The transmission speeds available with such connections are relatively low; typical values are 9.6 Kbps, 19.2 Kbps, and 38.4 Kbps. For these reasons such links are only used to transfer small amounts of data, because otherwise the overall transmission system would become very slow.

Finally, the distances covered with serial connections are limited to some tens of meters.

Communication Networks

The use of communication networks to connect "intelligent" devices is dramatically increasing in the processing industries. The communication networks used can be grouped into two categories:

1. Local area networks (LANs)
2. Fieldbuses

Considering the PC–PLC connection, both of these solutions require the use of interface boards in order to implement the particular protocol used by the networks.

LANs and the Ethernet Connection LANs have been standardized by the IEEE 802 committee, and the results have been subsequently recognized by the International Standards Organization in its 802 family of standards.

The IEEE 802 committee was concerned with only the first two layers of the OSI reference model, namely the physical layer and the data link layer. As shown in Figure 5.11b, the data link layer has been subdivided into two sublayers: the medium access control (MAC) and the logical link control (LLC) sublayers. The LLC provides a common interface

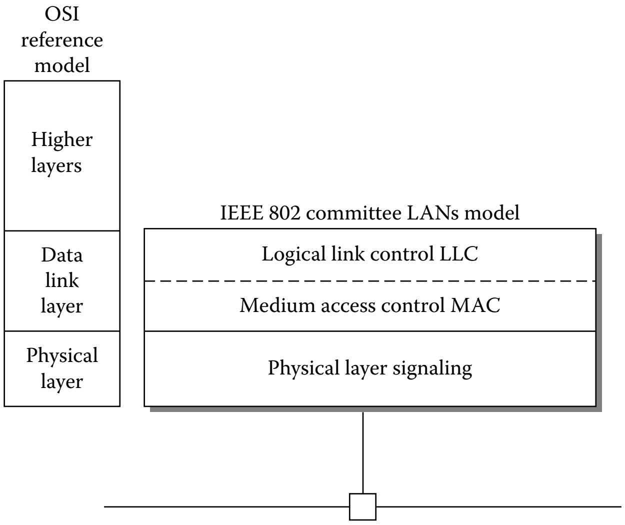

FIG. 5.11b
The model of the local area network (LAN) as specified by IEEE 802 committee.

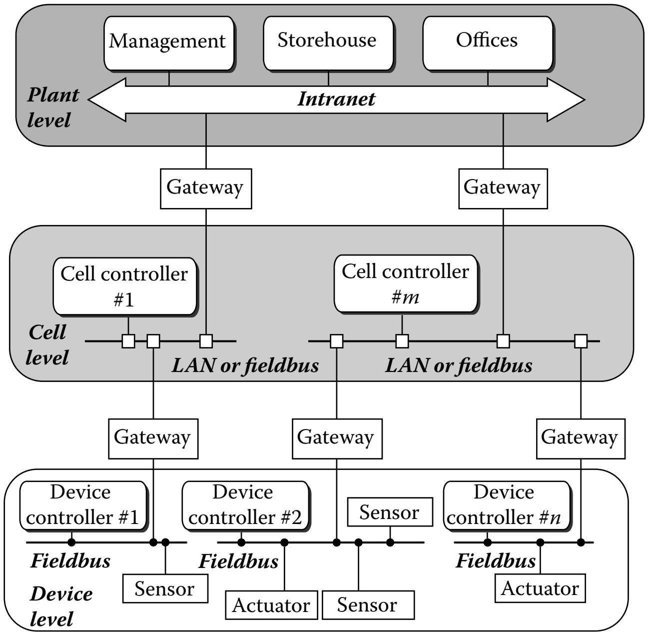

FIG. 5.11c

The three levels of plantwide communication networks used in process control and automation of complete plants.

toward the higher layers, while different MAC layers are used by the different types of networks.

Although the IEEE committee offers several choices, almost all of the LAN systems are based on the MAC specified by the IEEE 802.3 subcommittee. This MAC is universally known as Ethernet,[4] which is also used for the PC–PLC connections. Ethernet interface boards for both PCs and PLCs are available off the shelf and are widely used.

Fieldbuses Fieldbuses are networks that are designed to operate at the device and cell levels of plantwide automation systems.[5] As it is illustrated in Figure 5.11c, fieldbuses may implement control loops by providing the connection between a controller and its sensor (transmitter) and its final control element (control valve or actuator) at the “device” (the lowest) level of the plantwide automation systems. At the cell or intermediate level, fieldbuses provide the connection between intelligent devices.

In contrast with LANs, where Ethernet is the most widely used PC–PLC connection, among the various fieldbuses, there is no leading product. This is probably due to the slowness of the process of international standardization. Therefore, today there are a number of proprietary fieldbus products on the market, including DeviceNet, ControlNet, Fieldbus Foundation, Interbus, Profibus and WorldFIP. All of these products are now included in the various European and international standards: EN50170,[6] EN50254,[7] EN50325,[8] and IEC61158.[9]

Because each fieldbus product requires its specific interface board, and because all the interface boards for all these systems are not always available, the implementation of PC–PLC connections is easier using LANs than with fieldbuses. Nevertheless, if the same fieldbus is used throughout the plant, it ensures the compatibility of the connections at the device level of factory automation systems. For this reason, and because of their good performance, fieldbuses are often used.

Transmission Speeds and Distances Communication networks have several advantages over serial links. In particular, the communication networks are faster in terms of their transmission speeds and can transmit over longer distances. Moreover, they can provide high-layer protocols, which can make the data transfer sessions more efficient.

The typical Ethernet transmission speed is 100 Mbps, and the maximum distance between a station and the switch is 100 m; however, many available network components allow for the implementation of very complex configurations, extending the coverable distance between PC and PLC to several thousands of meters. Moreover, Ethernet components working at 1 Gbps are already available, and the migration to 10 Gbps is expected very soon.

The fieldbus’s transmission speed depends on the product used. For example, Profibus may work at 12 Mbps, Interbus at 2 Mbps, ControlNet at 5 Mbps, and DeviceNet at 500 Mbps. Although the above speeds are lower than that of Ethernet, it has to be considered that fieldbus protocols are in general more efficient, so that the performance of fieldbus-based PC–PLC connections can be equally satisfactory.

The transmission distance of a fieldbus is a function of its supplier; however, almost all of the available standards are suitable for distances of several hundreds of meters.

Communication networks make possible the use of standard high-layer protocols, which were explicitly designed for industrial applications. These permit a fast and efficient data transfer. For a long time, at the device and cell levels, the manufacturing message specification (MMS)[10] has been the sole application layer protocol, defined by an international standard. MMS is based on the definition of “communication objects” representing the unique data that may be exchanged among stations of the network.

The most important communication objects are variables, domains, and program invocations. Variables are used to carry statuses and commands of the plant and typically can be single values, arrays, or structures.

Domains are memory areas that may be used to transfer considerable amounts of data.

Program invocations are executable programs constituted by groups of domains that can be remotely invoked.

Interface Choices If the PC–PLC connection is implemented via a LAN, the MMS protocol (or an equivalent application layer protocol) has to be installed on both of the interface boards used. This is usually provided by means of software

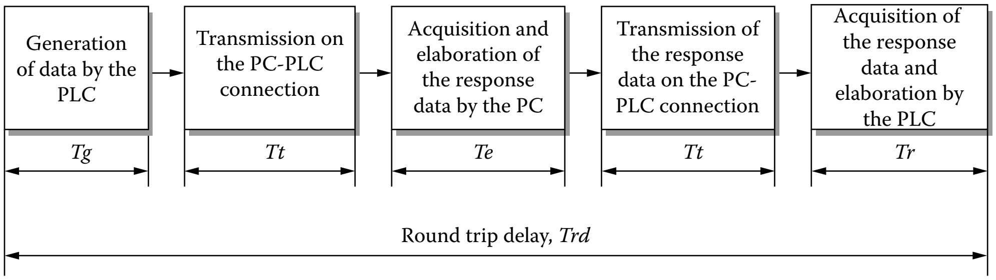

FIG. 5.11d
The steps and their associated time requirements, which add up to the total round trip time delay of a PC–PLC connection.

libraries, such as the product described in Reference 11, which is the MMS library for a specific Ethernet interface board.

The situation is slightly different for PC–PLC connections based on fieldbuses. In this case, the application layer protocol it is already included in the native fieldbus protocol tack. For example, the first version of Profibus had an application layer protocol named fieldbus message specification (FMS),[12] which is completely based on MMS. The same choice was adopted for the application layer of another important fieldbus, World-FIP,[13] included in the EN50170 standard.

Another technique that may be used for PC–PLC connections is the OLE for Process Control (OPC) interface, which is based on Microsoft's COM/DCOM™ technology. OPC[14] is not concerned with the communication protocols used, because it specifies an independent and high-level common interface between the applications located on the connected systems. The adoption of OPC makes use of client/server relationships. It introduces a unique way to exchange data between applications that are distributed on different systems, because it allows the client applications to access the data stored in the servers in a consistent manner.

It is also possible to use the type of protocols that are used for the Internet to connect PCs and PLCs with communication networks. The industrial use of such protocols is increasing. In particular, the file transfer protocol (FTP)[15] is well suited for PC–PLC connections, because it can exchange large amounts of structured data, which might be related to remote configuration procedures, trend analysis, and so on.

In addition, this type of configuration provides a possible link to the Internet and therefore the possibility for remote access to the connection via the Internet, because both the PC and the PLC are using suitable protocols.

PERFORMANCE

In installations where all control is executed in the PLC, and the PC serves only monitoring and supervisory purposes, the transmission time for passing the data over the PLC–PC connection is usually not critical. However, considering that the plant status monitoring information on the PC should also be up to date, it is still important to keep the "round trip" time delay of the connection as short as possible.

The steps and the associated time components of the total round trip time delay of a PC–PLC connection are shown in Figure 5.11d. Such communication can take place either through a serial link or over a communication network. In Figure 5.11d it has been assumed that the session was initiated by the PLC, but the same results would be obtained if the initiator of the transmission was the PC.

Generation Time (*Tg*)

As can be seen in Figure 5.11d, the generation time of the data is identified by the letter Tg and can be determined by the use of Equation 5.11(1):

$$Tg = Ta + \alpha \cdot Tc \qquad \textbf{5.11(1)}$$

where

Ta is the time required to acquire the transmitted signal from the field

Tc is the PLC's cycle time,

$\alpha \in [0,1]$ represents the percentage of the cycle time that has to elapse before the data is in fact acquired by the PLC

The PLC reads the input data at the beginning of each program cycle. The term $\alpha \cdot Tc$ in Equation 5.11(1) takes into account the fact that the signal from the field instrument can be received while the PLC is executing some instruction of its program. Thus, if the signal from the field is received immediately after that signal has been read by the PLC, it will be necessary to wait for one whole program cycle, hence $\alpha \cong 1$. On the other hand, if the generation occurs immediately before the signal is read, $\alpha \cong 0$.

Transmission Time (*Tt*)

Tt is the time necessary to transmit the data over the communication link between the PLC and the PC. If N is the number of bits to be transmitted and B is the bit rate of the link, then Tt is

$$Tt = \frac{N}{B} \qquad \mathbf{5.11(2)}$$

It is important to note that N has to include not only the data bits, but also the bits used by the transmission protocol, such as, for example, the bits used for error control and addressing.

Te, *Tr*, and *Trd*

The elaboration time Te cannot be expressed by an equation, because it depends on many factors. It comprises a first delay component, which is caused by the transmission of the data inside the PC from the network interface board to the task that will perform the elaboration. Next is the time it takes for the PC operating system to schedule the execution of the task, which depends on all the activity and occurrences in all the other tasks. Finally, the data are transferred to the network interface board for transmission over the connecting link.

The return transmission time Tr (similarly to Tg) is determined by the arrival time of the data at the PLC in relation to the program cycle. Thus, Tr can be expressed as

$$Tr = \beta \cdot Tc \qquad \mathbf{5.11(3)}$$

where Tc is the cycle time and $\beta \in [0,1]$.

In conclusion, the round trip delay (Trd), which is the time interval that has to elapse from the generation of the data by the PLC and the arrival of the corresponding response from the PC, may range between two values, which can be calculated by Equations 5.11(4) and 5.11(5):

$$Trd^{\mathrm{MIN}} = Ta + 2Tt + Te \qquad \mathbf{5.11(4)}$$

and

$$Trd^{\mathrm{MAX}} = Ta + 2Tc + 2Tt + Te \qquad \mathbf{5.11(5)}$$

Equation 5.11(4) assumes that $\alpha = \beta = 0$ while Equation 5.11(5) assumes that $\alpha = \beta = 1$.

CONCLUSIONS

The integration of DCS systems with various communication networks was discussed in Section 4.9, and the integration of DCS systems with PLCs or PCs was discussed in Section 4.10. In this section, the integration of PCs and PLCs was discussed.

"System integration" is a nebulous term. It can mean just about anything the integrator desires. It is up to the system owner to define the level of integration expected and to justify the cost of integration. The current trend is away from simple point to point connections and toward Ethernet and fieldbus connections using either standards-based open protocols, or industry-accepted proprietary protocols. The high speeds associated with these connections support not only massive information transfer, but also, in many cases, shared control.

Flow sheet symbol

Type of Design:	A. Thermal devices, bimetallic strip springs B. Dashpots C. Pneumatic delays D. Inertial devices, weights, flywheels E. Solid state F. Motor-driven delays G. Software delay
Type of Delay:	On-delay, off-delay, interval, single-shot, pulse detection, and repeat cycle
Delay Settings:	A. 0.2 to 3 sec B. 1 to 120 sec C. 0.1 to 300 sec D. 0.05 to 0.2 sec F. Can be many hours
Timing Inaccuracy:	Generally 5 to10%. Type A is 5 to20%; for better accuracy use interval timers instead of time delays. Crystal-controlled oscillators can provide 0.1%
Reset Time:	About 100 ms
Life Expectancy:	Electrical types at full load usually operate a minimum of 100,000 times; mechanical types are good for 20 million operations or more
Load Switching:	Relay contacts, snap-action switches, SCRs, transistors, triacs
Environmental Limits:	14 to 140°F (–10 to 60°C); 5 to 95% relative humidity
Mounting Configurations:	Plug-in, surface-mount, panel-mount, in-line module
Costs:	From \$20 to \$200

Time delay devices are used for delaying the start-up, shutdown, recycling, or continuation of processing operations until the desirable requirements have been satisfied or the required conditions have been obtained.

GENERAL CHARACTERISTICS

Time delay relays are special-purpose relays or logic components that have some characteristics of both relays and timers. Time is one of the variables of any process, and it often need to be monitored or controlled. Some operating steps in a process might need to coincide or may need to be separated from some other steps by a specific interval of time. Time delay relays serve to satisfy such timing requirements.

The two main components of time delay relays are the timing circuit mechanism that produces the required time interval and the load switching contacts that are actuated at the end of that time interval. For a time interval to be determined, the following prerequisites must be present:

1. A power source (if needed in addition to signal power)
2. Signal power
3. A change of state of the time-determining device
4. An indication that the time-determining device has changed to the desired state

The power or signal power can be thermal, pneumatic, AC, or DC electric current. The change in the state of the timer can be mechanical (e.g., caused by the rotation of a motor, the motion of a plunger in a restricting fluid, or the bending of a bimetal strip caused by a change in temperature), electrical (e.g., caused by an accumulation of charge of a capacitor or a count of oscillations or pulses), or software-based (e.g., based on the number of program scans or interrupt-driven).

The load switching can occur via snap-action switches, snap-action valves, relay contacts (e.g., SPDT, DPDT, reed [hermetically sealed], or mercury [hermetically sealed]), or solid-state devices (e.g., transistors, SCRs, or triacs).

Timer Modes and Characteristics

The mode of the time delay determines the relationship between the time when the signal power is applied to the time of load switching. This relationship may also depend on the continuous presence of the power source. The four most prevalent modes are on-delay, off-delay, interval, and single-shot. A special combination of the on-delay and the off-delay is called a repeat cycle timer.

In addition to the aforementioned combinations, one must consider the following characteristics when choosing time delay relays from among the vast number available:

1. Timing range
2. Fixed versus adjustable timing
3. Accuracy
   a. Dial setting accuracy
   b. Tolerance
   c. Repeat accuracy
   d. Time between operations
4. Environmental factors
   a. Temperature range
   b. Vibration, shock
5. Loading switching
   a. Duty cycle
   b. Type of load: resistive, inductive, lamp
   c. Life expectancy with load
6. Mounting considerations
   a. Size limitations
   b. Mounting style: surface-mount, panel-mount, plug-in, in-line module
   c. Terminals: plug-in, quick connect, solder lug, screw terminal

7. Housing
   a. Open chassis
   b. Dustproof
   c. Weatherproof
   d. Explosionproof
   e. Totally encapsulated

Types of Time Delays

Recovery Time *Recovery time* is the minimum amount of time between removal of the signal power and its reapplication, which is necessary so that the subsequent operation will have the desired repeatability. The analog or digital solid-state timing circuits have the shortest recovery time.

On-Delay An *on-delay* is alternatively called delay on make, delay on operate, delay on pull-in, delay on energize, slow-acting, or slow-operating. The load switching occurs a certain time after the application of the signal power (Figure 5.12a). If a power source is normally required and the power is interrupted before load switching takes place, the timing cycle has to be repeated from 0 to effect a delayed load switching (except in certain synchronous motor-driven delay relays).

Off-Delay An *off-delay* is alternatively called delay on break, delay on de-energize, delay on drop-out, delay on release, slow release, drop-out delay, or delayed drop-out. The load switching occurs a certain time after the removal of the signal power (Figure 5.12a). If the power source is normally required and the power is interrupted before the minimum amount of time or after removal of the signal power prior to load switching, the amount of time delay may be inaccurate.

Interval An *interval* timer is alternatively called interval on, on interval, pulse shaping, bypass timing, interval delay, and delay on energization with instantaneous transfer. After application of the signal power and while the signal power is maintained, the load switching occurs for a certain time only, and then the load switching is de-energized (Figure 5.12a). If the signal power is interrupted or the power source (if normally required) is removed before the completion of the time delay, the load switching is de-energized instantaneously.

Single-Shot A *single-shot* is alternatively called latched interval, latching off delay and latching delay on de-energization, momentary actuation, or one-shot. Load switching occurs for a certain time only, and then the load switching de-energizes after a momentary application of the signal power (Figure 5.12a). The signal power may be applied longer without altering the load switching interval. If the power source is normally required and it is interrupted while the load switching is energized, it de-energizes instantaneously.

Pulse Detection A *pulse detection* relay monitors a contact or control input to activate an interval time period. The output contact may already be activated or on with the application of power or it may wait until the control input is active. Once the control input is on the control input must cycle within the interval time period to either maintain the output or to drop the output as selected.

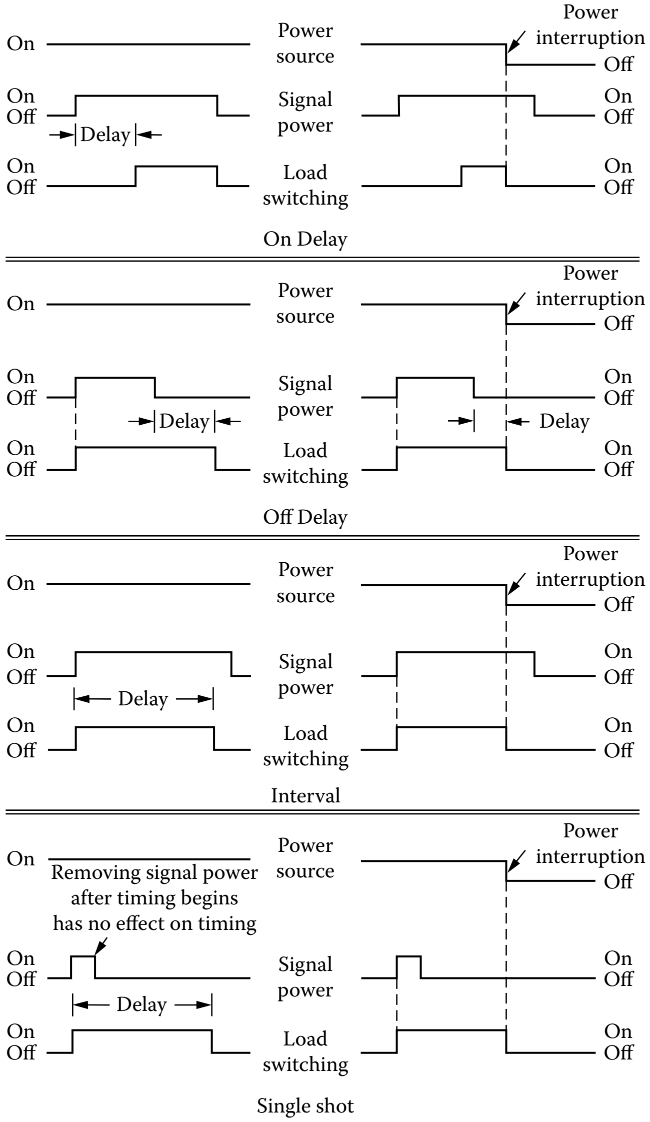

FIG. 5.12a
Timing charts of the various types of time delays.

Repeat Cycle A *repeat cycle* relay is alternatively called dual delay; combination delays; on-delay, off-delay; or slow acting-slow releases; or asymmetric pulser. The load switching occurs a certain time delay after the application of the signal power, and remains energized for another time delay after the removal of the signal power. If the power source is normally required and it is interrupted while the load switching is energized, it may be de-energized prematurely. The asymmetric pulser has the added feature of two time periods, one for the on period and one for the off period.

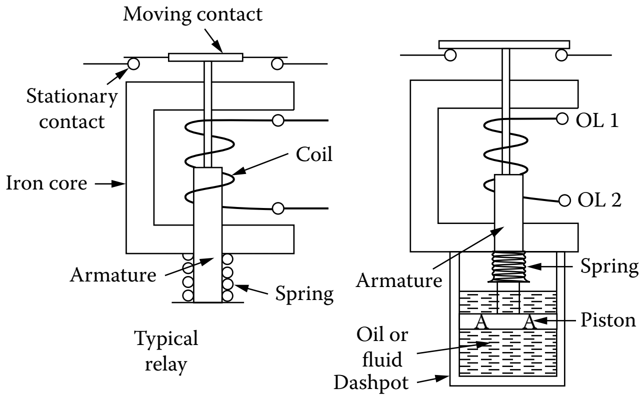

FIG. 5.12b
Dashpot time delay.

Types of Designs

Dashpot or Pneumatic In a *dashpot*-type time delay the armature of a relay is augmented with a piston that travels in an oil or fluid. The piston contains several holes through which the fluid passes. The current of the coil must be applied continuously to exert a pull on the armature. The armature travels slowly because of the resistance of the fluid, if it has the required viscosity to produce the necessary delay. The size of the aperture holes may be modified to vary the time delay. Once the armature travels the required distance, the moving contacts engage the stationary contacts. A dashpot time delay is shown in Figure 5.12b.

In a *pneumatic* time delay, the time it takes for a certain volume of air to pass through a preset size of opening is used for timing. This design is made dustproof by a diaphragm and a cap, which encase the head in which the air is recirculated.

Thermostatic In this version of a time delay design, one of the contacts is a bimetallic element that is wrapped with an insulated heating coil. The signal power is applied to the heating coil. The delay time is the time required to raise the temperature of the contact high enough to produce warping, which will finally cause the contact to transfer.

The timing tolerance (accuracy) of standard thermostatic time delay relays is typically only ±20% but special designs are available with better tolerances. These units are also only repeatable to approximately ±5%, but on the other hand, they are of low cost and inherently resistant to transients. A thermostatic time delay along with two forms of packaging is depicted in Figure 5.12c.

Motor-Driven This type of relay is powered by a synchronous motor. A tripping arm is driven through a simple train of machine-cut spur gears. The arm actuates a snap-action switch, and the motor speed and the gear reduction determine the time delay. Resetting is instantaneous by means of an electromagnetic coil that clutches and declutches the trip locking gear as required. The clutch coil is often equipped with a set of auxiliary contacts.

The power source is normally applied to the motor circuit, while the signal power is normally applied to the clutch coil. In this manner, there are instantaneous contacts actuated by the clutch coil and time-delayed contacts actuated by the tripping arm. When the power to the clutch is maintained, the time delay is increased by the delay in power interruption. Viewed otherwise, the relay accumulates all of the time that the power source has applied to the motor until it equals the time that is preset on the time delay relay.

The use of a synchronous motor ensures great accuracy and, with appropriate gearing, allows for very long delays, up to and including hundreds of hours. Sometimes these relays are provided with a progress pointer. A motor-driven delay is illustrated in Figure 5.12d.

Analog Solid State Analog time delays are based on the RC circuit, in which a capacitor is charged via a resistor until it reaches a certain voltage. When the predetermined voltage is reached, the load switching electromechanical relay or a solid-state switching device turns on or off, depending on the function.

This type of timing is much simpler, more reliable, and less expensive than the mechanically complex synchronous motor-driven delay relay. However, there are some shortcomings, which include the fact that the time-constant curve for the capacitor charging is exponential, making it difficult to set a potentiometer (the variable R) accurately.

Another limitation is that the RC circuit is sensitive to variations in supply voltage. Also, the setability and repeat accuracy of this design are affected by variations in the resistance because of variations in temperature, and in addition the

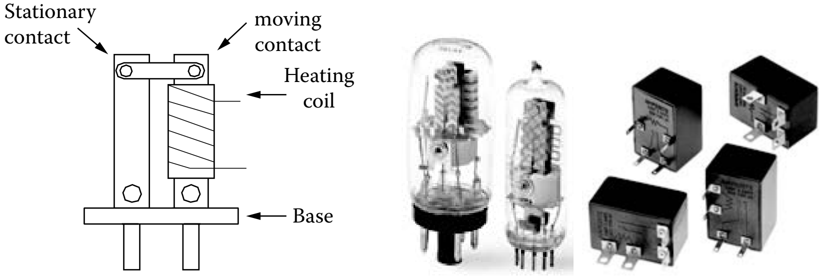

FIG. 5.12c
Components of thermostatic time delay relay in hermetically sealed, glass tube and plastic case. (Courtesy of Amperite Co.)

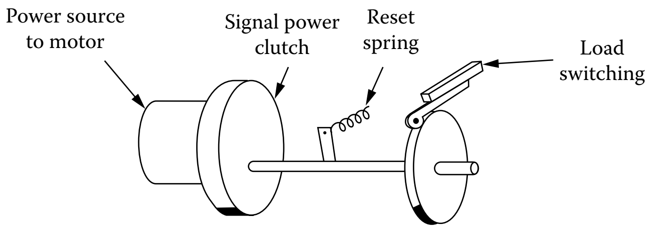

FIG. 5.12d
Motor-driven delay.

capacitor shifts its value as it ages. Steps can be taken to offset or lessen these adverse effects of voltage or temperature variations, but these steps add to the cost of the analog time delay relay. An analog time delay is shown in Figure 5.12e.

Digital Solid State The digital method for creating a time delay uses a frequency counting or dividing circuit. This approach, although more expensive than the analog RC circuit, provides better accuracy and repeatability and lends itself to medium- or large-scale (chip) integration. In this type of circuit, pulses from an oscillator or from the frequency of the power line are applied to a counter or a divider chain, which is preset to output a pulse at a specific count. This output pulse turns on or off the load switching electromechanical relay or solid-state switching device.

The power line frequency, 50 or 60 Hz, is used because of its stability. Using a higher frequency free-running oscillator provides finer time increments. For ultimate accuracy, a crystal-controlled oscillator is used, providing absolute accuracy and repeatability, setable to the fourth significant figure. This type of delay relay would most often be supplied with a thumbwheel switch or dip switches to program the dividing counter. A digital time delay is shown in Figure 5.12f.

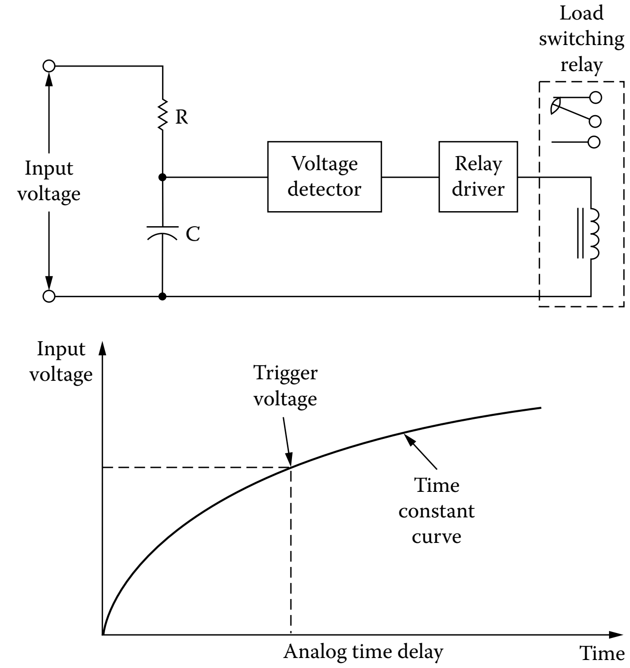

FIG. 5.12e
Analog time delay.

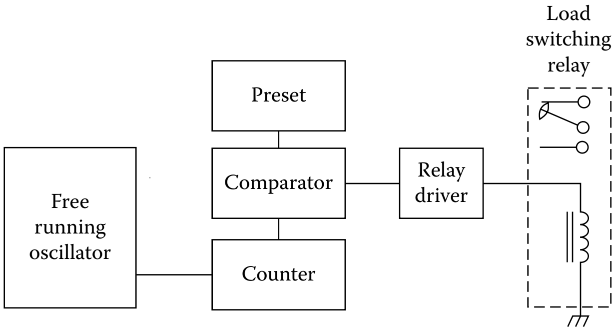

FIG. 5.12f
Digital time delay.

Software-Based Time Delays Modern control systems make increasing use of programmable controllers or microprocessors for all the logic, sequencing, and timing functions. All these functions are emulated in software by a program stored in memory. The program is merely a series of binary instructions written by the applications designer, upon which the central processing unit interprets and acts.

The software-based delays use the digital method of generating delays. Internal clock pulses are accumulated in a memory register or in a counter, which subsequently transfers its count to a memory register. The program regularly compares the accumulated count with a preset value that is stored in another memory register. When the accumulated count equals or exceeds the preset value, the program branches to another set of instructions that require the delay for further logic sequence.

An error may be present in the aforementioned method, affecting accuracy and repeatability. Because the software program takes varying amounts of time for acting on a set of instructions, successive scans through the whole program involve differing amounts of time. Therefore, when the software program returns each scan to compare the actual count with the preset count, the actual may exceed the preset by an unacceptable amount for the accuracy desired.

Some microprocessor-based devices have a modified digital method that corrects this problem. The actual count takes

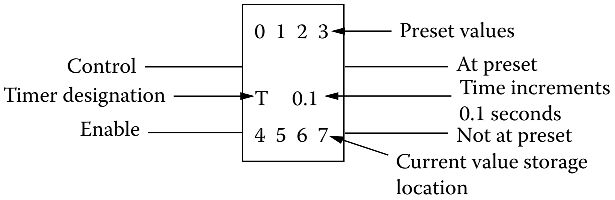

FIG. 5.12g
Software-based time delay. Timer block general form as viewed on a CRT of a typical programming panel of a PLC.

place in an integrated circuit, which creates an interrupt when it reaches the preset count. This interrupts the main software program immediately, and load switching can be executed without incurring additional time delay. A software-based delay is depicted in Figure 5.12g.

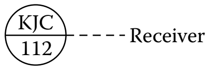
5.13 Timers and Programming Timers



Multipoint on–off
time–sequencing
programmer

Flow sheet symbol

H. C. ROBERTS (1970) R. A. GILBERT (1985, 1995, 2005)

Types:	A. Mechanical B. Digital C. Electronic
Timing Ranges:	Typical ranges are 0.001 to 1 ms, 0.1 to 1 sec, 1 to 300 sec, 1 to 300 min, 1 to 24 h
Output Signals:	Voltage: 5 V DC, 12 V DC, 24 V DC, 24 V AC, 120 V AC
Currents:	From 20 mA to 500 mA
Sizes:	PC board assembly is 2 in. × 4 in. × 1 in. (50 mm × 100 mm × 25 mm) Plug-in component for single timer is about 2.5 in. × by 4 in. high (16 cm × by 100 mm high) Stand-alone chassis-based units are 10 in. × 12 in. × 16 in. (250 mm × 300 mm × 400 mm)
Costs:	B. $25 to $500 C. $10 to $300
Partial List of Suppliers:	Amperite (www.amperite.com) Crouzet (www.crouzet-usa.com) Magnecraft & Struthers-Dunn (www.magnecraft.com) Macromatic (www.macromatic.com) (A, B, C) Midtex (www.ciitech.com) and (www.tycoelectronics.com) NCC (www.natcon.com) (B, C) Potter & Brumfield (www.tycoelectronics.com)

INTRODUCTION

Time and the sequence of events create and characterize all processes. The human control of both defines a process as repeatable and inevitably determines if the process is industrially viable.

Timers and programming timers are tools that mark time and direct timed events. Timers and sequencers provide a method of controlling a process that has a prescribed set of states with expected time periods in each state. This section reviews the properties of digital and electronic times and includes a discussion of the fundamental aspects of monostable and a-stable multivibrators. Sequencers are also presented as synchronous and asynchronous devices.

This section begins with a brief review of such mechanical sequencers as the cam-operated timers, band-programming timers, and punched-card programmers.

MECHANICAL TIMERS AND SEQUENCERS

Historically, mechanical programming timers represented a landmark event in the industrial revolution. Today, these devices are still employed in manufacturing processes that have some degrees of freedom with respect to manufacturing tolerance or time required per manufacturing step. They are the devices of choice when the manufacturing environment is unfriendly to humans or to electronics, but they display a duel maintenance personality.

On the one hand, they are straightforward mechanical devices that can be repaired by most shop personnel. On the other hand, they are mechanical devices with moving parts that are subject to mechanical wear and sometimes bizarre mechanical failures.

Although most modern instrumentation and controls applications use digital or electronic timers and sequencers, they are in principle quite similar to cam-operated programming multiple-circuit time switches, drum programmers, band-programming timers, and punched-card programmers.

Cam Timers

Illustrations of both cam- and band-type mechanical devices are presented in Figure 5.13a. Cam-operated timers or time switches are provided with mechanical switches, which are arranged in line with an actuating cam attached to a shaft. A clock or a synchronous motor turns this cam shaft at the desired speed—one revolution corresponding to the desired

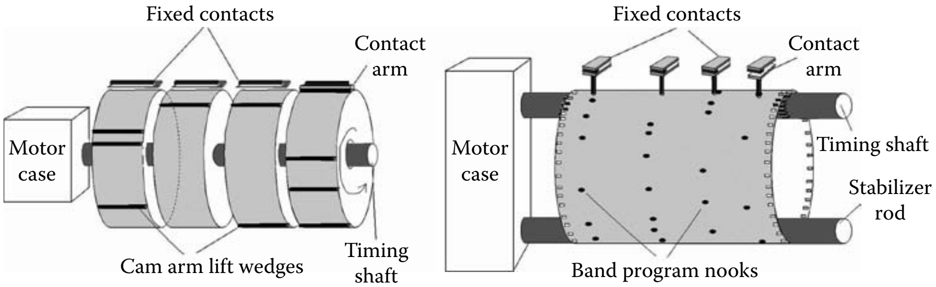


FIG. 5.13a
Illustration of cam-operated and band-operated timers.

cycle duration. During the cycle, each of the switches is closed and opened once (occasionally, two or three times are permissible) for the duration established by the cam settings.

Such a timer can control as many as 60 circuits, with a cycle as short as a few seconds or as long as weeks. Usually about 95% of the cycle can be programmed either “on” or “off” for each circuit; the contacts can handle currents as large as 10 A at 120 V. These timers are available in a variety of sizes and speeds.

Cam-operated timers are often used in conjunction with (either in cascade or in parallel) interval timers, which permits much greater flexibility of action. They are moderately priced and reliable, and their timing accuracy is high, limited by facility in adjustment. A notable limitation of cam-operated timers is that each switch can be actuated only a few times during each timing cycle. This limitation is entirely overcome in drum programmers, band-programming timers, and punched-card programmers.

Band or Drum Programmers

Band-programming timers consist of a belt, or band, of flexible metal or plastic material, several inches wide and as long as is needed to provided the required cycle length. An array of switches is provided, each with an actuating finger or contact arm resting on the band.

Although normally open contact band-programming timers are also available, the right side of Figure 5.13a illustrates the design where, when the band is intact, the switch is pressed closed, but where it is perforated the switch can open. As many as 80 such switches can be used; the band can be of any reasonable length. Many hours of operation can be controlled with many distinct on/off cycles for each switch during the total cycle.

Quite complicated switching patterns can be provided. In a band or drum programmer, the patterned band is often made to move against the switch array by a pulsed stepping motor rather than a simple synchronous motor. Timed pulses drive the stepping motor at varying rates according to a subsidiary pattern.

Punched-Card Programmers

Punched-card programmers operate analogously to band-programming devices. The cards are usually handled singly instead of in a continuous band. Such programmers are in fact quite similar to the Jacquard loom principle. Drum programmers are somewhat comparable in that a drum in which many movable studs are placed rotates in a time cycle under an array of switches.

TIMERS

Although the time of day is a significant factor when people are part of an industrial process, the process itself seldom depends on “the time of day.” The mechanical devices discussed earlier testify to this fact. Only the relative time in or between process steps and stages is important, with the real time not being a feature of any of these devices. The various time delay relays discussed in Section 5.12 are examples of control elements where time is important, used, but not logged.

One-Shot Timers

Figure 5.13b illustrates the “one shot” background concept for timers. The 74121 is representative of a mono-stable device that can produce a single square wave signal, a “one shot,” on command. Although this is a transistor-transistor logic (TTL) device, other technologies including a combination of discrete resistor and capacitor components can be used to create this pulse feature.

Figure 5.13b shows the 74121 pin on the left and an abbreviated time event log on the right. The log indicates that the two outputs, pin 1 and pin 6, respond to a rising edge event at pin 5 when pin 3 and pin 4 are at a low, logic “0,” signal level. Pin 5 is the input for a Schmitt trigger included in the 74121 package. This feature is useful when the triggering event has a slow rising edge.

The duration of the opposite output signals at pins 1 and 6 is the same and dependent on the value of the RC circuit connected to pins 14, 11, and 10. It is the ability to produce a “one shot” event with a desired and determined pulse length and duty cycle that defines the range and accuracy of a timer. A required increased value in both of these timing parameters is what dictates the increase in the cost of a timer.

Monostable and AStable Designs

A monostable device can produce a variety of timed event signals other than the “one shot” described above. Figure 5.13c

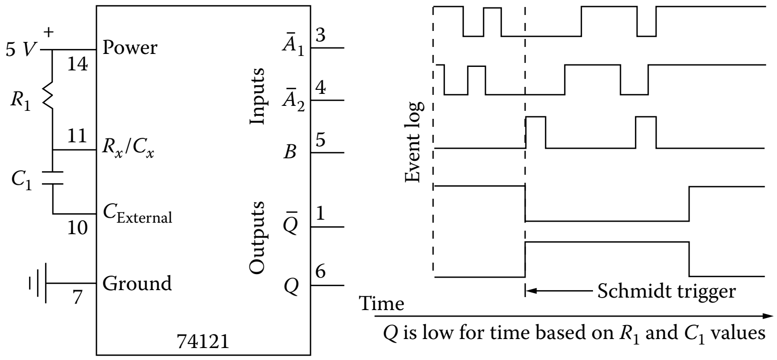

FIG. 5.13b
Pinout and event log for an example one shot timing circuit.

uses an event log to summarize the most popular types, but the corresponding 74121 circuits are not provided. Six different pulse event profiles are introduced: the One Shot, the Delay on Break, the True Delay on Break, the Delay on Make, the Interval On, and the Repeat Cycle. Drawing panels (i) through (v) are single pulse timing signal profiles, while panel (vi) represents a multiple pulse application discussed later.

In practice, the power is continuously supplied to the input voltage terminals of the one shot design. Upon closure of an active high external contact set, a trigger pulse is generated and the load is energized for the time dictated by an RC circuit. A maintained high signal on the external contact set will not affect the time the load is in the ON state.

Delay on Break

Panel (ii) of Figure 5.13c shows the operation of a Delay on Break. Power is also continuously applied to the input terminals, and upon closure of a normally open external initiate switch, the load transfers immediately and remains ON as long as the external contacts are closed. The load will remain ON after the external trigger contacts return to the normal state. The time delay is started instantly by opening these contacts. At the end of this delay period the load de-energizes and the timer is ready for another cycle.

In the True Delay on Break application, the supply voltage energizes the load. The timing period begins upon removal of this input voltage. At the conclusion of the fixed time period, the load is de-energized. In the Delay on Make, the timing period follows the application of the input voltage. Once the fixed timing period has expired, the output is energized. The load stays energized until it is reset by interrupting the input voltage.

Finally, the Interval On energizes the load immediately upon the application of the input voltage. At the end of this fixed time delay, the timer transfers back to its prepower position. Like the other timers summarized in Figure 5.13c, the removal and reapplication of the input voltage resets the timer.

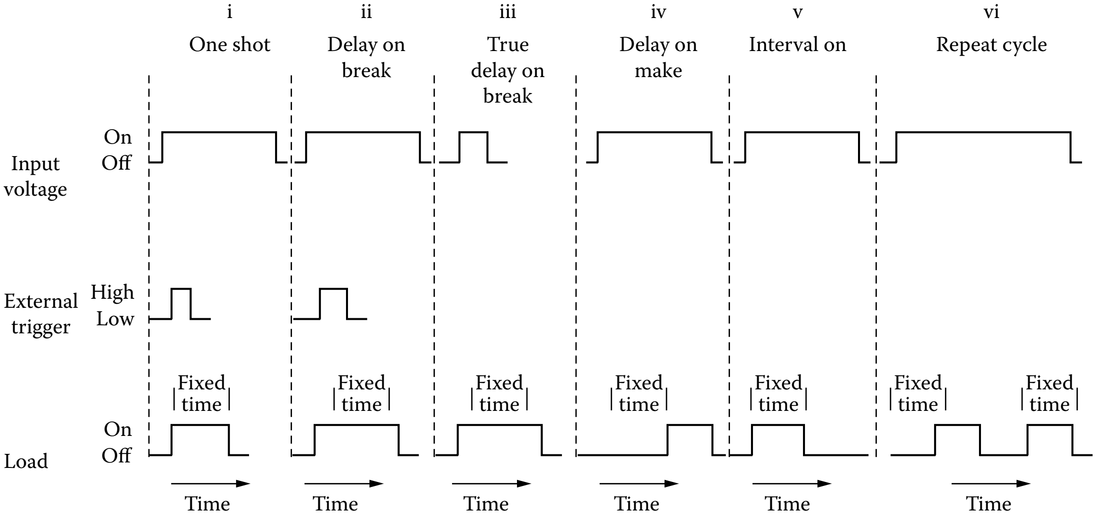

FIG 5.13c
Monostable and astable mode configurations for a 555 device.

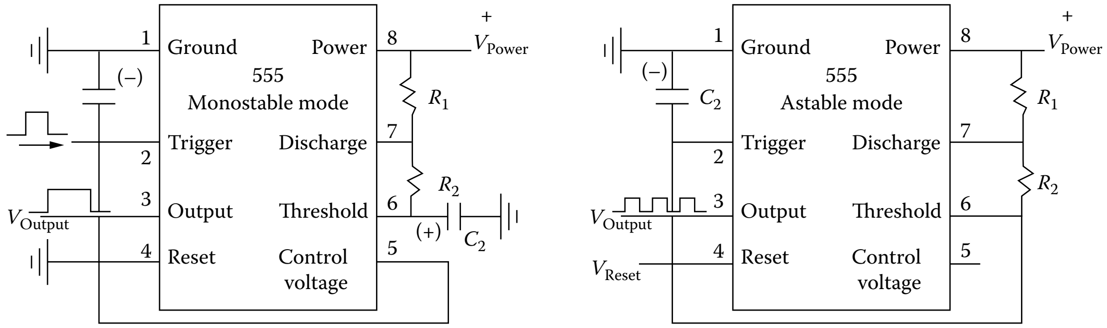

FIG. 5.13d
Example of a serial configuration of two 555 devices.

