. Since a 1-PSI (0.067-bar) change in input resulted in a 1/2-PSI change in output, the proportional band is said to be at 200% or the gain is said to be 0.5.

If the proportional band needle valve were wide open, so that it provided negligible resistance, then if the measured variable pressure increased ever so slightly above set point, the full effect of the resultant change in output would be felt on top of the detector stack. This would cause the output to increase further, which in turn would feed upon itself, and the action would continue to regenerate until the output reached its maximum limit. Therefore, with the proportional band needle valve wide open, the narrowest proportional band is obtained.

If the proportional band needle valve is set to where its resistance equals that of the restriction separating the reproducing relay from the top of the detector section, then the following action results. If the measured variable deviates from set point by 1 PSI (0.067 bar) in an increasing direction, instantly the output will rise 1/2 PSI (0.03 bar) because of the construction of the detector section. The difference in pressure between the controller output and the reproducing relay will cause a flow through the reset needle valve and the intermediate restriction.

Since the resistance of the two is equal, the pressure drop will divide equally, causing a 1/4-PSI (0.017-bar) increase on the top of the detector section. This 1/4-PSI increase directly causes the output to increase 1/4 PSI, which further causes the pressure on top of the detector to increase by 1/8 PSI (0.008 bar). The action continues until equilibrium is obtained, with the output having changed a total of 1 PSI (0.067 bar) and with the pressure on top of the detector section having increased 1/2 PSI (0.03 bar). Since a 1-PSI change in variable resulted in a 1-PSI change in output, this needle valve opening provides a 100% proportional band.

The reset action in this controller is similar to that in Figure 3.1a in that any change in reset pressure propagates down through the unit to directly affect the output. The controller will not come to equilibrium until all forces are balanced, i.e., the measured variable will have to equal set point and the reset pressure will have to equal controller output.

Derivative Relay

It was noted earlier that the type of derivative circuit used in Figure 3.1a interacted with the effects of the other control modes. Derivative action is more effective if it is noninteracting and if it can be applied *ahead* of the contributions of the proportional and reset actions of the controller. Such a derivative unit can be built into the controller, or it can be a separate relay as shown in Figure 3.1e. This relay employs diaphragms, but the design can also use bellows.

In this design the signal from some process transmitter is connected to the input port at the top. Because of the difference between input and output diaphragm areas, the result of the force balance design is that a step change in input pressure will produce an amplified step change in output pressure.

In a steady-state condition (with no change in input), the output pressure acts on both sides of the output diaphragm — and output pressure rebalances the input pressure directly. The output pressure is connected to the intermediate chamber through the needle valve. There is therefore a lag between a change in output and a change in intermediate pressure.

If the input changes with a continuous ramp, the intermediate pressure will lag the output by a constant amount, proportional to the rate of change in output. Thus, the intermediate pressure will partially rebalance the input, reducing the effective gain. The result is that the output will continuously lead the input by a definite amount, which is proportional to the rate of change in input. The time by which the output leads the input is the "derivative time." The graduated needle valve is used to set the derivative time.

An inverse derivative relay is also shown in Figure 3.1e. It works in the opposite manner and thereby attenuates high-frequency signals. It can therefore serve as a noise filter and stabilizing relay on "noisy" processes.

Miniature Control Stations

Miniature control stations with a panel face of nominally 6 in. × 6 in. (150 mm × 150 mm) and inserted into individual cutouts having approximately 10 in. (250 mm) center-to-center distances are one of the common types found on central control room panels in the various process industries. Figure 3.1f shows a typical cross section of some of the types of units available.