555 Devices

As suggested above, the "one shot" can be created in different technologies. Figure 5.13d shows two configurations for the 555. The 555 is a semiconductor-based device that can be configured as a "one shot." The output signal from this monostable mode shown on the left in the figure functions identically as the 74121 but differs from the 74121 "one shot" output with respect to current and pulse duration. The 555 output pin can deal with currents at least 10 times higher than the 74121's nominal 16 mA, as well as extended pulse duration times.

The astable 555 configuration is illustrated on the right side of Figure 5.13d. The diagram emphasizes that the difference between the monostable and astable modes is the feedback of the trigger, pin 2, signal to the threshold pin, pin 6, in the a-stable mode. In this mode, the 555 will adopt the oscillator role in a timer.

The 555 astable multivibrator circuit configuration shown is a typical arrangement for a digital sequencer time-based oscillator. The circuit generates a continuous train of clock pulses. A review of some of the circuit connections emphasizes the function of the 555. When the circuit is first engaged, the capacitor, C_2, connected between pin 2 and ground discharges and pin 2, is activated as the voltage drops below 1.4 V.

Once activated, the trigger sets the output line high and brings the discharge terminal, pin 7, to an open circuit state. Because the connection from the 555 to the junction of R_2 and R_3 is now essentially open, the capacitor recharges through the two resistors until the threshold voltages reach approximately 3.6 V. Once this voltage level has been reached, pin 6 is activated, pin 2 is deactivated, and the output and discharge pins move to 0 V. The 0 output on pin 7 provides a path for the capacitor to discharge through R_3.

When the capacitor discharge drops the voltage to one-third the supply voltage, the trigger input is reactivated, and the process starts over. It should be noted that all of the figures in this section omit some circuit details for the sake of concept illustration. In this case, pin 5 of the 555 astable configuration is shown with no connection. Often this pin is connected to ground by means of a 0.01 mF capacitor. Pin 5 is the control voltage input for the threshold voltage.

It is good practice to use the capacitor connection to ground because the capacitor and R_2 form a decoupling element that prevents power supply noise from altering the threshold-input voltage. The fundamental clock frequency for a 555 as an astable multivibrator can be calculated according to the formula:

$$1.44/(R_2 + R_3)C_z \qquad \textbf{5.13(1)}$$

The duty cycle, which in this case is the ratio of the time spent in the logic 0 state to the sum of the times spent in the logic 0 and 1 state, has a calculation formula:

$$D = R_3/(R_2 + 2R_3) \qquad \textbf{5.13(2)}$$

Thus, a duty cycle of 0.5 produces a square wave and is available when $R_3 >> R_2$.

Hybrid Timing Circuits

Figure 5.13e presents two a-stable devices connected in series. This arrangement allows a cluster of pulses, three shown in this diagram, to be delivered within a single pulse, self-triggered by the 555 on the left side of the diagram. Additional versatility is possible because the duty cycle of either a-stable device is adjustable. This concept is also commercially available with the 555 or equivalent on the left of the figure configured in the monostable mode. With this monostable circuit adjustment, the example suggests the fundamental characteristic of the Repeat Cycle timer outlined in panel (vi) of Figure 5.13c.

The assimilation of an a-stable oscillator into an electronic timer is straightforward. The illustrative example in Figure 5.13f merges the 555 in its a-stable mode to an operational amplifier. This combination emphasizes the manipulation of the output signal for the combination circuit at pin 6 of the arbitrarily selected AD 645. The input signal, $V(t)_{in}$, influences the shape and magnitude of the output signal. Although a ramp-input signal is portrayed, a constant signal is a common option reflecting the power needs of the intended application for the timer.

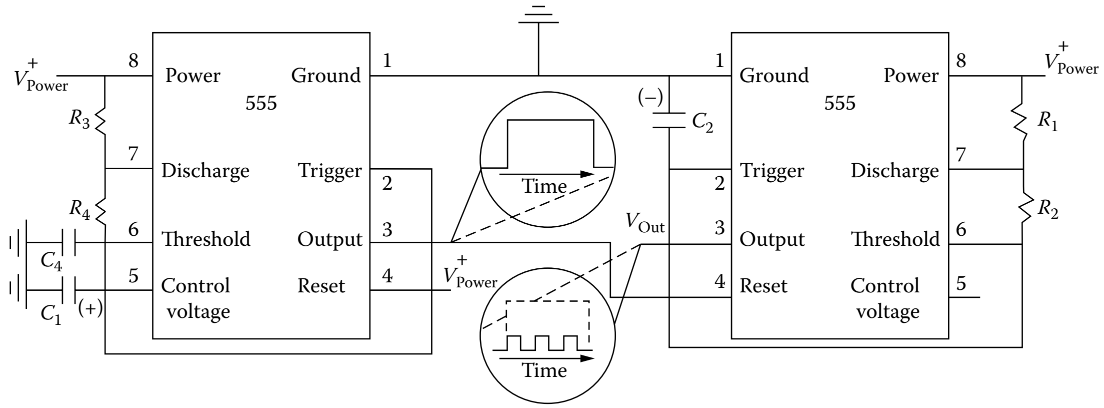

FIG. 5.13e
Elements of a digital-to-analog hybrid electronic timing circuit.

DIGITAL SEQUENCERS

The digital sequencer is a relatively simple digital circuit that mimics the behavior of mechanical sequencers without the mechanical mass and movement inherent in such devices. A simplified synchronous digital sequencer that summarizes the rudimentary idea is illustrated in Figure 5.13g. An understanding of these components and their role in the sequencer will provide a sound basis for selecting and using commercially available digital or electronic programmable sequencers.

The heart of any programmable sequencer is the element that provides the mechanism to generate the timing sequence. For mechanical sequencers it is the motor with the desired gear ratio. For the digital and electronic sequencers it is the a-stable multivibrator. As suggested above, an astable multivibrator is a device that repeatedly changes output states from one extreme to another. The duration of time in one of these extreme states is determined by resistance and capacitance elements in the astable circuit. The 555 in Figure 5.13g fills this role.

The figure illustrates another critical element of a digital sequencer. The 4017 has eight outputs that will go low in turn as a string of pulses is delivered to its clock pin, pin 14. The event log for these outputs and the synchronous pin, pin 3, is provided to the right of the 4017 device pin out. Once the 4017 is enabled via a low signal placed on pin 13, the 4017 responds to the next clock pulse by bringing pin 3 and pin 2 to logic “0.”

There are countless applications for synchronous timers and sequencers. The operation is straightforward and the arrangement of events is usually fixed and easy to determine.

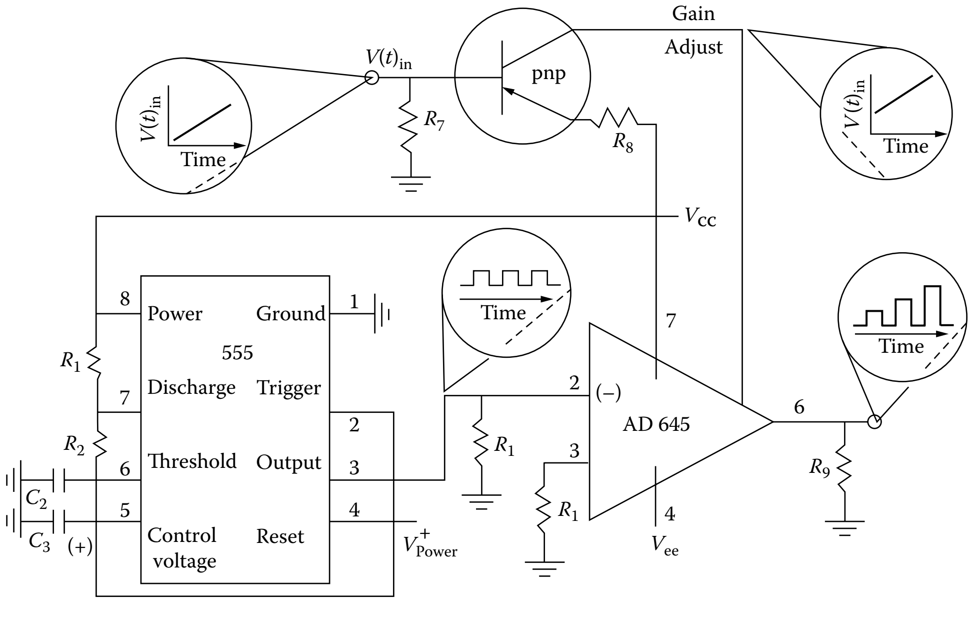

FIG. 5.13f
The assimilation of an astable oscillator into an electronic timer.

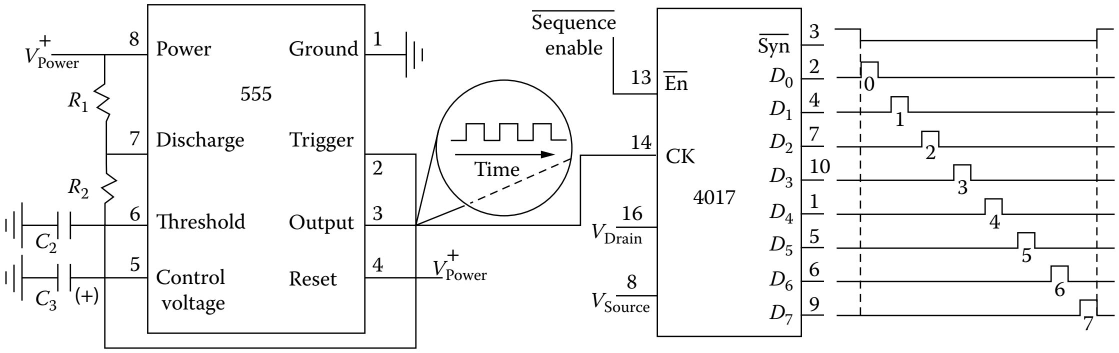

FIG. 5.13g
Elements of a simple synchronous sequencer circuit.

However, synchronous control applications all have the same potential drawback. The time for each step in the process will be fixed by the task that requires the most time.

This downside can be overcome by the use of timers that permit programmed time intervals between process events. Electromechanical timers are very popular in this situation, because they usually use a set of pegs or wedges that mark units of time in which the timer is in the ON or the OFF position.

Asynchronous Sequencers

The idea that real time is not a major issue in a sequential process timer application was introduced above. Upon closer consideration, it is also true that time itself is not the focus of attention during many multiple-step processes. The issue usually reduces down to the fact that each step in a process sequence requires a characteristic time, and then it is time to move to the next process step. In addition, many sequential processes may require other asynchronous process actions to be accomplished before the current step is completed. Figure 5.13h outlines the characteristics of an asynchronous sequencer for such applications.

Figure 5.13h introduces several digital components not employed in previous figures. The event mark is provided by the 555 configured as a monostable oscillator. This device triggers the next process event in the sequence, and that pulse is generated when the 9324 comparator device indicates that the binary pattern on its B_4, B_3, B_2, and B_1 inputs are identical to the pattern presented to its A_4, A_3, A_2, and A_1 inputs, respectively. The single output pulse from the 555 will generate a new counter value on the Q_C, Q_B, and Q_A outputs of the 74192 synchronous counter.

This three-bit output pattern will have a value one bit higher than the previous count. If, for example, the pattern 010, the number 2_8, were displayed, then 3_8, 011, would be the next pattern to be presented at the 74192 Q outputs. This new pattern, 011, is delivered to the inputs of the decoder, in this example the 74138, which proceeds to simultaneously

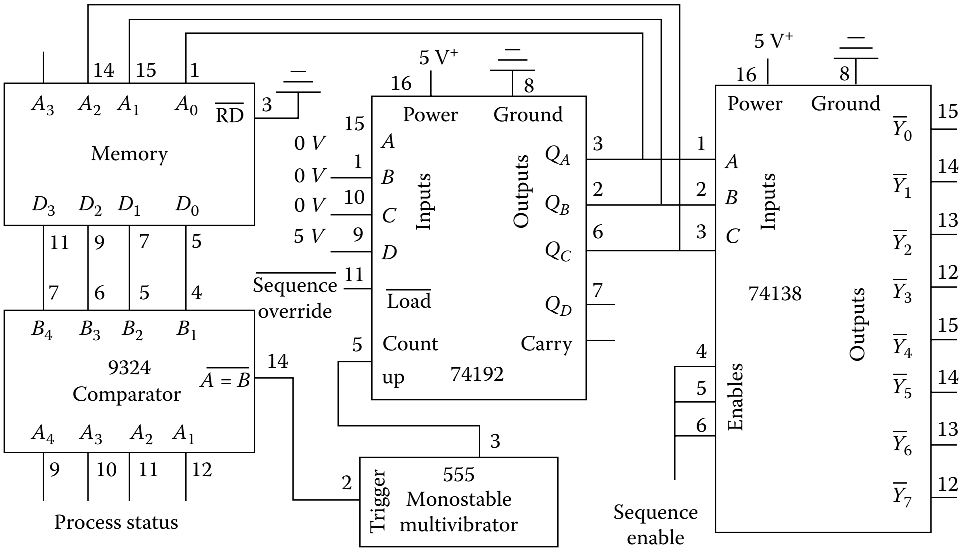

FIG. 5.13h
Illustrative example of a simplified asynchronous sequencer.

return output Y_2 to logic “1” and bring output Y_3 to logic “0.” All of the other 74138 *Y* outputs remain at logic “1,” and the process sequence moves from the process associated with the low signal at Y_2 to the process associated with the low signal at Y_3.

As this stepping from one process in the sequence to the next process occurs, the 74192 also delivers its count value to the address pins, A_2, A_1, and A_0 of a memory device. At this point in the circuit operation, the contents of this memory location are presented to the *B* inputs of the 9324, which are in turn compared to the bit pattern presented to the *A* inputs of the same 9324.

Although the abbreviated example in Figure 5.13h still has several contiguous logic steps, the operational scheme is quite simple. The content of each memory location corresponds to the expected status of the sequential process at the end of each particular step. The current status of the process step in question is delivered to port *A* of the 9324.

When the step is completed, the current status will match the expected status from the memory location; the 9324’s $A = B$ pin, pin 14, goes low to trigger the 555; and the next decoder channel, in this case Y_4, goes low. As long as the correct end status condition for each sequential step of the process is known and stored in the memory device, a digital asynchronous sequencing circuit will move the process from step to step without any need for timed clock events.

Finally, Figure 5.13h does not show the necessary additional circuitry needed to interface the output signals from the eight decoder output channels to the actual process switching circuit elements. Nor does it present the three-state or open collector nature of the current process status input circuit associated with port *A* of the 9324. These interfacing circuit requirements differ for various applications. However, most common industrial interface requirements are compatible with available digital sequencers.

ELECTRONIC SEQUENCERS

Electronic timers and sequencers are hybrid circuits that use active and passive circuit elements. They have a distinct size advantage over mechanical sequencers and provide some logic control functions well beyond the capabilities of their mechanical counterparts. Solid-state augmented electronic sequencers can function as a timed mechanical stepping switch.

When the circuit is powered up it starts out in the first operation step. When an event external to the circuit—typically, a start signal—activates the enable switch, the unit steps through a number of active positions preset at predetermined ON then OFF time intervals. After the completion of the last operation time cycle, the circuit returns to a passive state to await a new external start command.

Asynchronous electronic sequencers are also available. In these circuits, the current process step remains active until a new enable pulse is generated by the system under control. Once triggered, the electronic sequencer de-energizes the current solenoid and then activates the next.

Both synchronous and asynchronous electronic timers and sequencers are popular in dedicated and OEM applications. Usually available as small single circuit board units, they easily interface with existing electronic and hardware components. Although maintenance at the component level is possible, these electronic circuits can be purchased as modular assemblies and thus are suited for a modular replacement-based maintenance philosophy.

CONCLUSIONS

Electronic and digital sequencers have major advantages over mechanical sequencers with respect to versatility, performance, and size; however, when compared to each other, performance is not usually an issue. Electronic sequencers can be miniature and have thick conformal coatings to protect them from the environment.

Larger digital sequencers, however, have more versatility. In addition, most commercially available digital timers and sequencers can be computer interfaced via an RS-232 or other specified industry-related standard interface.

Both types of sequencer technologies provide a variety of timing actions (e.g., on delay, off delay, interval delay), timing ranges, and output relay actions (e.g., normally open, normally closed, DPDT contacts). Both are adaptable to various operating voltages and currents, and both have performance and environment parameters that exceed most industrial application requirements.

INTRODUCTION

In the field of control valve design, the most important developments of the last decade occurred in the areas of electric and digital actuators (Section 6.3), in valve diagnostics (Section 6.8), dynamic performance evaluation (Section 6.9), safety shutdown systems (Section 6.10), fieldbus interaction (Section 6.11), intelligent positioners (Section 6.12), valve status detection and use for control (Section 6.13), and in the increased availability of special valve designs (Section 6.12). Because each of these topics are covered in the noted separate sections, they are not treated in detail in this section.

While this section attempts to discuss all basic aspects of control valve selection and application, in this area too, there exists some overlap with other sections. For example, as noted in the alphabetic listing above, the topics of valve characteristics and rangeability are discussed in more detail in Section 6.7; noise and its reduction in Section 6.14; sizing in Section 6.15; valve actuators and accessories including positioners in Sections 6.2 and 6.4; and the features of the particular valve designs in Sections 6.16 to 6.23. Therefore, the reader is advised to treat this section only as an overview of the subject of control valve applications and refer to the individual sections of this chapter for the detailed discussion of its many specific aspects.

It should also be noted that in most of the sections in this chapter English units are used with their SI equivalents given in parenthesis. An exception is Section 6.14 on valve noise calculation, which follows the general practice of acoustics and uses SI units. Appendices 1 and 2 (at the end of this handbook) give all the conversion factors that are required to go from one to the other system of units.

So, for example, 1 lb/in.^{2} equals 6.89 kPa (kilo Pascals) or 0.0689 bars. Hence, a 3–15 PSIG range is the approximate equivalent of 20–100 kPa. The valve capacity coefficient used in this chapter is the C_v, which is unity, if the valve passes 1.0 gpm of cold water at a specific gravity of 1.0 at a pressure drop of 1.0 psid. The metric equivalent is the K_v, which corresponds to a valve passing 1 m^3 of cold water per hour at a pressure drop of 1 bar. Therefore, if the reader wishes to convert any *Cv* value into K_v, the multiplier is 1.17, and therefore $C_v = 1.17\ K_v$.

Orientation Table

In order to provide some overall orientation about the relative merits of the different valve designs, an orientation table, Table 6.1a, was prepared. In this table some of the more common applications are described, together with some indications of the suitability of the various valve designs. At the end of this section, a standard control valve specification form, prepared by Instrumentation, Systems, and Automation Society, is provided together with an explanation of each of the entries in that form. The discussion of the various topics related to valve selection follows the approximate order of the entries in that form. Therefore, after some introductory remarks, the discussion begins with topics related to the service conditions (process data) and then continues with topics related to the features and accessories of the valve and its installation.

CONTROL VALVE TRENDS

When this handbook was first published some 35 years ago, the overwhelming majority of throttling control valves were the globe types, characterized by linear plug movements and actuated by spring-and-diaphragm operators. At that time, the rotary valves were considered to be on/off shut-off devices. Today, globe valves are still widely used, but their dominance is being challenged by the less expensive rotary (ball, butterfly, plug) valves, which are usually actuated by cylinder operators. This trend represents a mixed blessing and, therefore, is worth further discussion.

Globe vs. Rotary Valves

The main advantages of the traditional globe design include the simplicity of the spring-and-diaphragm actuator; the availability of a wide range of valve characteristics; the relatively low likelihood of cavitation and noise; the availability of a wide variety of specialized designs for corrosive, abrasive, and high/low temperature and pressure applications; the linear relationship between control signal and valve stem movement; and the relatively small amounts of dead band and hysteresis in its operation. These features make the globe valve usable without positioners, which on fast processes is an advantage.

The main reason why rotary valves have been increasing their market share is their lower manufacturing cost and higher relative flow capacity ($C_d = 20$–40 instead of $C_d = 10$–15, as for globe). They also weigh less, can act as both control and shut-off valves, and are easier to seal at the stem to meet OSHA and EPA requirements.

The limitations of globe valves, in addition to their higher cost per unit C_v (in Europe, the equivalent term K_v is used), include their relatively slow speed and low “stiffness” (plug position is affected by dynamic forces in the process fluid), both of which can be improved by using hydraulic cylinder actuators operating at higher pressures.

Major disadvantages of rotary valves are their higher tendency to cavitate and to produce excessive amounts of noise. They are also more likely, due to their smaller size per unit C_v (K_v), to have larger pipe reducers with the associated waste of pressure drop and distortion of characteristics. Their control quality can suffer from the nonlinear relationship between actuator linear movement and valve rotation, plus from the linkages, which can introduce substantial hysteresis and dead play. These characteristics result, in most cases, in a definite requirement for using a positioner, which on fast processes can cause the deterioration of control quality.

Valves vs. Other Final Control Elements

Before proceeding through the steps of selecting a control valve, one should evaluate if a control valve is truly needed in the first place, or if a simpler and more elegant system will result through some other means. For example, an overflow weir can suffice to keep levels below maximum limits, and choke or restriction fittings can serve the function of pressure letdown at constant loads. In other locations, it might be possible to reduce the investment by using regulators instead of control valves.

The advantages of regulators include their high speed (high gain) and their self-contained nature, which eliminates the need for power supplies or utilities. If remote set point adjustment is needed, regulators can be provided with air-loaded pilots to accommodate that requirement. While all regulators (being proportional-only controllers) will display some offset as the load changes, the amount of offset can be minimized by maximizing the regulator gain.

In still other applications, it is prudent to replace whole flow control loops with positive-displacement metering pumps or to replace the control valve with variable-speed centrifugal pumps. The cost-effectiveness of the approach is usually found to be in lowered pumping costs, because the pumping energy that was “burned up” in the form of pressure drop through the control valve is not being introduced, and therefore it is saved.

CONTROL VALVE SIZING

Control valve sizing is discussed in depth in Section 6.15, and therefore only a few general recommendations are made here.

One should first determine both the minimum and maximum C_v (K_v in Europe) requirements for the valve, considering not only normal but also start-up and emergency conditions. The selected valve should perform adequately over

a range of 0.8 $C_{v\min}$ to 1.2 $C_{v\max}$. If this results in a rangeability requirement that exceeds the capabilities on one valve, use two or more valves.

Control valves should not be operated outside their rangeability. Driskell (see Bibliography) properly points to the fact that all "fat" settles in the control valve. In constant speed pumping systems, each design engineer will add their own safety margin in calculating pressure drops through pipes and exchangers, and finally in selecting the pump.

Therefore, the control valve will end up with all these safety margins as added pressure drops, resulting in a much-oversized valve. A highly oversized valve will operate in a nearly closed state, which is an unstable and undesirable operating condition. In variable-speed pumping systems, this problem does not exist, because there the pump speed is adjusted to meet the load, and therefore the effect of accumulated safety margins is eliminated.

Collecting the Process Data

In order to select the right control valve, one must fully understand the process that the valve controls. Fully understanding the process means not only understanding normal operating conditions, but also the requirements that the valve must live up to during start-up, shutdown, and emergency conditions. Therefore, all anticipated values of flow rates, pressures, vapor pressures, densities, temperatures, and viscosities must be identified in the process of collecting the data for sizing.

In addition, it is desirable to identify the sources and natures of potential disturbances and process upsets. One should also determine the control quality requirements, so as to identify the tolerances that are acceptable in controlling the particular variable. The process data should also state if the valve needs to give tight shut-off, if the valve noise needs to be limited, or any other factors that might not be known to the instrument engineer. These can include subjective factors, such as user preferences, or objective ones, such as spare parts availability, delivery, life expectancy, or maintenance history.

Lines 1–12 in the "Specification Form for Control Valves" (at the end of this section) describe the service conditions (process data) that must be provided for the control valve. It is important to carefully determine not only the "normal" values for this data but also the "minimum" and "maximum" values, because the valve must operate properly throughout its range — not just under normal conditions.

Determining the Valve Pressure Drop

Assigning the sizing pressure drop for the valve is more complex than picking a number like 10% or 25% of the total system drop or a number like 10 or 25 psi (0.69 or 1.72 bar). It requires an understanding of the interrelationships that exist in pumping, fan, or compressor systems. If a system consists of nothing else but a pump, a control valve, piping, vessels, and an elevated destination, the energy profile through the system will be as illustrated in Figure 6.1b.

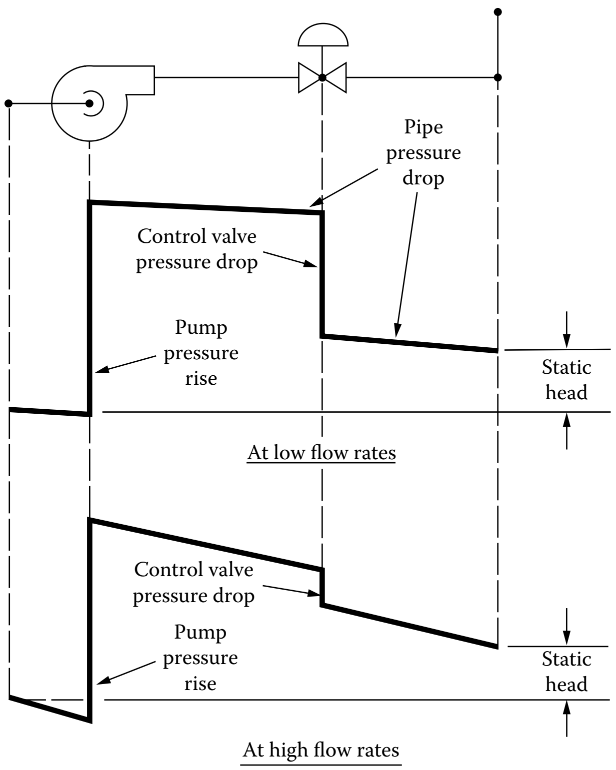

FIG. 6.1b
Pressure profiles of a pumping system at high and low flow rates.

Note that the pressure drop available for the control valve drops as the flow rate rises. This is because at higher flows, the pump discharge pressure will be lower, while the pressure drop through the piping will rise. In other words, the control valve does not work with a fixed pressure drop, nor with a fixed percentage of the total system drop, but it simply takes whatever is left over from what is available and what is required by the rest of the system. Therefore, as shown in Figure 6.1c, the valve energy loss at any particular flow rate (load) is the difference between the corresponding points on the pump and system curves.

As can be seen in Figure 6.1c, the available pressure drop increases as the load (flow rate) drops, and it becomes the minimum when the process flow rate (load) is the maximum. This means that the actual control valve rangeability (in terms of C_v) must be much larger than the ratio of maximum and minimum flows. There is a similar effect on the valve characteristics, which will be discussed (together with rangeability) in both the paragraphs that follow and also in more detail in Section 6.7.

Because of the complexity of the problem, no simple rule of thumb can be used in assigning the valve pressure drop; thus, it is important for the engineer to have a good understanding of the pump and system curves together with the rangeability and characteristics (gain) requirements of the valve. In the process of deciding what pressure drop to assign, you must acknowledge the conflict between control quality and energy conservation. The higher the pressure drop through the valve (relative to the rest of the system), the more

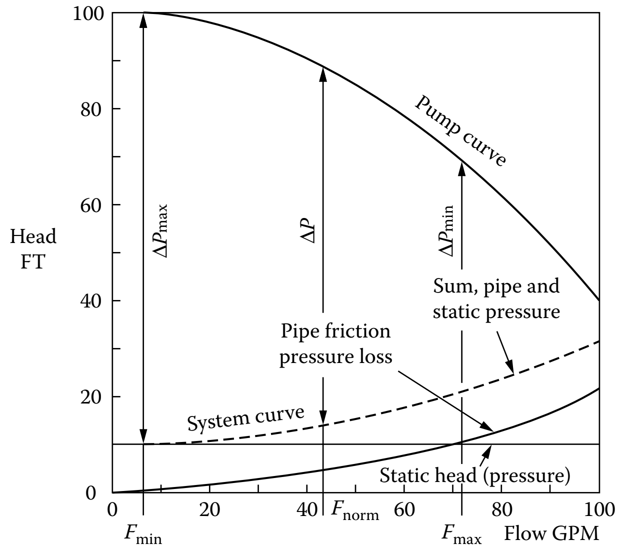

FIG. 6.1c
The difference between the pump discharge pressure curve and the system curve (which is the sum of the static head and the pipe friction loss) is the available valve differential.

impact it will have on the process while, at the same time, the more pumping energy it will waste.

Some might argue that, in fact, no pressure drop needs to be assigned to the control valve during the design phase because as safety margins accumulate, the pump will be oversized anyway. There is some practical wisdom in this attitude, because it is true that by the time the pump service conditions pass from the process engineer to the mechanical engineer, then are sent out for bidding to the manufacturers, and finally a pump is selected, its flow and pressure capabilities will always much exceed the originally specified requirements, and there will be plenty of pressure drop for the valve. While this argument sounds convincing and convenient, it is wrong. It is wrong because it results in unpredictable performance (possibly high noise) and usually also results in oversized control valves, which tend not only to be unstable, but also to have low rangeability.

Therefore, the proper approach to the selection of valve pressure drop is to first determine the total *friction energy loss* (excluding static energy) of the system at *normal* load (flow) and assign 50% of that to valve pressure energy drop. Based on that assignment, one should next determine the resulting valve drop at minimum and maximum loads (flows) and select a valve that can handle the required C_v rangeability. As will be discussed later, one should also select a valve characteristic that, after being "distorted" by the change in valve drop as the load varies, will give acceptable (stable) loop performance.

CHARACTERISTICS, GAIN, AND RANGEABILITY

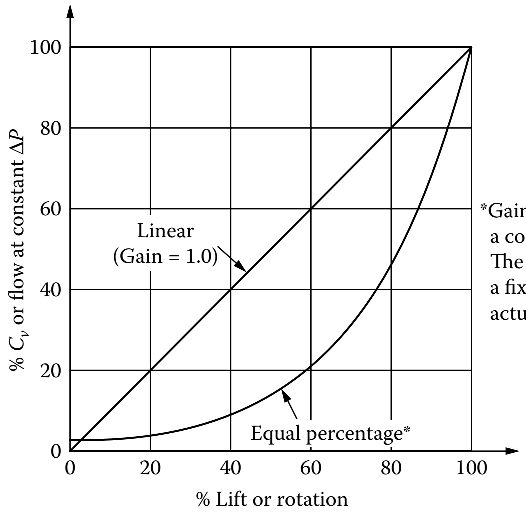
Good control valve performance usually means that the valve is stable across its full operating range, it is not operating near to one of its extreme positions, it is fast enough to correct for process upsets or disturbances, and it will not be necessary to retune the controller every time the process load changes. In order to meet the above goals, one must consider such factors as valve characteristics, rangeability, installed gain, and actuator response. These topics will be separately addressed here and in Section 6.7.

Characteristics and Gain

Characteristics and gain are discussed in more detail in Section 6.7, but they are also briefly covered here. The reason process control engineers must be concerned with "selecting" the right valve characteristics (Figure 6.1d) is because the valve is part of the control loop, and the loop will be stable only if the products of all its gain components (the gains of the process, sensor, controller, and valve gains) is constant. Usually, the controller is tuned so that this gain product is 0.5, in order to give quarter-amplitude damping. This was discussed in some detail in connection with Figure 2.1x in Chapter 2.

If the gains of the loop components do not vary with load, but are constant, the desirable choice is to use a constant gain control valve. A constant gain valve is a linear valve whose theoretical gain (change of flow per unit change of lift) is 1. If the gain of any of the loop components (such as the process) decreases with load (flow through the valve), the proper choice of control valve gain is 1, which increases with load (equal percentage), because this combination will keep the gain product of the loop relatively constant.

Installation Causes Distortion As was pointed out in connection with Figure 6.1c, in mostly friction systems, such as pumping through long pipes (where only a small portion of the total pump energy is used to overcome constant static pressure),



*Gain increases at a constant slope. The rate of rise is a fixed % of the actual flow.

FIG. 6.1d
Inherent characteristics of control valves.

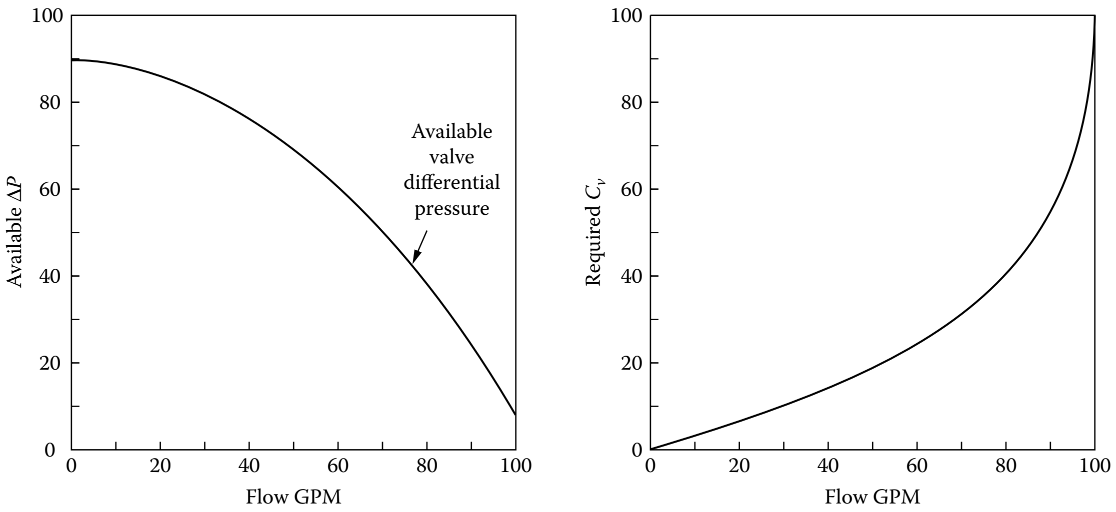


FIG. 6.1e

In mostly friction systems, an increase in load (flow rate) results in a drop in the pressure drop, which is available for the control valve. Therefore, the same amount of increase in flow rate requires a larger increase in the valve capacity coefficient C_v (K_v). For such application, an equal-percentage valve is needed.

the pressure drop available for the control valve is dropping as the load (flow rate) is increasing, and therefore more C_v is needed for unit flow increases as the flow rises (Figure 6.1e).

This is a different condition from the condition at which the valve characteristics were established in the testing facility of the manufacturer, where the flow rate through the valve was measured under *constant* pressure drop conditions. Therefore, when such valves are installed, their gain (characteristics) shift, as will be discussed in Section 6.7. One way to correct for such distortion is to obtain "near-linear" installed characteristics by installing a valve with "ideal inherent" equal-percentage characteristics.

As will be discussed in connection with positioners (Section 6.2), it is also possible to use a cam in the positioner to modify the installed characteristic of the valve, but this can dramatically both change the loop gain of the positioner and limit its dynamic response. Therefore, it is preferred to change the inherent characteristic of the valve trim than to install cams in the valve positioner.

The installed characteristic of the valve can also be modified by characterizing the control signal going to the positioner. This characterization occurs outside the positioner feedback loop, and therefore it has the advantage of not changing the loop gain of the positioner. This method also has its dynamic limitations. For example, a 1% change in the controller output signal may be electronically narrowed to a change in the valve signal of only 0.1% (in the flat regions of the valve characteristic), but such change is too small for some valves to respond to at all.

Therefore, the best solution to obtaining a constant loop gain is to select the inherent characteristics of the valve trim to compensate for the nonlinearity of the process and, thereby, arrive at an installed flow characteristics, which is nearly linear over the operating range of the valve.

Selecting the Valve Characteristics Different engineers have approached the problems caused by process nonlinearity (drop in process gain) in different ways. One approach, that of the old school, was to oversize the pump so that the ratio between the minimum and maximum energy loss in Figure 6.1c will not be large, and therefore the gain of the process will not change much with load. This approach works, but it wastes pumping energy.

Different engineers began to develop different rules of thumb to be used in selecting valve characteristics for the various types of control loops. These recommendations vary in complexity. Shinskey, for example, recommends equal percentage for temperature control and the use of linear valves for all flow, level, and pressure control applications (except vapor pressure, for which he recommends equal percentage). According to Driskell, one can avoid a detailed dynamic analysis by just considering the ratio of the maximum and minimum valve pressure drops ($\Delta p_{\max}/\Delta p_{\min}$) and follow the rule of thumbs listed for the most common applications in Table 6.1f.

Lytle's recommendations are summarized in Table 6.1g; they are more involved, as they take more variables into account.

TABLE 6.1f

Valve Characteristics Selection Guide

Service	*Valve ($\Delta p_{max}/\Delta p_{min}$) Under 2:1*	*Valve ($\Delta p_{max}/\Delta p_{min}$) Over 2:1 but Under 5:1*
Orifice-type flow	Quick-opening	Linear
Flow	Linear	Equal %
Level	Linear	Equal %
Gas pressure	Linear	Equal %
Liquid pressure	Equal %	Equal %

TABLE 6.1g

Recommendations on Selecting Control Valve Characteristics for Flow, Level, and Pressure Control Loops‡

LIQUID LEVEL SYSTEMS

Control Valve Pressure Drop	*Best Inherent Characteristic*
Constant Δ*P*	Linear
Decreasing Δ*P* with increasing load, Δ*P* at maximum load > 20% of minimum load Δ*P*	Linear†
Decreasing Δ*P* with increasing load, Δ*P* at maximum load < 20% of minimum load Δ*P*	Equal-percentage
Increasing Δ*P* with increasing load, Δ*P* at maximum load < 200% of minimum load Δ*P*	Linear
Increasing Δ*P* with increasing load, Δ*P* at maximum load > 200% of minimum load Δ*P*	Quick-opening

PRESSURE CONTROL SYSTEMS

Application	*Best Inherent Characteristic*
Liquid process	Equal-percentage†
Gas process, small volume, less than 10 ft of pipe between control valve and load valve	Equal-percentage
Gas process, large volume (process has a receiver, distribution system, or transmission line exceeding 100 ft of nominal pipe volume), decreasing Δ*P* with increasing load, Δ*P* at maximum load > 20% of minimum load Δ*P*	Linear†
Gas process, large volume, decreasing Δ*P* with increasing load Δ*P* at maximum load < 20% of minimum load Δ*P*	Equal-percentage

FLOW CONTROL PROCESSES

		Best Inherent Characteristic	
Flow Measurement Signal to Controller	*Location of Control Valve Relation to Measuring Element*	*Wide Range of Flow Setpoint*	*Small Range of Flow but Large ΔP Change at Valve with Increasing Load*
Proportional to *Q*	In series	Linear	Equal-percentage†
Proportional to *Q*	In bypass*	Linear	Equal-percentage
Proportional to Q^2 (orifice)	In series	Linear†	Equal-percentage
Proportional to Q^2 (orifice)	In bypass*	Equal-percentage	Equal-percentage

* When control valve closes, flow rate increases in measuring element.

† Most common.

‡ From Reference 1.

Process Nonlinearity Yet another approach in overcoming the process nonlinearity caused by the variation in valve pressure drop is to modify the controller output signal to eliminate that nonlinearity (discussed in Section 6.7) or to replace the control valve with a complete flow control loop (Figure 6.1h). By selecting a linear flow transmitter, the characteristics of the slave loop will also be linear, and therefore its gain will be 1.0.

This approach works fine, but it also increases the system cost. In addition, while it eliminates a nonlinearity, it introduces a slave loop, which on fast processes can degrade the quality of control quality. By using intelligent control valves (Section 6.12), one can obtain flexibility in implementing one or the other approach.

Process nonlinearity also exists for reasons other than variations in the available valve pressure drop. The gain of heat-transfer processes, for example, always drops as the load increases, because the heat-transfer surface is constant, and therefore the heat transfer is more efficient when small amounts of heat need to be transferred. Consequently, in order to keep the gain product of the control loop constant, it is necessary to compensate the dropping process gain with an increasing valve

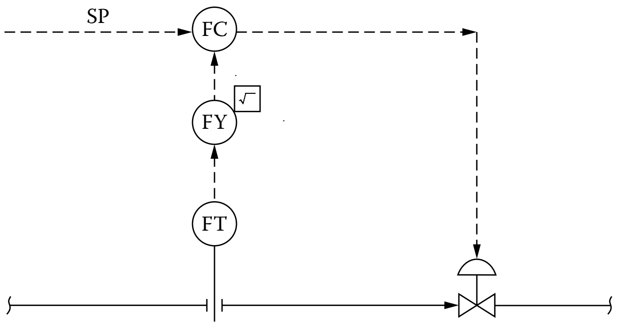

FIG. 6.1h

Valves can be linearized by replacing them with a complete slave control loop.

gain. For this reason, all temperature control valves are always equal percentage.

Composition processes can also be nonlinear, but their nonlinearity is usually more complex, such as the titration curve of a pH control system. In these situations, the likely solution is to use a linear valve (constant gain) and a nonlinear controller (Figure 2.19d), one whose gain varies as the mirror image of the process gain.

Valve Rangeability

Control valve rangeability is also discussed in more detail in Section 6.7. Here, it should suffice to state that the required rangeability should be calculated as the ratio of the C_v (K_v) required at maximum flow (and minimum pressure drop) and the C_v (K_v) required at minimum flow (and maximum pressure drop). The decision on whether a particular control valve is capable of providing the required rangeability should be evaluated on the basis of a plot of valve gain vs. valve C_v. If the actual valve gain is within 25% of the theoretical valve gain between the minimum and maximum C_v, the rangeability is acceptable. As will be discussed in Section 6.7, the rangeability definitions used by manufacturers are usually not based on valve gain.

One way to increase the rangeability is to have the controller operate more than one control valve. As will be discussed below, such multiple valves can be split-ranged, sequenced, or operated in a floating mode.

Control Valve Sequencing When the rangeability requirements of the process exceed the capabilities of a single valve, control valve sequencing loops must be designed that will keep the loop gain constant while switching valves. This requires careful thought.

Assuming that the task is to sequence two linear valves, with sizes of 1 and 3 in. (25 and 75 mm) having C_vs (K_vs) of 10 (8.62) and 100 (86.2), respectively, Shinskey's recommendation is the following: If the large valve were to operate from 9 to 15 PSIG (0.6 to 1.0 bar) and the small one from 3 to 9 PSIG (0.2 to 0.6 bar), the loop gain would change by 10 when passing through 9 PSIG (0.6 bar).

The only way to keep the loop gain constant in this example would be to operate the small valve from 0 to 10% and the large valve from 10 to 100% of controller output. This would result in a 3–4.2 PSIG (0.2–0.28 bar) range for the 1 in. (25 mm) and a 4.2–15 PSIG (0.28–1.0 bar) range for the 3 in. (75 mm) valve. Therefore, if more than one valve is required to increase rangeability, in most cases equal-percentage valve characteristics are needed.

Sequencing Equal-Percentage Valves The sequencing of equal-percentage valves is done as follows: If the small valve had a C_v of 10 and a rangeability of 50:1, its minimum C_v would be 10/50 = 0.2. A line drawn on semilogarithmic coordinates connecting C_v (K_v) 100 (86.2) and 0.2 (0.172) appears in Figure 6.1i. Observe that the C_v of 10 of the small valve falls slightly above the mid-scale of the controller output (to about 65%), providing a much more favorable span for the calibration of the positioner.

In order to have the two valves act as one without disturbing the smooth equal-percentage characteristics at the points of switching, only one valve must be open at any one time. Therefore, the large valve must be prevented from operating at low flows, because in its nearly closed position its characteristics are not equal-percentage. For these reasons, only one valve must be open at any one time.

In the scheme shown in Figure 6.1i, the small valve alone is manipulated until the controller output reaches the value corresponding to its full opening. At this point the pressure switch energizes both three-way solenoid valves, venting the small valve and opening the large to the same flow that the small had been delivering. Switching takes place in 1 sec or less, adequate for all but the fastest control loops.

When the controller output falls to the point of minimum flow from the larger valve (35%), the solenoids return to their original position. Thus, the switch has a differential gap adjusted to equal the overlap between valve positioners (30%). The range of the positioner for the large valve is found by locating its minimum C_v in Figure 6.1i. A rangeability of 50 would give a minimum C_v of 2.

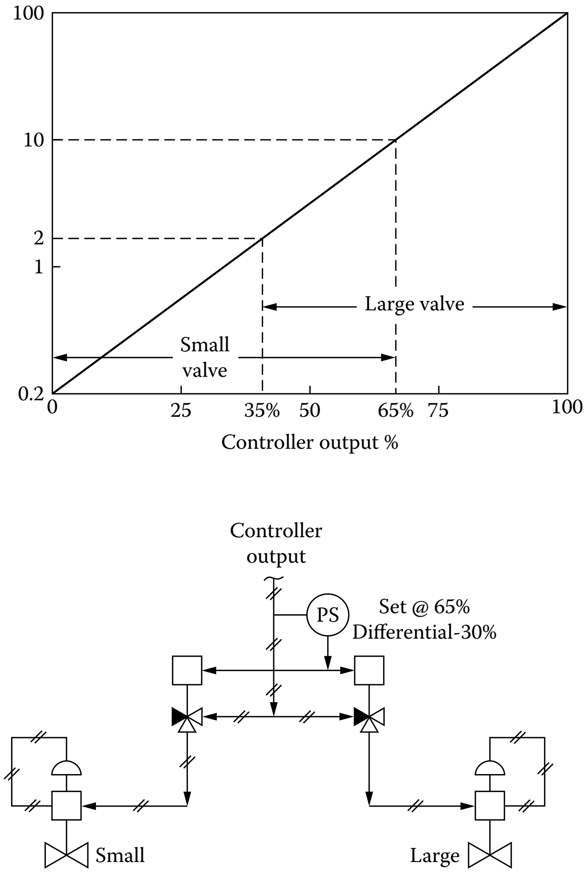

FIG. 6.1i
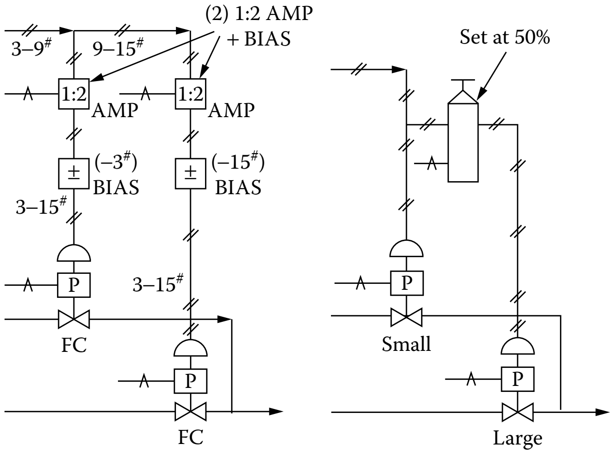
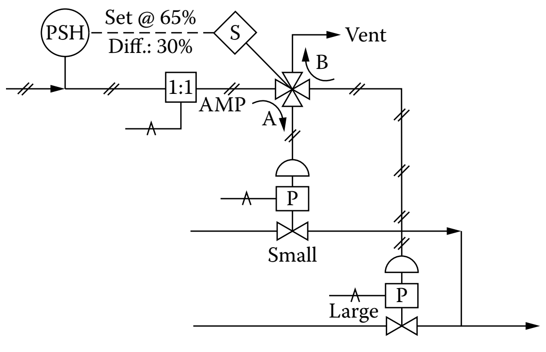
Sequencing two equal-percentage valves, while minimizing the upset caused by switching valves.



Split ranging
(Gain plus BIAS)

"Floating" control of
large valve



Small/Large valve select

FIG. 6.1j
Alternate methods of obtaining high turndown through the use of multiple control valves.

This same approach can be used to sequence three or more valves. If linear characteristics are required, one should insert a 10:1 multiplier relay in the controller signal to the small valve, so that a 0–10% controller output will result in a 0–100% signal to the small valve.

Split-Ranging or Floating Some process control engineers feel that the switching scheme in Figure 6.1i is too abrupt or could cause a maintenance problem. For these reasons, they prefer the methods of valve sequencing illustrated in Figure 6.1j.

The split-ranging loop shown in the upper left of the figure contains both gain and bias relays to provide the added rangeability. Even better response can be provided by the use of a "floating" valve position controller, shown on the top right of Figure 6.1j. This controller slowly moves the larger valve so as to keep the smaller one near its 50% opening. This way, the small valve provides sensitivity and fast response to the loop within its capacity. The large valve is a sort of an automatic bypass, which sets the capacity and has a limited frequency response.

The "large/small valve selection" scheme shown at the bottom of Figure 6.1j differs from the one in Figure 6.1i only in that it uses only one four-way solenoid pilot instead of two three-way units. The purpose of the 1:1 amplifier is to eliminate the bounce when the solenoid switches.

As the purpose of valve sequencing is to increase the rangeability of the loop without upsetting its stability, the existence of two or more valves should not be noticeable by the controller. In other words, in a well-designed sequencing system, the controller would operate as if its final control element were a single valve, having the desired gain characteristics and a very wide rangeability.

In order to keep the gain characteristics of the valve pair correct, there should be no "bumps" when the larger valve is opened. This requires that only one valve be throttled at a time and the other be closed. From this perspective, the performance of the small/large valve selection scheme in Figure 6.1j is superior to that of the split-ranging or the floating methods.

ACTUATOR SELECTION

Sections 6.3 and 6.4 discuss the applications and relative advantages of the different pneumatic, electric, digital, and hydraulic actuator designs.

The popularity of the spring-and-diaphragm actuator is due to its low cost, its relatively high thrust at low air supply pressure, and its availability with "fail-safe" springs. By trapping the pressure in the diaphragm case, it can also be locked in its last position. It is available in various designs: springless, double diaphragm (for higher pressures), rolling diaphragm (for longer strokes), and tandem, which provides more thrust. One of the limitations of this design is the lack of actuator "stiffness" (resistance to rapidly varying hydraulic forces caused, for example, by flashing). For such applications, hydraulic or electromechanical (motor gear) actuators are preferred, although a stiffer spring (6–30 PSIG, which corresponds to 0.41 to 2.59 bars) in a spring-and-diaphragm unit is sometimes sufficient to correct the problem.

Piston Actuators

Linear piston actuators provide longer strokes and can operate at higher air pressures than the spring-and-diaphragm actuators. When used to operate rotary valves, the linear piston or spring-and-diaphragm actuator does not provide a constant ratio of rotation per unit change in air signal pressure. Therefore, the use of positioners is always advisable.

Rotary piston actuators operate at higher air pressures and can provide higher torque, suitable for throttling large ball or butterfly valves. The double-acting version of this actuator does not have a positive failure position, but such a position can be added by extending the piston case and inserting a helical spring.

For higher torque (over 1000 ft lb_f, which corresponds to 1356 Nm), heavy-duty transfer linkages are required (Scotch yoke or rack and pinion); such units cannot be easily disassembled and maintained in the field. These actuators

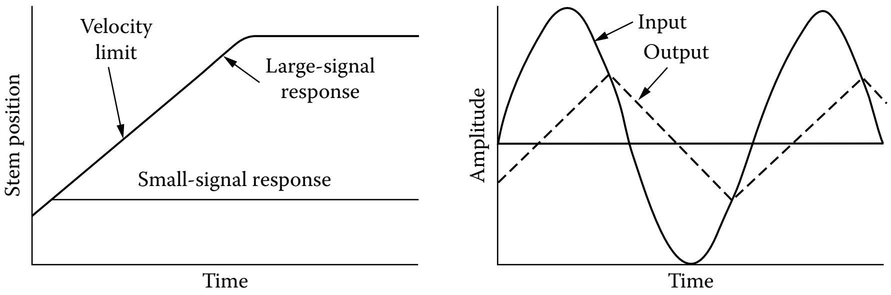


FIG. 6.1k
Response of velocity-limited actuators to a step change (left) and to a high-amplitude sine wave (right) in the control signal, according to Shinskey.

also require positioners, because the relationship between air signal change and resulting rotation is not linear. The use of positioners on fast loops can deteriorate the loop's performance, as it will need to be detuned.

Actuator Speeds of Response

In the family of pneumatic actuators, the spring-and-diaphragm actuators are the slowest (1–30 sec/stroke), spring-returned pistons with supply/exhaust at both ends of the piston are the fastest. Dual pistons can stroke valves in 0.5 sec.

In the family of electric actuators, the slowest are the electromechanical motor-driven valves (5–300 sec/stroke); hydroelectric actuators can move at 0.25 in./sec (6 mm/sec) or faster if hydraulic accumulators are used. The fastest are the small, on/off solenoids, which can close in 8–12 ms, while throttling solenoids require about 1 sec to stroke.

Valve actuators can be velocity limited because they cannot move faster than their maximum design speed. This is true of both electric and pneumatic motors or actuators. In case of the latter, maximum speed is set by the maximum rate at which air can be supplied or vented. If the full stroking (100%) of a valve takes 4 sec, then its velocity limit is 25% per second.

Valve signal changes usually occur in small steps, and therefore the velocity limit does not represent a serious limitation because, for example, the time required to respond to a 5% change is only 0.2 sec. This is fast enough for most loops. Figure 6.1k illustrates the response of velocity-limited actuators to various types of control signals.

Actuator speeds can be increased by enlarging the air flow ports and by installing booster relays. On on/off valves, the addition of a quick-dump valve (Figure 6.2o) will dramatically increase the venting rate. The dynamic performance of the actuator can also be affected by modifying the tare volume, pressure range, or dead band. In order to reduce the dead band, one usually needs to modify the piston seals, linkages, or rack and pinion connections.

Most valve actuators display some dead band or hysteresis band due to packing friction (Figure 6.1l). This can cause instability if the change in the control signal is small enough to fall within the hysteresis band width.

Actuator Power

The actuator is sized on the basis of the power or thrust required to overcome the unbalanced forces in the valve body and the seating force, and on the basis of the "stiffness" necessary for stability. In pneumatic actuators, the thrust is a function of piston or diaphragm area times air pressure. While the control signal is usually 3–15 PSIG (0.2 to 1.0 bar), the actuating pressure can be as high as the air supply pressure, if positioners or amplifier relays are installed. If their costs can be justified, electrohydraulic actuators will give the highest power and speed of response.

Valve Failure Position

In pneumatic actuators, the fail-safe action can be provided by a spring or from an air reservoir, but the latter represents added expense, complexity, and space requirements.

Electric actuators are usually more expensive, except for such designs as the spring-loaded or modulating solenoid valves discussed in Section 6.3. Electric actuators are therefore most often used where air is not available, where the thrust required is less than 1000 lb_f (4448 N), where it is acceptable to have the valve fail in its last position, and where slow response is not a drawback.

Like most generalizations, however, these are not completely true: Electromechanical motor and hydraulic actuators are available with high thrusts and can be provided with positive failure. Hydraulic actuators are also available with

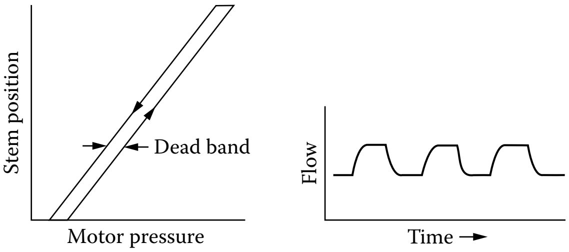

FIG. 6.1l
Dead band in the valve (left) can result in limit cycling (right) when the loop is closed.

fast response speeds. To gain an in-depth understanding of the capabilities of actuators, refer to Sections 6.3 and 6.4.

It is the responsibility of the process control engineer to specify the valve failure position. It is the general practice to fail energy supply valves (steam, hot oil, and so on) closed and energy-removing valves (cold or chilled water) open. The flow sheet abbreviations can be FC (fail closed), FI (fail indetermined), FL (fail in last position), and FO (fail open). Spring-loaded actuators are the most convenient means of providing FC or FO action, while two-directional air or electric motors will naturally tend to fail in their last positions.

In addition to anticipating the consequences of actuator power failure, one should also consider the results of other component failures, such as the spring, diaphragm, piston, and so on. When such failures occur, the ultimate valve position will *not* be a function of the actuator design, but of the process fluid forces acting upon the valve itself. The choices are FTO (flow to open), FTC (flow to close), or FB (friction bound—tends to stay in last position). FTO action is available with globe valves. FTC action can be obtained from butterfly, globe, and conventional ball valves. Rotary plug, floating ball, and segmented ball valves tend to be friction bound, with the flow direction possibly affecting the torque required to open the valve.

POSITIONERS

The positioner is a high-gain plain proportional controller that measures the valve stem position (to within 0.1 mm), compares that measurement to its set point (the controller output signal), and, if there is a difference, corrects the error. The open-loop gain of positioners ranges from 10 to 200 (proportional band of 10–0.5%), and their periods of oscillation range between 0.3 and 10 sec (frequency response of 3–0.1 Hz). In other words, the positioner is a very sensitively tuned, proportional-only controller.

Positioners that are electronically and digitally controlled, or are intelligent and are capable of self-diagnostics, communication on fieldbuses, and other advanced features, are not discussed here, because they are described in detail in Section 6.12.

When to Use Positioners

The main purpose of having a positioner is to guarantee that the valve does, in fact, move to the position where the controller wants it to be. The addition of a positioner can correct for many variations, including changes in packing friction due to dirt, corrosion, or lack of lubrication; variations in the dynamic forces of the process; sloppy linkages (dead band); or nonlinearities in the valve actuator. The dead band of a valve/actuator combination can be as much as 5%; when a positioner is added, it can be reduced to less than 0.5%. It is the job of the positioner to protect the controlled variable from being upset by any of the above variations.

In addition, the positioner can also allow for split-ranging the controller signal between more than one valve, can increase the actuator speed or thrust by increasing the pressure or volume or the actuator air signal, and can modify the valve characteristics by cams or electronic function generators.

While the above positioner capabilities can be convenient, they can also be obtained without the use of positioners. For example, split-ranging can also be done by the use of split-ranged valve springs or by multiple/biasing relays in the air signal line to the valve. Similarly, increasing the speed/thrust of the valve can be achieved by booster relays, and changes to the control valve characteristics can be obtained, not only by replacing the plug, but also by pneumatic or electronic characterizing of the controller signal. Therefore, these reasons do not necessitate the use of positioners.

Actuators without springs always require positioners. When a valve is in remote manual (open loop) operation, it will always benefit from the addition of a positioner, because a positioner will reduce the valve's hysteresis and dead band while increasing its response. When the valve is under automatic (closed loop) control, the positioner will be helpful in most slow loops, which control analytical properties, temperature, liquid level, blending, slow flow, and large volume gas flow.

A controlled process can be considered "slow" if its period of oscillation is three times the period at which the positioned valve oscillates. In such installations as B in Figure 6.2b, the addition of a positioner increases the open-loop gain and, therefore, the loop response. As a consequence, the tuning of the controller could also be improved by increasing the gain (making the proportional band narrower) and adding more repeats per minute in the integral setting.

When Not to Use Positioners

In the case of fast loops, positioners are likely to degrade loop response, contribute to proportional offsets, and cause limit cycling (fast flow, liquid pressure, small volume gas pressure).

The positioner in effect is the cascade slave of the loop controller. In order for a cascade slave to be effective, it must be faster than the speed at which its set point, the master output signal, can change. The rules of thumb used in this respect suggest that the time constant of the slave should be ten times shorter (open-loop gain ten times higher) than that of the master and the period of oscillation of the slave should be three times shorter (frequency response three times higher) than that of the primary. The criteria for positioners need not be this stringent, but still, it is recommended not to use positioners if the positioned valve is slower than the process variable it is assigned to control.

A controlled process can be considered "fast" if its period of oscillation is less than three times that of the positioned valve. In such situations, the positioned valve is one of the slowest components in the loop and, therefore, slows down the load (by limiting the open-loop gain of the loop and lengthening the period of oscillation). Part A in Figure 6.2b illustrates such a situation, where the loop can be tuned more tightly (higher gain, more repeats/minute) and, therefore, responds better without a positioner. It might also be noted that after a new steady state is reached, the positioned installation gives more noisy control because of the hunting and limit cycling of the positioner, which cannot keep up with the process.

Some will argue that all loops can be controlled using positioned valves if they are sufficiently detuned. This is true, but "detuning" means that the controller is made less effective (the amount of proportional and integral correction is reduced), which is undesirable. A 0.2 gain (500% proportional) setting on a level controller means that the tank can be flooded or drained before the controller fully strokes the valve. Also, there are cases where the gain must be so low (the proportional band so wide) that it is outside the available PB setting range of the controller.

Positioners to Eliminate Dead Band

All valves and dampers will display some dead band because of friction in their packing, unless positioners are used. Whenever the direction of the control signal is reversed, the stem remains in its last position until the dead band is exceeded, as shown in Figure 6.1l.

This figure on the right shows that if a sine wave control signal is driving the valve actuator (motor), it produces a stem motion that is distorted and shifted in phase. This phase shift, when combined with the integrating characteristic of certain processes and with the reset action of a controller, causes the development of a limit cycle. According to Shinskey, widening the proportional band will not dampen the oscillation, but only make it slower.

The limit cycle will not appear if a proportional-only controller is used, and if the process has no integrating element. Processes that are prone to limit cycling in this way are liquid level, volume (as in digital blending), weight (not weight-rate), and gas pressure—all of which are related to the integrals of flow. Whenever one intends to control such a process with a proportional and integral (PI) controller, the use of positioners should be considered. In case of level control, one can accomplish the same goal by using a plain proportional controller and a booster or amplifier instead of a positioner.

Positioners in general will eliminate the limit cycle by closing a loop around the valve actuator. Positioners will also improve the performance of valves on slow processes, such as pH or temperature. On the other hand, dead band caused by stem friction should not be corrected by the use of positioners on fast loops, such as flow or "fast" pressure.

The positioner's function as a cascade slave, as was explained earlier, can cause oscillation and cycling on fast loops if the controller cannot be sufficiently detuned (minimum gain is not low enough). Similarly, negative force reactions on the plug require an increase in actuator stiffness and not the addition of a positioner. Actuator stiffness can be improved by increasing the operating air pressure or by using hydraulic actuators.

Split-Range Operation

The use of positioners for split-range applications is usually accepted regardless of the speed of the process. This is not entirely logical, because on fast loops the control performance can be degraded by the use of positioners. In such cases, some instrument engineers do discourage the use of positioners to implement split-ranging. Instead, they recommend gain-plus-bias relays so that the positioner (the less-accurate device) will operate over its full range (Figure 6.1j). This also eliminates the need for a special calibration.

One can also consider accomplishing the split-range operation through the use of different spring ranges in the valve actuators. In addition to the standard 3 to 15 PSIG (0.2 to 1 bar) range spring, valves can also be obtained with other spring ranges. These include 3–7 PSIG (0.2–0.5 bar), 4–8 PSIG (0.28–0.55 bar), 5–10 PSIG (0.34–0.68 bar), 7–11 PSIG (0.5–0.75 bar), 8–13 PSIG (0.55–0.9 bar), and 9–13 PSIG (0.62–0.9 bar).

Lastly, if split-range positioners are installed on fast processes, the resulting degradation of control quality can be limited by adding a restrictor or an inverse derivative relay in the control signal to it and, thereby, artificially making the controller appear to be slower than it really is. This technique is not highly recommended (except to reduce wear and tear on the valve in noisy loops), because restrictors are prone to plugging or maladjustment and because they both degrade the loop performance.

Accessories

If the need is to increase the speed or the thrust of the actuator, it is sufficient to install an air volume booster or a pressure amplifier relay, instead of using a positioner. Boosters will give better performance than positioners on fast processes, such as flow, liquid pressure, or small-volume gas pressure control, and they will not be detrimental (nor will offer advantages) if used on slow processes.

If the reason for adding a positioner is to alter or modify the control valve characteristics, this is not a valid justification on fast processes, because this aim can be satisfied by the use of dividing or multiplying relays in the controller output, which will not degrade the quality of control (see Section 6.7).

PROCESS APPLICATION CONSIDERATIONS

In selecting control valves, the properties of the process fluid must be fully considered. The process data should be carefully and accurately determined because even small variations in temperature or pressure can cause flashing or cavitation. Considerations include such obvious variables as pressure, temperature, viscosity, slurry, or corrosive nature, or the less obvious factors of flashing, cavitation, erosion, leakage, sterilization, and low flow rates. These are discussed in the paragraphs that follow below.

Pressure Considerations

The available design pressures for each valve type are listed in the feature summaries in the front of Sections 6.16–6.24.

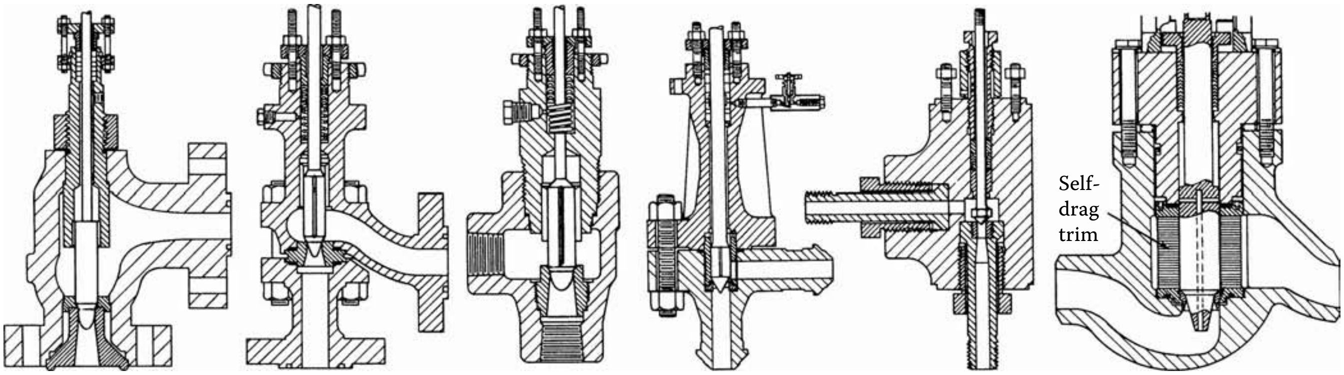

FIG. 6.1m
High-pressure valve designs.

In selecting the control valve for a particular application, one should pay particular attention to high pressure, high differential pressure, and vacuum services. These will be discussed in the paragraphs below.

High-Pressure Services When designing valves for high-pressure services, the following features are of particular importance:

1. Increased physical strength
2. Selection of erosion-resistant material
3. Use of special seals

Valve bodies can usually withstand higher pressures than can the piping. Valve bodies for high-pressure services are usually forged to provide homogeneous materials free of voids and with good mechanical properties. The loads and stresses on the valve stem are also high. For this reason, higher strength materials are used with increased stem diameters. As shown in Figure 6.1m, the stems are usually kept short and are well-guided.

High-pressure services will also increase the probability of noise, vibration, and cavitation, which will be discussed in later paragraphs.

High Differential Pressure With high flow rates and high pressure drops, a large amount of energy is dissipated in turbulence. A fraction of this energy is radiated as noise (see Section 6.14). For most (but not all) gases and conditions, one result of the high pressure drop can be a very low outlet temperature. It is not always proper to use the gas laws to predict these temperatures, and instead, actual thermodynamic properties should be used. The very low temperature will cause some valve materials to become brittle, and careful selection of alloys and other materials is always required.

Depending on the gas involved and other materials in the flowing fluid, hydrates or other solids may form in the valve. Liquid droplets may develop and cause erosion. It is necessary to investigate for any peculiarity of the flowing fluid. A high-velocity jet leaving the valve can erode downstream piping. Very high forces are developed on the valve body and internal parts and can cause valve instability. With the change in magnitude and, often, direction of the fluid, substantial reaction forces are developed. Serious damage may result if the valve and piping are not properly restrained.

High operating pressure frequently involves high pressure drops. This usually means erosion, abrasion, or cavitation at the trim. These will be discussed in detail in the coming paragraphs, but it should also be mentioned here that cavitation and erosion resistance are usually not properties of the same metal. Materials resistant to erosion and abrasion include 440C stainless steel, flame-sprayed aluminum oxide coatings (Al_2O_3), and tungsten carbide.

On the stem, where the unit pressure between it and the packing is high, it is usually sufficient to chrome-plate the stem surface to prevent galling. Special "self-energizing" seals are used with higher pressure valves (above 10,000 PSIG, or 69 MPa, service) so that the seal becomes tighter as pressure rises. Popular body seal designs for such service include the delta ring closure and the Bingham closure (Figure 6.1m).

As discussed in more detail in Section 6.19, the self-energizing seals are used in connecting the high-pressure valves into the pipeline. These designs depend on the elastic or plastic deformation of the seal ring at high pressures for self-energization.

Special packing designs and materials are also required in high-pressure service, because conventional packing would be extruded through the clearances. To prevent this, the clearance between stem and packing box bore is minimized, and extrusion-resistant material, such as glass-impregnated Teflon, is used for packing.

Some of the likely causes of valve failure in high pressure drop services include:

1. Elastomer elements in Saunders or pinch valves (particularly if they fail to open) can be ruptured.
2. The stem thrust can be excessive for globe valves. If globe valves are flow to close, high Δp can damage the seat or prevent the actuator from opening the valve. If they are flow to open, they might open against the actuator.

3. High Δp can exceed the capabilities of plug or floating ball valves, and it can bend the shafts of butterfly valves, damage the bearings of trunion-type ball valves, or damage the seat of floating ball valves.
4. Pressure cycling generated by positive-displacement pumps can cause bolt fatigue if the number of cycles is excessive.

Vacuum Service Low pressures can prevent some pressure-energized seals from properly operating, or they can cause leakage. In some processes, the in-leakage from the atmosphere results in overloading the vacuum source; in others, it represents a contamination that cannot be tolerated. Potential leakage sources include all gasketed areas and, to an even greater extent, the locations where packing boxes are used to isolate the process from the surroundings.

For vacuum service, valves that do not depend on stuffing boxes to seal the valve stem generally give superior performance. Such designs include Saunders valves and pinch valves. These designs, unfortunately, are limited in their application by their susceptibility to corrosion and their temperature and control characteristics. Their applicability to vacuum service is further limited by their design.

The jacketed pinch valve versions, for example, require a vacuum source on the jacket side for proper operation, and the mechanically operated pinch and Saunders designs are limited in their capability to open the larger-size units against high vacuum on the process side. The vacuum process tends to keep the valve closed, and this can result in the diaphragm's breaking off the stem and rendering the valve inoperative.

For services requiring high temperatures and corrosion-resistant materials, in addition to good flow characteristics and vacuum compatibility, conventional globe valves can be considered, with special attention given to the type of packing and seal used.

One approach to consider is the use of double packing, as shown in Figure 6.1n. The space between the two sets of packing is evacuated so that air leakage across the upper packing is eliminated. The vacuum pressures on the two sides of the lower packing are approximately equal, and therefore there is no pressure differential to cause leakage across it. Usually, the space between the two packings is exposed to a slightly higher vacuum than the process, so that no in-leakage is possible.

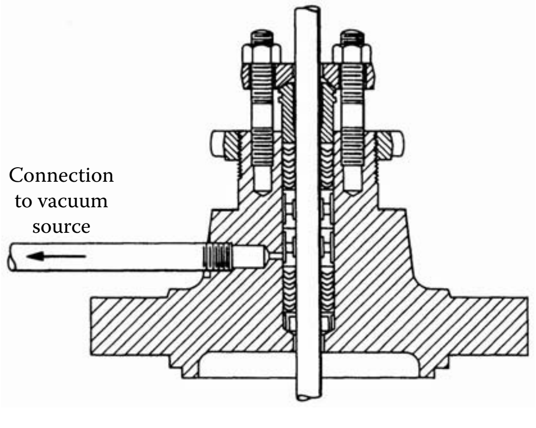

FIG. 6.1n
Double packing is used to seal the valve stem if the process is under vacuum.

Double packing provides reasonable protection against in-leakage under vacuum, but it does not relieve the problems associated with corrosion and high temperatures. When all three conditions exist (vacuum, corrosive flow, and high temperature), the use of bellows seals (discussed in Section 6.19) can be considered. The bellows are usually made of 316 stainless steel and are tested by mass spectrometers for leakage. They not only prevent air infiltration but also can protect some parts of the bonnet and top-works from high temperature and corrosion. Like all metallic bellows, these too have a finite life, and therefore it is recommended that a secondary stuffing box and a safety chamber be added after the bellows seal. A pressure gauge or switch can be connected to this chamber between the bellows and the packing to indicate or warn when the bellows seal begins to leak and replacement is necessary.

Considerations similar to those noted for high-vacuum service would also apply when the process fluid is toxic, explosive, or flammable.

High-Temperature Service

The temperature limitations of each valve design are listed in their feature summaries in Sections 6.16–6.24.

All process conditions involving operating temperatures in excess of 450°F (232°C) are considered high temperature. The maximum temperatures at which control valves have been successfully installed are up to 2500°F (1371°C).

High operating temperatures necessitate the review of at least three aspects of valve design:

1. Temperature limitations of metallic parts
2. Packing temperature limitations
3. Use of jacketed valves

Metallic Parts High temperatures can cause galling, can affect clearances, and can soften hardened trims. Temperature cycling can cause thermal ratcheting and stress, resulting in body or bolting rupture if the rate or frequency of temperature cycles is high.

The high operating temperatures are considered in selecting materials for both the valve body and trim. For the body, it is suggested that bronze and iron be limited to services under 400°F (204°C), steel to operation below 850°F (454°C), and the various grades of stainless steel, Monel, nickel, or Hastelloy alloys to temperatures up to 1200°F (649°C).

For the valve trim, 316 stainless steel is the most popular material, and it can be used up to 750°F (399°C). For higher temperatures, the following trim materials can be considered: 17–4 pH stainless steel (up to 900°F, or 482°C), tungsten carbide (up to 1200°F, or 649°C), and Stellite or aluminum oxide (up to 1800°F, or 982°C).

At high temperatures, the guide bushings and guideposts tend to wear excessively, and this can be offset by the selection of proper materials. Up to 600°F (316°C), 316 stainless steel guideposts in combination with 17–4 pH stainless steel guide bushings give acceptable performance. If the guideposts are surfaced with Stellite, the above combination can be extended up to 750°F (399°C) service. At operation over 750°F (399°C), both the posts and the bushings require Stellite.

Packing Designs The ideal packing provides a tight seal while contributing little friction resistance to stem movement. With TFE packing, which is industry standard, the required stem finish is between 6 and 8 μ in. RMS (0.15 and 0.2 μm).

A common packing design might consist of Teflon V-rings, which are discussed in more detail in Section 6.19. Double packing with leak-off connection in between can be used on toxic or vacuum service (Figure 6.1n). On toxic services, an added seal can be provided by the injection of high-viscosity silicone or plastic packing, but this is rarely done.

Solid rings or ribbons of pure graphite (Graphoil), while more expensive than Teflon, are also popular because they are suited for higher temperatures. On the other hand, they require more loading to energize the packing than does Teflon, and the resulting friction can cause stem lockup. On less demanding services, O-rings are also used, but not frequently because under pressure these elastomers will absorb gases, which can destroy the O-ring when depressurized rapidly.

Metallic bellows-type seals are seldom used because of their pressure limitations and unpredictable lives. On toxic services, they should be provided with automatically monitored guard packing for security.

The bonnets are usually flanged and are extended on hot or cold services so as to bring the operating temperature of the packing closer to the ambient. Screwed bonnets are not recommended for severe duty, and welded bonnets are not used at all, except as an extreme precaution on hazardous services. The sliding stems can sometimes drag atmospheric contaminants or process materials into the packing, but this can be overcome by close tolerance guide bushings or wiper rings. Packing contamination is less likely with rotary valves. In case of LPG, the packing should be isolated from outboard roller bearings and the intervening space vented to protect the lubricant.

Packing Limitations Packing and bonnet designs in general were discussed in the previous paragraph and will also be covered in Section 6.19. Here only their suitability for high-temperature service is reviewed.

The packing temperature limitation for most nonmetallic materials is in the range of 400–550°F (204–288°C), the maximum temperature for metallic packing is around 900°F (482°C), and Teflon should not be exposed to temperatures above 450°F (232°C). Pure graphite (Graphoil) can be used from –400 to 750°F (–240 to 399°C) in oxidizing service and up to 1200°F (649°C) in nonoxidizing service, with an ultimate potential of 3000°F (1649°C).

Bonnets can be screwed, welded, or flanged. Screwed bonnets are not recommended for high-temperature service. Finned bonnet extensions were used in the past on high-temperature services, when packing material capabilities were more limited. These finned designs were not effective, and therefore with the introduction of Graphoil, their use was largely discontinued on rotary valves. For sliding stem valves, Teflon V-rings within extension bonnets are frequently selected and used up to 850°F (454°C).

On high-temperature services, it can be effective to mount the bonnet below the valve. In liquid service, with the bonnet above the valve, the packing is exposed to the full process temperature due to the natural convection of heat in the bonnet cavity.

If the bonnet is mounted below the valve, no convection occurs, and the heat from the process fluid is transferred by conduction in the bonnet wall only. Therefore, by this method of mounting, the allowable process temperature can be substantially increased in some processes. This is not the case for all applications, because some processes do not generate effective condensate seals, and in other services the liquid-vapor interface line can cause metallurgy problems.

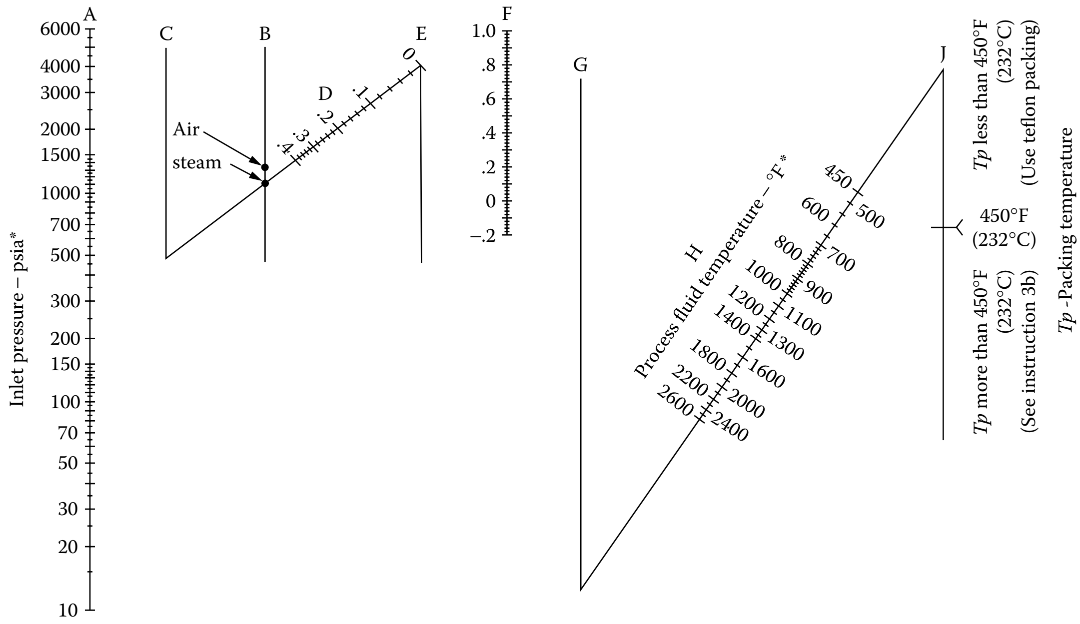
Figure 6.1o provides a method for determining packing temperature, in gas or vapor service, with the bonnet above the valve for one particular valve design. With vapor service, it is likely that vapors will initially condense on the wall of the bonnet, lowering the temperature to the saturation temperature of the process fluid, but in some cases the heat conducted by the metallic bonnet wall will be sufficient to prevent this condensation from occurring.

In short, the packing temperature will be at or above saturation temperature (T_s) in vapor service, but if the bonnet is mounted below the valve, the packing temperature is substantially reduced, due to the accumulated condensate. If the bonnet is below the valve, the relationship between process and packing temperature is not affected by the phase of the process fluid.

In case of ball or plug valves with double-sealing, it is important to vent the space between the seals to the line, so that damage will not be caused by thermal expansion.

Jacketed Valves A number of control valve designs are available with heat-transfer jackets. Others can be traced or jacketed by the user. Jacketed valves can be installed for either cooling or heating. When a cooling medium is circulated in the jackets, this is usually done to lower the operating temperature of the heat-sensitive working parts.

Such jacketing is particularly concentrated on the bonnet, so that the packing temperature is reduced relative to the process. For certain operations at very high temperatures, intermittent valve operation is recommended, such that when the valve is closed it is cooled by the jacket, and when it is opened, it is kept open only long enough to prevent temperature equalization between the valve and the process.



*See Section A.1 for SI units

Instructions

1. Determine constants from table at right corresponding to bonnet selection to locate points on scales "D" and "F."

2. Solve nomograph Key:

Line Up Straight Edge On	*Locate Intersection On*
A TO B	C
C TO D	E
E TO F	G
G TO H	J

3a. If Tp ≤ 450°F (232°C), use Teflon packing.

3b. If Tp > 450°F (232°C), either use high-temperature packing or select another bonnet with smaller "F" value and recheck packing temperature.

Nomograph for packing temperature determination on hot gas or vapor services. (From "Determination of Proper Bonnet and Packing for High-Temperature Processes," R.F. Lytle, Fisher Controls, Emerson Process Management.)

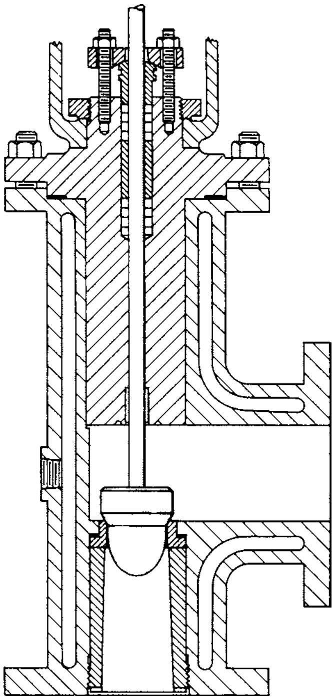

FIG. 6.1p
Jacketed control valve for high-temperature service.

Heating jackets with steam or hot oil circulation are used to prevent the formation of cold spots in the more stagnant areas of the valve or where the process fluid otherwise would be exposed to relatively large masses of cold metal. Figure 6.1p shows one of these valves, designed to prevent localized freezing or decomposition of the process fluid due to cold spots.

Many standard globe pattern valves can be fitted with a jacket to allow heating or cooling as required (Figure 6.1q). Normally, these jackets are for services requiring steam.

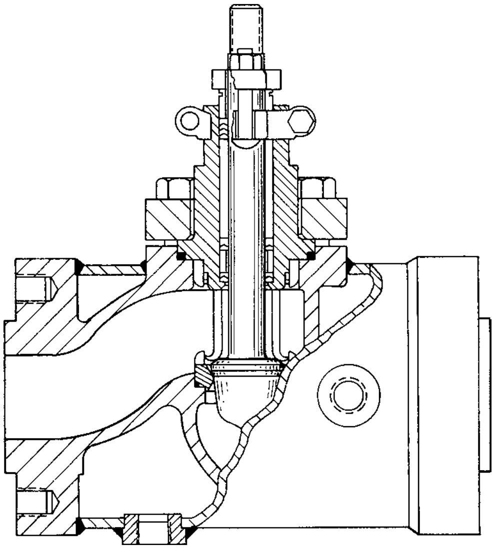

FIG. 6.1q
Steam-jacketed valve. (Courtesy of Flowserve Corp.)

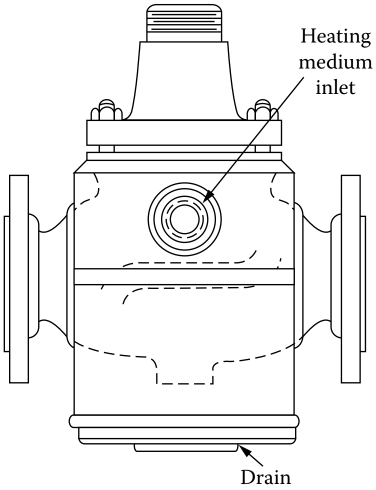

FIG. 6.1r
Special steam jacket for retrofit installation on valve.

Dowtherm or similar heating fluids prevent solidification or crystallization of certain fluids. Often, the manufacturer can provide these jackets, but where this is not available, there are firms that specialize in designing and installing such jackets on valves and other equipment.

These special jackets can be designed either to weld to the valve as a permanent fixture (Figure 6.1r) or as separate devices bolted or clamped to the valve body. In the latter case, it may be necessary to use a heat-transfer paste between jacket and valve body to give efficient transfer by eliminating the air gap.

Low-Temperature Service

Cryogenic service is usually defined as temperatures below –150°F (–101°C). Properties of some cryogenic fluids are listed in Table 6.1s. Valve materials for operation at temperatures down to –450°F (–268°C) include copper, brass, bronze, aluminum, 300 series stainless steel alloys, nickel, Monel, Durimet, and Hastelloy. The limitation on the various steels falls between 0 and –150°F (–17 and –101°C), with cast carbon steel representing 0°F (–17°C) and $3^1/_2$% nickel steel being applicable to –150°F (–101°C). Iron should not be used below 0°F (–17°C).

Conventional valve designs can be used for cryogenic service with the proper selection of construction materials and with an extension bonnet (as described in detail in Section 6.19) to protect the packing from becoming too cold. The extension bonnet is usually installed vertically so that the boiled-off vapors are trapped in the upper part of the extension, which provides additional heat insulation between the process and the packing.

If the valve is installed in a horizontal plane, a seal must be provided to prevent the cryogenic liquid from entering the extension cavity. When the valve and associated piping are installed in a large box filled with insulation (“cold box”), this requires an unusually long extension in order to keep the packing box in a warm area.

TABLE 6.1s
Properties of Cryogenic Fluids

	Methane	*Oxygen*	*Fluorine*	*Nitrogen*	*Hydrogen*	*Helium*

Cryogenic Valves A special design variation on the globe valve is the cryogenic valve. Section 6.19 shows a number of cryogenic service designs, including the Y-valve design. The most common design for this service is shown in Figure 6.1t.

This design is specific to cryogenic (down to –454°F, or –270°C) service and no other. Body configurations are straight through, as shown, or angle body. Because of the need for Charpy impact for the extremely cold service, the materials are limited to bronze and austenitic stainless steels such as 304, 316, and 316L. Normally, the valves are welded into the piping or soldered in some cases with bronze. Small valves, 1 in. (25 mm) and 2 in. (50 mm), can be socket weld or butt weld, but butt weld in larger sizes up to the 10 in. (250 mm) maximum are available.

Body ratings through ANSI 600 and flange ends, either integral or separable, are available depending upon manufacturer. Seat rings may be integral hard-faced with Stellite, screwed-in metal, or soft seat for tight shut-off. The metal shut-offs will be ANSI Class III or IV, depending upon manufacturer, and the soft seat using Teflon or Kel-F will provide Class VI.

Cold Box Valves Cold box valves are designed to have a low body mass for fast cool-down and reduced heat transfer. The long extended bonnet is provided with a plug stem seal to minimize liquid "refluxing" into the bonnet and packing area, thereby minimizing the heat loss due to conduction and convection. Actually, the small amount of liquified gas passing into the bonnet vaporizes and provides a vapor barrier between the liquified gas and the packing area. In addition, the pressure resulting from the vaporization of the liquid prevents additional liquid from passing into the bonnet area. Excess pressure vents back into the body. It is possible to fit these valves with vacuum jackets where the application requires this additional insulation.

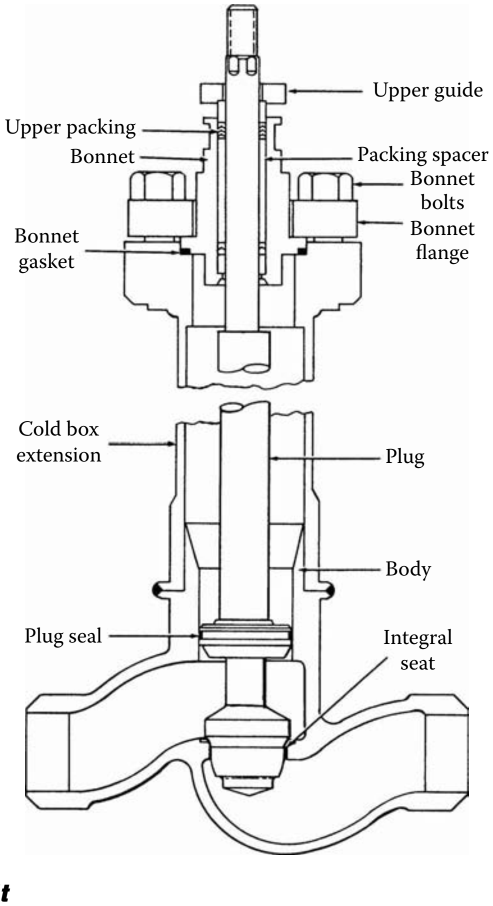

FIG. 6.1t

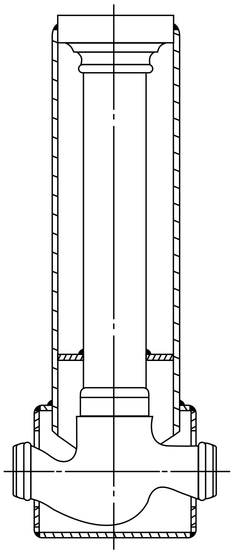

FIG. 6.1u
Vacuum jacketing of cryogenic valve.