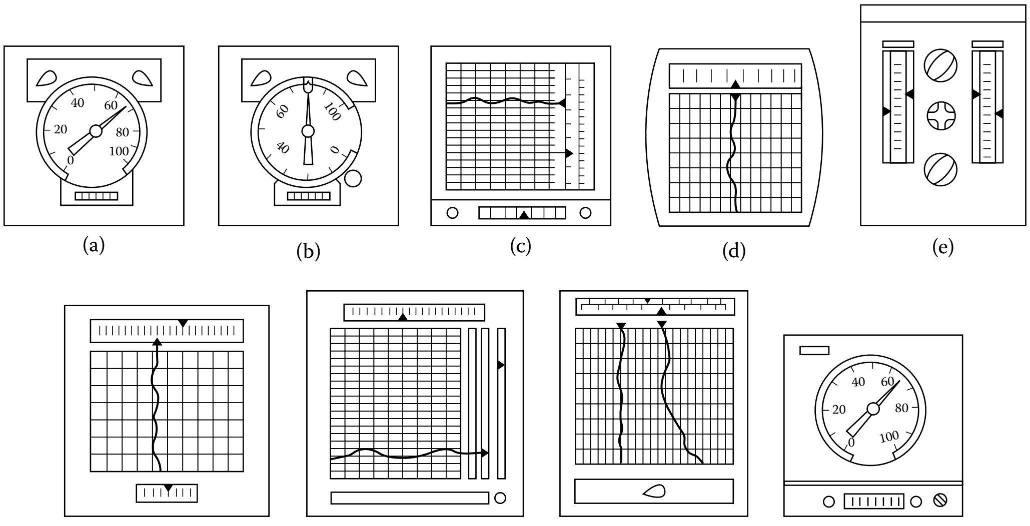

FIG. 3.1f
Types of miniature pneumatic controllers. (a) Typical indicating control station. (b) Indicating control station with 12 o'clock scanning features. (c) Recording control station with 30-day strip-chart and vertical moving pen. (d) Recording control station with horizontal moving pen and daily chart tear-off feature. (e) Indicating control station with two duplex vertical scale indicators (f) Recording control station with no "seal" position. (g) Recording control station with servo-operated pen. (h) Recording control station with procedureless switching. (i) Indication control station with instant procedureless switching.

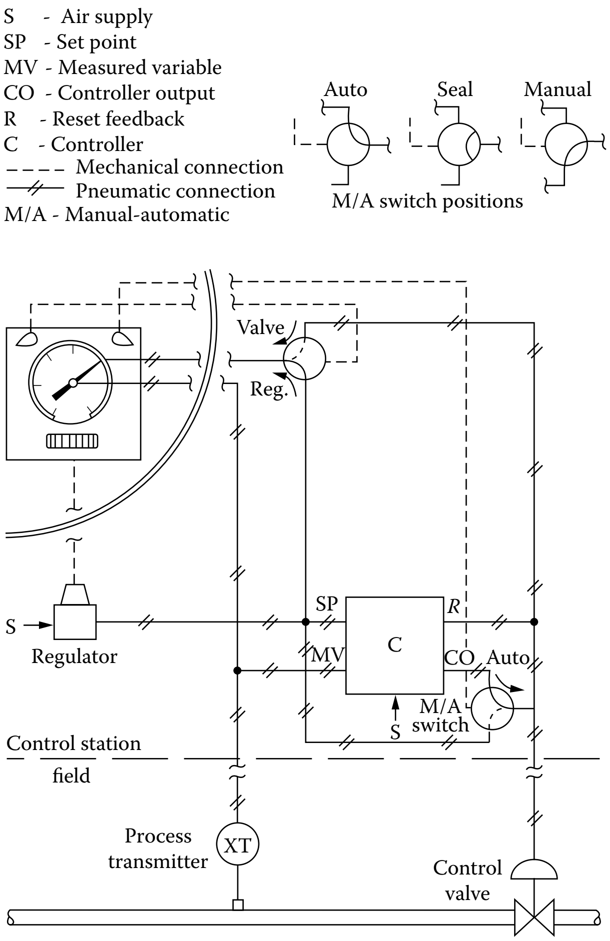

FIG. 3.1g
Miniature control station with integral-mounted controller.

The interconnections of an indicating miniature control station are shown in Figure 3.1g. The measured variable is indicated on the center pointer, and the set point is indicated on the peripheral pointer of a duplex gauge. On automatic, the operator changes the set point by adjusting the set point regulator and noting the set point on the gauge.

The controller is connected to the control valve via the manual–automatic switch. The controller compares the measured variable with the set point and manipulates the control valve to bring the variable on set point. If the operator wishes to switch to manual, he or she notes the valve pressure by operating the upper left-hand switch on the station. Next, the operator turns the right-hand switch to "seal," which isolates the controller from the control valve. After that, the operator adjusts the regulator to match the noted valve pressure and then turns the right-hand switch to the manual position, which connects the regulator directly to the valve. In manual, the operator directly adjusts the valve, while the controller reset follows the changes that are made to the valve.

In switching back to automatic, the operator goes to "seal" position and adjusts the set point regulator to match the measured variable. If the set point and measured variable are equal at switchover, and if the reset is equal to the valve pressure, the controller output should then equal the valve pressure, and the switchover is effected without a "bump."

Four-Pipe System Since a lag exists in the transmission of pneumatic signals, the dynamic capability of a control loop can be affected by increasing the distance between the controller and the process. Transmission lag will interfere with the performance of fast control loops such as liquid flow control but will not be significant if the distance is up to 100 ft (30 m).

For control loops where the transmission lag cannot be tolerated, the controller can be mounted locally, near the measuring transmitter and control valve, as shown in Figure 3.1h.

In this design, four air signal tubes are run between the control station and the field-mounted equipment. These carry the measured variable, set point, valve pressure, and relay operating pressure lines. Hence, the name "four-pipe system," whereas the configuration in Figure 3.1g is referred to as a "two-pipe system." Since the lines going back to the station amount to dead-ended parallel connections, the dynamics of

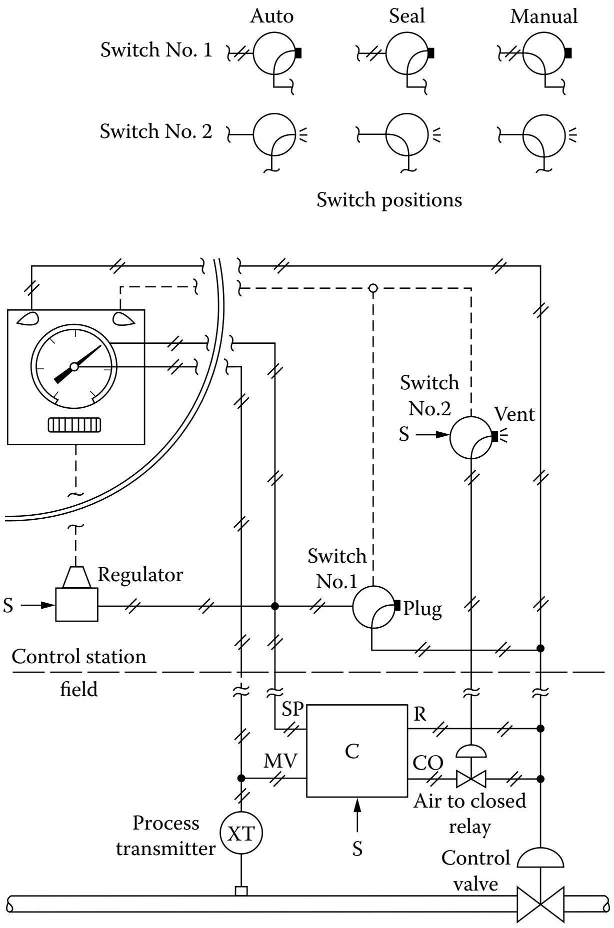

FIG. 3.1h
Miniature control station with field-mounted controller (four-pipe system).

the control loop are the same as they would be with any closed-loop system.

In switching from automatic to manual, the operator switches the loop to the “seal” position, which actuates the cutoff relay, to isolate the controller from the valve and permits the operator to change the set point regulator to match the noted valve pressure. This pressure is then connected to the valve when the operator turns the switch to manual. Returning to automatic involves the same procedure as was described for Figure 3.1g.

The disadvantages of this circuit are that:

1. It is more costly to run four transmission tubes between the control station and the field-mounted equipment.
2. The controller settings cannot be adjusted from the control panel.

Effect of Transmission Distance Since there is a transportation lag caused by pneumatic transmission, control is affected as the distance between the process and controller increases. Figure 3.1i shows the effect of increasing transmission distance between the process and the controller. As can be seen, a 10% upset in liquid flow will result in longer and longer recovery times as the transmission distance increases. Since liquid flow control is one of the fastest processes, this amounts to a worst-case example; the effect on slower processes will be proportionately less.