Features that are desirable for cryogenic valves include small body mass, which ensures a small heat capacity and, therefore, a short cool-down period. In addition, the inner parts of the valve should be removable without removing the body from the pipeline, and if the valve is installed in a cold box, no leakage can occur inside this box because there are no gasketed parts.

The most effective method of preventing heat transfer from the environment into the process is by vacuum jacketing the valve and piping (Figure 6.1u). The potential leakage problems are eliminated by the fact that there are no gasketed areas inside the jacket.

For cryogenic services where tight shut-off is required, Kel-F has been found satisfactory as a soft seat material because cold can cause many other elastomer materials to harden, set, or shrink. If used as seals, this can cause leaking.

Cavitation and Erosion

The cavitation and erosion phenomena in connection with globe valves are discussed in detail in Section 6.19. The choking effect of cavitation and its influence on valve sizing is covered in Section 6.15. Sections 6.14 and 6.15 describe how the liquid pressure recovery factor (F_L) is related to the ratio between the valve pressure drop and the difference between the inlet and the vena contracta pressure.

As was shown in Section 6.15, the cavitation coefficient K_c is the ratio between the valve pressure drop at which cavitation starts and the difference between the inlet and the vapor pressure of the application. Section 6.15 also shows how the F_{LP} factor can be calculated if the valve is placed within reducers, and it also shows the valve pressure differential at which choking starts can be calculated.

The allowable maximum Δp before cavitation begins is $\Delta p = K_c\,(p_1 - p_v)$. As the F_L and K_c values of the different valve designs drop, the probability of cavitation increases. F_L and K_c values for fully open valves are also given in Section 6.15, and F_L values for throttled valves are given in Figure 6.1v.

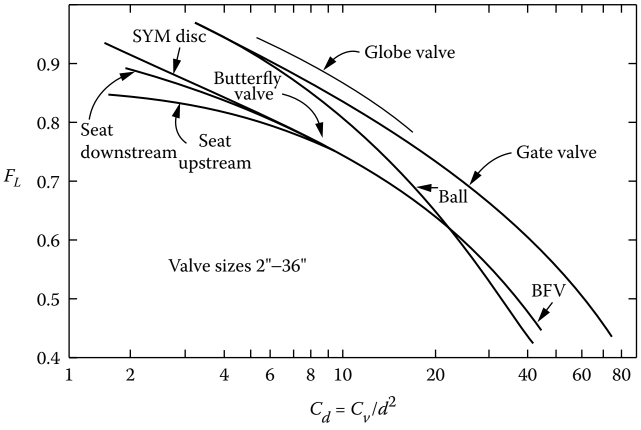

FIG. 6.1v
In this figure, the pressure recovery factor (F_L) of different valve designs is shown as a function of their discharge coefficients (C_d values, which in the metric system are defined as $\varepsilon = K_v / DN^2$) as these valves are throttled from their full open positions.[2]

The high flow velocity at the vena contracta of the valve is reached by obtaining its energy to accelerate from the pressure energy of the stream. This causes a localized pressure reduction that, if it drops below the fluid's vapor pressure, results in temporary vaporization. (Fluids form cavities when exposed to tensions equal to their vapor pressure.) Cavitation only occurs when the pressure in the vena contracta region drops below the vapor pressure of the flowing fluid. The vapor pressure is a function of fluid temperature and chemical structure.

Cavitation damage always occurs downstream of the vena contracta when pressure recovery in the valve causes the temporary voids to collapse. Destruction is due to the implosions that generate the extremely high-pressure shock waves in the substantially noncompressible stream. When these waves strike the solid metal surface of the valve or downstream piping, the damage gives a cinder-like appearance. Cavitation is usually coupled with vibration and a sound like rock fragments or gravel flowing through the valve.

Cavitation damage always occurs downstream of the vena contracta at the point where the temporarily formed voids implode. In case of flow-to-open valves, the destruction is almost always to the plug and seldom to the seat.

Methods to Eliminate Cavitation

Because no known material can remain indefinitely undamaged by severe cavitation, the only sure solution is to eliminate cavitation completely. Even mild cavitation over an extended time will attack the metal parts upon which the bubbles impinge. Hard materials survive longer, but they are not an economical solution except for services with mild intermittent cavitation. Cavitation damage also varies greatly with the type of liquid flowing.

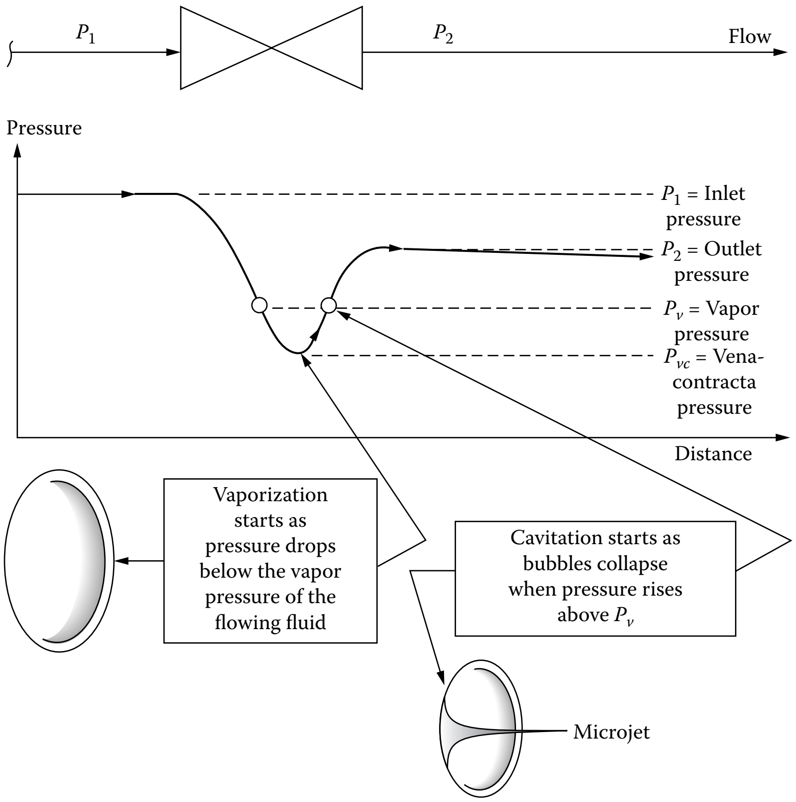

FIG. 6.1w

Cavitation occurs when downstream of the vena contracta the pressure rises. When it reaches the vapor pressure of the process fluid, the vapor bubbles implode and release powerful microjets that will damage any metallic surface in the area.

The greatest damage is caused by a dense pure liquid with high surface tension (e.g., water or mercury). Density governs the mass of the microjet stream, illustrated in Figure 6.1w, and surface tension governs the more important jet velocity. Mixtures are least damaging, because the bubble cannot collapse as suddenly. As the pressure increases, partial condensation in the bubble changes the vapor composition, leaving some vapor to slow the collapse. Some applications of cavitating mixed hydrocarbons show no mechanical damage or high noise level. Cavitation can be reduced or eliminated by several methods, listed in the following paragraphs.

Revising the Process Conditions A reduction of operating temperature can lower the vapor pressure sufficiently to eliminate cavitation. Similarly, increased upstream and downstream pressures, with Δp unaffected, or a reduction in the Δp can both relieve cavitation. Therefore, control valves that are likely to cavitate should be installed at the lowest possible elevation in the piping system and operated at minimum Δp. Moving the valve closer to the pump will also serve to elevate both the up- and downstream pressures.

If cavitating conditions are unavoidable, then it is preferred to have not only cavitation but also some permanent vaporization (flashing) through the valve. This can usually be accomplished by a slight increase in operating temperature or by decreasing the outlet pressure. Flashing eliminates cavitation by converting the incompressible liquid into a compressible mixture.

Revising the Valve Design Where the operating conditions cannot be changed, it is logical to review the type of the valve in terms of its pressure recovery characteristics. The more treacherous the flow path through a particular valve, the less likelihood exists for cavitation. Inversely, the valves most likely to cavitate are the high recovery valves (ball, butterfly, gate) having low F_L and F_c coefficients (Section 6.15). Figure 6.1x illustrates some of the ways available to eliminate cavitation.

Figure 6.1y shows a number of anticavitation valve designs that combine multiple-port and multiple-flow-path features.

If cavitation is anticipated, the engineer should select valves with low recovery and, therefore, high F_c and F_L coefficients. Different valve designs react differently to the effects of cavitation, depending upon where the bubbles collapse. If the focus is in midstream, materials may be unaffected. For example, in the "Swiss cheese"-type design, small holes in the skirt or cage are arranged in pairs on opposite sides of the centerline of the valve. Streams from opposing holes impinge on each other, causing the cavities to collapse in the liquid pool (theoretically). This method, illustrated in Figure 6.1z has been used successfully for mild cavitation.

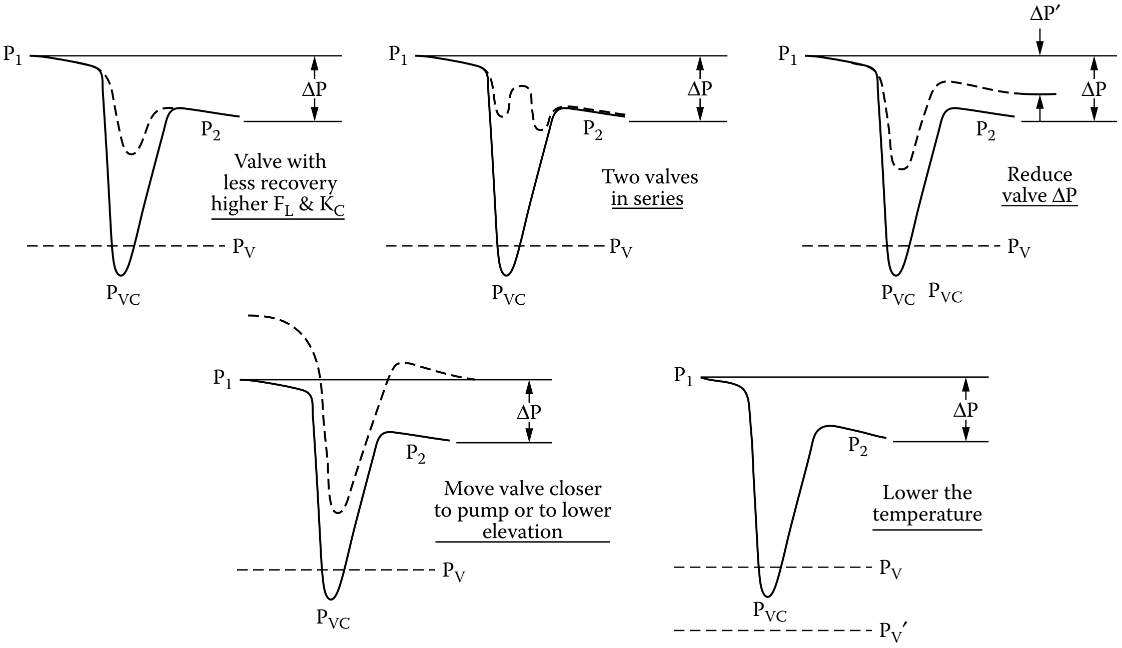

FIG. 6.1x
The pressure profiles shown in dotted lines illustrate some of the options available to the process control engineer to eliminate cavitation.

Labyrinth-type valves avoid cavitation by a very large series of right-angle turns with negligible pressure recovery at each turn, but the narrow channels are subject to plugging if particulate matter is in the stream (Figure 6.1aa).

The multistep valves at the bottom of Figure 6.1aa can avoid cavitation by replacing a single and deep vena contracta, as would occur in a single-port valve, with several small vena contracta points as the pressure drop is distributed between several ports working in series. If the vapor pressure of the process fluid is below the outlet pressure of the valve (Condition A), this valve is likely to work.

On the other hand, if P_v is greater than P_2 (Condition B), this valve is likely to cavitate in its noted intermediate port. One might note that if Condition B occurred in the conventional valve (noted by the dotted line), no cavitation would occur, because some of the vapor formed at the vena contracta would never recondense but would stay in the vapor state (flashing). Therefore, these multistep valves are not recommended for flashing applications.

Gas Injection Another valve design variation that can alleviate cavitation is based on the introduction of noncondensible gases or air into the region where cavitation is anticipated. The presence of this noncompressible gas prevents the sudden collapse of the vapor bubbles as the pressure recovers to values exceeding the vapor pressure, and instead of implosions, a more gradual condensation process occurs. As shown in Figure 6.1bb, the gas may be admitted through the valve shaft or through downstream taps on either side of the pipe, in line with the shaft and as close to the valve as possible. Because the fluid vapor pressure is usually less than atmospheric, the air or gas need not be under pressure.

Revising the Installation In order to eliminate cavitation, it is possible to install two or more control valves in series. Cavitation problems can also be alleviated by absorbing some of the pressure drop in restriction orifices, chokes, or in partially open block valves upstream or downstream to the valve. The amount of cavitation damage is related to the sixth power of flow velocity or to the third power of pressure drop. This is the reason why reducing Δp by a factor of two, for example, will result in an eightfold reduction in cavitation destruction.

In some high-pressure let-down stations, it might not be possible to completely eliminate cavitation accompanied by erosion or corrosion. In such installations, one might consider the use of inexpensive choke fittings (shown in Figure 6.1cc) instead of (or downstream to) control valves.

A single, fixed-opening choke fitting is applicable only when the process flow rate is relatively constant. For variable-flow applications, one can provide several choke fittings of different capacities isolated by several full bore on/off valves, providing a means of matching the process flow with the opening of the required number of chokes. If the chokes discharge into the vapor space of a tank, this will minimize cavitation damage because the bubbles will not be collapsing near to any metallic surfaces.

Material Selection for Cavitation While no material known today will stand up to cavitation, some will last longer than others. Table 6.1dd shows that the best overall selection for cavitation resistance is Stellite 6B (28% chromium, 4% tungsten, 1% carbon, 67% cobalt). This is a wrought material and can be welded to form valve trims in sizes up to 3 in. (75 mm). Stellite 6 is used for hard-facing of trims and has the same

chemical composition but less impact resistance. Correspondingly, its cost is lower.

In summary, the applications engineer should first review the potential methods of eliminating cavitation. These would include adjustment of process conditions, revision of valve type, or change of installation layout. If none of these techniques can guarantee the complete elimination of cavitating conditions, the design engineer should install chokes or special anticavitation valves that can last for some reasonable period, even if some cavitation is occurring.

Control Valve Noise

The calculation of noise levels generated by control valves and the methods of lowering these noise levels are both covered in Section 6.14 and, therefore, will not be repeated

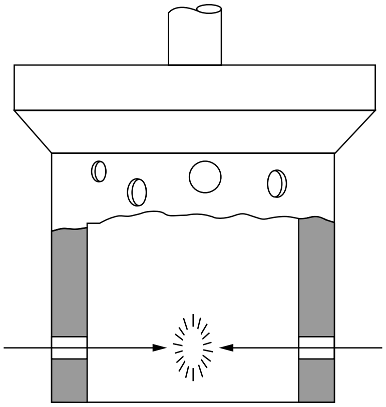

FIG. 6.1z
The "Swiss cheese" design can withstand mild cavitation.

here. As can be seen in that section, many of the features of low-noise control valves are similar to the features of the anticavitation valves shown in Figure 6.1y.

Flashing and Erosion

Cavitation occurs when (in Figure 6.1w) $p_2 > p_v$, while flashing takes place when $p_2 < p_v$. When a liquid flashes into vapor, there is a large increase in volume. In this circumstance, the piping downstream of a valve needs to be much larger than the inlet piping in order to keep the velocity of the two-phase stream low enough to prevent erosion. The ideal valve to use for such applications is an angle valve with an oversized outlet connection. In Section 6.15, the method for calculating the exit velocity in such two-phase flashing applications is illustrated

FIG. 6.1aa
The labyrinth (top) and multistep (bottom) valve designs help to reduce the probability of cavitation.

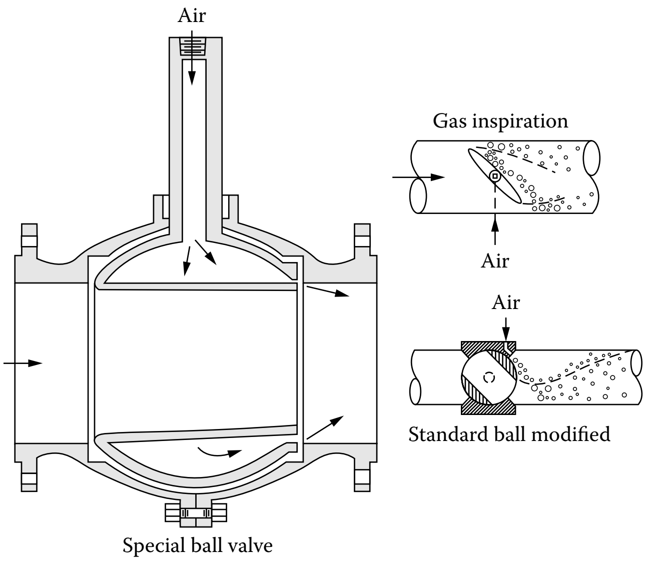

FIG. 6.1bb
Cavitation can also be alleviated by the admission of air into the flowing stream.

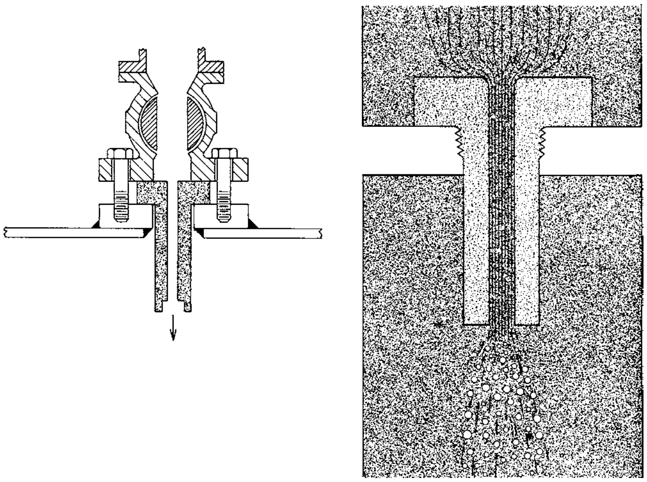

FIG. 6.1cc
The probability of cavitation can also be reduced by installing a choke fitting downstream of the valve.

by an example. In addition, the piping must be designed so that it is not damaged by slug flow.

The impingement of liquid droplets can be erosive if the velocity is great enough (> 200 ft/s, or 60 m/s, across the orifice), such as in applications involving high-pressure let-down of gas or vapor with suspended droplets. On high-pressure let-down applications, the ideal valve to use is the dynamically balanced plug valve provided with a hard-faced plug.

Section 6.15 gives an example on how the exit velocity from a steam let-down valve can be calculated. Erosion caused by high exit velocities can also cause corrosion problems.

TABLE 6.1dd
Relative Resistance of Various Materials to Cavitation

Trim or Valve Body Material	*Relative Cavitation Resistance Index*	*Approximate Rockwell C Hardness Values*	*Corrosion Resistance*	*Cost*
Aluminum	1	0	Fair	Low
Synthetic sapphire	5	Very high	Excellent	High
Brass	12	2	Poor	Low
Carbon steel, AISI C1213	28	30	Fair	Low
Carbon steel, WCB	60	40	Fair	Low
Nodular iron	70	3	Fair	Low
Cast iron	120	25	Poor	Low
Tungsten carbide	140	72	Good	High
Stellite #1	150	54	Good	Medium
Stainless steel, type 316	160	35	Excellent	Medium
Stainless steel, type 410	200	40	Good	Medium
Aluminum oxide	200	72	Fair	High
K-Monel	300	32	Excellent	High
Stainless steel, type 17-4 pH	340	44	Excellent	Medium
Stellite #12	350	47	Excellent	Medium
Stainless steel, type 440C	400	55	Fair	High
Stainless steel, type 329, annealed	1000	45	Excellent	Medium
Stellite #6	3500	44	Excellent	Medium
Stellite #6B	3500	44	Excellent	High

Some metals do not corrode due to a self-regenerating protective surface film; however, if this film is removed by erosion faster than it is formed, the metal corrodes rapidly. For lining, either nobler metals or ceramics should be considered in such situations. The preferred arrangement for flashing service is to use a reduced port angle valve discharging directly into a vessel or flash tank.

Corrosion

Some information data on corrosion is contained in Table 6.1dd. A detailed tabulation of the chemical resistance of materials is given in Appendix A.3 of this volume. In evaluating a particular application, one should also consider the facts that most process fluids are not pure and that the corrosion rate is much influenced by flow velocity and the presence of dissolved oxygen.

On corrosive services, one can also consider the use of lined valves (tantalum, glass, plastics, and elastomers), but one should consider the consequences of lining failure. Damage can be caused by accidentally exposing the lining to high concentrations of inhibitors or line cleaning fluids. Gas absorption in elastomer linings can also cause blistering.

Viscous and Slurry Service

When the process stream is highly viscous or when it contains solids in suspension, the control valve is selected to provide an unobstructed streamline flow path.

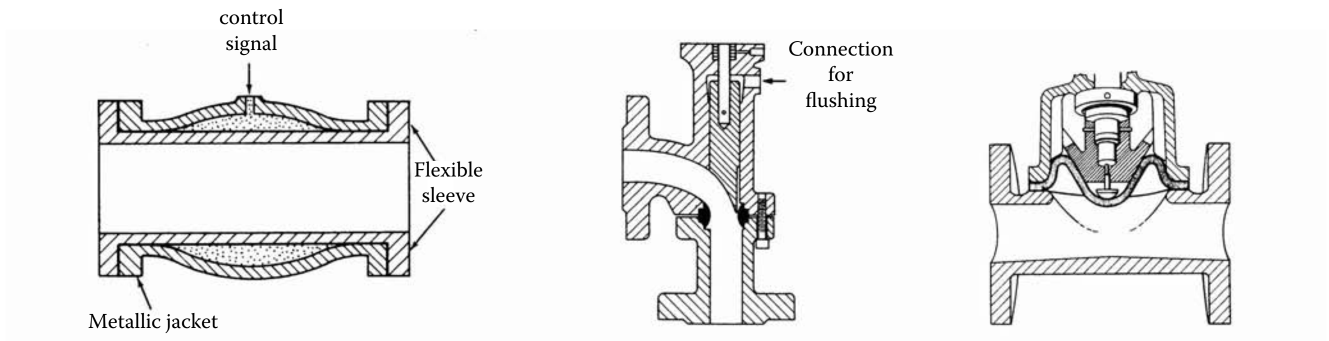
The chief difficulty encountered with heavy slurry streams is plugging. Conditions that can contribute to this include a difficult flow path through the valve, shoulders, pockets, or dead-ended cavities in contact with the process stream. Valves with these characteristics must be avoided because they represent potential areas in which the slurry can accumulate, settle out, and gel, freeze, solidify, decompose, or as most frequently occurs, plug the valve completely.

The ideal slurry valve is one that

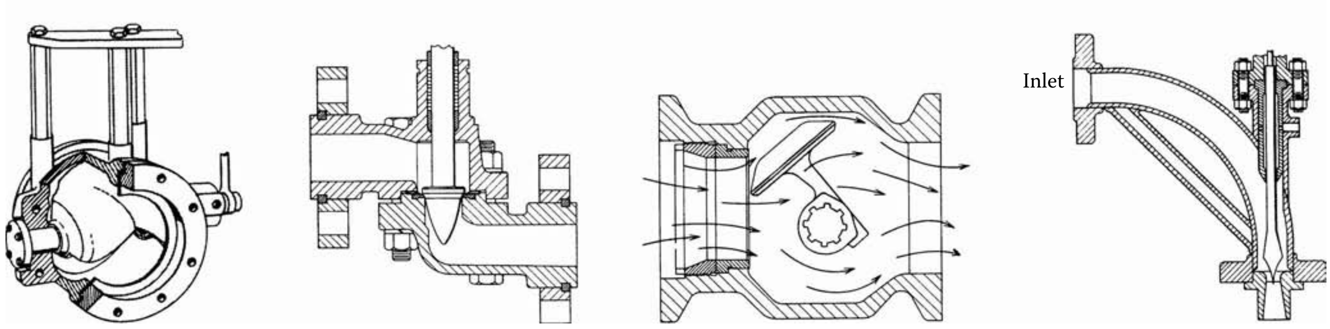
1. Provides full pipeline opening in its open position
2. Provides for unobstructed and streamlined flow in its throttling position
3. Has high pressure and temperature ratings
4. Is available in corrosion-resistant materials
5. Is self-draining and has a smooth contoured flow path
6. Will fail safe
7. Has acceptable characteristics and rangeability
8. Has top works that are positively sealed from the process

Unfortunately, no one valve meets all of these requirements, and the instrument engineer has to judge which features are essential and which can be compromised.

If, for example, it is essential to provide a full pipe opening when the valve is open, there are several valves that can satisfy this requirement. They include the various pinch valves (A in Figure 6.1ee), the full opening angle valves (B



A Jacketed pinch valve B Full opening angle valve C Saunders valve



D Characterized ball valve E Self-draining valve F Eccentric rotating plug valve G Sweep angle valve

FIG. 6.1ee
Valves for viscous and slurry services.

in Figure 6.1ee), some of the Saunders valve designs (C in Figure 6.1ee), and the full-ported ball valves (Section 6.16). While these units all satisfy the requirement for a fully open pipeline when open, they differ in their limitations.

The pinch valves, for example, are limited in their materials of construction, pressure, temperature ratings, flow characteristic, speed of response, and rangeability, but they do provide self-cleaning streamlined flow, which in some designs resembles the characteristics of variable venturi.

The Saunders valves and pinch valves have similar features, including the important consideration that the sealing of the process fluid does not depend on stuffing boxes. They are superior in the availability of corrosion-resistant materials, but they are inferior if completely unobstructed streamline flow is desired. Pinch valves are suitable for very low pressure drop services only, while Saunders and wedge plug valves can operate at slightly higher pressures. Lined butterfly valves are a good choice if the process pressure is high while the valve drop is low.

The angle valve with a scooped-out plug satisfies most requirements except that its flow characteristics are not the best, and it is necessary to purge it above the plug in order to prevent solids from migrating into that area.

Full-ported ball valves in their open position are as good as an open pipe section, but in their throttling positions both their flow paths and their pressure recovery characteristic are less desirable.

Valves that do not open to the full pipe diameter but still merit consideration in slurry service include the following designs: characterized ball valves (D in Figure 6.1ee), various self-draining valve types (E in Figure 6.1ee), the eccentric disc rotating globe designs (F in Figure 6.1ee), and the sweep angle valves (G in Figure 6.1ee).

Each of these has some features that represent an improvement over some other design. The characterized ball valve, for example, exhibits an improved flow characteristic in comparison with the full-ported ball type. It is well-suited for process fluids containing fibers or larger particles. The self-draining valve allows slurries to be flushed out of the system periodically. Complete drainage is guaranteed by the fact that all surfaces are sloping downstream.

The sweep angle valve, with its wide-radius inlet bend and its venturi outlet, is in many ways like the angle slurry valve. Its streamlined nonclogging inner contour minimizes erosion and reduces turbulence. In order to prevent the process fluid from entering the stuffing box, a scraper can be furnished, which if necessary can also be flushed with some purge fluid. The orifice located at the very outlet is built like a choke fitting. Both orifice and plug may be made of abrasion-resistant ceramic or hard metals.

For slurries with large solid particles, the ideal orifice shape is a circle, such as that of an iris valve or a jacketed pinch valve (A in Figure 6.1ee).

Orifice size, particle size, and rangeability are interrelated. For any particle size and orifice shape, there is a minimum opening below which plugging can be expected. To get good rangeability (control at low flow rates) the valve Δp should be made small. One way to accomplish this is by use of a "head box" (Figure 6.1ff). The selection of the valve style and the piping configuration around the valve inlet must be guided by the intractability of the particular slurry.

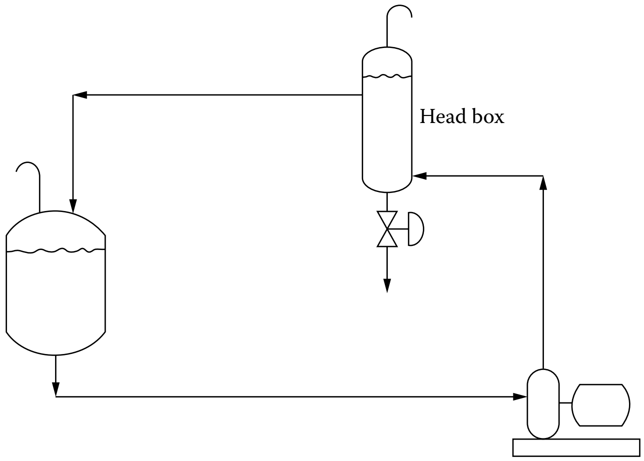


FIG. 6.1ff
In slurry service, the use of a head box can provide a small and constant pressure drop across the control valve.

Valves That Can Be Sterilized

In food processing applications, in addition to the above, valves must not contain pockets where process material can be retained, and they should be constructed so that they can be easily sterilized and disassembled for cleaning. Materials of construction should not contain compounds that are prohibited by the FDA, such as some of the elastomer compounding materials.

Valve Leakage

Any flow through a fully closed control valve when exposed to the operating pressure differentials and temperatures is referred to as leakage. It is expressed as a cumulative quantity over a specified time period for tight shut-off designs and as a percentage of full capacity for conventional control valves.

According to ANSI B16.104, valves are categorized according to their allowable leakage into six classes. These leakage limits are applicable to unused valves only:

Class I valves are neither tested nor guaranteed for leakage.
Class II valves are rated to have less than 0.5% leakage.
Class III valves are allowed up to 0.1% leakage.
Class IV valves must not leak more than 0.01% of their capacity.

TABLE 6.1gg
Valve Seat Leakage Classifications per ANSI B16.104-1976 (FCI 70–2)

Class	*Maximum Leakage*
I	No test required
II	0.5% of rated valve capacity
III	0.1% of rated valve capacity
IV	0.01% of rated valve capacity
V	5×10^{-4} ml/minute of water per inch of orifice diameter per psi differential
VI	ml per minute of air or nitrogen vs. port diameter per the following tabulation

Nominal Port Diameter		*Maximum Seat Leakage, ml/minute*
in.	*mm*	
1	25	0.15
$1^1/_2$	38	0.30
2	50	0.45
3	75	0.90
4	100	1.70
6	150	4.00
8	200	6.75

Class V valves are specified to have a leakage of 5×10^{-4} ml/min water flow per inch (25.4 mm) of seat diameter, per 1 psi (0,0685 bar) differential pressure.

Class VI is for soft-seated valves, and leakage is expressed as volumetric air flow at rated Δp up to 50 psi (3.45 bar).

Generally the functions of tight shut-off and those of control should not be assigned to the same valve. The best shut-off valves are rotary on/off valves, which are not necessarily the best choices for control.

Table 6.1gg gives a summary of the ANSI leakage classes, and Table 6.1a lists the leakage capabilities of the various control valve designs. For added details on soft-seated designs and other special designs, refer to the feature summaries at the front of each section.

Some valve manufacturers list in their catalogs the valve coefficients applicable to the fully closed valve. For example, a butterfly valve supplier might list a C_v of 13.2 (K_v = 11.4) for a fully closed, metal-to-metal seated 24 in. (600 mm) valve. It should be realized that such figures apply only to new, clean valves operating at ambient conditions. After a few years of service, valve leakage can vary drastically from installation to installation as affected by some of the factors to be discussed.

It should also be noted that some fluids are more difficult to hold than others. Low-viscosity fluids such as Dowtherm, refrigerants, or hydrogen are examples of such fluids.

Soft Seats One of the most widely applied techniques for providing tight shut-off over reasonable periods of time is the use of soft seats. Standard materials used for such services include Teflon and Buna-N. Teflon is superior in its corrosion resistance and in its compatibility to high-temperature services up to 450°F (232°C). Buna-N is softer than Teflon but is limited to services at 200°F (93°C) or below.

Neither should be considered for operating conditions such as static pressures of 500 PSIG (34.5 bar) or greater, for use with fluid containing abrasive particles, or if critical flow is expected at the valve seat.

The leakage of double-ported valves is much greater than that of single-ported ones, and it can be as high as 2–3% of full capacity in metal-to-metal seated designs.

Temperature and Pipe Strain It is frequently the case that either the valve body is at a different temperature than the trim or the thermal expansion factor for the valve plug is different from the coefficient for the body material. It is usual practice in some valve designs (such as the butterfly) to provide additional clearance to accommodate the expansion of the trim when designing for hot fluid service. The leakage will, therefore, be substantially greater if such a valve is used at temperatures below those for which it was designed.

Temperature gradients across the valve can also generate strains that promote leakage. Such gradients are particularly likely to exist in three-way valves when they are in combining service and when the two fluids involved are at different temperatures. This is not to imply that three-way valves are inferior from a leakage point of view. Actually, their shut-off tightness is comparable to that of single-seated globe valves.

Pipe strains on a control valve will also promote leakage. For this reason, it is important not to expose the valve to excessive bolting strains when placing it in the pipeline and to isolate it from external pipe forces by providing sufficient supports for the piping.

Seating Forces and Materials The higher the seating force in a globe valve, the less leakage is likely to occur. An average valve has a seating force of 50 lb_f per linear inch (8750 N/m) of seat circumference. Where necessary, a much increased seating force will create better surface contact by actually yielding the seat material. Seating forces of this magnitude (about ten times the normal) are practical only when the port is small.

Seating materials are selected for compatibility with service conditions, and Stellite or hardened stainless steel is an appropriate choice for nonlubricating, abrasive, high-temperature, and high pressure drop services. These hard surface materials also reduce the probability of nicks or cuts occurring in the seating surface, which might necessitate maintenance or replacement.

Small-Flow Valves Valves with small flow rates are found in laboratory and pilot plant applications. Even in industrial installations, the injection of small quantities of neutralizers, catalysts, inhibitors, or coloring agents can involve flows in the range of cubic centimeter per minute.

Valves are usually considered miniature if their C_v is less than 1 ($K_v = 0.862$). This generally means a $^1/_4$ in. (6.25 mm) body connection and a $^1/_4$ in. (6.25 mm) or smaller trim. The top works are selected to protect against oversizing, which could damage the precise plug.

The field of small-flow control valves is a highly specialized area, unlike any other application. The mechanical design and fluid flow constraints encountered essentially make these valves custom applied for the service. Small-flow valves are used in laboratories, process pilot plants, and some areas of full-scale plants.

The design and building of these valves test the ingenuity of any manufacturer. There are several design types available, and great care must be taken to match the application with the valve design. While the manufacturers publish C_v (K_v) ratings for their valves and trims, these should be treated with extreme caution and used for reference purposes only (below 0.01 C_v [0.00862 K_v]).

In many cases, the flow may shift from laminar to turbulent with flowing conditions and valve stroke changes. It is quite common for a laminar flow pattern to predominate, particularly with viscous fluids or in low-pressure applications. Laminar flow means the flowing quantity will vary directly with pressure drop instead of with the square root of pressure drop.

It is wise to devise a test procedure simulating the service application to evaluate performance of a specific valve before using it in actual service. It is not uncommon for two "identical" small valves to exhibit somewhat different $C_v(K_v)$ capacities and flow curves under the same test conditions.

Needle Valves There are at least three approaches to the design of miniature control valves: (1) the use of smooth-surfaced needle plugs, (2) the use of cylindrical plugs with a flute or flutes milled on it, and (3) positioning the plug by rotating the stem.

One of the most common designs looks like a miniature version of the standard globe control valve (Figure 6.1hh). The trim consists of a precision honed and close-fitting plug fitted into an orifice made of a hard alloy. The control area consists of a fine taper slot milled into the outer surface of the piston-shaped plug or a long shallow taper plug. In smaller C_v (K_v) trims, this slot may be a calibrated scratch in the surface.

It is not uncommon to find up to 30 trims available in a given body to cover the C range of 0.000002 to 0.1 (K from 0.00000172 to 0.0862 K_v). The rangeability, i.e., the ratio between maximum and minimum controllable flow, can be limited for this type of valve due to the inherent leakage flow between piston and orifice. The smaller the trim size, the lower the rangeability.

Needle plugs give more dependable results than the ones with grooves, scratches, or notches because the flow is distributed around the entire periphery of the profile. This results in even wear of the seating surfaces and eliminates side thrusts against the seat. The trim is machined for very small clearances, and hard materials or facings are recommended to minimize wear and erosion.

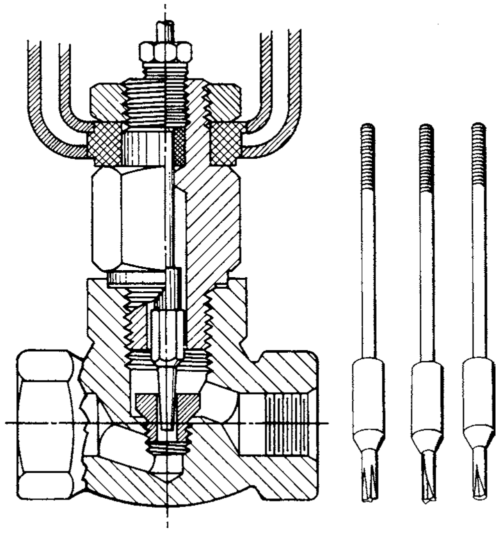

FIG. 6.1hh
Needle-type small-flow valve and plugs with flutes milled on cylindrical surface.

Needle plugs are available with equal-percentage (down to $C_v = 0.05$ [$K_v = 0.043$]), linear, and quick-opening characteristics (Figure 6.1hh). Some manufacturers claim the availability of valves with coefficients of $C_v = 0.0001$ ($K_v = 0.000086$) or less. At these extremely small sizes it is very difficult to characterize the plugs (equal-percentage is not available), and the valve rangeability also suffers.

It is easier to manufacture the smaller cylindrical plugs with one or more grooves (Figure 6.1hh) and obtain the desired flow characteristic by varying the milling depth. Both the needle and the flute plugs are economical, but it is difficult to reproduce their characteristics and capacity accurately.

Ball Valves In contrast to the relatively long stroke piston and orifice valve discussed, there is another valve design for small-flow applications that has a very short and variable adjusted stroke (Figure 6.1ii). Here, a synthetic sapphire ball is allowed to lift off a metal orifice and throttle the flow. The particular advantage of this valve is that the diaphragm stroke can be adjusted to produce various stem lifts with a standard 3–15 PSIG (0.2–1.0 bar) signal.

Two versions are available. One can be adjusted to cover 0.07 to 0.00007 C_v (0.06 to 0.00006 K_v) and the other can be adjusted from 1 to 0.001 C_v (0.862 to 0.000862 K_v). These can be used for high-pressure, high-drop applications ranging from 3000 to 30,000 PSIG (207 to 2068 bar), depending upon the model.

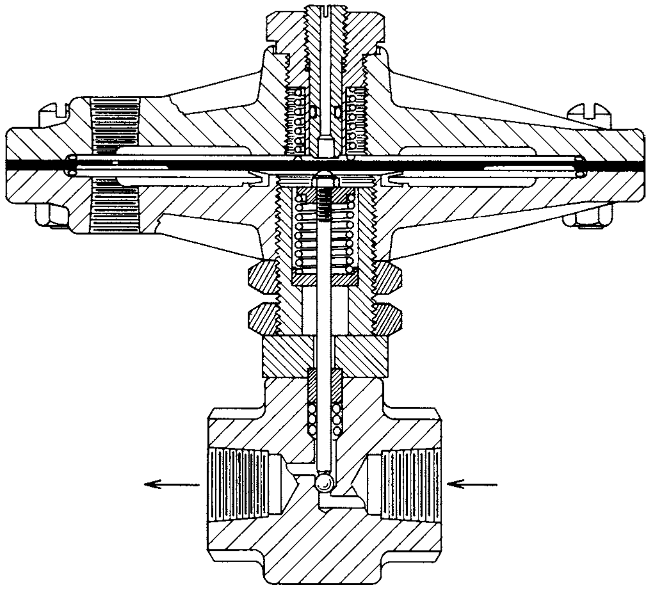

FIG. 6.1ii
Low-flow ball valve with adjustable short-stroke actuator. (Courtesy of A.W. Cash Co.)

Stem Rotation Type Another short-stroke valve especially suitable for high-pressure service (up to 50,000 PSIG, or 3447 bar) is shown in Figure 6.1jj. Variation in C_v (K_v) rating of identical plugs and seats is achieved by mechanical adjustment of a toggle arrangement. The toggle can change the valve stroke between 0.010 and 0.150 in. (0.25 to 3.75 mm). With different trim inserts, a C_v range of 1 to 0.000001 (K_v range of 0.862 to 0.00000086) can be covered.

In this design, the lateral motion of the plug is achieved by rotating the stem through a lead screw. The linear diaphragm motion is transferred into rotation by the use of a slip ball joint. Valve capacity is a function of orifice diameter (down to 0.02 in., or 0.5 mm), number of threads per inch in the lead screw (from 11 to 32), amount of stem rotation (from 15 to 60°), and the resulting total lift, which generally varies from 0.005 to 0.02 in. (0.125 to 0.5 mm).

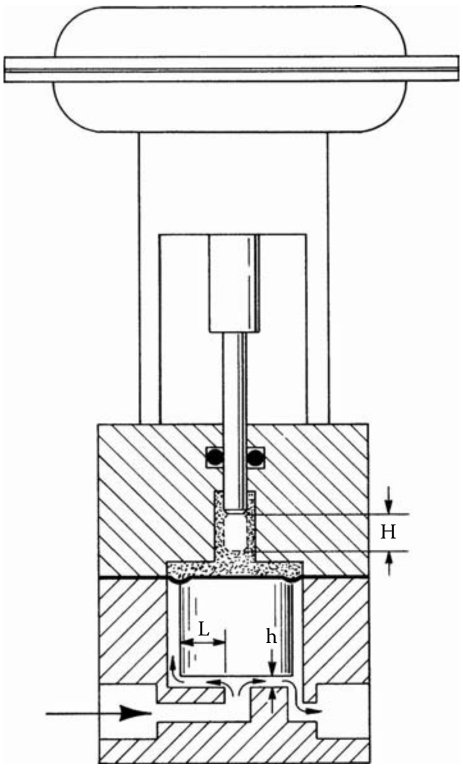

FIG. 6.1kk
Low-flow valve using laminar flow element. (Courtesy of Emerson Process Management.)

The extremely short distance of valve travel makes accurate positioning of the plug essential, and this necessitates a positioner. The combination of a long stem and short plug travel makes this valve sensitive to stem load and temperature effects. Because this differential thermal expansion can cause substantial errors in plug position, this valve is limited to operating temperatures below 300°F (149°C).

Laminar Valve Finally, the latest addition to the low-flow valve family is shown in Figure 6.1kk. This valve is designed

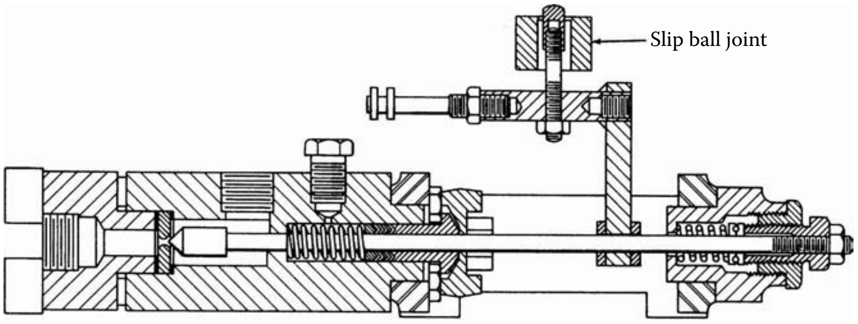

FIG. 6.1jj
Small-flow plug positioned by stem rotation.

to operate on the laminar flow principle. The flow is controlled by forcing the fluid through a long and narrow path, formed between two parallel surfaces. The actuator varies the laminar gap through a diaphragm and O-ring-sealed hydraulic ram. Because, in the laminar regime, flow varies linearly with pressure drop across the valve and with the third power of the gap width between the two surfaces (valve travel), this design has extremely high control rangeability along with a wide C_v range of 0.02 to 0.000001 (K_v from 0.017 to 0.00000086). The laminar principle also eliminates cavitation effects with liquids and sonic choking velocities with gases. This design can be used with inlet pressures and pressure drops up to 2675 PSIG (185 bar).

While it is not commonly thought of for low-flow valve application, the labyrinth disc valve design (see Figure 6.1aa) can be manufactured for this purpose. Its most common application is for reducing high-pressure fluid samples for analyzers, but obviously it can be used in other services. One common factor for this design, as well as for all of the others discussed, is the need for the fluid to be extremely clean. These valves are not tolerant of dirt or sediment due to the small passage and close clearances. Unless the fluid is known to be clean, it is necessary to provide for a high level of filtration upstream.

INSTALLATION

When a valve is larger than 4 in. (100 mm) or sometimes when it is more than one size smaller than the pipe, it is advisable to use pipe anchors to minimize force concentrations at the reducers and more frequently to relieve flange stress loading due to valve weight. The end connections on the valve should match the pipe specifications. If welded valves are specified, the nipples should be factory-welded and the welds should be stress-relieved. If lined valves are specified, their inside diameters should match that of the pipe to avoid extrusion. On flangeless valves, the bolting and the tightness of the gaskets can be a problem if the valve body is long.

If valves are fast closing (or fail) in long liquid lines, water hammer can result in the upstream pipe or vacuum can develop in the downstream line. Fast-opening steam valves can thermally shock the downstream piping. Steam traps should be provided at all low points in a steam piping network. Anchors should be provided in all locations where sudden valve repositioning can cause reaction forces to develop.

Flow-to-close single-seated valves should not be used because if operated close to the seat, hydraulic hammer can occur. If the damping effect of the actuator alone will not overcome the vertical plug oscillation, then either the actuator should be made "stiffer" (higher air pressure operation) or hydraulic snubbers should be installed between the yoke and the diaphragm casing.

Climate and Atmospheric Corrosion

In humid environments such as the tropics, moisture will collect in all enclosures, and therefore drains should be provided. Electrical parts should all be encapsulated where possible or be provided with suitable moistureproof coating.

Vent openings should be provided with storage plugs and insect screens. Even with such precautions, the vents and seals will require preventive maintenance and antifungus treatment in some extreme cases.

Cold climates can produce high breakaway torque of elastomers, and in general, metals and plastics will become more brittle. Electrohydraulic actuators will require heating because oils and greases can become very viscous.

In high-temperature environments, the weak link is usually the actuator, but liners, plastic parts, and electric components are also vulnerable. The damage is not only a function of the temperatures but also of the lengths of time periods of exposure. Diaphragm temperature limits are a function of their materials: Neoprene — 200°F (93.3°C), Nordel — 300°F (148.7°C), Viton — 450°F (232.2°C), silicone glass—500°F (260°C). For higher temperatures, one can replace the diaphragms with pistons (or with metallic bellows in some extreme cases) or add heat shields.

In power plant applications, valves frequently must be designed to withstand anticipated seismic forces. If the atmosphere contains corrosive gases or dusts, it is desirable to enclose, purge, or otherwise protect the more sensitive parts. The stem, for example, can be protected by a boot.

In hazardous areas, all electrical devices should either be replaced by pneumatic ones or be made intrinsically safe or explosionproof.

CONTROL VALVE SPECIFICATION FORM

Compiling the information necessary to specify a control valve is best done with the aid of a tabulation sheet. Many large companies have their own customized forms. Figure 6.1ll shows a general-purpose form (ISA Form S20.50 Rev. 1) standardized by the Instrumentation, Systems, and Automation Society. After the form, general instructions are provided to assist in completing the form.

A similar data sheet standard has been published by IEC as publication IEC 60534-2-3, "Industrial Process Control Valves, Part 7: Control Valve Data Sheet."

Instructions for Filling Out the Valve Specification Sheet

Line	*Explanation of Terms and Definitions*	*Examples*
PROJECT	Specify project name for which control valve is intended.	XYZ Nuclear PS
UNIT	Specify unit within project.	#1
P.O.	Specify purchase order number from purchaser to control valve manufacturer.	P.O. 12345
ITEM	Specify item number of purchase order.	3
CONTRACT	Specific contract number of project for purchaser's reference.	56-V-32510
MFR SERIAL	This line may show the valve manufacturer's serial number(s) and is normally filled in at the time of shipment of the valve. Serial numbers often contain the manufacturer's shop order number.	C12650-3

Line	*Explanation of Terms and Definitions*	*Examples*
DATA SHEET	Specify data sheet number. Normally assigned by purchaser.	3 of 12
SPEC	Specify number of technical specification on which valve selection is based.	FL-13265-A
TAG	Specify tag number, if any, used to designate location of valve.	FV-103
DWG	Specify piping and instrumentation diagram number, loop diagram number, engineering flow diagram number, etc.	17-453
SERVICE	Describe service of control valve and/or pipe line number.	Feedwater control Reheat spray 2" MA 1051 WA7

NOTE: The above lines are suggestions only and may be modified to fit the individual company's needs. If the provided space is insufficient, add an additional sheet and refer to it.

Line No.	*Explanation of Terms and Definitions*	*Examples*
1	Describe fluid flowing into valve and its state. Indicate corrosive or erosive service and the corrosive or erosive agents.	Superheated stream Saturated water Crude oil and natural gas
	Specify thermodynamic critical pressure of the fluid.	3206 psia
2	Specify volumetric or mass flow rate at inlet or standard conditions. Maximum flow condition, if greater than normal flow condition, is the condition for which the valve is sized.	3000 gpm 10 000 bpd 600 std. m^3/s 7500 scfm 300 kg/h
3	Specify inlet pressure (gauge or absolute).	5000 psig 2000 kPa abs.
4	Specify outlet pressure (gauge or absolute).	1000 psig 400 kPa gauge
5	Specify inlet temperature in °F, °R, °C, or K. Must agree with state of fluid and its inlet pressure.	750°F 200°C 815 K
6	Specify specific weight (in lb/ft^3 or kg/m^3), specific gravity, or molecular weight of fluid. Identify the appropriate term.	61.9 lb/ft^3 1.03 44.01
7	Specify viscosity in appropriate units for liquids or specific heats ratio for gases.	20 centipoise 17.8 centistokes 1.27
8	Specify vapor (saturation) pressure at inlet temperature in absolute units. Only required for liquid flow.	680 psia 46.9 bar abs.
9	Specify required C_v as calculated for each condition per ANSI/ISA S75.01-1986. No additional safety (oversize) factor should be included at this point.	260

Line No.	*Explanation of Terms and Definitions*	*Examples*
10	Specify travel of the valve in percent of rated travel calculated from required C_v, rated C_v of the valve, trim selected, and characteristic (see lines 33, 34, and 36). 0% is full closed, 100% is full open.	78%
11	Specify laboratory-measured allowable and predicted sound pressure levels, both normally in dBA as measured per ISA-S75.07-1987.	90/87 dBA
12	Extra line for information not covered in lines 1 through 11.	Compressibility factor Z Ambient temperature Base pressure and temperature
13 & 14	Specify size and schedule (or wall thickness if nonstandard) of pipe line into which valve is installed.	8" SCH 40 15" OD × 0.500" wall DN200, PN100
15	Specify pipe line insulation. This information is required for predicted sound pressure level calculations.	2" thermal None
16	Specify type of valve body.	Globe (through, angle) Split body Double port Butterfly Ball Pinch
17	Specify nominal size of valve body. Specify ANSI class in accordance with ANSI B16.34-81.	4" 600 2500 SPECIAL

Instructions for Filling Out the Valve Specification Sheet Continued

Line No.	*Explanation of Terms and Definitions*	*Examples*
18	Specify maximum pressure and temperature of the valve.	2500 psig, 650°F
19	Specify manufacturer and model number.	XYZ Controls Model 719-2
20	Specify body and bonnet material.	Steel, ASTM A216, WCB
21	Specify body liner material, if any, and its inside diameter.	Polyurethane, 3.9″
22 & 23	Specify end connection. May be integral or welded onto body.	6″ RTJ Class 1500 flange Buttweld end 2″ FNPT
24	Specify flange face finish per ANSI B16.5-81 or special finish as required.	ANSI B16.5-81 Special finish: 32 RMS
25	Specify end extensions, if any. Normally, refers to sections of pipe or reducers welded to the body by the valve manufacturer.	6″ long, SCH 80, A106, GR. B
26	Specify direction of the flow through the body. FTO = flow-to-open, FTC = flow-to-close valve. NOTE: The descriptors "FTO" and "FTC" refer to the direction of fluid forces on the closure member. If immaterial, leave blank. When FTO and FTC are not applicable, specify direction as appropriate.	FTO FTC
27	Specify type of bonnet.	Standard Cooling fin Extended
28	Specify whether a lubricator and isolation valve are required. Specify lubricant.	Yes Silicone
29	Specify packing material.	Graphite impreg. asbestos TPE Non-asbestos
30	Specify type of packing.	Braided Molded V-ring Laminated filament Pressure/vacuum
31	Extra line for special body or bonnet not covered in lines 16 through 30.	Body drain Separable flanges Flangeless
32	Specify type of trim.	Single seat cage-guided Multi-stage Multi-hole Top- and bottom-guided Double seat
33	Specify nominal size and rated travel of installed trim.	2″ 50 mm
34	Specify inherent flow characteristic of installed trim.	Linear Equal % Modified parabolic Quick-opening
35	Specify whether trim is balanced or unbalanced. Semi-balanced trim should be considered as balanced.	Balanced Unbalanced
36	Specify rated C_v, F_L, and X_T of installed trim. Refer to ANSI/ISA-S75.01-1986.	260 0.9 0.68
37	Specify closure member, i.e., plug, ball, or disk material as applicable.	17-4 PH, H-1150 316
38	Specify seat material.	420 hardened 316 hardfaced
39	Specify cage, bearing, or guide material.	410 hardened
40	Specify stem material.	17-4 PH H-1150 316
41 & 42	Extra lines for additional trim requirements not covered in lines 32 through 40.	Chrome-plate Pilot-operated
43	Specify hazardous location classification per the *National Electrical Code®*, ANSI/NFPA 70-1987.	NEC® Class 1, Div. 1, Group C
44–52	Specify special requirements and/or accessories not covered elsewhere.	Solenoid valves E/P transducer NACE MR-01-75 Seismic Net weight = 275 lb
53	Specify type of actuator.	Diaphragm, pneumatic Hydr. piston, double-acting Pneumatic rotary vane
54	Specify manufacturer and model number.	XYZ Controls P-100-160
55	Specify nominal size and effective diaphragm/piston area.	8″ 160 square inch 0.2 m^2
56	Specify whether actuator is for on/off or modulating service.	Modulating On/off
57	Specify whether spring, if any, acts to open or to close valve.	Open Close None
58	Specify maximum pressure for which the actuator is designed.	100 psig 60 kPa
59	Specify minimum pressure required to fully stroke the installed valve under specified conditions.	65 psig
60 & 61	Specify limits of available air or hydraulic supply pressure. If upper limit is greater than line 58, a reducing valve (air set) should be furnished. Lower limit or reducing valve setting must be higher than pressure shown on line 59.	90 psig/70 psig

Instructions for Filling Out the Valve Specification Sheet Continued

Line No.	*Explanation of Terms and Definitions*	*Examples*
62	Specify the pressures in the actuator when valve starts travel and at its rated travel position without fluid forces acting on the valve.	8/32 psig 10/22 psig 1.2/2.1 kPa
63	Specify orientation of actuator as "VERT.UP" or "VERT.DOWN" (vertical) or "HORIZ." (horizontal). For rotary valves, also specify whether mounting is "RH" (right-hand) or "LH" (left-hand) as viewed from valve inlet, if appropriate. Specify additional information as appropriate or provide sketch.	VERT.UP HORIZ. RH LH
64	Specify type and orientation of handwheel (manual override), if any.	Top-mounted Side-mounted/LH
65	Specify if air failure valve (actuator air lock-up valve) is required and at what supply pressure it shuts.	Yes 40 psig
66	Extra line for additional actuator requirements not covered in lines 53 through 65.	Hydraulic damper Stroking speed 1"/sec. Stainless steel tubing
67	Specify input signal range for full travel.	3–15 psig 200–100 kPa 4–20 mA
68	Specify type of positioner.	None Single acting Double acting
69	Specify manufacturer and model number.	XYZ Control Co. Model AB
70	Specify whether an increasing signal increases or decreases output pressure to actuator.	Incr. Decr.
71	Specify whether air pressure gauges and positioner are required.	No Yes
72	Specify cam characteristic, if positioner has a cam. Normally linear.	Linear Square root
73	Extra line for positioner requirements.	Aluminum-free
74	Specify type and quantity of limit switches.	Mech. (lever arm) Proximity Pneumatic 2
75	Specify manufacturer and model number.	ABC Electric Co. Model A20Z
76	Specify electrical rating and number of contacts and action.	10A, 600 V AC/ DPDT
77	Specify valve travel at which switches are to actuate.	Full open/full closed
78	Extra line for additional limit switch requirements not covered in lines 74 through 77.	NEMA 4 IP 65
79	Specify manufacturer and model number of air set (pressure regulator).	RBJ Co. Model R-70
80	Specify output pressure setting.	70 psig 20 psig
81	Specify whether filter and/or output pressure gauge is required.	Yes No
82	Extra line for additional air set requirements not covered in lines 79 through 81.	Mount separate from valve
83	Specify pressure of hydrostatic test. Normally per ANSI B16.37-80 or API 6A-83.	3350 psig
84	Specify leakage class per ANSI/ FCI 70-2-76.	Class IV
85 & 86	Extra lines for additional test requirements not covered in lines 83 and 84.	Hydro for 30 minutes Helium leak test Stroking time test Dead band test

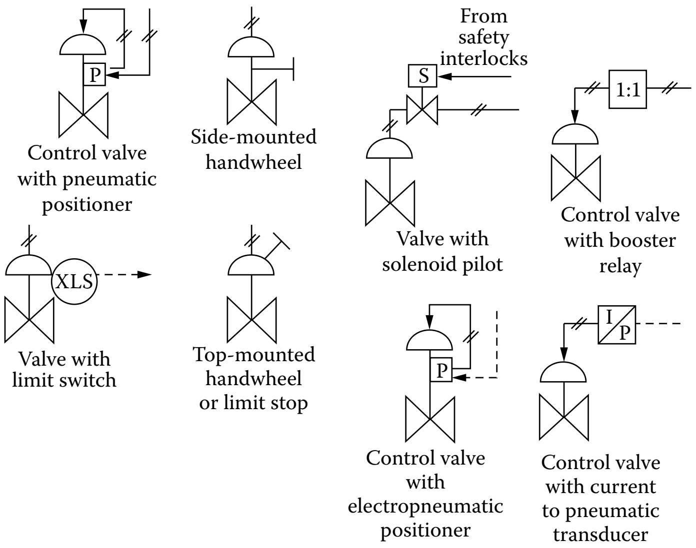
6.2 Accessories and Positioners

H. D. BAUMANN (1970) **C. G. LANGFORD** (1985, 2005)

B. G. LIPTÁK (1995)



Flow sheet symbols

Types:	Air accumulators, air sets, handwheels, I/P transducers, limit stops, limit switches, positioners, relays (biasing, booster, lock-up, quick-exhaust, reversing), smart (microprocessor-based) valve electronics, solenoid pilots, stem position transmitters, servo solenoid valve.
Materials of Construction:	Bodies and cases: die-cast zinc, "white metal," aluminum. Bellows: copper alloys. Diaphragms: elastomer-coated fabric, thin metal. Misc. parts: steel, brass, aluminum.
Supply Pressure (Gauge):	Varies from 20 to 25 PSIG (140 to 170 kPa) for signal relays to 60 to 100 PSIG (400 to 700 kPa) for positioners or boosters, some to 150 PSIG (1000 kPa).
Inaccuracy:	Positioners: repeatable to ± 0.1 to 1% and accurate to ± 0.5 to 2% of span. Transducers: ±0.5 to 1% of span. Boosters: ±0.1 to 1% of span.
Signal Ranges (Gauge Pressure):	Pneumatic: 3–9, 3–15 (preferred), 6–30, and 9–15 PSIG (20–60, 20–100, 40–200, and 60–100 kPa). Electronic: Digital Fieldbus and other, 1–5, 4–20 (preferred), and 10–50 mA DC. Others are used such as 0–10 and 1–10 VDC.
Costs:	Air sets, \$40; handwheels, \$500 for larger size; I/P transducers, \$300; limit stops, \$100; limit switches, \$50 to \$150; positioners, \$400 (pneumatic), \$600 (electronic); \$1500 (special) solenoid pilots, \$80; stem position transmitter, \$250 to \$500.

INTRODUCTION

This section describes some of the traditional valve accessories, including positioners. For the valve accessories that provide self-diagnostic capability or can communicate on the fieldbuses, the reader is referred to Section 6.12, which is fully devoted to an in-depth discussion of intelligent valves, positioners, and accessories.

The word "accessories" applies to the many devices added to control valves. Many of these are more necessities than accessories, depending on the application. This section lists and discusses some of the many accessory devices that can be attached to both throttling and on/off valves. The purpose is to improve their performance or to obtain remote feedback on their status. The positioner is the single most important valve accessory, and this section will emphasize the design and the application of positioners. Before starting that discussion, a brief summary will consider the contribution of microprocessors to the development of smart valve accessories. See also Section 6.9, Dynamic Performance of Control Valves, for a more detailed look at valve dynamics.

SMART VALVES

Section 6.3 discusses some of the more common applications of intelligent actuator systems, and Section 6.12 is fully devoted to an in-depth discussion of intelligent valves, positioners, and accessories.

The microprocessor can provide logic to improve the positioning and the performance of the valve. Additional services may include operational and maintenance communications with the valve.

Microprocessor-based systems are available in watertight or explosionproof (NEMA 6 or 7) construction and can tolerate ambient temperatures from –40 to 185°F (–40 to 85°C). They can also be used where any or all of high humidity, fungus, or dust are present. As shown in Figure 6.2a, these devices have become quite complex, and any proposed application for "smart" positioners should review the operating conditions and the application requirements with the manufacturer. Some of the positioners emphasize maintenance services; some make improved control their main goal.

Microprocessor-based systems can incorporate self-tuning and self-calibrating electronic positioners or electronic proportional, integral, derivative (PID) controllers, which respond to a digital or analog external set point and commands. Locating the controller logic at the valve and dedicating it to full-time control is an advantage on critical loops, providing fast response for applications such as compressor surge protection, where speed of response is a major consideration.

There may also be an improvement in control robustness and reliability if the system can continue to control without the central control system. This does not mean that positive control is lost, because the system is still "under orders" from the central system, only the continuous cycle of measure-compute-act-feedback is local. Commands for set point, mode of operation, and data collection reside in the central system. Local control eliminates the time lost during communications and response of the central control system like a programmable logic controller (PLC) or distributed control system (DCS).

Smart positioners can modify the characterization of the valve to reduce control nonlinearities in the valve and actuator and to provide special action. It is possible to match the valve to the process requirements to reduce the change in process gain over the range of operation or to provide special response or action as required.

Smart actuator circuitry can also protect electric motor operators from electrical overload when the valve is jammed or from reverse phase operation. Smart systems can also take advantage of the lower cost of digital communications over a single loop of two-conductor or fiber-optic cable. This method of communications can substantially reduce the wiring cost of installations that can control a number of actuators, pumps, and other devices.

The smart valves can have calibration changed and reconfigured and can detect such performance changes as pressure drop changes resulting from a fouled pump or pipeline. They can also limit the valve travel to stay within the range where the required characteristics (gain) are guaranteed or to limit maximum or minimum flows.

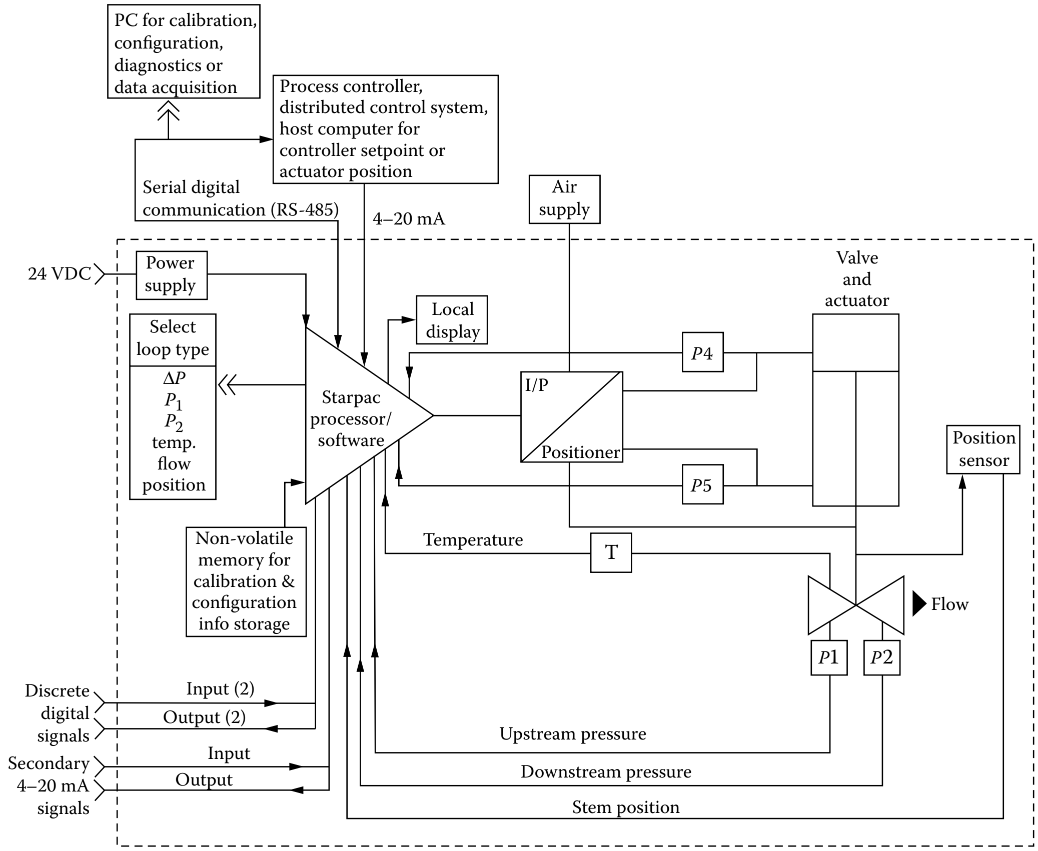

FIG. 6.2a

Smart valve packages may have local display and sensors for temperature, flow, pressures, pressure differential, and stem position. (Courtesy of Valtek, Flowserve Corp.)

Some of the smart valve packages incorporate additional sensors installed on or in the valve. These measurements may include upstream and downstream process pressure, pressure difference, flow, process fluid temperature, stem position, and actuator operating pressures (Figure 6.2a). This allows both for total distributed control and for the flexibility of manipulating the valve to control any one of the variables.

These valves may also include local indicators and the capability of calibration or reconfiguration of the valve, transmitters, or controller. Diagnostic capabilities include self-tuning and the ability to evaluate the valve and process responses to step or to ramp changes in the valve position. Upon failure of the electrical power supply the valve functions can be supported by battery backup.

The user is cautioned that some of these more sophisticated accessories may require more than the usual two-wire 4–20 mA DC power/signal wiring. Some are "four-wire" with separate power required. Some are two-wire, but may present a higher impedance load to the system than the simpler field instruments. This higher source voltage requirement may prevent wiring two positioners in series for split ranging.

Primarily used with on/off valves, on-line partial stroke testing may be provided for safety applications to provide verification of the valve actuation system. The user is advised to check the current versions of applicable standards because there is significant interest and activity in this area.

POSITIONERS

The positioner along with the associated actuator constitutes a simple position control loop. The valve begins to act only after the error is detected and the controller output has changed. Inherently, this is a lagging action.

With the typical air supply pressure used, 15–100 PSIG (100–700 kPa), any large change in valve signal will result in a critical pressure drop within the positioner. When the internal flow restriction has a pressure drop (ΔP) greater than 50% of the absolute inlet pressure, then sonic flow velocities will exist. This sets a constant and limiting flow rate through the pilot valve.

This maximum flow rate capacity is probably the one listed in the product specifications. As the valve stem approaches the desired position, the ΔP decreases and the flow decreases to be more nearly proportional to the signal error. This results in some slowing of the response at the end of the stroke change and may help to stabilize response.

When to Use Positioners

The purpose of a positioner is to improve the accuracy of control valve response. This means that the valve position will more closely approach the position commanded by the control system. A positioner can reduce the effects of many dynamic variations. These include changes in packing friction due to dirt, corrosion, lubrication, or lack of lubrication; variations in the dynamic forces of the process; sloppy linkages (causing dead band); and nonlinearities in the valve actuator.

The dead band of a good valve/actuator is 2% (Section 6.4), but it has been measured at up to 5%. Large plug valves and ball valves with less than perfect linkages and inadequate actuators may be far worse. A better positioner with the proper actuator can often have a dead band of less than 0.5% of stroke.

The positioner increases the actuator speed or thrust by increasing the actuator pressure or airflow volume, and can modify the valve characteristics through the use of mechanical links and cams or electronic function generators. While these positioner capabilities are very important, some of these capabilities can also be obtained or approximated with other accessories.

For example, split-ranging is possible using pneumatic relays. Multiplier/biasing relays in the air signal line to the valve modify the relationship between controller output and actuator air pressure. The response speed/thrust of the valve can be increased with the use of airflow booster relays, and changes to the control valve characteristics can be obtained, not only with a different plug characteristic shape, but also by pneumatic or electronic characterizing of the controller signal. Consider that the computing relays may have a lower flow capacity than a positioner and the speed of response may be affected.

When the valve is in remote manual (open-loop) operation, the positioner will reduce the effects of the valve hysteresis and dead band and improve the accuracy of the response. When the valve is under automatic (closed-loop) control, the positioner will normally improve control, but will do that only if the loop response is slow when it is compared to the control valve response (analysis, temperature, liquid level and blending, slow flow, large volume gas flow).

An imperfect positioner may degrade loop response, contribute to proportional offsets, and cause limit cycling in fast loops where the valve cannot keep up (fast flow, liquid pressure, small volume gas pressure). Older and simpler positioners did limit response and create problems.

The issue is more of the speed of the valve relative to the controlled process rather than absolute speed (Figure 6.2b). It is not uncommon for the valve to be the slowest part of the loop and limit process response. This may be a problem, or it may be perfectly acceptable. The needs of the process should be the basis for determining the performance requirements of the control system. The very worst situation occurs when the valve system and the process have equal or similar time constants.

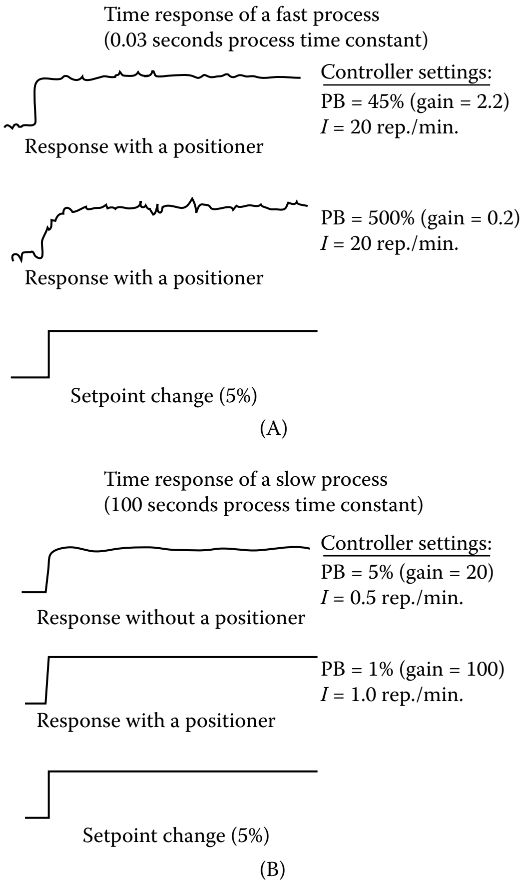

FIG. 6.2b
The response of a "fast" process (A, on top) is better without a positioner, while the response of "slow" processes (B, on bottom) is better with a positioner.[2]

Actuators without springs or equivalent padding pressure to provide the spring return function will usually require positioners with dual outputs to drive both sides of the diaphragm or piston. The spool valve or relay valve will have a second output, with its action the reverse of the first one. Because the opposing air pressure below the diaphragm decreases when the air pressure above the diaphragm increases, the actuator has a greater net force available without the opposing spring force.

It is necessary to have a packing gland or O-ring seal around the valve stem for the lower air pressure. A positioner with only a single output can be used with a reversing relay to provide the second output.

A number of different control design requirements can be accomplished with positioners. A reverse-acting positioner (increase in input causes a decrease in output) makes an air-to-open, spring-to-close valve function as an air-to-close, spring-to-close valve.

This combination may be specified for systems with interlocks or batch operations. The use of reverse acting positioners is discouraged by some users for maintenance reasons. Beware of terminology here: "Fail Open" has been

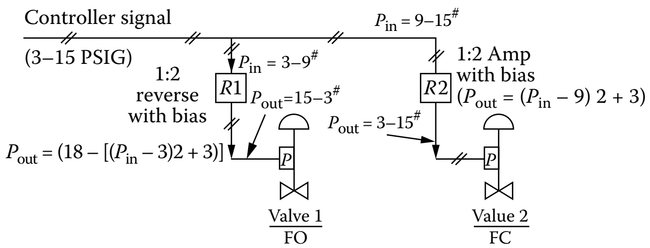

FIG. 6.2c

Split-range operation of two valves can be obtained by the use of amplifying and reversing relays. They can be either be pneumatic (shown here) or electronic.

confused with "Flow to Open," and "Fail Closed" has been confused with "Flow to Close." These are different and must be defined and understood especially in safety applications.

Heating, ventilation, and air-conditioning (HVAC) systems with low-pressure pneumatic thermostats may use some sort of simple positioner to increase actuator pressures. The alternative is electric signals and electric motor-activated valves. These services rarely need fast response or tight control.

Split-Range Operation Split-ranging is the use of two valves controlled from one controller output signal. With positioners, each positioner moves its valve over only a part of the controller output range.

One typical application is for temperature control. Here, the cooling valve is full open at 0% controller signal and closed at 50% signal and beyond, while the heating valve is closed over the 0–50% range and begins to open at 50% controller signal and fully opens at 100%. See Figure 6.2c and Table 6.2d.

The example is a simple one and has many possible difficulties. The specific application may require a different sort of calibration. A dead zone with both valves closed at a controller output of 50% will have no total flow over that dead band. This may be used to reduce costs of heating and cooling.

Other applications may require that both valves be partly opened at the 50% controller output point. For a system where the valves add the temperature control fluid into a circulating system, it might work well. But, as an example, if the system is "once through" where the heat transfer rate is proportional to the heating/cooling fluid velocity, the valves are usually set up with some overlap in valve position. That is, the cooling flow might not shut off until the Controller Output (CO) is 75%, and the heating flow might start at 25% CO. The total flow and thus heat transfer rate will remain more nearly constant and stabilize the operation.

With this approach, maintenance is simplified because standard positioner calibrations are used and the full positioner accuracy is retained. Note that the specifications for the positioner are defined for the full range of the positioner and that if only half the output range is used, the effective dead band for each valve is doubled. For a maximum in flexibility, control each valve from a separate control system output.

TABLE 6.2d

As it is Shown in Figure 6.2c, it is Possible to Use Relays instead of Split-Range Positioners

Signals in %

Controller Output	*Output Relay 1*	*Output Relay 2*	*Control Valve 1*	*Control Valve 2*
0	100	0	100	0
25	50	0	50	0
50	0	0	0	0
75	0	50	0	50
100	0	100	0	100

Signals in PSIG (bar)

Output Controller	*Output Relay 1*	*Output Relay 2*	*Control Valve 1*	*Control Valve 2*
3 (0.2)	15 (1.0)	3 (0.2)	100%	0%
9 (0.6)	3 (0.2)	3 (0.2)	0%	0%
15 (1.0)	3 (0.2)	15 (1.0)	0%	100%

Signals in % (with overlapping flows)

0	100	0	100	0
25	75	25	75	25
50	50	50	50	50
75	25	75	25	75
100	0	100	0	100

Tight Shut-Off In some applications, there is a need for special tight shut-off. A positioner calibration can provide the full actuator pressure applied to the valve stem when the valve is commanded to be closed.

High Rangeability A special application might require accurate flow control for a small percentage valve opening. The positioner calibration can provide that the valve moves very little for a large fraction of the low end of the signal range but still opens fully at 100% of signal. Examples include a drastic difference between operating conditions and start-up or emergency shutdown, or a large butterfly valve.

An application as simple as a level control may be very poor because the valve is oversized for special operating problems. A very simple flow control loop will add considerable accuracy at a modest cost. The primary requirement for the flow sensor is to be reliable; even poor accuracy is adequate. A simple field controller, even pneumatic, will constitute an inexpensive secondary control loop requiring little attention.

Gap Action If there is a great problem with packing wear, it is possible to set up the controller or the positioner for "gap action." Here, the valve signal changes only when the control error exceeds a certain limit.

Condensate pots that accumulate steam condensate are an example of this. A partly opened valve will experience damaging cavitation. A valve that quickly switches between fully open at a high condensate level and fully closed at a low level will avoid cavitation. Boiler blowdown valves are a similar application.

When Not to Use a Positioner

The positioner/actuator can be defined as the secondary control loop in the cascade loop, working with the process controller output providing the control signal. In order for a cascade secondary to improve control, it must respond more quickly than the primary loop. The ideal situation would be if the time constant of the secondary was one tenth (open-loop speed of response ten times as fast) of that of the primary and if the period of oscillation of the secondary loop was three times that of the primary.

Even if the valve response is not as fast as these ideals, there still may be very helpful isolation of the process from process fluid changes. No process control response time can be faster than the slowest element in the control loop. The advantages of a cascade system are achieved with good secondary response.

A general principle is to use a cascade system when the advantages of isolating the primary control loop from the nonlinearity, and variations in the secondary system, justify the added cost and complexity. In such installations (B in Figure 6.2b shows a gas pressure control process), the addition of a positioner increases the open-loop (steady state) gain and improves the loop response. For this situation, the process response may be further improved because the primary controller can be tuned with increased gain (narrower proportional band) and increased integral action (reset) to speed up the integral action.

It is clear that poor valve response reduces the quality of control much more than the poor valve response would imply. In this situation the controller tuning must be modified (gain reduced, integral lengthened) to avoid oscillation due to dead band and response delay. In typical real applications controller tuning is conservative and avoids any hint of oscillation, and the response is even worse than it might be. Operators usually object to cycling processes.

Part A in Figure 6.2b illustrates a fast liquid flow process, where the loop without a positioner can be tuned more tightly (for higher gain and more repeats/minute); such a loop responds better without a poor positioner. It might also be noted that after a new state is reached, the positioned installation gives better and noisier control because of increased speed of response.

Some argue that all loops can be (and should be) controlled with positioned valves "because they provide improved response." This is true, but there are situations where the positioner will add unjustified cost. The very fast flow loop of Figure 6.2b is one example.

Another is a small valve with a relatively large actuator and good available force; it has a small valve stem and little friction and a small plug with low fluid forces. Situations where cost is primary and quality of control is not highly important may also omit positioners. Examples are HVAC where forces are low and signal changes are slow, but there is a desire to control the cost. Positioners are not normally required for on/off service.

Positioner Performance

The valve positioner is a servo-amplifier acting with the valve actuator to control the position of the valve stem. Without a positioner, the stem position may be changed or motion restrained by varying fluid pressures on the plug and by unpredictable friction forces. See Section 6.9 for more details on control valve response.

The pneumatic input signal is typically 3–15 PSIG (20–100 kPa), and the typical stroke is between $^1/_2$ and 3 in. (12–75 mm). Errors of 0.05 in. (0.1 mm) are typical. The usual input air signal is the output of a pneumatic controller in the field or from a control panel or control system. The controller signal is the result of comparing a set point pressure to a measured variable as presented by a 3–15 PSIG value and the output is intended to reduce the error.

Most positioners use air both as the operating fluid and as the source of power. Hydraulic actuator/positioners use high-pressure oil and are used on applications requiring large valves for high differential pressure services. These are units requiring actuator pressures higher than the normally available 60–100 PSIG (0.4–0.7 MPa) instrument air supply pressure. Hydraulic actuator/positioners are considerably more expensive; and they may be acoustically noisy and require specialized maintenance.

Electric motor operators are also available (Section 6.3). They are used where air is not available and where their typically slow operating speed is acceptable. There are some specialized electric valve actuators that can provide very high position precision; others can provide very fast response.

The analog electropneumatic positioner input section responds to a standard milliampere signal. Such units usually consist of a pneumatic positioner plus an integral I/P. Some users prefer to use a pneumatic positioner with a separate I/P (current to pressure converter), usually located near the valve. A few systems provide for packaging all of these accessories into one unit.

An all-electric server solenoid motor-type positioner/actuator valve is also available. At least one control valve design uses a servo solenoid valve (SV) to achieve very fast and accurate response using the process fluid pressure for actuation. This approach requires a relatively clean fluid.

The positioner normally provides a substantial improvement in valve and control loop performance, with the greatest improvement realized on slow control loops with low controller gains typically level, temperature, or analytical control (Figure 6.26).

Positioners have typical open-loop gain (change in output pressure per change in input signal, with the valve stem locked in position) of 10:1 up to 200:1. Dead band (the minimum input change for a detectable output change) is claimed as 0.1–0.5% of span. Vendors claim positioning accuracy of 0.002–0.005 in. (0.05–0.13 mm) under bench test conditions.

Positioner Designs

The control valve positioner as used with a globe-style valve is typically mounted on the valve yoke and has mechanical linkage, which is connected to the valve stem to sense position. The pneumatic positioner is powered by compressed air at pressures between 25 and 150 PSIG (170 and 1000 KPa).

Tubing conveys the positioner output air to and from the actuator. There are some standards defining standardized mounting details for positioners, solenoid valves, and other accessories.

Other designs mount the positioner directly in line with the valve stem, and installed on the end of the actuator. In this design the linkage to the valve stem is direct in a straight line. In this scheme, the positioner provides air directly to the top of the actuator. Figure 6.2e illustrates such a force-balance positioner design.

For rotary valves, the positioner is mounted above the valve body. In every case, the mountings must be solid and not allow any relative motion, which adds directly to the dead band. The installation should be so arranged that there is little temptation for workers to damage the connecting tubing and linkages by climbing on the valve. The exterior of the positioner should have a finish compatible with the chemical environment.

The interior is (mostly) protected from corrosion by the steady bleed of dry clean air from the pilot valve. If the valve will be exposed to a very high level of vibration or acoustic noise, the purchase specifications should note this. Some positioner designs will withstand vibration better than others.

Pipeline applications may use the pipeline gas to operate the pneumatic instruments. For these applications, the instrument vents are purchased with tapped connections to carry the vented gas to a safe location. Because the gas used may not be totally dry, there may be a need for filters and separators to protect the instruments. Consult the valve and instrument manufacturers for requirements. Also consider the area electrical classification for electropneumatic positioners.

Because all positioners use small restrictions to reduce the air consumption at steady state, it is vital that the air be clean. Some positioner designs include a small integral filter. Satisfactory long-term operation of the instruments is considerably improved if all the dirt and moisture are removed in a good external supply filter before it reaches the positioner.

Liquids are efficient transporters of dirt and solids in supply lines to places where they will cause trouble. Liquids also can lead to ice, which can block flow in restrictors resulting in positioner malfunction, and then it may vanish without a trace after causing an unexplained upset. A simple mechanical separator will normally not remove enough moisture to properly protect the instruments.

Force-Balance Positioners The force-balance positioner shown in Figure 6.2e has an element that compares the force generated by the input signal with the force generated by the feedback spring connected to the valve stem. Figure 6.2f shows the electropneumatic force-balance positioner.

Motion-Balance Positioners The motion-balance positioner in Figure 6.2g compares the motion of an input bellows or diaphragm with linkage attached to the valve stem. Either can be very accurate. Bellows-type input elements are generally thought to be more accurate than diaphragms, and although slightly more likely to fail in fatigue, both types are used successfully. New and mostly electronic positioners differ widely in design and performance.

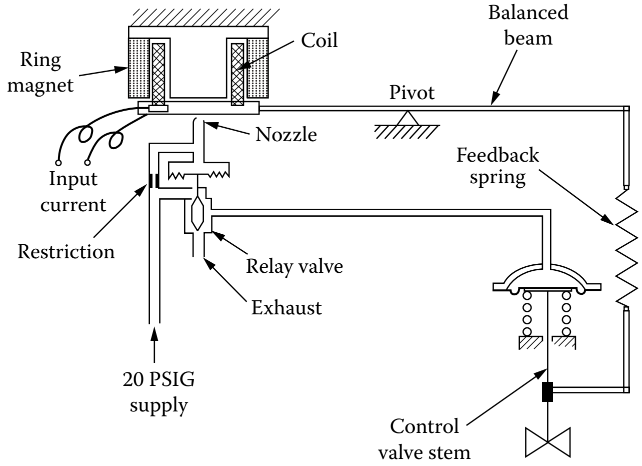

FIG. 6.2f
Electropneumatic force-balance positioner.

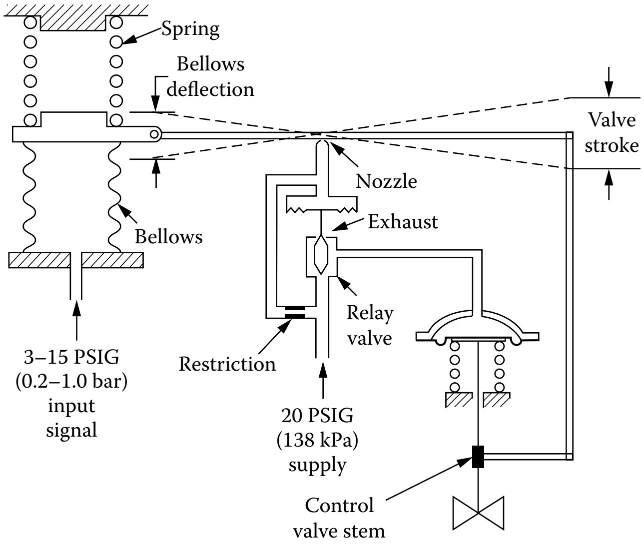

FIG. 6.2g
Motion-balance positioner.

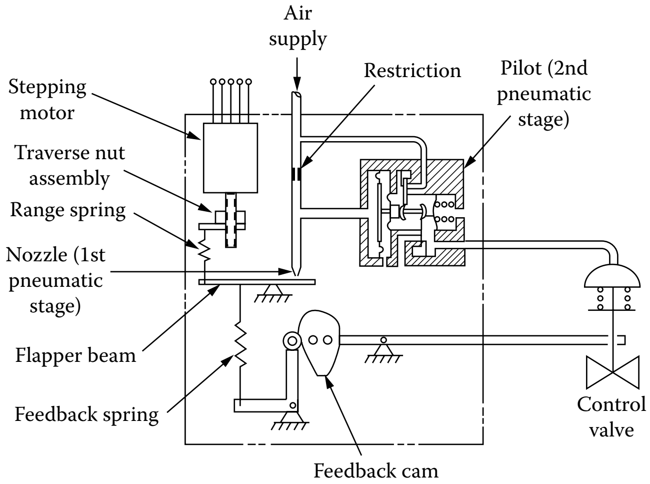

FIG. 6.2h
Digital-to-pneumatic valve positioner.

Electrohydraulic Positioners The electrohydraulic positioner addresses the need to control actuators on very large valves and for high-pressure differential applications. These systems typically require an external motor-driven pump, reservoir, pressure control regulators, high-pressure accumulators, and filters. The positioners may use high pressure oil jet tubes that are directed by linkages to regulate the oil pressure in the actuator.