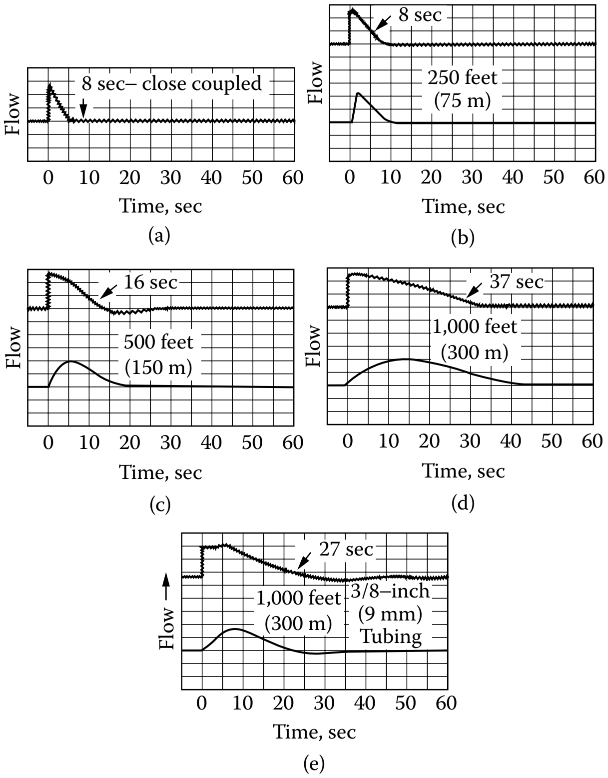

FIG. 3.1i
Effect of transmission distance on control of a liquid flow control process (worst-case example) with 10% step upset. Upper noisy curves show flows recorded locally; lower smooth curves show flows recorded remotely at controller. (J.D. Warnock, “How Pneumatic Tubing Size Influences Controllability,” Instrumentation Technology, *February 1967.)*

From the charts it can be seen that with all instruments close-coupled it took 8 seconds for the system to recover. At a transmission distance of 250 ft (75 m), the recovery time was still approximately 8 seconds. At 500 ft (150 m), it was 16 seconds, and at 1000 ft (300 m), 37 seconds. These results were obtained using 1/4 in. (6 mm)-OD tubing, which is conventional.

When 3/8 in. (9 mm) tubing was used, there was a significant improvement. At 1000 ft (300 m), the recovery time was reduced from 37 to 27 seconds. An equivalent electronic control loop had an 8-second recovery time. The upper, noisy record on the charts (b), (c), (d), and (e) is a plot of the flow as it was recorded at the transmitter. The lower, smoother records are the flows as they appeared on the remotely located recorder-controller.

If this lag is objectionable, the four-pipe system shown in Figure 3.1h can be used, and if it was, the dynamic performance would be equivalent to that of the closed-loop system. Other options include the installation of booster relays in the transmission lines or the use of larger-diameter transmission tubing.

Remote-Set Stations If a modification as shown in Figure 3.1j is added to the basic station in Figure 3.1g, the control station can accommodate a remote set point signal from sources such as remote ratio or proportioning relay, primary cascade controller, or computer.

Computer-Set Station The addition of a stepping motor to the set point regulator or to the set point motion transmitter as in Figure 3.1k allows the control station to be set from a digital computer. The station provides the option of switching the loop from computer control of the set point to manual, as shown in the Figure. The stepper motor, which operates the regulator, can be driven by time-duration signals or by individual up-down pulses. A resolution of at least 1000 pulses for full scale is provided.

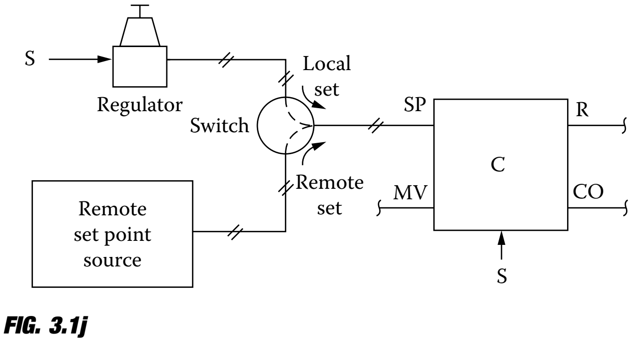

FIG. 3.1j
Control station circuit for remote set point adjustment.

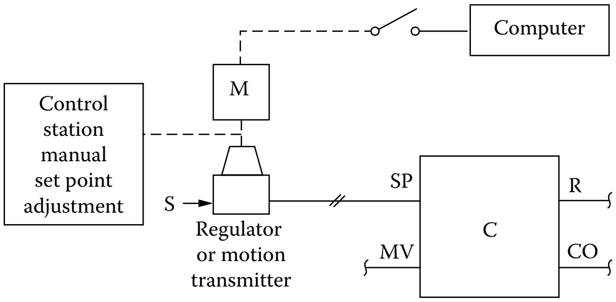

FIG. 3.1k
Control station circuit for computer-adjusted set point control.

Single-Station Cascade Cascade control can be implemented either with two controller stations, with the master controller (such as Figure 3.1g) generating the set point for the slave (or secondary), which is connected as in Figure 3.1j. The other option is to use a single station, such as shown in Figure 3.1l. The latter scheme not only eliminates one of the two stations but also offers operating safety and convenience.