Hydraulic pressures are typically 750–1,500 PSIG (5,000–10,000 kPa). A hydraulic pressure accumulator is often provided to store the energy for peak requirements. The valve vendors can suggest or supply the hydraulic system packages. Specification issues to be determined include the use of flammable or nonflammable oils, electrical classification, peak needs, noise, space required, costs, and maintenance. If the area has several large valves, a larger central hydraulic system may be used.

Digital to Pneumatic Positioners The digital valve actuators are described in Section 6.3. Some of the digital to pneumatic positioner designs have used rotary motors to control the pilot system. These tend to feature lock-in-place on loss of input signal. Others use a small fast solenoid valve that switches rapidly between open and closed to create an average air pressure for the actuator.

Still others may use a piezoelectric valve (electrical signals cause a deflection in a special crystal structure), either proportional or pulsating. A pulse stepping motor may rotate a shaft to set a follower, which develops an input signal force or position (Figure 6.2h). The remainder of the positioner is pneumatic. Stroke speed may be limited by stepping motor response. The only way to make decisions during the selection process with the many different designs with their many subtle differences may be to rely on proven performance.

Positioner Accessories

A number of options are available for most positioner designs, such as gauges to display the supply, signal, and output pressures. These add little cost but are a great help during checkout and maintenance.

Bypass air switches will connect the controller output directly to the actuator. These were once popular when 15 PSIG (100 kPa) pressure was adequate to move the spring-diaphragm actuator if the positioner was direct acting (increase input–increase output). The bypass is rarely specified now because this feature permits only very limited maintenance on the positioner and most modern high-performance positioners do not offer this option.

There are also safety implications in providing the possibility of changing the valve response. At one time, the usual justification for the bypass valve was to provide a way to get a poor performing positioner out of the loop for field troubleshooting. In some corporations the only control valves now purchased without positioners are small (1 in. [25 mm] and less), for low-pressure differential (0–20 PSIG [0–140 kPa]), and less critical service (comfort heating and ventilation), and where absolutely minimum cost is required.

Mechanical switches are used to provide a signal to the operator or control system that the valve stem is at or beyond a specified position. The specifications for these switches should consider the voltage and current surges caused by lightning strikes on long wire runs. These are available to suit the local electrical classification requirements. For some manufacturers of piston-type actuators, springs to provide for fail-safe action on loss of air are considered an accessory and are not supplied except as specified.

Position Indicators

Globe-style valves normally have a simple stem position pointer mounted on the stem with a simple scale on the yoke. A local valve position indicator may be mounted on rotary valves to allow the operator to see the state of the valve. Stem position transmitters, usually derived from positioner designs, are used to provide independent remote indication of valve stem position.

TRANSDUCERS

I/P (Electropneumatic) Transducers

A large variety of converters (transducers) are discussed in detail in Section 3.3. The electropneumatic transducer (I/P) converts electrical signals (usually 4–20 mA DC) into a pneumatic signal, usually 3–15 PSIG (0.2–1.0 barg). The most common application is the interface between an electronic controller output and the pneumatic control valves. It is also used between digital control systems and control valves. A few designs use signal feedback to improve accuracy (Figure 6.2i).

Most I/P transducer designs are of the "motion-balance" type (Figure 6.2j), where the small force developed by the milliampere current through a coil in a magnetic field causes motion in a nozzle-baffle assembly, resulting in a changing pneumatic pressure. The nozzle-baffle system is an amazingly accurate mechanism for measuring small distances.

When an I/P is used within a control loop between the controller and the control valve, its error is combined with the valve error, which is detected by the loop controller and then driven towards zero error. Repeatability and reasonable linearity are required, and most I/Ps have advertised accuracies of 0.35–1.0% of full scale. Most I/Ps have relatively low air capacity, and a booster relay may be needed to drive a pneumatic actuator unless a positioner is used.

Digital Electropneumatic Transducers

A variety of devices are used to convert digital signals in addition to the electronic digital-to-analog converter. One device uses a stepper motor, as in the digital positioner mentioned above.

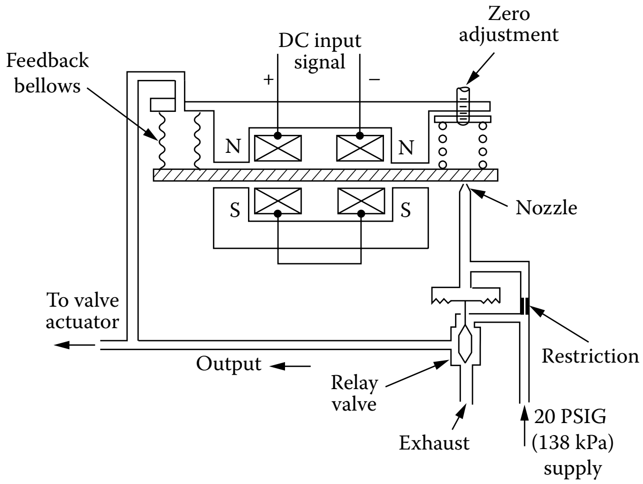

FIG. 6.2i
Electropneumatic force-balance transducer design and components.

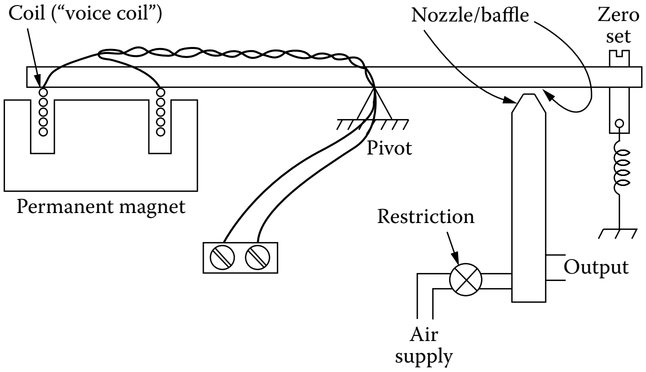

FIG. 6.2j
In a motion-balance electropneumatic transducer, the coil is of similar construction to the voice coil of a loudspeaker. Leads are arranged to go through a pivot point to reduce their effect on output.

A second device has a number of wires connected to it and receives data on all these wires simultaneously. This "parallel" data signal is converted to an analog current, and this controls the output pressure. Another device responds to a string of pulses ("serial" data) to set the output pressure.

RELAYS

Booster Relays

A "booster" relay, Figure 6.2k, is a device that amplifies pneumatic signals in volume (capacity) or in pressure, or both. Most booster designs were derived from a pressure regulator, with the input signal providing the loading force in place of the regulator spring. Internal pressure feedback

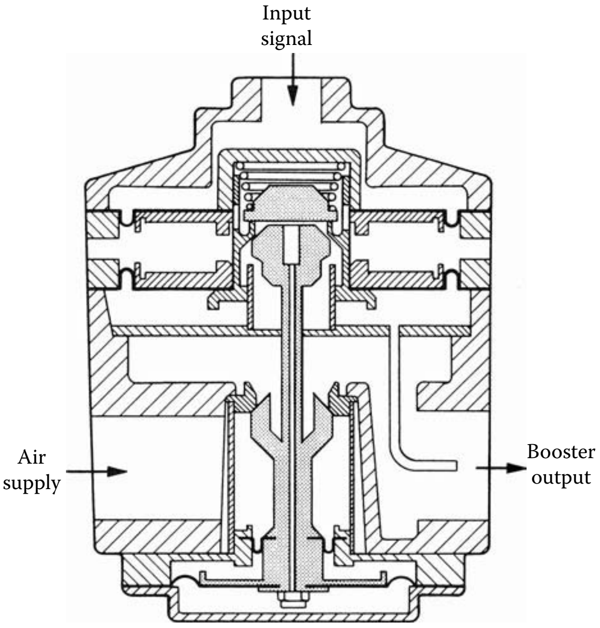

FIG. 6.3k
Volume booster relay.

may improve accuracy. The downstream-facing pitot tube compensates for flow-related pressure drop.

The feedback diaphragm has a smaller area than the input diaphragm so that greater pressure is required to achieve force balance. Volume boosters with a pressure ratio of 1:1 (gain of 1) are sometimes used to speed up a valve actuator response if a positioner is not used. The booster cannot overcome inaccuracies due to friction or forces on the valve plug, but it will reduce their effects because of faster response.

The stroking times of pneumatic piston actuators (Section 6.4) are a function of their size and of the size of the connecting tubing. A size 300 actuator with $^3/_8$ in. (9.5 mm) tubing has a stroking time of 27.7 sec. If the output of the positioner operating that actuator is piped to one booster on each side of the piston, the stroking time is reduced to 5.4 sec, and if two boosters in parallel are used on each side, the striking time is reduced to 2.7 sec.

Large control valves and large actuators may require flow or pressure boosters installed between the positioner and the actuator to achieve the required speed. One special "dead band booster" design, Figure 6.2l, does not respond until an (approximately) 1 PSIG (6.9 kPa) difference between input and output is exceeded.

A built-in needle valve allows a limited airflow to bypass the booster gain portion and provides adjustable damping. Springs provide the 1 PSIG dead band with this relay. Very large volume amplification occurs for fast input signal change, but it does not amplify a slow change.

One common application for this relay is the centrifugal compressor antisurge control, where the control valve must open very quickly (1–3 sec) but then is required to throttle smoothly. The needle valve is adjusted with the complete control system assembled and operating. Careful tuning is vital to proper operation. With the booster needle valve fully closed, the positioner-valve system may be unstable.

Best operation occurs when the needle valve is open only enough to smoothly dampen the oscillations. If more than one of these relays is used to add capacity for one side of the piston actuator, it is absolutely necessary to set the needle valves as identically as possible to avoid a complex and probably unstable interaction between the relays.

It is worth repeating here that no air device will operate properly without an adequate air supply. With their large air-handling capacities, valve booster relays require 0.5–0.75 in. (12–20 mm) air supply and output tubing to the valve operator. Large filters are used to minimize any air supply restriction. In one special case, a large air tank 10 ft^3 (0.3 m^3) was installed near the valve in order to provide adequate local air surge capacity.

Reversing and Other Relays

Besides the booster function, pneumatic relays can meet other control valve requirements. The fixed-gain-plus-adjustable-bias relay for split-ranging was mentioned in connection with Figure 6.2c. Another 1:2 reversing relay is shown in Figure 6.2m. This design has a reverse gain of two (0% input results in 100% output, 50% input results in 0% output). It will reverse the operation of a valve and provide the gain and bias needed for split-ranging, while retaining the native failure action on loss of the supply air.

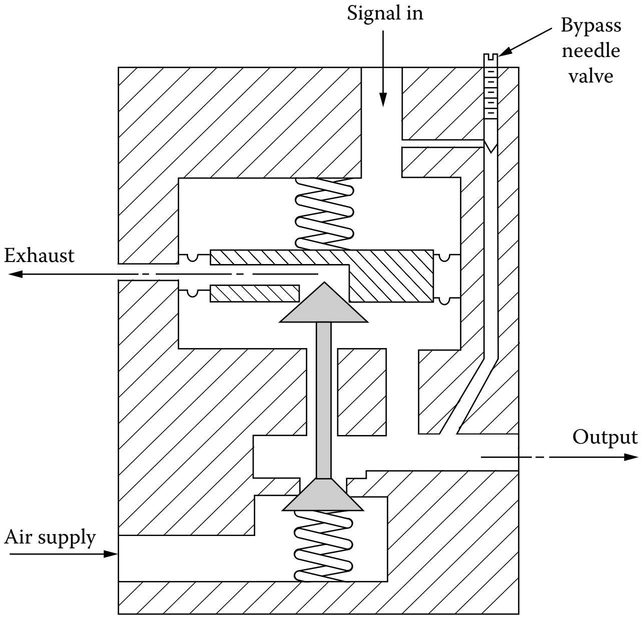

FIG. 6.2l
The design of a dead band booster in which the springs provide the 1 PSIG (6.9 kPa) dead band.

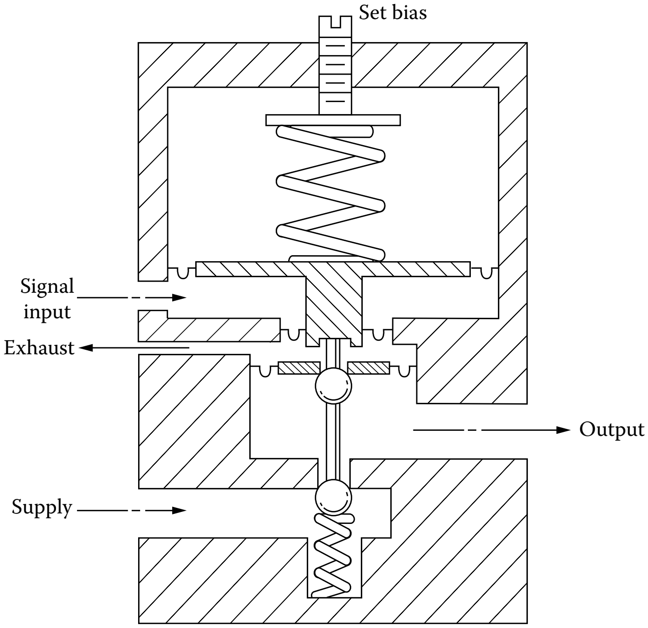

FIG. 6.2m
2:1 reversing relay.

The relay is a force-balance device. The output pressure generates a force on a diaphragm with one half the area of the input diaphragm so that the output pressure must be twice the input pressure. A wide variety of relays are available, amplifying, "reducing" (gains of less than one), computing (averaging, square root, and so on.), selecting (highest, lowest), some with provision for biasing the output.

Complex control concepts have been implemented entirely with pneumatic logic. This functionality is more commonly accomplished today with electronic circuits or in the control system. Very successful override control systems have been designed with one valve position controlled by several process variables such as pressure, level, and temperature.

Table 6.2n lists the air capacity for a few selected pneumatic components to show the range of typical devices. The data was found in various places and some is old. If the exact capacity of a relay or the stroking speed of a valve is important, it would be wise to check with the manufacturer.

Quick-Exhaust Relays

The quick-release valve or quick-dump valve, Figure 6.2o, is a pilot valve that opens a high-capacity vent when the input pressure drops below a set pressure. This is used where it is needed to quickly open a valve that vents a vessel or system during a shut-down.

It is not unusual for a positioner to bleed excess air from the actuator for some seconds before a valve begins to move, because the actuator is completely filled (saturated) with supply pressure air. The quick exhaust helps reduce the lost time. The controller continues to call for valve action after it reaches its mechanical stop.

5. Supply/exhaust

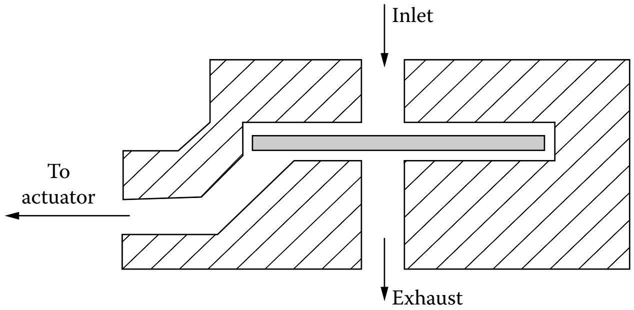

FIG. 6.2o
Quick-exhaust valve in which the elastomer flapper normally allows air to flow to the actuator while sealing the exhaust; if the inlet pressure is below that in the actuator, it allows the air from the actuator to be exhausted.

Quick-exhaust three-way solenoid valves having a large exhaust port for a similar effect can also be used.

Relays to Lock-up Valve Position

A lock-up relay or "fail in last position" relay, Figure 6.2p, is available to seal in the existing actuator pressures if the air supply is lost. It is intended to hold the valve in the last controlled position. If the valve is partly open at the time of air failure, this "frozen" position is not absolutely predictable because the servo-action is lost, variable plug forces may move the stem, and air may leak out in an unpredictable manner.

When a piston actuator is to be locked in its last position when the air supply fails, it is necessary to install two lock-up valves at the two ends of the piston and use a three-way switching valve to vent their actuators when the air supply pressure drops to some preset limit (Figure 6.2q).

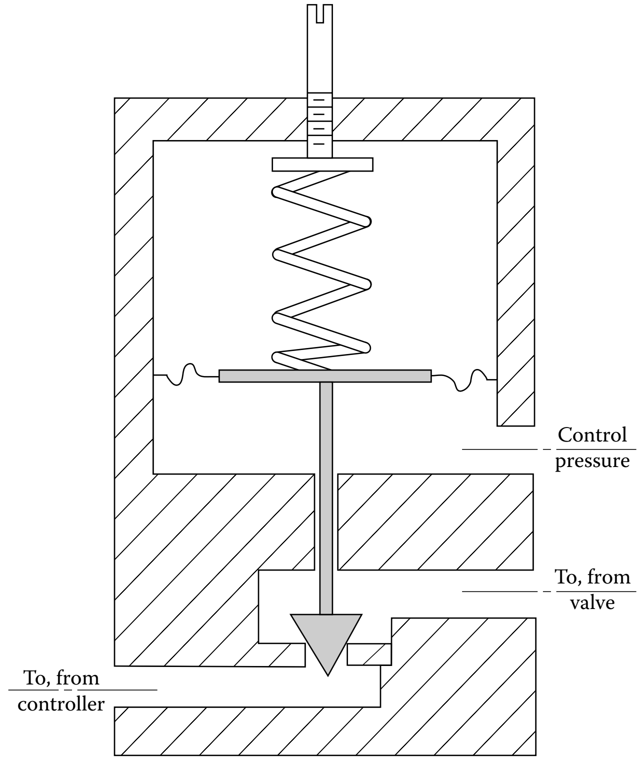

FIG. 6.2p
Lock-up relay: If control pressure drops below the spring setting of this relay, then the relay valve closes and seals in the last air pressure in the actuator.

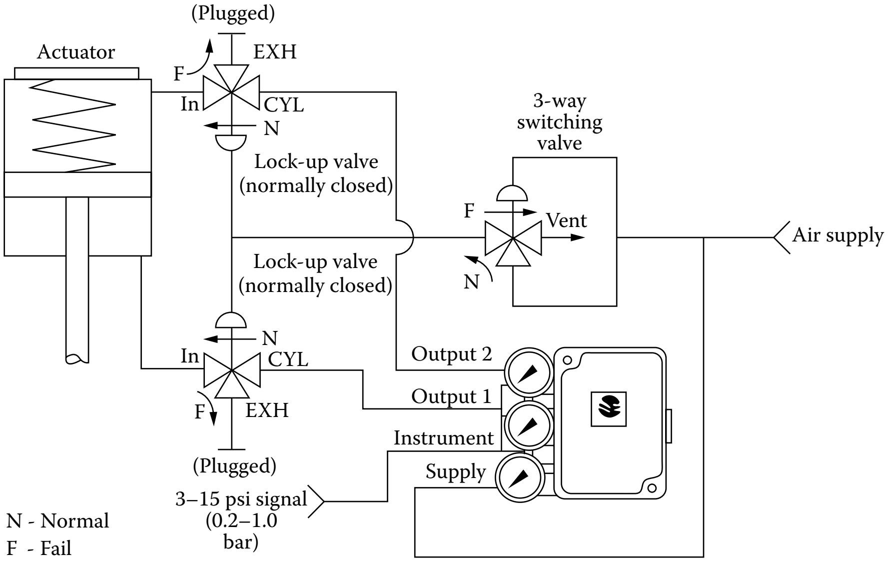

FIG. 6.2q

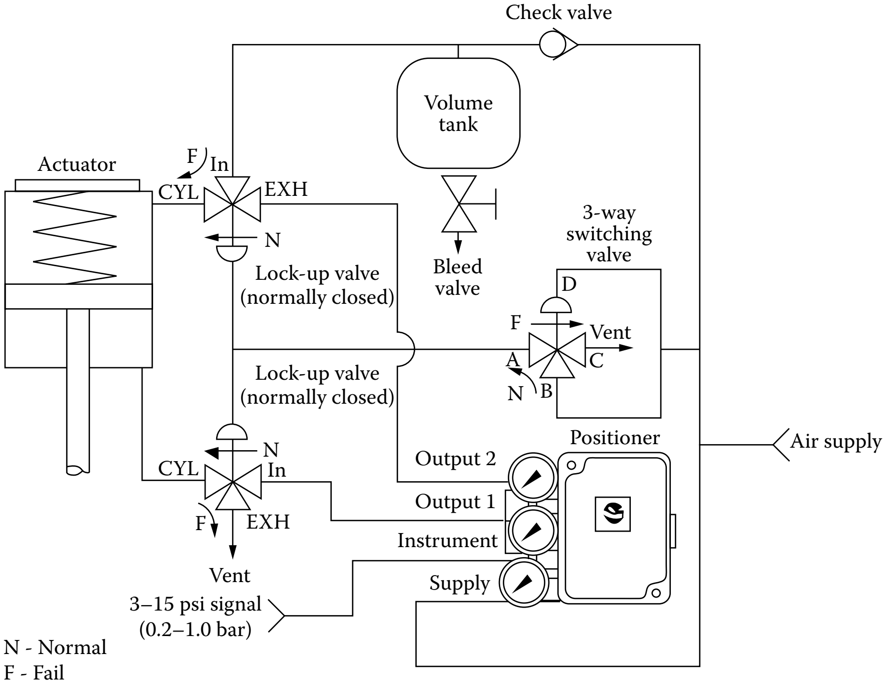

FIG. 6.2r

External air tank can provide the energy source to guarantee a positive failure position for piston-actuated valves. (Courtesy of Valtek, Flowserve Corp.)

Failure Position Guaranteed by Stored Air

In piston-operated valves, the air stored within the piston can also be used as the energy source to move the valve to a safe position when the air supply is lost. This can be achieved by locking the air in on one side of the piston while venting the other, when the air supply pressure drops to a predetermined value.

If there is concern that the piston volume is insufficient to fully stroke the valve under all conditions when the air supply might fail, an external tank can be used as the source of driving energy. Figure 6.2r illustrates such an installation for a fail-closed (air-to-open) valve.

Some piston-type actuators have no spring, and others have a spring too weak to guarantee valve action on loss of air supply. For these, an air tank (typically 0.5 ft^3, or 0.014 m^3) with a check valve on the inlet may be used to allow limited operation or orderly shutdown (Figure 6.2s). Because everything leaks, this will only be reliable for a reasonable time. Longer term requirements may be satisfied if the process pressure tends to hold the valve plug in the desired direction.

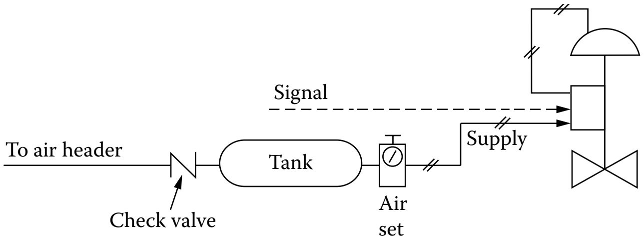

FIG. 6.3s

A temporary air supply can be provided by an air accumulator tank, which thereby will guarantee orderly shutdown.

ENERGY SUPPLIES

Air Sets

The "air set" is the air regulator with filter and drip pot used to supply air to the positioner or other instrument. It is often purchased with the valve, mounted, and piped. The regulator must have the pressure range to cover the spring range of the actuator, and it should have a built-in overpressure vent to protect the actuator; a gauge is valuable to aid in setting the output pressure and for discovering a failed or plugged supply.

Flow capacity is a problem only with very large valves. Some piston actuators and positioners will operate with up to 150 PSIG (1 MPa) supply, and there is a trend toward eliminating the regulator, but the filter is retained for reliable valve operation. Most manufacturers recommend that each control valve have its own individual air set.

The risk in providing air sets for high-pressure actuators such as air cylinders is that field operators can thereby limit the supply pressure, which in turn reduces actuator stiffness (resistance to the dynamic forces of the process). An air set must be used when the pressure rating of the actuator or positioner is lower than the air supply pressure.

The use of air filters is always recommended. They should be installed in the air supply serving the positioner and should be designed for the maximum air supply pressure. Their purpose is to remove moisture, oil, and all particles that are 5 μ or larger. In industry it is axiomatic that dirt is everywhere, and it will always find small restrictions to plug.

Hydraulic (High-Pressure) Operation

High-pressure, high-performance, hydraulic oil-filled systems are used for special needs, such as very large valves or those that require forces beyond 150 PSIG air supply. These function much like larger versions of the hydraulic power steering used on automobiles.

Very high speed performance and power is available, all at added cost. Most of the accessories and functions commonly found in pneumatic systems are available. These include: positioners, flow boosters, and pressure regulators.

Hydraulic (Water) Operation

There are two sorts of "hydraulic" operations. The first was addressed above. The second "hydraulic" system is the ubiquitous but rarely considered municipal water supply and wastewater systems, which have their own special set of requirements and solutions.

Actuators, pilot valves, regulators, and control relays are available that operate using water pressure just like the pneumatic systems used elsewhere. These control the water to fill elevated storage tanks and stop flow when the tanks are filled, and then implement the desired operating logic when water pressure is lost. Even fluid flow rate flow control is possible.

Self-contained water operation eliminates the need for electrical or air power and signals. Relays and valves to control water pressure surges can be provided. Users should contact the appropriate specialized suppliers for further information.

LIMIT SWITCHES

Switches are installed on electric motor-driven valves to open the circuit and stop driving the motor when the valve is at its limit (fully open or closed) or on motor over-torque. The name "limit switch" is also used to describe switches installed to signal when a valve is at or beyond a predetermined position. These switches are used for operator information, interlock inputs, or computer feedback.

It is necessary to consider the mounting problems, electrical classification of the area, the electrical characteristics of circuit, overtravel of actuating arm, and corrosive nature of the area. Usually, it is easiest to purchase the valve complete with the required switches already installed.

Because of environmental problems, some users have been using sealed magnetically actuated or proximity switches. Note that it is difficult to adjust limit switches closer than ±5–10 % and that dead bands of 2–5% can occur. Problems with failure of small contacts have been traced to voltage surges picked up on long field wiring.

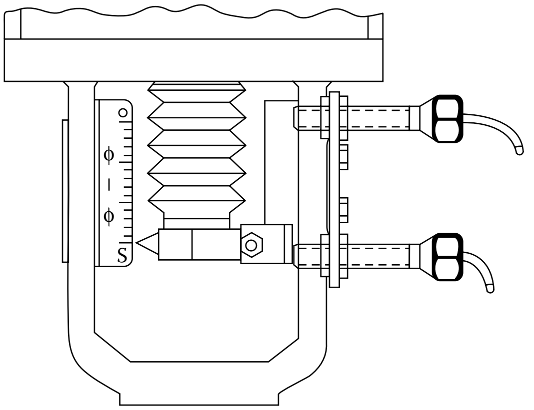

FIG. 6.2t
Installation of proximity switches to detect the open and closed position of a valve or a linear valve actuator. (Courtesy of Valtek, Flowserve Corp.)

Plantwide standardization on limit switch specifications for makes and model number will reduce spare part storage and simplify maintenance. When specifying the limit switches, one should specify the required contact ratings, the contact configurations (SPDT, DPDT, and so on), and the type of housing required. Typical choices include weatherproof, explosionproof, or hermetically sealed explosionproof.

Figure 6.2t illustrates a proximity switch installed on a linear actuator. The maximum spacing allowable between the switch and the sensed surface is 0.11 in. (3 mm). The switch is available in UL- and CSA-approved explosionproof designs.

SOLENOID VALVES

The solenoid valve (see Section 6.3 for more details) as a control valve accessory is used (1) to operate on/off pneumatic actuators or (2) to interrupt the action of modulating valves by switching air or hydraulic pressures. It is common practice to use a solenoid valve as the pilot for a pneumatically operated on/off valve because of the wide choice of features and capabilities available in the solenoid valve.

Solenoid valves are primarily used as parts of start-up or shutdown, interlock, or batch systems to cause the control valve to take some predetermined action under certain conditions. Three philosophies are in common use.

Three-Way Solenoids

In the first, the 3–15 PSIG (0.2–1.0 bar) signal to the positioner is blocked and the downstream tubing either vented or connected to some other preset pressure (Figure 6.2u).

This approach is reliable because the solenoid valve is lightly stressed, the positioner and valve have been in continuous use, and any failure or poor operation should have been detected during normal operation. With this scheme, the substituted signal can be any value over the operating range, the

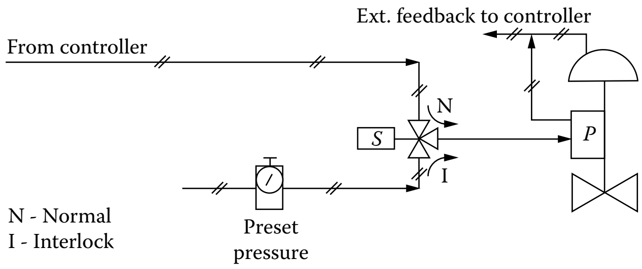

FIG. 6.2u

Under normal conditions the solenoid passes the controller signal to the positioner. Under abnormal conditions the interlock solenoid valve blocks the controller signal and opens the path for a manually preset air signal to reach the positioner.

valve will go to the desired opening, and the advantages of the positioner are retained. If the actual positioner input is fed back to the controller external feedback connection, then a smooth return to normal control may be expected when the control loop is returned to normal operation.

In the second philosophy, the solenoid valve is installed in the tubing between the positioner and the actuator (Figure 6.2v). Solenoid valves with adequate pressure rating and flow capacity are required. Only three control valve actions are possible: fully closed, fully open, or lock-up existing pressures.

A third philosophy is to shut off the air supply to the positioner and let the valve act as designed on loss of air supply. This is one scheme used in batch operations where the valves are switched into service when a process unit or pump is turned on.

In order for the system to shut down (valve to close) in case of loss of power or emergence of an unsafe condition, it is desirable for the solenoid valve to be continuously energized during normal operation. This will guarantee that any failure, loss of power, or a broken wire will cause a fail-safe action.

As a control valve accessory, usually a three-way (three ports) solenoid valve is required. Some designs require that pressure be always applied to one certain port and that another certain port always be used as the vent. This does not always suit the required logic, but valves can be found designed for "universal" operation where there is more freedom in assigning port function.

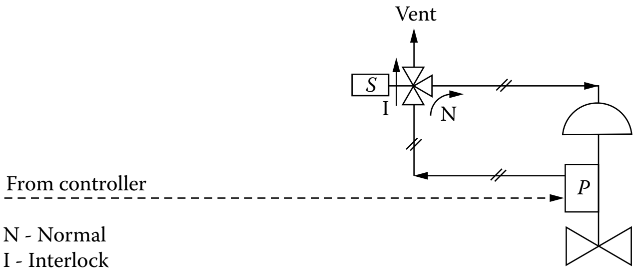

FIG. 6.2v

Interlock solenoid valve controlling actuator directly.

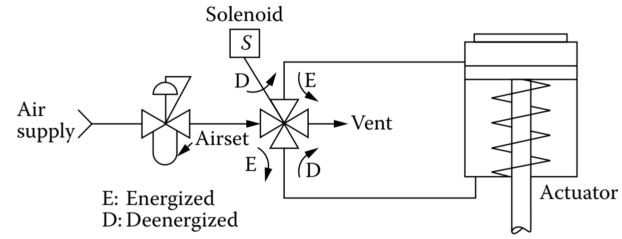

FIG. 6.2w

On/off cylinder actuator operated by four-way solenoid.

Also, note that clean, dry, oil-free instrument air provides no lubrication, and some types of solenoid valves (spool-type) will have a short life or become unreliable without lubrication. See also the discussion of the impact of solenoid valve operation on valve response in Section 6.9.

Four-Way Solenoids

For on/off cylinder-operated valve actuators, four-way solenoids are often used (Figure 6.2w). They are fast, provide positive operation, and are available for a variety of AC or DC voltage services and with Class F coils for up to 310°F (154°C) temperature services.

Solenoid Capacity

Each approach must consider the flow capacity of these solenoid valves. The desired solenoid valve C_v must be greater than the C_v of the positioner to avoid a reduction in stroke speed. If they are equal, then the valve speed will be roughly half of that without the solenoid.

It is typical of solenoid valves that small valves are directly operated and the larger ones are pilot operated. In pilot-operated valves, a small direct-operated valve uses air pressure to switch the larger main valve. Pilot-operated valves require a certain minimum air pressure differential in order to operate the main valve.

If the solenoid valve is tripped while the air pressure is less than this pressure, the main valve will not change state and tripping the pilot will have no effect. The valve will trip later when the pressure differential becomes high enough to operate it. Where full pressure is always present this is not an issue.

HANDWHEELS

Handwheels are used to provide for partial or complete manual control of the valve and to override the pneumatic actuator. Some, mounted on top of the actuator, Figure 6.2x, can only push on the valve stem to close (or open with inverted trim).

Others can be configured for continuous, bidirectional operation with force amplification ratios from 40:1 up to over 100:1. These top-mounted designs are illustrated in Figure 6.2y.

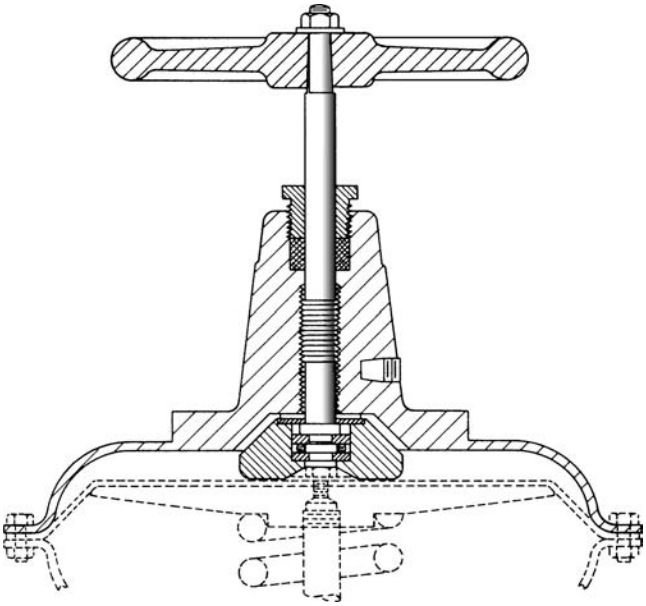

FIG. 6.2x
Top-mounted handwheel can be used to manually operate a spring-opposed pneumatic actuator, but only in one direction.

Side-mounted handwheels have engagement clutches to allow the handwheel to fully stroke the valve open and closed, Figure 6.2z. In the continuously connected handwheel design, the handwheel is provided with a "neutral" position. When placed in that position, the handwheel does not interfere with automatic operation of the valve.

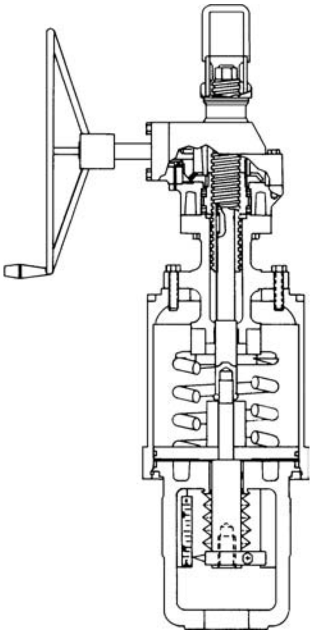

FIG. 6.2y
Top-mounted, continuously operated bidirectional handwheel. (Courtesy of Valtek, Flowserve Corp.)

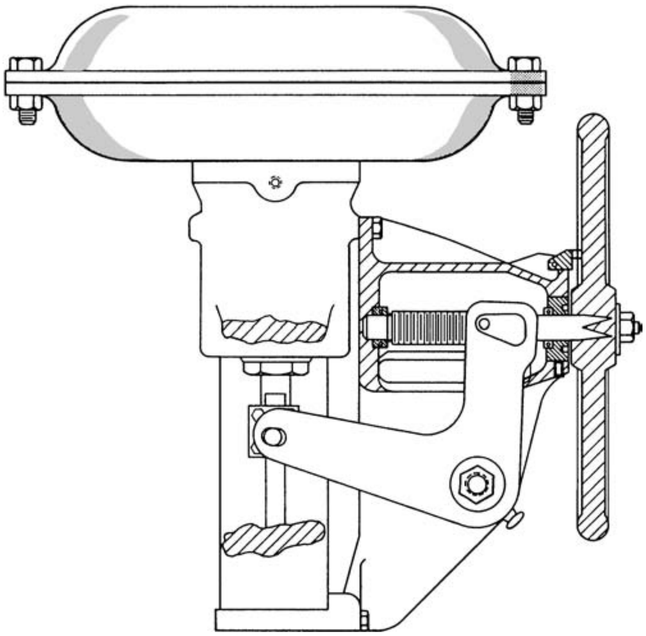

FIG. 6.2z
The side-mounted handwheel, if engaged, can fully stroke a spring-opposed pneumatic actuator in both directions.

Turning the handwheel one way forces the stem to extend, and turning it the other way forces the stem to retract. Adjusting the handwheel screw away from the "normal" position introduces a "limit stop" on the valve travel in one direction or the other, but not both. Consider that some handwheels may interfere with interlock shutdown operation of the valve.

For the manual operation of rotary valves, either hand levers 15–22 in. (38–56 cm) in length or clutch-equipped gearbox-type handwheels are used.

If manual throttling control is intended, the plant design must consider how the human operator will know how to set the valve and if the process can be safely controlled manually. This is not always the case, and handwheels have limited application in modern continuous process plants.

LIMIT STOPS

It is possible to install fixed limit stops to limit valve stem motion to either ensure a minimum opening or limit a maximum opening (Figure 6.2aa). These are usually purchased with the valve. Consider how to document the purpose and settings for these for maintenance purposes.

BYPASS VALVE

Perhaps not thought of as an accessory, the manual bypass for steam shut-off valves are critical to start-ups. The manual valves are "cracked open" to pressurize and heat up the steam

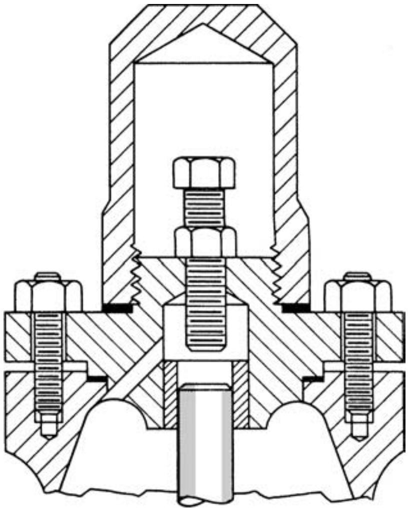

FIG. 6.2aa

Externally adjustable limit stop, shown in a valve body subassembly.

header. Opening the large valve could result in serious damage downstream as slugs of water are propelled into equipment. Other applications may have similar issues.

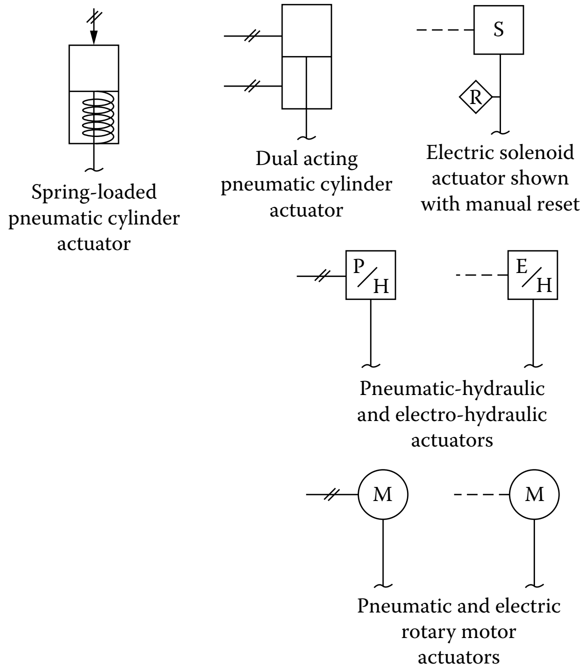
P. M. B. SILVA GIRÃO (2005)



Flow sheet symbols

Types:	1. Digital 2. Electromechanical (linear and rotary) 2a. Stepping motors in smaller sizes 2b. Reversible motor gears for larger sizes 3. Hydraulic and electrohydraulic (the pump can be driven by stepping or servomotors) 4. Solenoid
Energy Sources:	Electric, hydraulic or both
Speed Reduction Techniques:	Worm gear, spur gear, or gearless
Torque Ranges:	0.5–30 ft · lb$_f$ (0.7–41 N · m) for type 2a, and 1–250,000 ft · lb$_f$ (1.4–338,954 N · m) for type 2b actuators with gearboxes
Linear Thrust Ranges:	The maximum of about 500 lb$_f$ (2224 N) output force can be obtained from type 2a actuators; 100–10,000 lb$_f$ (445–44,500 N) can be obtained from type 2b ones. The thrust capability of type 3 actuators can exceed 100,000 lb$_f$ (445,000 N).
Speeds of Full Stroke:	Small solenoids can close in 8–12 msec. Throttling solenoids can stroke in about 1 sec. Electromechanical motor-driven valves stroke in 5–300 sec. Electrohydraulic actuators generally move at 0.25 in./sec (6.35 mm/sec) but can be speeded up by the use of hydraulic accumulators.
Costs:	0.25 in. (6.35 mm) solenoid pilot in stainless steel costs about \$50; with a two-way design in explosionproof plastic construction it costs about \$250, and when built for high-temperature service it costs about \$300. An electromechanical, type 2a actuator for 0.5–1 in. (12.7–25.4 mm) small ball valve can be obtained in explosionproof construction with limit switches for on/off service for \$750; with positioner and feedback potentiometer such an actuator costs about \$1500.

A typical rotary actuator with 300 ft · lb_f (407 N· m) torque rating costs about $2500.

The cost of larger type 2b or type 3 actuators can exceed $10,000.

INTRODUCTION

This section covers a variety of valve actuators, except the pneumatic ones, which are discussed in Section 6.4. The various accessory items such as positioners, handwheels, limit switches, potentiometers, and the like are also discussed in Section 6.2. The discussion of digital actuators in this section is intended to complement Section 6.12 on intelligent valves and Section 6.18 covering digital control valves.

The discussion in this section begins with some selection and application guidelines, which is followed by the description of the five actuator categories: 1) digital, 2) electromechanical, 3) electrohydraulic, 4) motors and pumps, and 5) solenoids. The section ends with a brief discussion of the trends in valve actuation, including the features of microprocessor-based “smart” and intelligent actuators.

SELECTION AND APPLICATION

The following are some of the characteristics to consider in the application and selection of all types of actuators. Table 6.3a gives a summary of advantages, disadvantages, and applications for some of the designs.

Actuator Types

Valve actuator types discussed in this section belong to one of the following categories: (a) electric actuators, which use a motor to drive a combination of gears to generate the desired torque or thrust level. This category includes (i) rod linear actuators, whose output rod provides linear motion via a motor-driven ball or ACME screw assembly. In this design, the actuator’s load is attached to the end of a screw, or rod, and is often unsupported; (ii) rodless linear actuators, whose load is attached to a fully supported carriage. Rodless linear actuators provide linear motion via a motor-driven ball screw, ACME screw, or belt drive assembly; and (iii) electric rotary actuators that use a motor to drive components rotationally.

The next category (b) are the hydraulic and electrohydraulic valve actuators, which convert fluid pressure into motion. They include (i) linear actuators or hydraulic cylinders, which use a cylinder and hydraulic fluid to produce linear motion and force, and (ii) hydraulic rotary actuators that use pressurized hydraulic oil to rotate mechanical components.

The third category (c) are the linear solenoids that convert electrical energy into mechanical work via a plunger with an axial stroke in either a push or pull action. They can be rated for continuous duty (100% duty cycle operation, continuous duty solenoids) or for off-on applications, less than 100% duty cycle (intermittent duty solenoids).

The last category (d) are digital actuators, which now include all types of valve actuation solutions where the valve is digitally controlled.

Pneumatic actuators are still the technology favored by valve actuators buyers. Nevertheless, the market share of electric, hydraulic, and electrohydraulic actuators is increasing, while the overall use of solenoid values has dropped.[1]

Actuator Features

Speed and Torque Ranges Speed requirements vary from less than 1 rpm to about 160 rpm. The upper limit of available torque is about 250,000 ft · lb_f (339,000 N · m) with gearboxes.

TABLE 6.3a
Applications, Advantages, and Disadvantages of Various Actuator Designs[2]

Actuator Types	*Advantages*	*Disadvantages*	*Applications*
Electromechanical	High thrust High stiffness coefficient Powered by electricity or pneumatics	Complex design No mechanical fail safe Large, heavy structure	Linear or rotary valves 2–36 in. body size
Electrohydraulic	High thrust High stiffness Fast speeds Powered by electricity; no pneumatic source required	Complex design Large, heavy structure Hydraulic temperature sensitive	Linear or rotary valves 2 in. to unlimited
Electric (servomotor or stepping motor)	Direct interface with computer system	Large structure Low thrust No mechanical fail safe Slow speed	Linear valves $^1/_2$–2 in. body size

Stem thrusts and rotational drive torques are limited only by the size of the motor used and the ability of the gear, bearings, shafts, and so on to carry the load. Speed of operation depends on the gear ratios, adequate prime move power, and means of overcoming the inertia of the moving system for rapid stopping. This is most important for proportional control uses. Some actuators have a limited selection of drive speeds, while others are furnished in gear ratios in discrete steps of 8–20% between speeds.

Manual Operation Manual operation is sometimes necessary for normal operational procedures, such as start-up, or under emergency conditions. Only units that are rotating very slowly or those with low output should have continuously connected handwheels. Most units have the handwheel on the actuator with a clutch for demobilizing the handwheel during powered operation. Clutches are manual engage and manual disengage, or manual engage and automatic disengage upon release of the handwheel. Others are manual engage when the handwheel is rotated, with the motor re-engaging when the handwheel is not being rotated; or power re-engage, which takes the drive away from the operator upon energization, leaving the handwheel freewheeling.

Electrical Equipment Most of these actuators include much of the electric gear within the housings of the unit. Components such as limit, auxiliary, and torque switches and position or feedback potentiometers are run by gearing to stem rotation, so they must be housed on the unit. Installation is optional concerning pushbuttons, reversing starters, lights, control circuit transformers, or line-disconnect devices in an integral housing on the unit. Any or all of these components may be located externally, such as in a transformer, switch, or control house. The enclosures must be designed to satisfy NEMA requirements for the area.

High Breakaway Force Resistance to opening requires a method of allowing the motor and gear system to develop speed to impart a “hammer blow,” which starts motion of the valve gate or plug. Selection of motors with high starting torque is not always sufficient. The dogs of a dog-clutch rotate before picking up the load, or a pin on the drive may move within a slot before picking up the load at the end of the slot. Systems are used that delay contact for a preselected time or until the tachometer indicates the desired speed of rotation.

Torque Control for Shutdown Torque control for shutdown at closure or due to an obstruction in the valve body is accomplished in numerous ways, but each one uses a reaction spring to set the torque. When rotation of the drive sleeve is impeded, the spring will collapse, moving sufficiently to operate a shut-off switch.

Position Indication An indicator can be geared to the stem rotating gear, but it becomes a problem when actuator rotation varies from 90 to as much as 240 revolutions. Gearing of a cam shaft operating the position indicator or auxiliary switches must be calculated to obtain a fairly uniform angle. Upon correct gearing, an indicating arrow or transmitting potentiometer can be rotated.

Maintenance of Last Position This is no problem when the actuator includes a worm gear or stem thread. Use of spur gears can cause instability when positioning a butterfly or ball valve. Status quo is obtained by use of a motor brake or insertion of a worm gear into the system.

Protection against Stem Expansion The status quo ability of a thread or worm gear is detrimental when the valve itself is subjected to temperatures high enough to expand the stem. This expansion, when restrained, can damage the seat or plug, bend the stem, or damage the actuator thrust bearings. One of the original patents for this type of actuator included Belleville springs to allow the drive sleeve to move with the thermal expansion and relieve the linear force.

Mounting Methods Industry has dictated a set of dimensions for the mounting flanges and bolt holes for newly manufactured valves. Retrofit mounting requires adaptation to existing valves. Mounting requires a plate to match the existing valve, which is screwed into the yoke upon removal of the manual drive sleeve, welded or brazed to the yoke, or, for a split yoke, bolted to the yoke.

Adaptability to Control This feature includes adaptability to many voltages and to single- or polyphase supplies. Polyphase motors of 240–480 V and 60 Hz predominate. Single-phase motors up to about 2 horsepower (hp) (1,492 W) are used. Reversing starters with mechanical interlocks are used for both proportional and on-off service.

The coils that open and close the contacts are energized by an open-center double-pole switch, which can be incorporated in the automatic control circuit. For manual control, the starter may be of the type that maintains contact, requiring the open or close button to be held in position. Some units are also wired for momentary depression so that the actuator runs until it reaches the limit switch, or until a stop button is depressed.

Proportional Control Proportional control of these large units can be accomplished by including the coils of the reversing starter in a proportional control circuit. This requires a position feedback, which may be a potentiometer. For this type of control, a Wheatstone bridge circuit would be used.

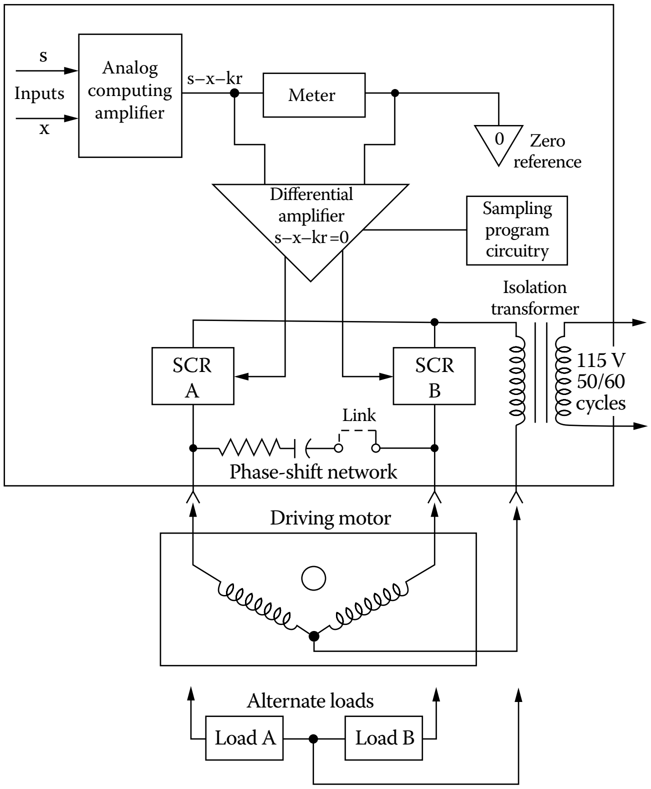
The reversing starter controls any voltage or phase required by the motor. A transducer to transform any of the accepted electronic controller outputs (e.g., 1–5 mA) to a resistance relative to controller output permits use of the actuator in these systems.

A smaller unit, with a force output of 1460 lb_f (6494 N) at stall and 500 lb_f (2224 N) at a rate 0.23 in./sec (5.84 mm/s), uses solid-state control of the motor. At the same time it eliminates stem position feedback into the controller.

A DC signal "*x*" (Figure 6.3b) from a process transmitter provides the loop with its measurement, such as temperature, as well as such high-responds systems as flow. A differential amplifier responds to the magnitude and the polarity of an internally modified error signal, which triggers silicon-controlled rectifiers (SCRs) to obtain bidirectional drive. The synchronous motor can be driven in either direction, depending upon the relation to the set point.

DIGITAL VALVE ACTUATORS

Digital actuators can accept the output of digital computers directly without digital-to-analog converters. Only simple on-off elements are needed for their operation. The number of output positions that can be achieved is equal to 2^n, where n is the number of inputs. Accuracy of any position is a function of the manufacturing tolerances. Resolution is established by the number of inputs and by the operating code selected for a given requirement. The smallest move achievable is called a 1-bit move.



s = instantaneous set point
x = instantaneous transmitter signal
k = adjustable transmitter compensation
r = instantaneous rate of change of transmitter signal

FIG. 6.3b
Proportional motor control circuit with position feedback.

The code may be binary, complementary binary, pulse, or special purpose. A three-input piston adder assembly produces eight discrete bit positions. The adders in Figure 6.3c are shown in the 6-bit extended position. The interlocking pistons and sleeves will move when vented or filled through their selector valves. This same adder can be used to position a four-way spool valve, with a mechanical bias to sense position. The spool valve controls the position of a large-diameter piston actuator or force amplifier.

Use of a DC motor featuring a disc-armature with low moment of inertia has created another valve actuator particularly adaptable to a digital input. Brushes contacting the flat armature conduct current to the armature segments. Incremental movement is caused by half-waves at line frequency for rotation in either direction. The rotation of the armature is converted to linear stem motion by use of a hollow shaft internally threaded to match the valve stem.

Actuator output is 5,000 lb_f (22,240 N) maximum for noncontinuous service at a rate of 0.4 in./sec (10 mm/s) through a valve stroke of 3 in. (76.4 mm). The actuator is de-energized at stroke limits or at power overloads by thermal overload relays.

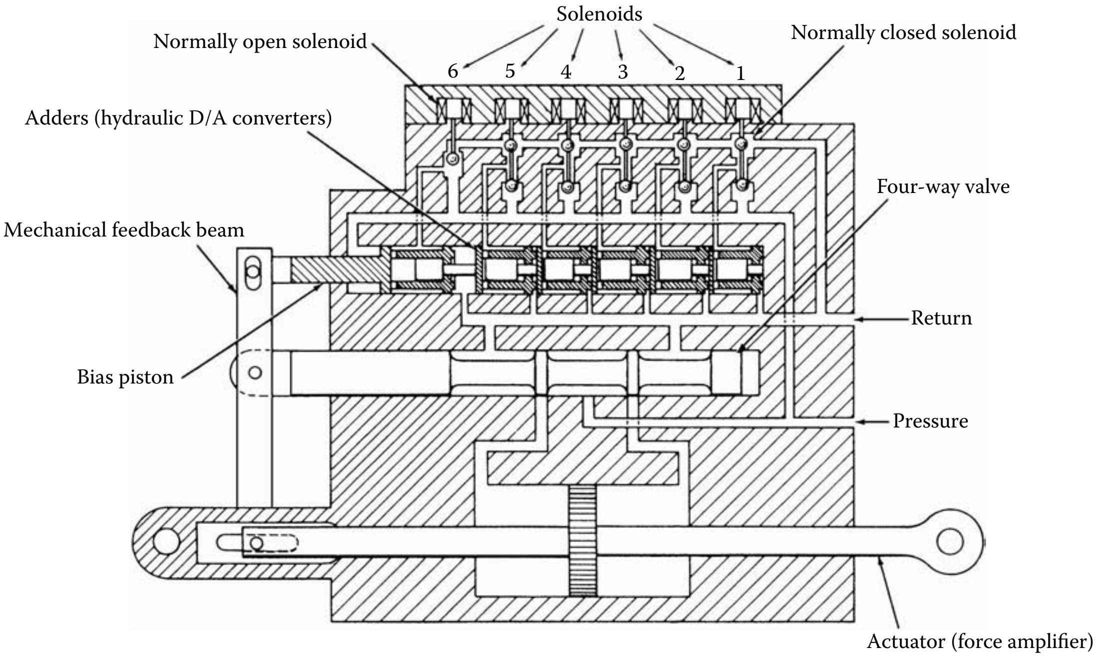


FIG. 6.3c
Digital valve actuator.

Operation of the actuator requires application of a thyristor (SCR) unit designed for this purpose. This unit accepts pulses from a computer or pulse generator. The thyristor unit consists of two SCRs with transformer, triggers with pulse shift circuit, facility for manual actuator operation, and the previously mentioned thermal overload relays. The output consists of half-waves to pulse the armature of the actuator.

Modules are also available for process control with the necessary stem position feedback, slow pulsing for accurate manual positioning, and full-speed emergency operation.

The digital-to-pneumatic transducer shown in Figure 6.3d is used to convert a controller output to a pressure signal for operating a pneumatic valve.

The concept of digital valve actuator has been extended to other valve actuating systems such as stepping motors, which are discussed in the following paragraph dedicated to electromechanical actuators, and to the so-called smart or intelligent actuators briefly introduced below in Smart and Intelligent Actuators. The discussion of digital actuators in this section is intended to complement Section 6.12 on intelligent valves and Section 6.18 covering digital control valves.

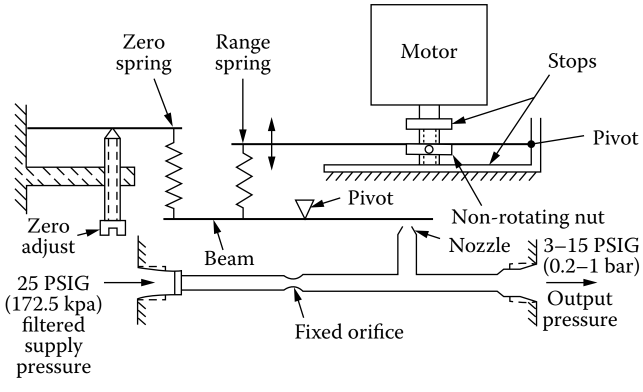

FIG. 6.3d
Digital-to-pneumatic transducer.

It is in this context that some of the suppliers in the partial list of suppliers at the beginning of this section identified as providing digital valve actuators indeed provide modern smart valve actuating solutions.

ELECTROMECHANICAL ACTUATORS

Electric actuators can utilize a reversible electric motor provided with an internal worm gear to prevent drive direction reversal (back-drives) by unbalanced loads. These units can operate both linear and rotary valves. Servomotor drives can position valves in response to feedback signals from linear or rotary encoders. Two-phase AC servomotors are available with up to 1 HP rating, while direct current servomotors can meet higher loads.

Stepping motors, which rotate the shaft by a discrete step angle when energized electrically, can also be used in valve actuators. The electromechanical device that rotates the shaft can be a solenoid used to operate a star-wheel or ratchet device; it can be the stepping movement of a permanent magnet, the flux of which causes poles or teeth to align and thereby affect rotation; or it can be a variable reluctance unit, where the rotor-stator poles or teeth are aligned by electric fields.

When used as valve actuators, the stepping motors are well suited for direct digital control, and pulse feedback can be provided for accurate closed-loop positioning.

Of the above designs the actuators using reversible motors are the most often used variety and therefore they will be discussed in more detail in the following paragraphs.

Reversible Motor Gear Actuators

Lever-operated valves and dampers are available with torques of 5–500 ft · lb_f (6.8–678 N · m) and with full stroke speeds of 10–60 seconds. For very large valves or dampers, this type of actuator can deliver torques of 150–10,000 ft·lb_f (203–13,558 N · m) and a full stroke speed of 30–300 seconds.

The power consumption of these larger units ranges from 0.5–5 kVA operating on 460 V three-phase power supply. Some of these designs can be obtained with springs to return the valve to a safe condition upon electric failure.

The motor gear actuator consists of an electric motor connected to a gear train; the gear train rotates a stationary drive nut, which in turn drives the threaded or keyed valve stem up or down. As the valve plug contacts the seat, the resistance is transmitted to a Belleville spring, which at a preset limit interrupts the motor power circuit.

For throttling applications, the actuator can be provided with a positioner that compares the external control signal (analog or digital) with an internal position feedback signal and keeps turning the motor until the error between the two signals is eliminated.

Rotary Output Actuators

Worm Gear Reduction The actuator shown in Figure 6.3e is an example of the use of a double worm gear reduction to obtain output speeds of around 1 rpm with an input motor speed of 1800 rpm. The worm gear is self-locking, so it prevents the load from moving downward by back-driving the motor. However, the worm gear is less than 50% efficient, so more power is used compared to spur gears. Also shown is a handwheel for manual operation during power loss.

Spur Gear Reduction The spur gear actuator in Figure 6.3f has very low power loss through the relatively efficient spur gears. Ordinarily the load could back-drive this system, but a friction member at the motor end of the gear train minimizes this undesirable action. Of course, if the load has a frictional characteristic, it will not impose a back-driving torque on the actuator.

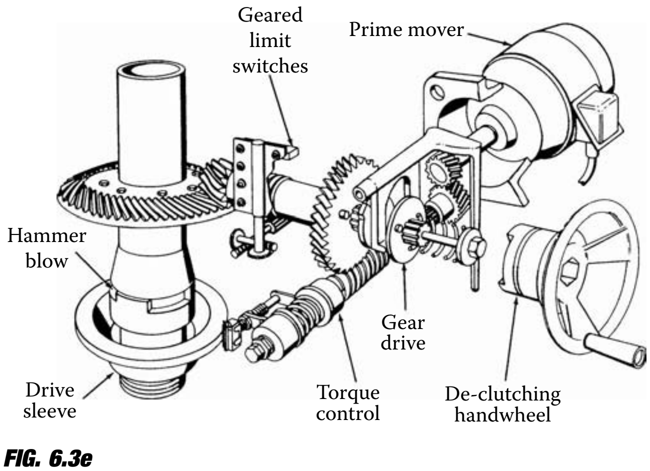

FIG. 6.3e
Electric actuator with worm gear reduction.

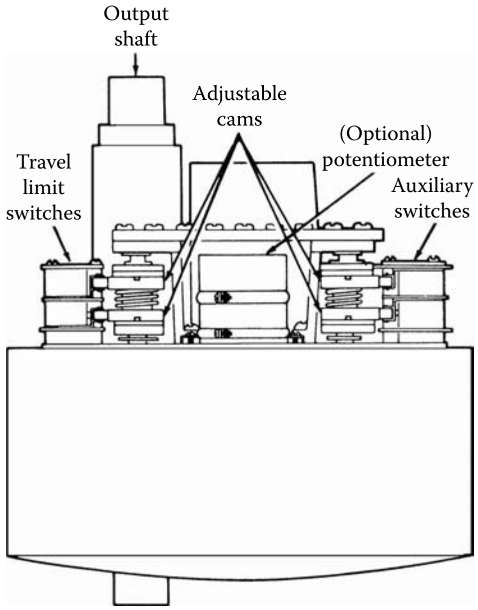

FIG. 6.3f
Spur gear reduction.

Actuators for larger outputs are externally mounted motors. Two motors operating a single gear train have been used to obtain 3,750 ft · lb_f (5084 N · m) of torque through 90° rotation in 75 sec. An actuator has been designed for accurate rotary positioning that develops 5000 ft·lb_f (6800 N · m) at stall and will rotate 90° in 10 sec. SCRs energize the motor as commanded by a servotrigger assembly housed separately.

Electrical gear may include adjustable cams to operate limit and auxiliary switches. A potentiometric feedback calibrated to the rotation of the actuator is required for use with a control circuit. The unit shown in Figure 6.3f was developed to slide over and be keyed to the shaft of a boiler damper. Actuators of this type must be adaptable to mounting on and operating a variety of quarter-turn valves. Because of the difficulty in setting limit switches to accurately stop the valve in the shut position, it is advisable to incorporate a torque-limiting device to sense closure against a stop.

Opening can be controlled by a limit switch. One compact unit contains the features noted with an output of 750 ft · lb_f (1017 N · m) of torque. The unit is powered by a motor with a high-torque capacitor and includes a mechanical brake, feedback potentiometer, limit switches, and a de-clutchable hand wheel.

Flex-Spline Reduction Figure 6.3g is an example of a unique single-stage, high-reduction system. Instant breakaway and efficient transfer of prime mover power is obtained

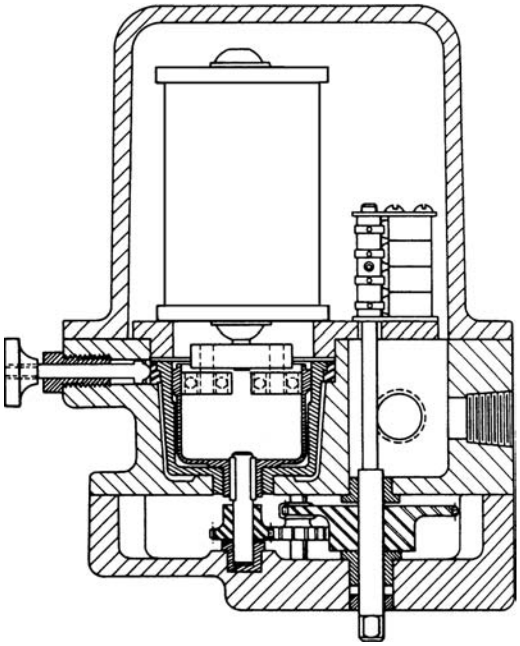

FIG. 6.3g
Flex-spline gear reduction.

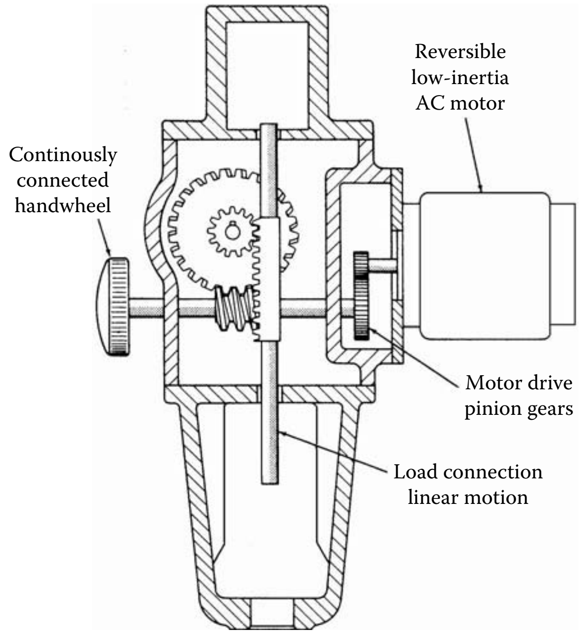

FIG. 6.3h
Rack and pinion assembly converts the rotation of a horizontal, motor-driven shaft into vertical, linear motion.

with a modified concentric planetary system consisting of a semiflexible gear within a rigid gear. A three-lobed bearing assembly transmits power to the gears by creating a deflection wave transmission that causes a three-point mesh of the gearing teeth on 30% or more of the external gearing surface.

The semiflexible geared spline has fewer teeth than the nonrotating internal gear it meshes with. The spline slowly rotates as it is pressed into the larger gear by the bearings on the motor shaft.

Linear Output Actuators

Motors and Rack Figure 6.3h uses a worm and a rack and pinion to translate horizontal shaft motor output to vertical linear motion. Maximum force output is approximately 1500 lb_f (6672 N) at about 0.1 in./min (2.5 mm/min). A continuously connected handwheel, which must rotate the rotor of the motor, can be used when there is short stem travel and relatively low force output.

The actuator is designed with a conventional globe valve bonnet for ease of mounting. Units operate on 110 V and have been adapted to proportional use with a 135 ohm Wheatstone bridge or any of the standard electronic controller outputs.

Motor and Travelling Nut Linear unit consists of the motor, gears, and a lead screw that moves the drive shaft (Figure 6.3i). A secondary gear system rotates cams to operate limit and auxiliary switches.

The unit may have a brake motor for accurate positioning and a manual handwheel. The bracket on the rear end allows the actuator to rotate on the pin of a saddle mount, so that the drive shaft can be pinned directly to the lever arm of a valve or a lever arm fixture that fits the shaft configuration of a plug cock or ball valve. Maximum output is 1600 lb_f (7117 N) at 5 in./min (127 mm/min).

Rotating Armature An internally threaded drive sleeve in the armature of the motor is used to obtain a linear thrust up to 6,600 lb_f (29,360 N) at a rate of 10 in./min (254 mm/min). Bearings in the end cap support the drive assembly (Figure 6.3j). The drive stem is threaded to match the drive sleeve and is kept from rotating by a guide key.

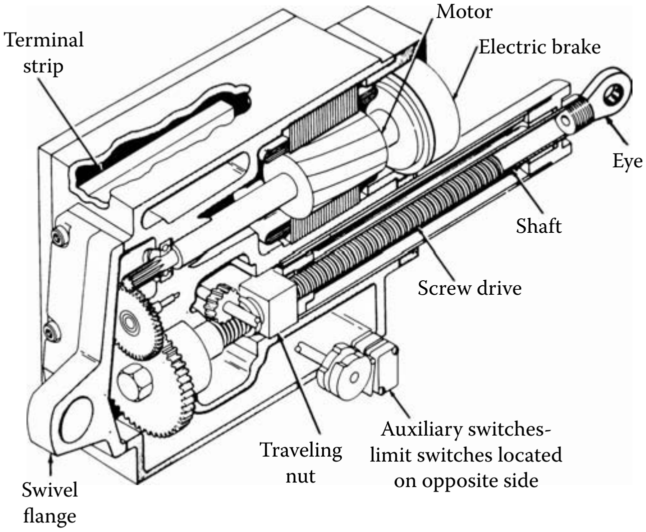

FIG. 6.3i
Electric quarter-turn actuator with linear output and with limit switches.

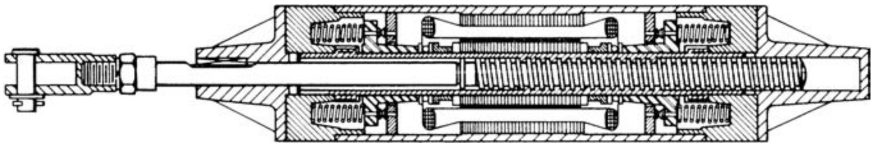

FIG. 6.3j
Electric actuator with rotating armature has been adapted for proportional control.

Thrust-limit switch assemblies are mounted in each end of the housing to locate the hollow shaft in mid-position. When the linear movement of the drive stem is restricted in either direction, the limit switch involved will operate to shut down the unit. Thermal cut-outs in the motor windings offer additional overload protection. Strokes are available from 2–48 in. (51–1219 mm).

The unit has been adapted for proportional control by use of an external sensing position for feedback. For use as a valve actuator, it must be mounted so that the drive stem can be attached to the valve stem, or a suitably threaded valve stem must be supplied.

Rotary to Linear Motion An electric proportional actuator (Figure 6.3k) is designed for continuous rotation of a drive-sleeve on a ball-screw thread. 3,000 lb_f of thrust (13,335 N) is obtained at a stem speed of 1 in./min (25 mm/min).

One or two DC signals are used separately or numerically added or subtracted. Triacs operate on position error to control a DC permanent magnet motor that positions a stem within an adjustable dead band. Degree of error and rate of return are sensed by a lead network to determine the direction and time that the motor must run.

Stem reversals are almost instantaneous. The back emf of the motor is used as a velocity sensor and is fed into a circuit that allows adjustment of the speed of drive sleeve rotation. Gain can be adjusted to control oscillation of the stem.

Stem position feedback is by a linear variable differential transformer (LVDT). Use of the DC motor allows for torque control through sensing of motor current. A manual handwheel is furnished that can only be used when the unit is de-energized by a manual/automatic switch.

Application of the linear requirement of a valve necessitates a linkage for translation from rotary to linear motion. Use of a linkage (Figure 6.3l) provides a thrust for operating the valve.

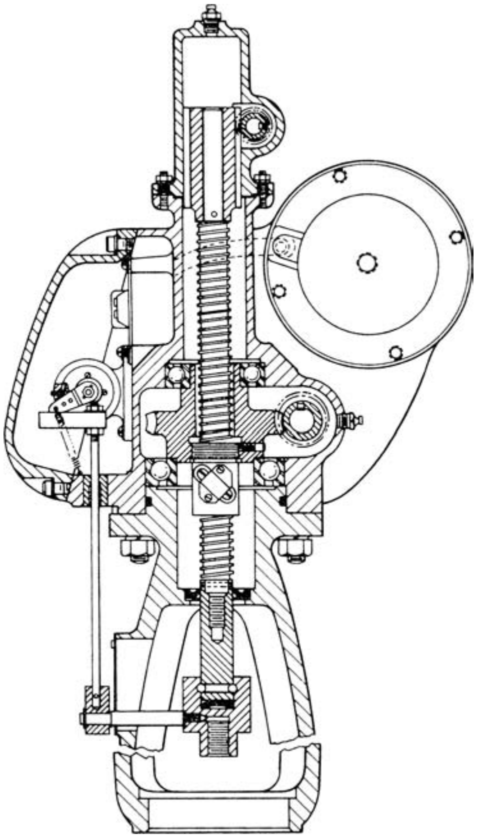

FIG. 6.3k
Proportional electrical drive converts rotary to linear motion.

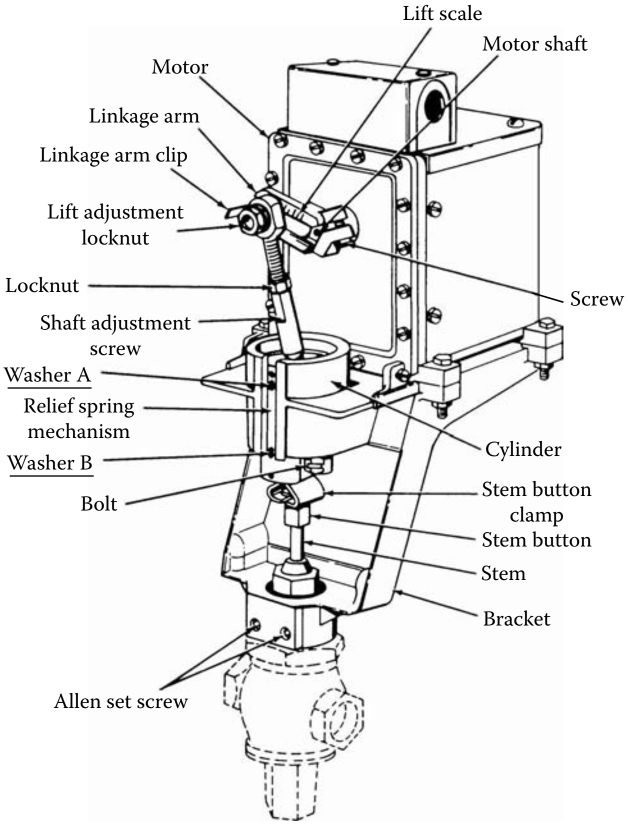

FIG. 6.3l
Electric actuator with linkage to convert rotary motion to linear.

ELECTROHYDRAULIC ACTUATORS

The main features of electrohydraulic actuators have been summarized in Table 6.3a. They are often used where instrument air is unavailable or where the required actuator stiffness or thrust cannot be obtained from pneumatic actuators. They are heavier than pneumatic actuators; therefore, in order to avoid straining the bonnet, vertical upright installations are recommended.

Electrohydraulic actuators are superior to electromechanical ones in the areas of speed, positioning without overshoot, actuator stiffness, and complexity. Electrohydraulic actuators can be stepping motor or servovalve driven. In the servovalve designs the pumps are running continuously, while in the stepping-motor configuration they run only when the valve needs repositioning.

Electrohydraulic actuators can be mounted directly onto the stems of valves that are 6 in. (152 mm) or smaller and can be provided with springs to guarantee a fail-safe position in case the hydraulic fluid is lost. The actuator usually consists of a hydraulic cylinder, a pump with motor, some feedback linkage on valve position, and a balancing arrangement. The balancing or positioning mechanism compares the external control signal with the valve position and actuates the hydraulic system if repositioning is required.

In spring-loaded designs the hydraulic fluid might drive the valve in one direction (opening it, for example), while the spring drives it in the other direction (closing it, for example). Open, closed, or last-position failure positions are available. When higher thrusts, longer strokes, or rotary valves are involved, the fail-safe position can be provided by storing energy in a hydraulic accumulator instead of using a spring.

Hydraulic actuators are sensitive to viscosity changes caused by ambient temperature variations and, therefore, in subfreezing temperatures must be provided with heaters, which can require substantial heat-up periods before the valve can be operated. Because the hydraulic fluid is incompressible, the actuator is "stiff" and provides stable and accurate positioning with hysteresis and dead band within 5% of span.

Their speed of operation is similar to pneumatic actuators—0.125–0.25 in. (3.2–6.4 mm) per second of stem movement—but can be speeded up substantially by the use of high-pressure accumulators. Intelligent, programmable electrohydraulic actuators can be provided with bidirectional hydraulic gear pumps, which are driven by microprocessor-controlled stepping motors.

External Hydraulic Source

The term "electrohydraulic" has been applied to actuator systems in which the hydraulic pressure to one or more actuators is supplied by a hydraulic mule. The hydraulic power is supplied to the actuator by electrical control means.

In the broad sense, the use of two three-way solenoids or one four-way solenoid externally mounted to the actuator constitutes an electrohydraulic system.

More extensively, "electrohydraulic" applies to a proportionally positioned cylinder actuator. This requires a servo-system, which is a closed loop within itself. A servo-system requires one of the standard command signals, which is usually electrical but can be pneumatic. This small signal, which often requires amplification, controls a torque motor or voice coil to position a flapper or other form of variable nozzle. This positions a spool valve or comparable device to control the hydraulic positioning of a high-pressure second-stage valve.

The second-stage valve directs operating pressure to the cylinder for very accurate positioning. Closing the loop requires mechanical (Figure 6.3m) or electrical feedback to compare the piston position with the controller output signal.

The electrical feedback can be a servoamplifier, illustrated in connection with a linear hydraulic actuator shown in Figure 6.3n.

Hermetically Sealed Power Pack

A much more compact electrohydraulic actuator combines the electrohydraulic power pack with the cylinder in one package. Many of these actuators are designed as a truly integral unit. An electric motor pump supplies high-pressure oil through internal ports to move the piston connected to the stem (Figure 6.3o).

The small magnetic relief valve is held closed during the power stroke until de-energized by an external control or

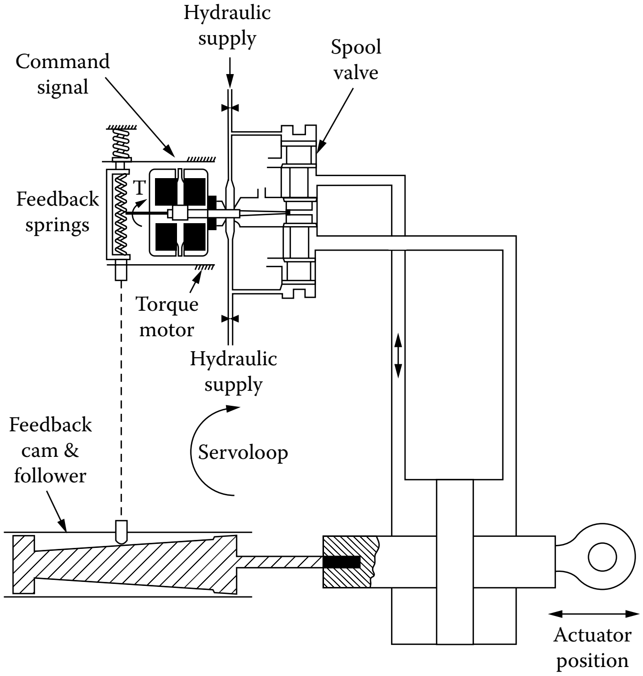

FIG. 6.3m
Two-stage servovalve with mechanical feedback.

emergency circuit to allow the spring to cause a "down" stroke. The same unit can be used to cause the spring to return to the up position using a Bourdon switch to produce force limit.

Motor and Pump Combinations

Reversible Motor and Pump A reversible motor can be used to drive a gear pump in a system to remove oil from one side of the piston and deliver it to the other side (Figure 6.3p).

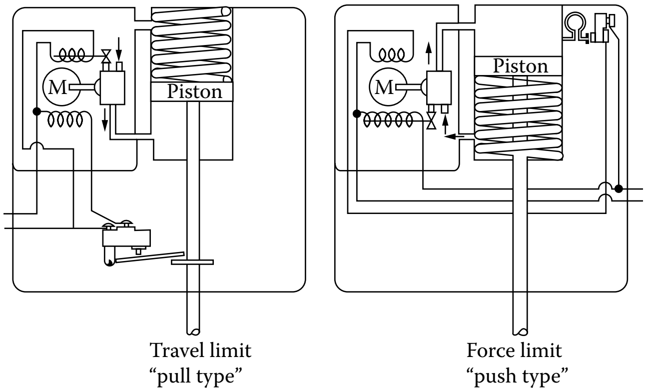

FIG. 6.3o
Hermetically sealed electrohydraulic power pack.

The check valves allow the pump to withdraw oil from the reservoir and position the directional control valve in order to pressurize the cylinder. Reversing the motor (and pump) reverses the direction.

When the motor is de-energized, the system is "locked up." For proportional control, feedback is necessary from stem position to obtain a balance with the control signal.

Jet Pipe System A very old control system for a cylinder, the jet pipe, is employed in an electrohydraulic actuator. An electromechanical moving coil in the field of a permanent magnet is used to position a jet that can direct oil to one end or the other of the cylinder actuator (Figure 6.3q). Force-balance feedback from stem position creates the balance with the controller signal.

Hydraulic Control of Pinch Valves Controlled hydraulic positioning of a sleeve valve is obtained with a moving coil and magnet to position the pilot (Figure 6.3r), which controls pressure to the annular space of the valve. Feedback is in the form of a Bourdon tube, which senses the pressure supplied to the valve and moves the pilot valve to lock in that pressure.

Multiple Pump The multiple pump system consists of three pumps running on the shaft of one prime mover (Figure 6.3s). There is one pump for each side of the piston and one for

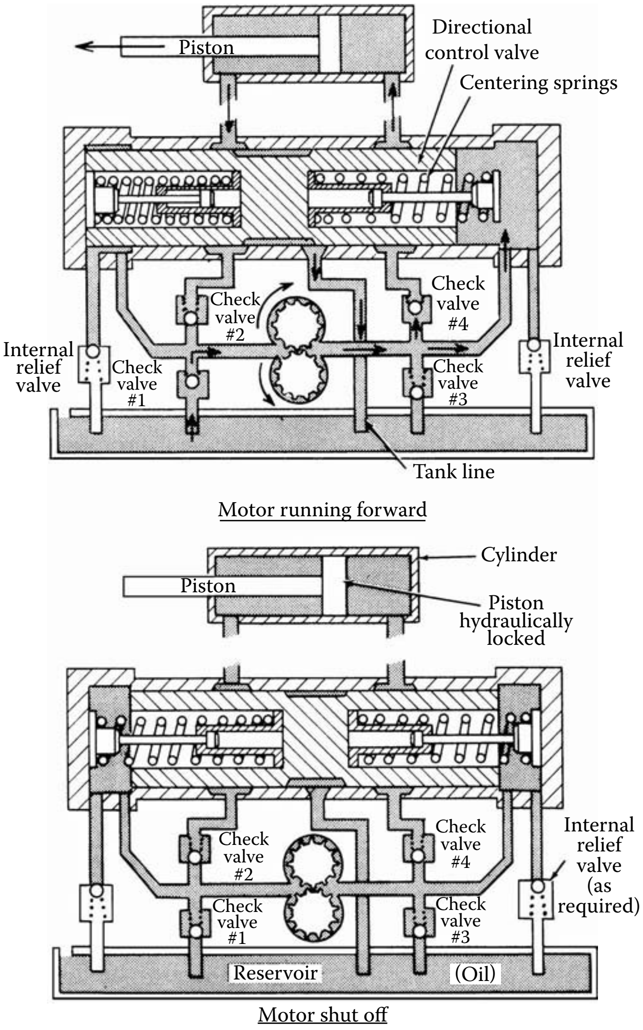

FIG. 6.3p
Pump with reversible motor combination, where the actuator is "locked" when the pump is de-energized.

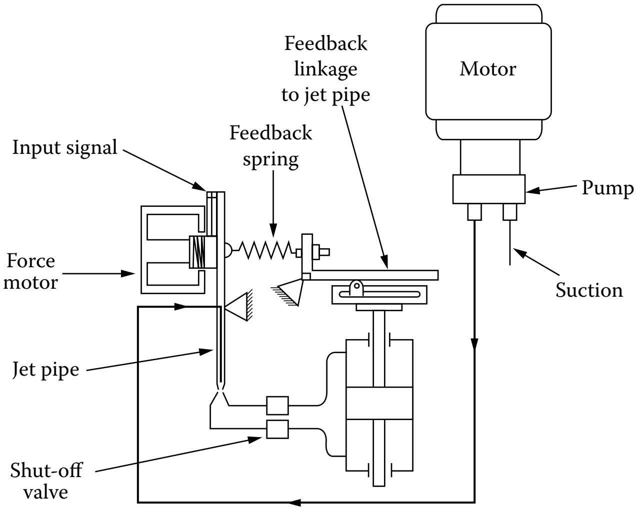

FIG. 6.3q

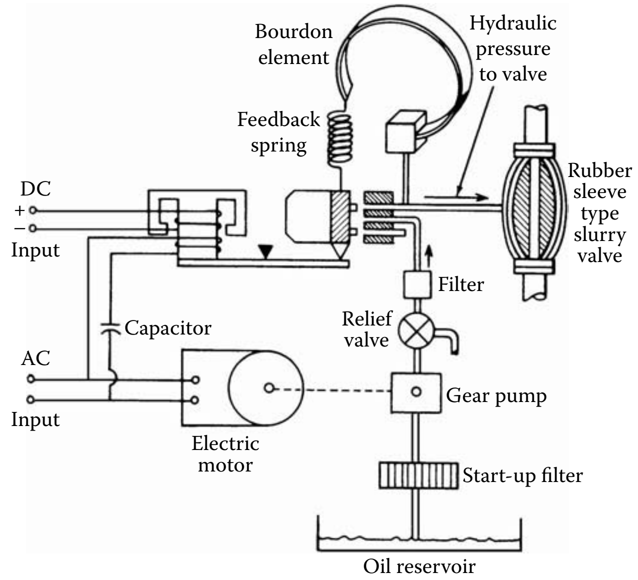

FIG. 6.3r
Electrohydraulic control of a jacketed pinch valve.

the control circuit. The force motor tilts a flapper to expose or cover one of two control nozzles. The flow through a restricting nozzle allows pressure to be transmitted to one side of the piston or the other.

Force-balance feedback is created by a ramp attached to the piston shaft, which positions a cam attached to the feedback spring. Upon loss of electric power, the cylinder shut-off valves close to lock up the pressure in the cylinder and assume a status quo. A bypass valve between the cylinder chambers allows pressure equalization to make use of the manual handwheel.

Vibrating Pump A vibratory pump is used in a power pack mounted on a cylinder actuator (Figure 6.3t). A 60 Hz alternating source causes a plunger to move toward the core, and, upon de-energizing, a spring returns it. The pump operates on this cycle and continues until the piston reaches the end of its stroke, when a pressure switch shuts it off.

The solenoid that retains the pressure is de-energized by an external control circuit. Maximum stem force is 2,500 lb_f (11,120 N) at a rate of about 1 in./min (25 mm/min), or 5,000 lb_f (22,240 N) at 0.3 in./min (7.6 mm/min).

Two-Cylinder Pump A two-cylinder pump, driven by a unidirectional motor, injects pressure into one end of a cylinder or the other, depending upon the positions of two solenoid relief valves (Figure 6.3u). The solenoid on the left is closed to move the piston to the right, with hydraulic pressure relieved through the other relief valve. Motion continues until the valve it is operating is seated.

The build-up of cylinder pressure operates the pressure switch at a predetermined setting to de-energize the motor and both solenoid relief valves. This locks the hydraulic

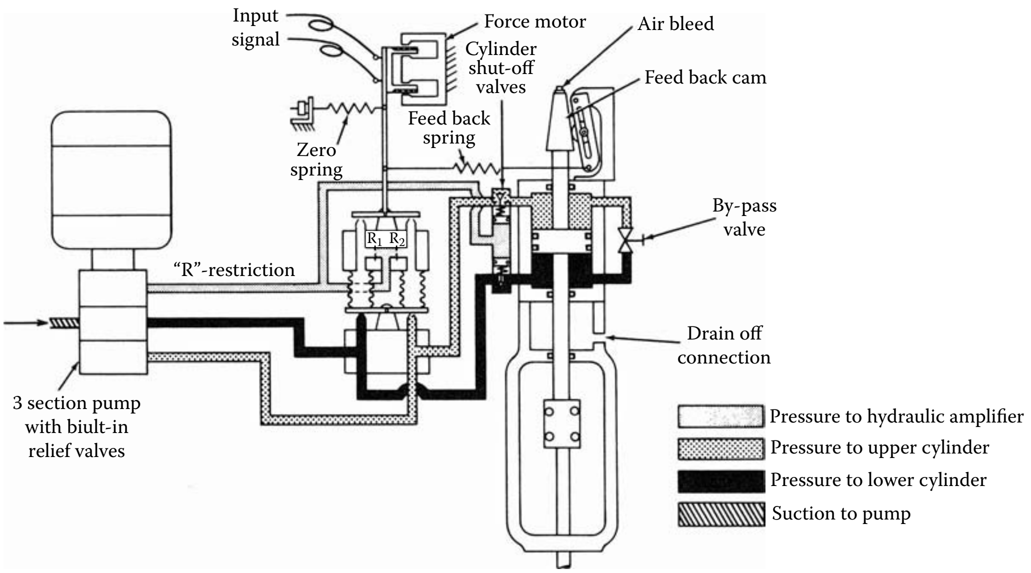

FIG. 6.3s
Hydroelectric valve actuator with three pumps running on the shaft of one mover.

pressure in the cylinder. Switching of the three-way switch will start the motor and reverse the sequence of the relief valves to move the piston to the left. At full travel (which is the up position of a valve stem), a limit switch shuts down the unit. Open-centering the three-way switch at any piston position will lock the piston (and valve stem) at that point.