A common problem with having separate master and slave stations is that when the operator switches the slave to manual, he or she often forgets to also switch the master station to manual as well. In such situation, the primary controller has no influence on the manipulated variable and will not be balanced when the loop is returned to cascade. This is particularly undesirable because cascade circuits are usually used on the most critical loops.

In Figure 3.1l, the regulator has three functions:

1. Set point to primary controller in cascade control
2. Set point to secondary controller for independent secondary control
3. Manual valve setting

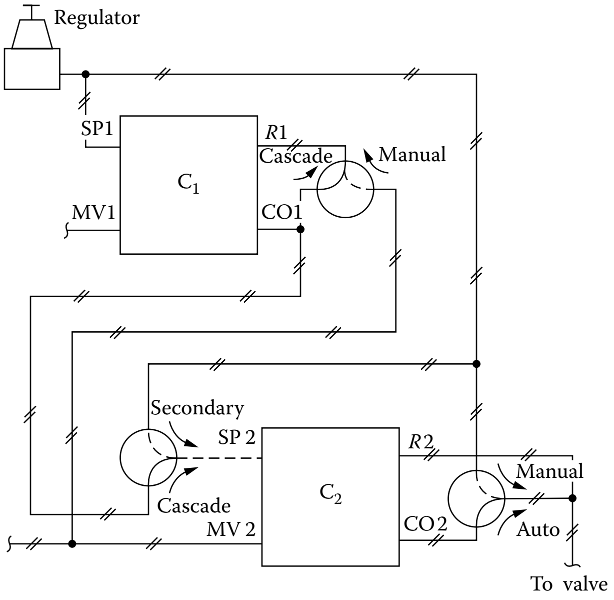

FIG. 3.1l
Single-station cascade controller.

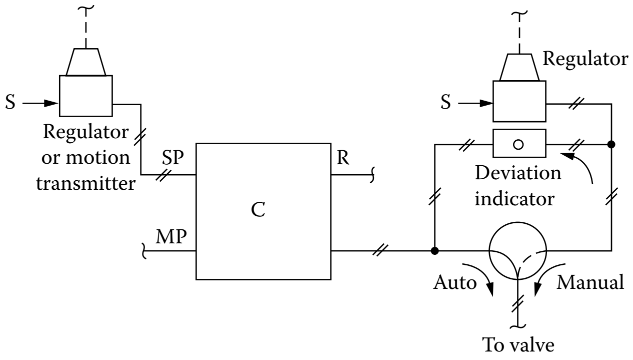

FIG. 3.1m
The use of two-regulator stations eliminates the need for a "seal" position.

There is a seal position between each step while the regulator is set for its upcoming function. The key to this station is the concept used in making the secondary measured variable (MV2) the reset feedback of the primary controller while on manual or secondary control. Versions are also available that allow cascade, independent automatic control on the primary and manual modes of operation.

"No Seal" Station By using two regulators or two motion transmitters in a station (Figure 3.1m), the need for a "seal" position can be eliminated. In this configuration, when the operator wishes to switch to manual, he or she adjusts the manual regulator to match the controller output while viewing a deviation indicator. When the deviation is zero, the operator transfers control.

Procedureless Switching Stations With procedureless switching, the operator simply turns a switch, and the station automatically takes care of the pressure-balancing requirements. Two designs are shown in Figure 3.1n. The mechanism on the top (a) is a motion transmitter/receiver combination. This motion transmitter provides the set point pressure when the controller is in automatic and the valve pressure when in manual—similarly to the regulator in Figure 3.1g.

As a motion transmitter, a friction clutch holds the index lever at whatever position the operator has set it. A restriction-nozzle circuit senses the position and converts it to a proportional pneumatic output that is fed back to the rebalancing bellows. A 0 to 100% movement of the index gives a 3- to 15-PSIG (0.2- to 1.0-bar) output pressure. When acting as a receiver, supply pressure is cut off from the restriction nozzle circuit and the pressure to be sensed is admitted to the rebalancing bellows.

The friction clutch is disconnected so that the index lever can be moved by the rebalancing bellows. The unit is so designed and calibrated that a 3- to 15-PSIG (0.2- to 1.0-bar) sensed pressure produces a 0 to 100% index movement. Therefore, as the operator moves the switch from automatic

to manual, the following actions take place in sequence and automatically:

The index is declutched; supply is cut off from the restriction nozzle circuit; controller output (valve) pressure is admitted to the bellows causing the index level to take a position proportional to the pressure; controller output is disconnected from the valve line; the clutch is engaged; supply pressure is readmitted to the restriction nozzle circuit; and the unit again acts as a motion transmitter, now providing valve pressure.

Switching back to automatic involves the same sequence, in reverse order. This is the same sequence as carried out in Figure 3.1g, except that here it is automatic.

A second system for procedureless switching involves the use of self-synchronizing regulators or synchros (see design b in Figure 3.1n). One regulator provides set point, while the other is used for manual valve loading. As the name implies, this regulator can synchronize itself to some varying pneumatic pressure and thereby provide automatic balancing.

The regulator employs a reaction nozzle circuit that results in very low spring force (approximately 1 oz or 0.28 N) to develop a 3- to 15-PSIG (0.2- to 1-bar) output. The setting spring is adjusted by rotation of a turbine wheel with an integral lead screw (part b in Figure 3.1n). If supply is connected to the comparator controller section, air is transmitted to the increase–decrease nozzles to make the regulator section output match the variable input pressure. If supply is cut off from the comparator controller, the regulator section output remains locked in, with the memory being a function of lead screw position. The unit can then be driven manually by the operator.

When this control station is in automatic, the set point synchro is manually adjusted by the operator, while the valve-operating synchro keeps itself matched to the controller output to allow instant transfer to manual. In manual, the operator adjusts the valve-loading synchro while the set point synchro tracks the measured variable.

In addition to procedureless switching, these stations can also be switched from a remote source, manually or automatically. They can also be gang-switched, and they can be operated in parallel. For example, it is possible to have one station in the central control room and the other out in the field. The operator can use either station and whichever is not in active service keeps itself fully synchronized and ready to take active duty at any instant.

High-Density Stations

Miniature high-density stations have a typical panel size of 3 in. × 6 in. (7.5 mm × 150 mm), mount adjacent to each other, and allow very compact and efficient panel arrangements (Figure 3.1o). The units incorporate packaging features that simplify panel construction and design and facilitate servicing. Much of the design is aimed at making the job of the operator simpler, faster, and safer, in line with the present trend to consolidate control rooms, minimize the number of operators, and handle increasingly fast, complex, and critical processes.

Mid-Scale Scanning Station Figures 3.1p, 3.1q, and 3.1r show three types of high-density control stations featuring a mid-scale deviation scanning pointer. The pointer is driven either by a differential detector or differential servo that compares the measured variable against set point. If the two are equal, the red deviation pointer is positioned at mid-scale, where it is screened off by a green scan band. If there is a deviation, the red pointer stands out prominently.

In Figure 3.1p, a fixed, nominal 4 in. (100 mm) vertical scale is employed, and there are separate pointers to indicate set point and measured variable. The station uses the two-regulator approach to achieve “no-seal” switching as in Figure 3.1m. The operator does have to balance pressures before switching, however.

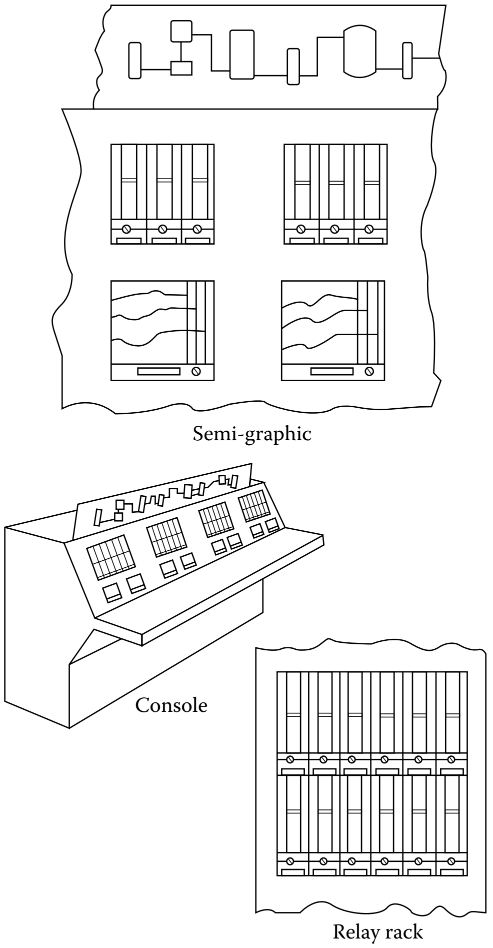

FIG. 3.1o
Typical mounting arrangements of high-density control stations.

In Figure 3.1q, the station employs an expanded scale, which provides greater readability. The only indication on the scale is deviation, however, and this requires that the set point transmitter scale and deviation servo stay in calibration relative to each other in order to provide an accurate reading of the variable. While the expanded scale gives greater readability, it does have to be moved to bring the reading on scale when the variable makes any excursions.

This station and the one in Figure 3.1r use the two-regulator approach to eliminate the need for a seal position. In both cases the operator balances pressures prior to switchover. In Figure 3.1q, the operator notes deviation on a ball-in-tube indicator. In Figure 3.1r, the valve switch has a detent action while the indicator switch operates at the mid-throw position, so that the operator moves the integral switch lever back and forth across center while manually matching pressures before switching. The controller in Figure 3.1r is a deviation type actuated by displacement of a deviation link in the indicator circuit. The controller acts to hold the link at its "zero" position.

While thousands of these control stations have been used in control rooms, mid-scale scanning stations have evolved

into a type combining mid-scale scanning with procedureless switching, using principles described in the next paragraph in connection with Figure 3.1t

Procedureless Switching Station Stations shown in Figures 3.1s and 3.1t offer procedureless switching for the operator. Both have a fixed 4 in. (100 mm) scale, separate indication of set point and measured variable, and a scanning technique that allows the set point indicator to overlap the measured variable indicator when the controlled variable is on set point.

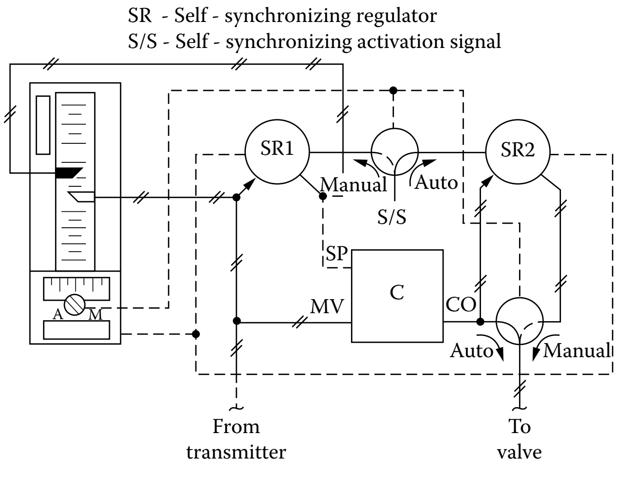

FIG. 3.1s
Self-synchronizing control station with procedureless switching.

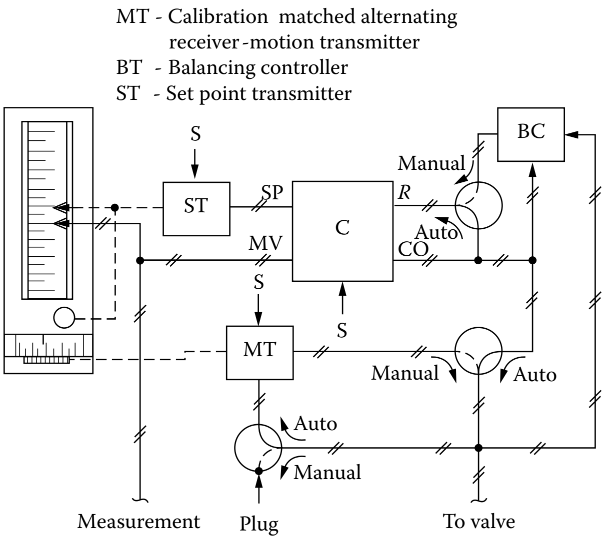

FIG. 3.1t
Self-balancing control station.

The station in Figure 3.1s employs two self-synchronizing regulators or synchros (see Figure 3.1n), one for set point and the other for manual valve loading. When the controller is in automatic, the operator manually adjusts the set point synchro, while the valve-loading synchro automatically tracks controller output. In manual, the operator adjusts the valve-loading synchro while the set point synchro tracks the measured variable. Thus, the station is always balanced allowing for instant transfer of the control mode.

Like its 6 in. × 6 in. (150 mm × 150 mm) counterpart, these stations can also be gang-switched, switched remotely or automatically, and operated in parallel from different locations while maintaining themselves in synchronism, and they are also available in single-station cascade arrangements.

Motion Transmitter/Receiver The station in Figure 3.1t employs a dual function motion transmitter/receiver for manual valve loading and valve pressure indication. This unit is similar to that described in Figure 3.1n. In automatic, the index lever is declutched and the feedback capsule, connected to the valve pressure line, moves the index accordingly. In manual, the clutch engages, and the mechanism reverts to a motion transmitter that provides manual valve loading. This allows procedureless switching to manual.

Switching to automatic is also procedureless, assuming that the set point of the process does not change. If the operator wishes the controller to operate at some new value, compared to where the process had been set on manual, the operator must change the set point to that value prior to switching to automatic. However, to facilitate switching to automatic on loops where the set point remains fixed, the station incorporates a separate balancing controller that operates while the station is in manual.

The balancing controller manipulates controller reset pressure to keep the controller output equal to the manual valve loading even though the measured variable may be off set point. This allows the operator to switch to automatic while off the intended set point and yet have the pressures balanced at switchover and therefore the system to return to set point without overshoot.

This feature of the circuit is somewhat limited on narrow proportional band applications, which is usually the case with slow processes. This is because it takes little deviation from set point before the reset would have to be at either a vacuum or considerably above the air supply pressure to obtain the balance between valve loading and controller output.

LARGE-CASE DESIGNS

Receiver Controllers

Because of their size, large-case receiver controllers are even less frequently used as miniature designs. They nevertheless still find use in some plants and industries where the 24-hour circular chart is traditional and preferred.

Most large-case controllers operate on a displacement balance principle. The set point is a mechanical index setting. The measured variable acts on a pressure spring such as a bellows, spiral, or helix that moves the recorder pen or indicator pointer. A differential linkage detects any deviation between the index and pen position and actuates the flapper-nozzle system in an effort to bring the deviation down to zero.

One example of a large-case recording controller is shown in Figure 3.1u. In this design, if the pen moves clockwise, the differential link moves upward, and the bell-crank moves the flapper toward the nozzle. The resultant increase in nozzle backpressure is reproduced by the relay, whose output is connected to the control valve and the housing of the proportioning bellows. The pressure increase is transmitted to the small inner bellows, causing the two connected inner bellows to move to the right. The spring in the left inner bellows compresses while the spring in the right distends.

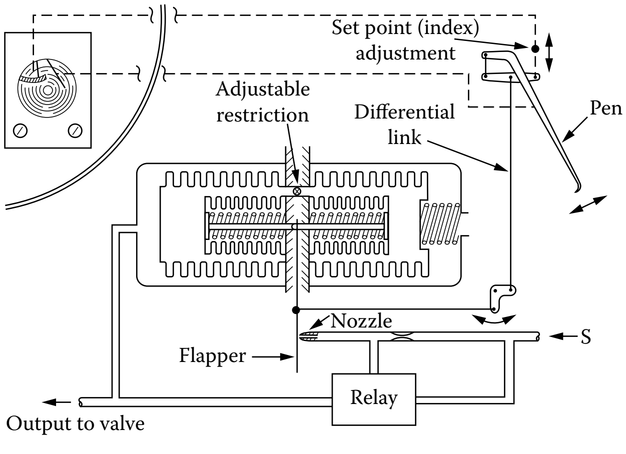

FIG. 3.1u
Large-case recording controller.

The motion also causes the large right-hand bellows to move to the right against the housed spring. As the center rod joining the inner bellows moves to the right, the flapper is moved back away from the nozzle. This negative feedback results in proportioning action. The greater this negative feedback, the greater the change that will be required in the measured variable to obtain a given change in the valve. Adjusting the linkage to change the amount of this negative feedback changes the proportional band.

Opening the adjustable restriction between the two large bellows allows flow from the bellows at higher pressure to the one at lower pressure. In this example, it would flow from the left to the right bellows, causing the inner bellows to move left, moving the flapper toward the nozzle and increasing output further. This action would continue to regenerate until the pen finally returned to the index, where full balance would be achieved with the pressure equal in the two large bellows and with the two inner bellows centered.

Large-case controllers are also available with remote air-operated set point adjustment as required in cascade and ratio control.

Direct-Connected Controllers

Direct-connected controllers have their own measuring elements, which, as the term implies, are directly connected to the process. They therefore eliminate the need for a transmitter. However, the fact that direct-connected controllers must be located in the vicinity of the process limits their use to mounting on local control panels. With this design, the process connections must be run to the local control panel, which is costly, troublesome, and hazardous. For these reasons, these units are seldom used, even on smaller installations and on local panels.

Direct-connected large-case controllers of the indicating and recording type predated the receiver type units by some 20 years. In the first designs, the receiver controllers were direct-connected pressure controllers with a 3- to 15-PSIG range.