Remote control is accomplished by manipulating the open-center switch. Automatic control is acknowledged by including this open-center function, which may be solid state, in the control circuit. A potentiometer or LVDT that senses the stem position is required for feedback.

Stem output is 6,000 lb_f (26,690 N) at a rate of 3 sec/in. (0.12 sec/mm). Stem travels up to 7 in. (178 mm) are available,

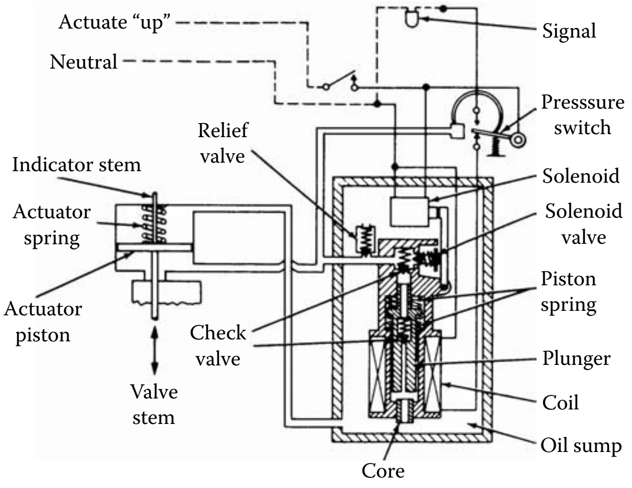

FIG. 6.3t
Electrohydraulic actuator with vibratory pump.

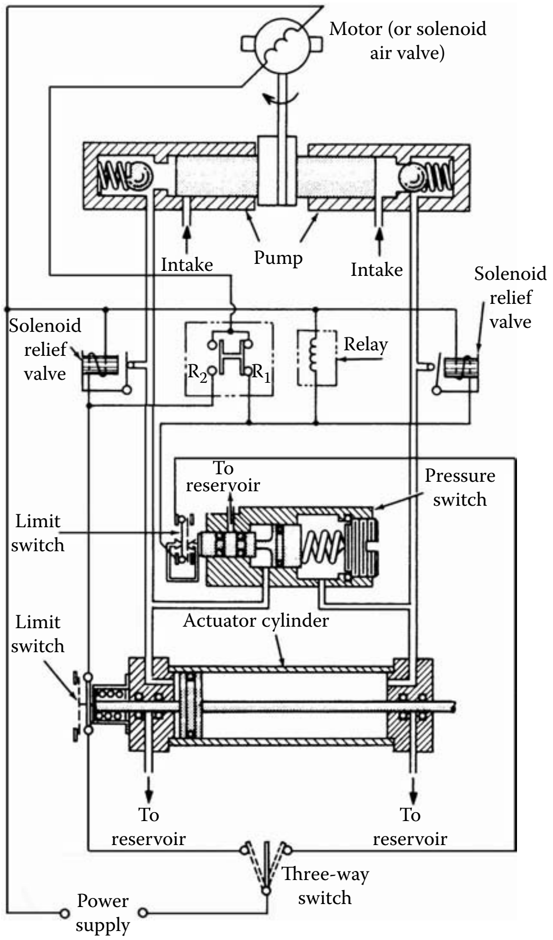

FIG. 6.3u
Two-cylinder pump-type electrohydraulic actuator.

although longer travels are feasible. The entire system is designed in a very compact explosionproof package that can be mounted on a variety of valve bonnets. The speed of response to energizing and de-energizing the control circuit makes it feasible to adapt the unit to digital impulses.

SOLENOID VALVES

Solenoids move in a straight line and therefore require a cam or other mechanical converter to operate rotary valves. These actuators are best suited for small, short-stroke on-off valves, requiring high speeds of response. Solenoid-actuated valves can open or close in 8–12 ms.

Their fast closure is not always an advantage: In water systems, it can cause water hammer. They are limited to pressure drops below 300 PSIG (20.7 bars), although when provided with pilots, levers, or double seats, they can handle higher pressure drops. They are available in two- or three-way designs, with power requirements ranging from 10–30 W with 6–440 VAC or 6–115 VDC power supplies. Solenoids are reliable devices, and they can provide multimillion cycles on liquid service.

Solenoids (consisting of a soft iron core that can move within the field set up by a surrounding coil) are used extensively for moving valve stems. Although the force output of solenoids may not have many electrical or mechanical limitations, their use as valve actuators has economic and core (or stem) travel limitations, and they are expensive.

A solenoid valve consists of the valve body, a magnetic core attached to the stem and disc, and a solenoid coil (Figure 6.3v). The magnetic core moves in a tube that is closed at the top and is sealed at the bottom; this design eliminates the need for packing. A small spring assists the release and initial closing of the valve. The valve is electrically energized to open.

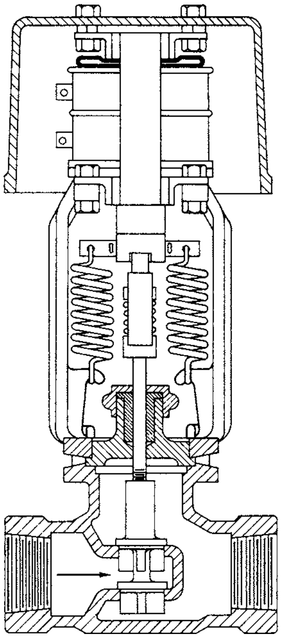

FIG. 6.3w
When valve packing is required, the increased friction can be overcome by a solenoid valve design with two or more strong return springs.

Stronger springs are used to overcome the friction of packing when it is required (Figure 6.3w). Reversing the valve plug results in reverse action (open when de-energized).

Even stronger stroking force can be obtained by using the force amplification effect of a mechanical lever, in combination with a strong solenoid (Figure 6.3x).

Using a solenoid to open a small pilot valve (Figure 6.3y) increases the port size and allowable pressure drop of solenoid-operated valves.

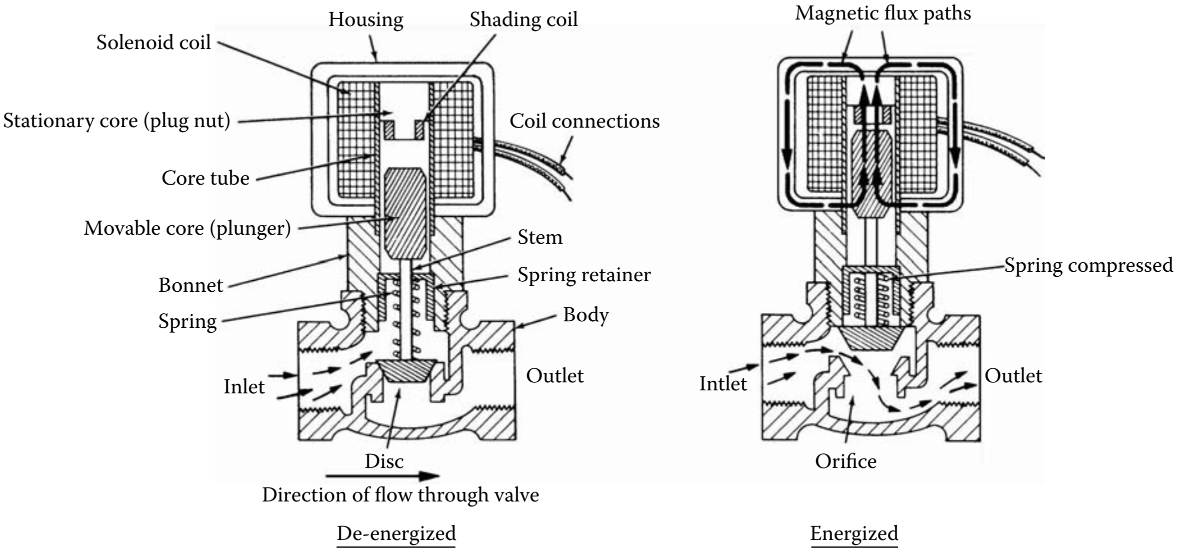

FIG. 6.3v
The operation of a direct-acting solenoid valve involves the lifting of the plunger when energized.

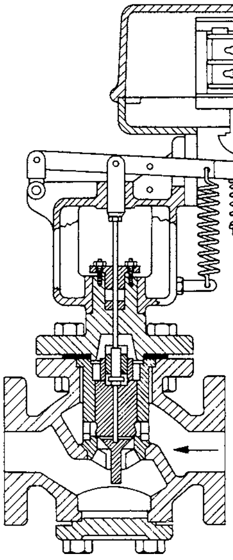

FIG. 6.3x
The force generated by the solenoid is amplified in the lever-type actuator.

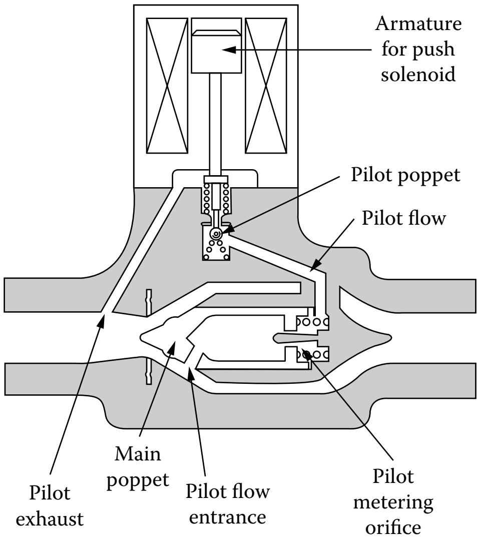

FIG. 6.3z
Pilot-operated in-line solenoid valve, where the pilot serves to apply pressure to the main poppet piston.

Small solenoid pilot valves are widely employed to supply pressure to diaphragms or pistons for a wide range of output forces. Pilot operation applies pressure to a diaphragm or piston or may release pressure, allowing the higher upstream pressure to open the valve. A good example is the in-line valve (Figure 6.3z).

Most solenoid valves are designed to be continually energized, particularly for emergency shutdown service. Thus the power output is limited to the current whose I^2R-developed heat can be readily dissipated.

Using a high source voltage and a latch-in plunge overcomes the need for continuous current. The single-pulse valve-closing solenoid is disconnected from the voltage source by a single-pulse delatch solenoid and hence does not heat up after it is closed. A pulse to the delatch solenoid permits the valve to be opened by a spring.

Three-way solenoid valves with three pipe connections and two ports are used to load or unload cylinders or diaphragm actuators (Figure 6.3aa). Four-way solenoid pilot

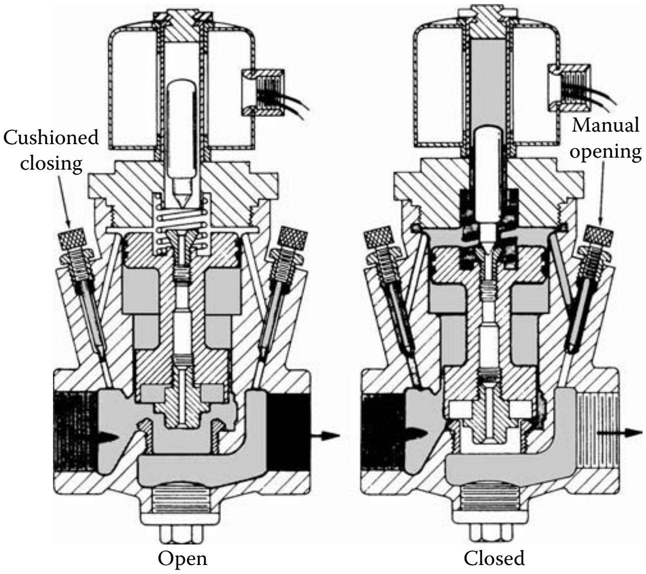

FIG. 6.3y

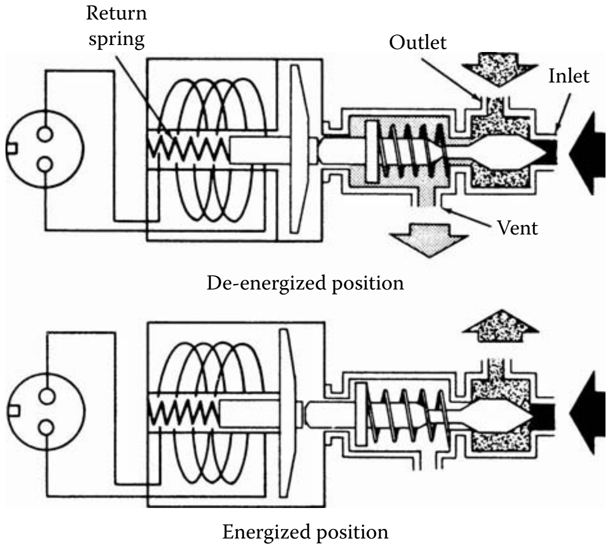

FIG. 6.3aa
The operation of a normally closed three-way solenoid valve.

valves are used principally for controlling double-acting cylinders.

Modulating Solenoid Valves

Modulating magnetic valves (Figure 6.3bb) utilize spring-loaded low-power solenoids to provide throttling action. The only moving part in this design is the valve stem, which has the valve plug attached to one end and an iron core attached to the other.

The valve opening is thereby a function of the voltage applied across the solenoid. (Figure 6.3cc illustrates the change in plunger force as a function of applied voltage and plunger air gap.)

Such throttling solenoids are frequently used in the HVAC industry and in other applications where the valve actuators do not need to be very powerful. The actuator thrust requirements are lowered by balancing the inner valve through the use of pressure equalization bellows or floating pistons. The positive failure position of these valves is provided by spring action.

Throttling solenoids are typically available in $^1/_2$–8 in. (127–203 mm) sizes and are limited by the pressure difference against which they can close. They are available in two- or three-way designs and can handle water flows up to 5000 gpm (19 m^3/m).

The use of throttling solenoids can completely eliminate the need for instrument air in the control loop. These valves

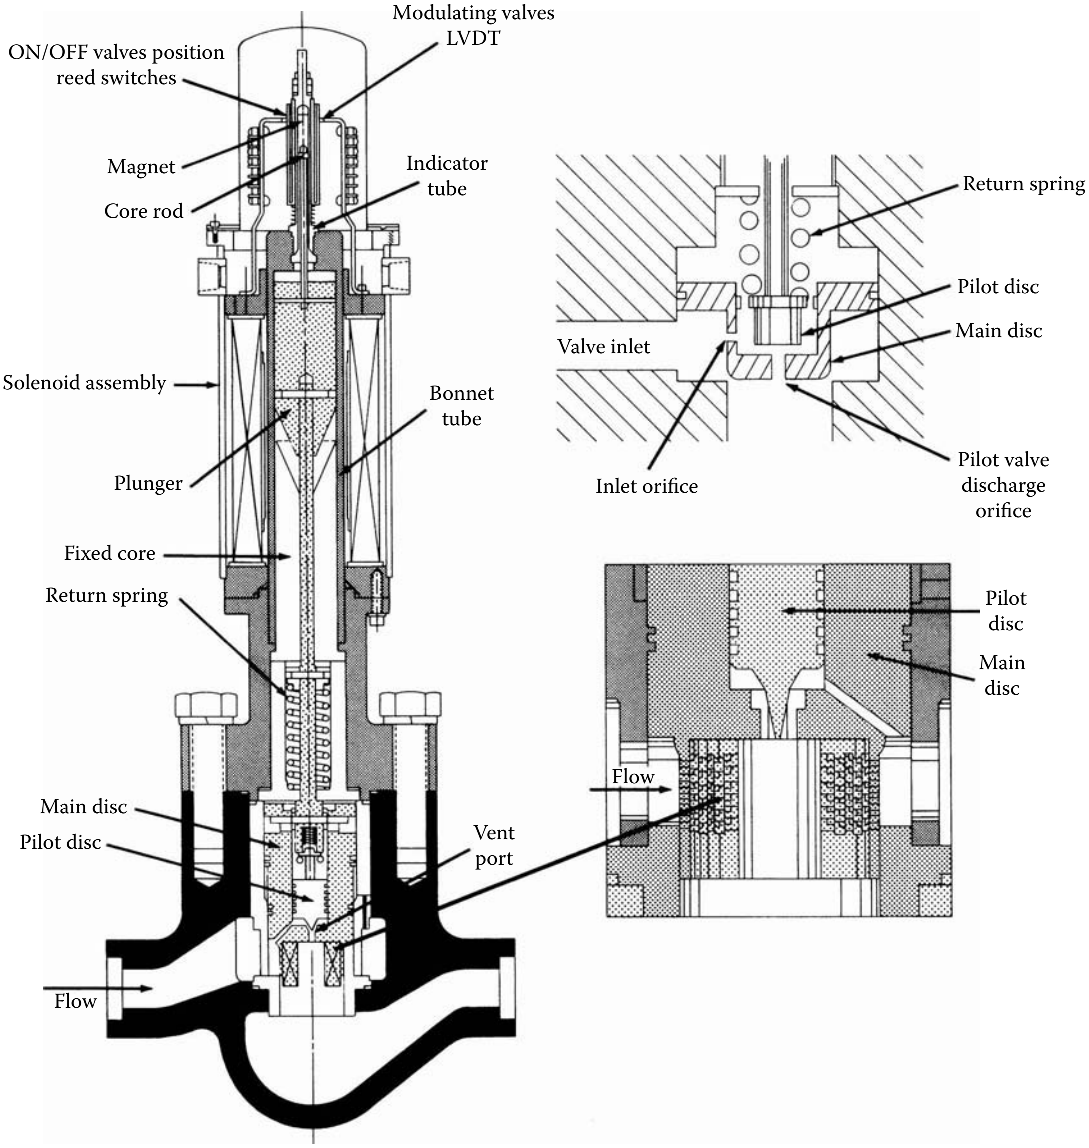

FIG. 6.3bb

offer a higher speed and better range than their pneumatic counterparts. Some manufacturers claim a range of 500:1 and a stroking time of 1 sec. The design illustrated in Figure 6.3bb can be driven directly from microprocessor-based building automation systems.

The design shown in Figure 6.3bb also includes a separate positioner, which accepts a 4–20 mA DC input from the controller and delivers a DC output signal to the throttling solenoid. Valve position feedback is obtained through the use of a linear variable differential transformer mounted directly on the valve.

SMART ACTUATORS

In addition to specifying the thrust, travel, failure position, control signal, power supply, speed, electrical area classification, and ambient conditions that an actuator must meet, one can also consider the use of microprocessor-based smart systems and of some other types of intelligent systems.

One of the trends in process automation is the use of distributed control and, in some cases, to locate the controller as close as possible to the final control elements (control valves). Often the control signal is digital (digital valve control, or DVC[3]). It is in this respect that an increasing number of features have been added to valves, valve actuators, and positioners through the integration of microprocessors with them.

Applications

Microprocessors have been included in valve actuators and valve positioners for some time (Figure 6.3dd), but the degree of exploitation of the possibilities of the smart and intelligent actuators for the purposes of process control is highly dependent on data access and thus on digital networking capabilities.

The tendency is to provide new actuators with some sort of network connection.[4] As discussed in more detail in Sections 4.16 and 6.11, Foundation fieldbus, HART, and Profibus are some of the leading suppliers. Open architectures, such as Foundation fieldbus, have made positive contributions, because by broadening the market they allowed more users to take advantage of better performing actuating systems at lower prices. Moreover, the compatibility problems between different fieldbus systems are in the process of being resolved, and it is hoped that through international standardization "plug and play" capabilities[3] will soon be available for such devices.

The intelligence provided by microprocessors can and is used for valve tuning, semiautomatic calibration, and data collection for maintenance and diagnostic purposes. It is also used for standalone control when that might improve the positioning, the protection, or the communication of the valve. Table 6.3ee lists some of the more common applications of smart and intelligent actuator systems.

TABLE 6.3ee
Applications for Integrated Intelligent Systems[5]

- Under-instrumented loops where additional information is required for optimization or improved control.
- Loops requiring very tight control with a fast update for the PID algorithm.
- Applications requiring a large turndown in flow measurement and control capabilities.
- Processes that need local supervisory and control capabilities to provide continuous operation or controlled shutdown upon loss of control signal.
- New or retrofit installations where there is insufficient space for conventional instrumentation systems.
- Critical systems requiring continuous monitoring and predictive diagnostics on the valve or process.
- Applications where changing conditions require the loop to be reconfigured to control diverse variables for best control.
- Standalone remote applications requiring programmable operation and remote interface for monitoring.
- New applications where an intelligent system can be used as a fully integrated system, reducing engineering, cost, and maintenance requirements.
- Specialized control functions such as gap control for very large turndown, or self-contained minimum pump recirculation systems for pump or compressor protection.

Microprocessor-based systems are available in watertight or explosionproof (NEMA 6 to 7) construction and can tolerate ambient temperatures from –40 to 185°F (–40 to 85°C), as well as the presence of moisture, fungus, or dust. They can incorporate sensors, an electronic positioner, or an electronic proportional, integral, derivative (PID) controller, which can operate off a digital or analog external set point.

Locating the controller card at the valve and dedicating it to full-time control is an advantage on very fast critical loops, such as compressor surge protection, where otherwise surge could evolve while the central DCS control system is scanning/updating other loops.

Smart systems can also take advantage of the lower cost of digital communications over a single loop of two-conductor or fiber-optic cable (Figure 6.3ff). This method of communication substantially reduces the wiring cost of installations that can control up to 250 actuators, pumps, or solenoids. The smart valves can be remotely calibrated and reconfigured and can be used to detect such performance changes as pressure changes resulting from a fouled pump or pipeline. They can also limit the valve travel to stay within the range where the required characteristics (gain) are available.

It is perhaps at the maintenance level that the most benefits can be obtained through the use of smart and intelligent systems.[6] Smart actuator circuitry can protect electric motor operators from burning out when the valve is jammed or from reverse phasing. More importantly, by close monitoring of the valve, the required information can be obtained to evaluate the valve and actuator performance and thereby replace preventive and corrective maintenance by predictive maintenance with the benefits of improved process performance and products quality at a lower cost.

INTRODUCTION

Pneumatic valve actuators respond to an air signal by moving the valve trim into a corresponding throttling position. This section covers the two basic designs most frequently utilized: the diaphragm and the piston actuator. The discussion of diaphragm- and piston-type actuators is followed by the treatment of pneumatic-rotary and pneumatic-hydraulic actuators.

In connection with the performance of these actuators, an analysis is presented of the various forces positioning the plug, including diaphragm, spring, and dynamic forces generated by the process fluid. An understanding of the interrelationships among these forces will allow the reader to properly size these actuators and make the correct spring selection.

The failure safety of valve actuators and the relative merits of diaphragm vs. piston actuators and the topic of high-speed actuation using pneumatics is also discussed. This section is concluded with a summary of the results of a long-term evaluation of the performance of pneumatically actuated control valves in the field.

DEFINITIONS

An actuator is that portion of a valve that responds to the applied signal and causes the motion resulting in modification of fluid flow. Thus, an actuator is any device that causes the valve stem to move. It may be a manually positioned device, such as a handwheel or lever. The manual actuator may be open-closed, or it may be manually positioned at any position between fully open and fully closed. Other actuators are operated by compressed air, hydraulics, and electricity.

The actuators discussed here are those capable of moving the valve to any position from fully closed to fully open and those using compressed air for power. Of such there are two general types: the spring-and-diaphragm actuator and the piston actuator.

In a spring-and-diaphragm actuator, variable air pressure is applied to a flexible diaphragm to oppose a spring. The combination of diaphragm and spring forces acts to balance the fluid forces on the valve.

In a piston actuator, a combination of fixed and variable air pressures is applied to a piston in a cylinder to balance the fluid forces on the valve. Sometimes springs are used, usually to assist valve closure. Excluding springs, there are two variations of piston actuators: cushion loaded and double acting.

In the cushion-loaded type, a fixed air pressure, known as the cushion pressure, is opposed by a variable air pressure and is used to balance the fluid forces on the valve. In the double-acting type, two opposing variable air pressures are used to balance the fluid forces on the valve.

An actuator can be said to have two basic functions: (1) to respond to the external signal of a controller and cause an inner valve to move accordingly (with the proper selection and assembly of components, other functions can also be obtained, such as a desired fail-safe action) and (2) to provide a convenient support for valve accessory items, such as positioners, limit switches, solenoid valves, and local controllers.

ACTUATOR FEATURES AND SELECTION

Table 6.4a describes the applications and relative advantages of a variety of actuator designs. The table lists both the advantages and the limitations of the various designs. The popularity of the spring/diaphragm actuator is due to its low cost, its relatively high thrust at low air supply pressures, and its availability with “fail-safe” springs. By trapping the pressure in the diaphragm case, it can also be locked in its last position. It is available in springless designs, double diaphragm designs (for higher pressures), rolling diaphragm designs (for longer strokes), and tandem designs (for more thrust).

One of the limitations of this design is the lack of actuator “stiffness” (resistance to rapidly varying hydraulic forces - for example, those caused by flashing). For such applications double-acting piston actuators are used and for extraordinary requirements hydraulic or electromechanical (motor gear) actuators may be preferred. A stiffer spring, 6–30 PSIG (41–210 kPa), in a spring/diaphragm unit is sometimes sufficient to correct the problem.

Linear piston actuators provide longer strokes and can operate at higher air pressures than can the spring/diaphragm actuators. When used to operate rotary valves, the linear piston or spring/diaphragm actuator does not provide a constant ratio of rotation per unit change in air signal pressure; therefore, the use of positioners is always a requirement.

Rotary piston actuators operate at higher air pressure and can provide higher torques, suitable for throttling large ball or butterfly valves. The double-acting version of this actuator does not have a positive failure position, but this can be corrected by extending the piston case and inserting a helical spring. For higher torques (over 1000 ft · $\mathrm{lb_f}$ [68 Nm]), heavy-duty transfer linkages are required (Scotch yoke or rack and pinion); such units cannot be disassembled and maintained in the field. These actuators also require positioners because the relationship between air signal change and resulting rotation is not linear.

SPRING/DIAPHRAGM ACTUATORS

This discussion is restricted to pneumatic actuators. The external signal, therefore, is an air signal of varying pressure. The air signal range from a pneumatic controller is commonly 0–18 PSIG (0–124 kPa). Signal or actuator input pressure starts at 0 PSIG, not 3 PSIG (21 kPa).

A common mistake is to confuse the 3–15 PSIG (21–104 kPa) range of transmitter output pressure with the signal to a valve. The higher value of 18 PSIG (124 kPa) is fixed only by the air supply to the controller (or positioner),

TABLE 6.4a
Features of Pneumatic Actuators

Type of Actuator	*Advantage*	*Disadvantage*	*Application*
Linear spring-and-diaphragm	Low cost Mechanical fail-safe Moderate thrust Small package Simple design Excellent control with or without control devices	Slow speed Poor stiffness Instability	Linear valves 1/2–8 in. (12–200 mm) body size
Linear piston	Moderate cost Moderate thrust Small package Simple design Excellent control with control device Long stroke High-speed options Moderate stiffness	Large spring compression when used for failure	Linear valves 1/2–30 in. (12–760 mm) body size
Rotary spring-and-diaphragm	Moderate cost Mechanical fail-safe Small package Simple design Easily reversible Excellent control with control device	Low thrust in spring cycle Instability	Rotary valves 1–6 inch (25–150 mm) body size
Rotary pistons	Low cost Moderate thrust Small or large package Good control with control device Mechanical fail-safe option	Slow speed Large spring Compression	Rotary valves 1–24 inch (25–600 mm) body size

See Section 4.3 for a detailed treatment of the features of hydraulic and electric actuators.

and it can easily be set to 20 PSIG (138 kPa) or higher. A variety of other input pressures are sometimes used, such as 0–30 or 0–60 PSIG (0–207 or 0–414 kPa).

Both the spring-and-diaphragm and the piston actuator produce linear motion to move the valve. These actuators are ideal for use on valves requiring linear travel, such as globe valves. A linkage or other form of linear-to-rotary motion conversion is required to adapt these actuators to rotary valves, such as the butterfly type.

Steady-State Force Balance

In spring-and-diaphragm actuators the stem positioning is achieved by a balance of forces acting on the stem. These forces are caused by the pressure on the diaphragm, spring travel, rubbing friction, and fluid forces on the valve plug (Figure 6.4b).

Equation 6.4(1) can be derived from a summation of forces on the valve plug adopting the positive direction downward.

$$PA - KX - P_v A_v = 0 \qquad \textbf{6.4(1)}$$

where A is the effective diaphragm area, A_v is the effective inner valve area, K is the spring rate, P is the diaphragm pressure, P_v is the valve pressure drop, and X is stem travel. Equation 6.4(1) applies to a push-down-to-close actuator and valve combination with flow under the plug. This type of actuator is commonly referred to as direct acting.

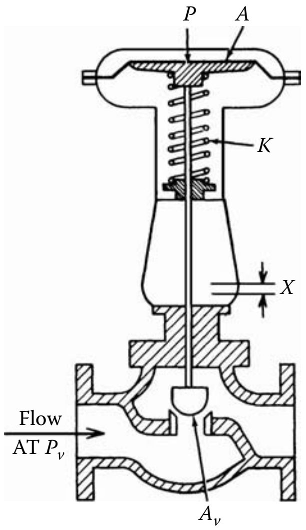

FIG. 6.4b
Forces acting on a spring-and-diaphragm actuated, fail open (FO) control valve.

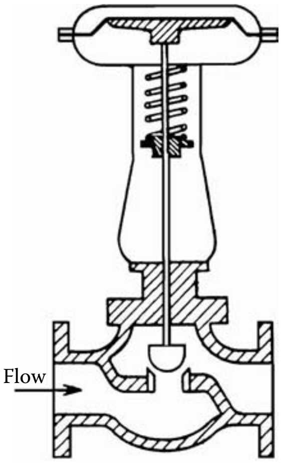

FIG. 6.4c
Reverse-acting spring-and-diaphragm actuator, attached to a flow to open, spring to close (fail closed = FC) control valve.

Another popular actuator configuration is one causing the stem to rise on an increase of air pressure. It is commonly called a reverse acting actuator (Figure 6.4c).

By using the same sign convention, the force balance equation for this valve configuration is given in Equation 6.4(2).

$$-PA + KX - P_vA_v = 0 \qquad \textbf{6.4(2)}$$

If the flow direction is reversed in Figure 6.4b, the equation becomes:

$$PA - KX + P_vA_v = 0 \qquad \textbf{6.4 (3)}$$

Likewise, reversing flow direction in Figure 6.4c results in Equation 6.4(4):

$$-PA + KX + P_vA_v = 0 \qquad \textbf{6.4(4)}$$

These equations are simplified because they do not consider friction and inertia. Friction occurs in the valve stem packing, in the actuator stem guide, and in the valve plug guide or guides. Usually, for static valve actuator sizing problems, negligible error is introduced by ignoring the friction terms.

If Equation 6.4(1) is plotted as signal pressure vs. stem travel and if the case of no fluid forces on the plug (bench test) is assumed, then the curve shown in Figure 6.4d is obtained.

Next, consider the case of plug forces due to fluid flow, assuming that the term P_v is constant for all travel positions. This has the effect of shifting the straight line to the right to some position depending on the magnitude of P_v. Curves similar to those in Figure 6.4d can readily be drawn for the other valve configurations represented by Equations 6.4(2), 6.4(3), and 6.4(4). The distance between the lines is the force resulting from A_v is the effective inner valve area, K is the spring rate, P is the diaphragm pressure, P_v is the valve pressure drop, intersecting the abscissa is the pressure needed to move the valve plug.

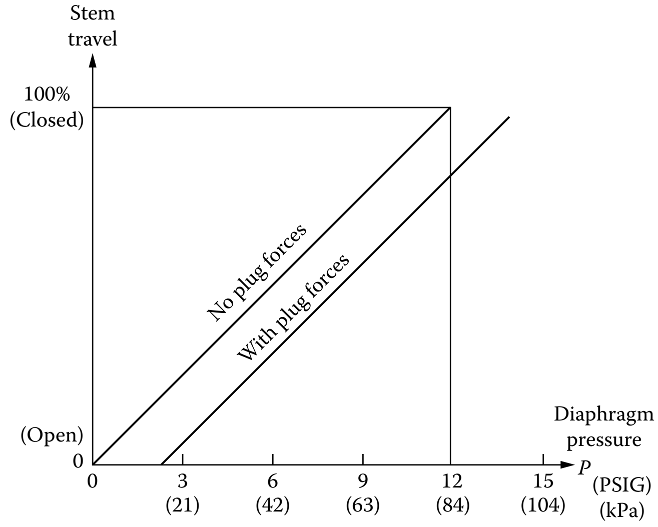

FIG. 6.4d
In a fail open (FO) valve, as the air pressure on the diaphragm rises, the valve closes. The distance between the two sloping lines corresponds to the force acting on the plug (A_v), which force is generated by the differential between the up and downstream pressures (P_v), when these forces tend to keep the valve open, as in Figure 6.4b.

Actuator Sizing Example

Let us assume that the forces acting on a 1 in. (25 mm) single-ported globe valve are to be evaluated. In that case:

A = 46 in.^{2} (0.03 m^2)
X = 5/8 in. (15.9 mm) full travel
K = 885 ft lb$_f$/in. (7.83 N/mm)

If no plug forces exist, Equation 6.4(1) reduces to $PA = KX$. Solving for the pressure change required to obtain full travel from open to closed:

$$P = KX/A = (885)(5/8)/(46) = 12.03 \text{ PSIG } (83 \text{ kPa})$$

This is reasonably close to the 12 PSIG (0.83 kPa) desired operating span. Practical considerations of variations in spring constants and in actuator-effective areas usually prevent such a close approach to the desired span, and frequently a ±10% leeway is permitted.

When there are plug forces, it is seen from Equation 6.4(1) that an additional actuator force is required to maintain balance. The actuator pressure required to begin stem motion can be calculated for the case of a 1 in. diameter (25 mm) plug ($A_v = \pi/4$) and 100 PSIG (690 kPa) pressure drop. Equation 6.4(1) can be used to solve for P as follows (stem travel is zero, thus there are no spring forces):

$$\begin{aligned} P &= [(K = 885)(X = 0) + (P_v = 100)(A_v = \pi/4)]/(A = 46) \\ &= 1.7 \text{ PSIG } (11.8 \text{ kPa}) \qquad \textbf{6.4(5)} \end{aligned}$$

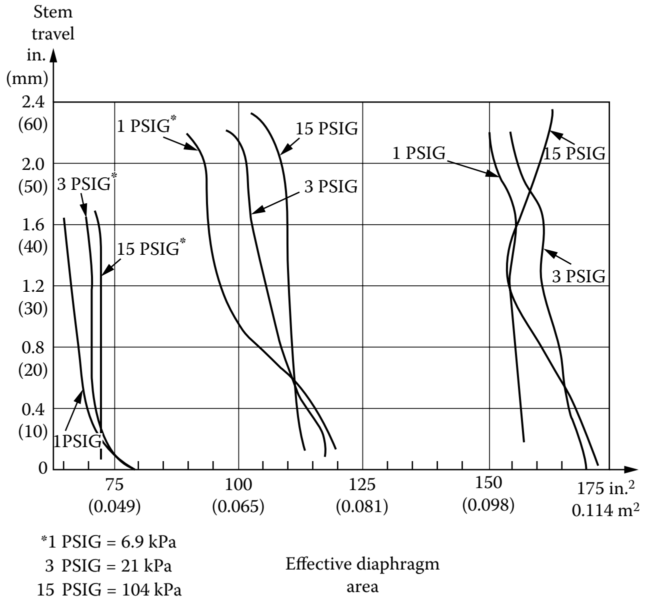

FIG. 6.4e
The effective diaphragm areas vary with both the stem travel and with the pressure acting on the diaphragm.

This means that the diaphragm pressure must increase to 1.7 PSIG (11.8 kPa) before stem travel begins. This is the distance between the two sloping straight lines in Figure 6.4d.

Actuator Nonlinearities

In practice we encounter many nonlinearities, and the ideal curves in Figure 6.4d are not obtained. These nonlinearities are due to several factors, such as the variable effective diaphragm areas. The effective diaphragm area varies with travel and with the pressure level on the diaphragm. Figure 6.4e illustrates this for three different sizes of diaphragms.

Another source of nonlinearity is in the variation of the valve plug forces (P_vA_v). Figure 6.4f illustrates the variations in these plug forces for two 4 in. (100 mm), single- and double-ported valves. The figure also shows the effects of flow over and under the plugs of a single-ported valve.

Springs are also nonlinear in that the spring rates vary with travel. By judicious selection of springs, considering their spring rate and travel, the effects of their nonlinearity on the valve assembly can be minimized.

When all of these nonlinearities are considered, a plot of actuator travel vs. diaphragm pressure would not be a straight line as shown in Figure 6.4d, but might be a curve such as the one shown in Figure 6.4g.

A nonlinear curve, such as the one labeled “actual” in Figure 6.4g, is not necessarily objectionable. When used in an automatic control loop, the static nonlinearities are compensated for by the controller. This curve is actually a part of the gain term in the valve’s transfer function, and the other part is the flow characteristic. When a valve positioner is used, the positioner overcomes these nonlinearities, and the result is similar to the ideal curve shown in Figure 6.4g.

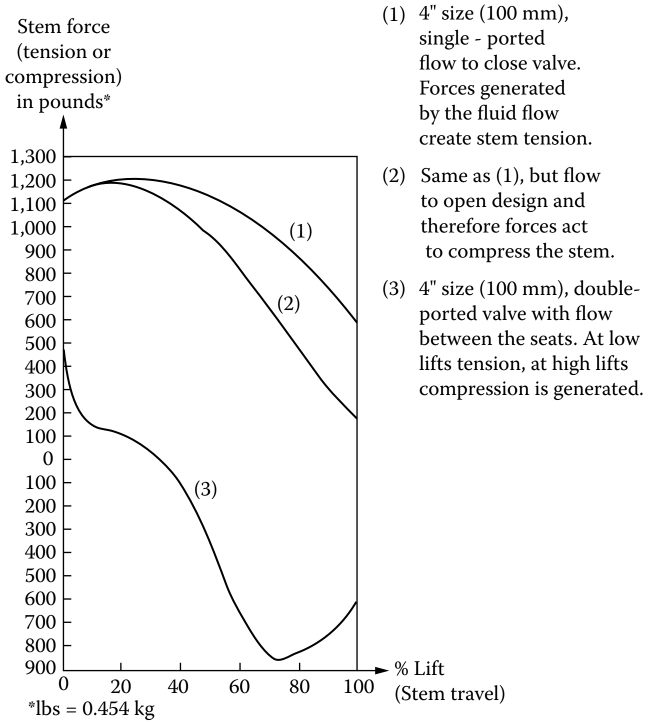

FIG. 6.4f
The forces acting on the valve plug are also nonlinear, because the pressure difference across the valve varies as a nonlinear function of stem travel.

Dynamic Performance of Actuators

Several control valve subsystems must be analyzed in order to thoroughly evaluate their dynamic performance. The separate systems include:

1. The spring-mass system of the valve’s moving parts.
2. The pneumatic system from controller output to valve diaphragm chamber. If a valve positioner is used, there are two separate pneumatic systems: one from the controller output to the positioner and another from the

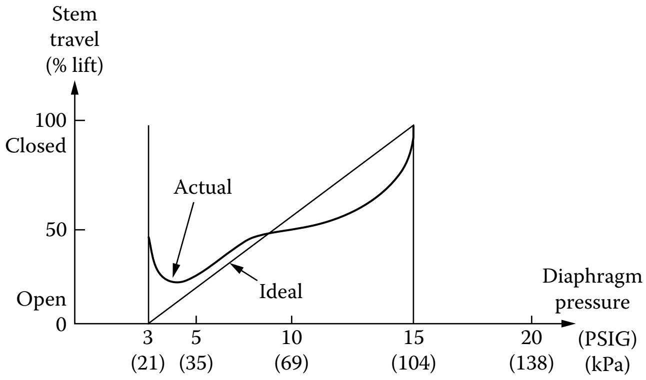

FIG. 6.4g
Ideal and actual relationship between diaphragm pressure and stem travel.

positioner output to the diaphragm chamber. The interconnecting tubing is consideration in all of the pneumatic systems.

Spring-Mass System Dynamics Analysis of the spring-and-mass system is only valid for linear systems. It is necessary either to neglect consideration of the nonlinear elements or have a system wherein the nonlinear effects are minor. In the case of control valves with sufficient power in the actuator, the latter case is approached. With such an understanding of the nonlinear effects, we proceed as though valve actuators were linear devices.

The spring-mass system is represented by the following differential equation:

$$M\frac{d^2X}{dt^2}+b\frac{dX}{dt}+KX=PA-P_vV_v \qquad \textbf{6.4(6)}$$

where b is the net friction force and M is mass. The net friction force would include friction due to seals, mechanical rubbing, and viscous friction on the plug.

The static, time-independent terms of Equation 6.4(6) are identical with Equation 6.4(1). The transfer function of the valve actuator is the LaPlace transform of differential Equation 6.4(6):

$$\frac{X(s)}{P(s)}=\frac{A/K}{(w/gK)s^2+(b/K)s+1} \qquad \textbf{6.4(7)}$$

where g is the gravitation constant, s is the LaPlace operator, and w is the weight of moving parts. This can be written in terminology more useful to instrument engineers using the time constant τ (tau) and damping factor ζ (zeta).

$$\frac{x(s)}{P(s)}=\frac{1}{\tau^2s^2+2\tau\varsigma s+1} \qquad \textbf{6.4(8)}$$

The coefficient of the s^2 term in Equation 6.4(7) is the square of the reciprocal of the undamped natural frequency of the spring-mass system. It is a useful number in understanding the relative importance of a control valve's dynamic components.

Table 6.4h is a list of the natural frequencies of different size valves of the "average" design. It should be noted that even the largest valve with its un-damped natural frequency of Hz = 9 is ten times faster than the typical pneumatic performance of a control valve.

For a more detailed discussion of the dynamics of diaphragm actuators and of the effect of standing pressure waves in the piping on that dynamics, the reader is referred to the discussion by Lynch.[1]

TABLE 6.4h
Natural Frequency of Control Valves

Valve Size (in.)	*Valve Size (mm)*	*Undamped Natural Frequency (Hz)*
1	25	32
$1^1/_2$	37.5	27
2	50	22
3	75	16
4	100	14
6	150	10
8	200	9

Resolution and Valve Oscillation The minimum change in the stem position of a control valve is called its resolution, which limits the ability of the control signal to position the valve exactly at a specific point of its travel. Because of this limitation, valves can continuously oscillate, as the increment of the stem position that can be delivered is larger than what is required. The result is a continuous sequence of overshooting and undershooting the stem position target. The valve's resolution, this minimum change in position, cannot be very accurately calculated, because of the variations between the valve designs.

The definition of resolution for all pneumatic actuators is the ratio of the change in friction force to the spring rate. The relative resolution (R) is calculated by taking the difference between the static and dynamic friction forces ($F_s - F_d$) and dividing that with the difference between the mechanical spring rate and the spring rate of the trapped air ($K_a - K_s$). The resolution is calculated or percent of full stroke is then obtained by dividing by the stroke. In equation form the resolution, R, in dimensions of length is:

$$R = (F_s - F_d)/(K_a - K_s) \qquad \textbf{6.4(9)}$$

where:

R is the resolution in units of either length or percentage of full stroke
F_s is the static spring friction
F_d is the dynamic (running) spring friction
K_a is the spring rate of the trapped air
K_s is the spring rate of the spring

The spring rate of the trapped air (K_a) is shown by Equation 6.4(10):

$$K_a=\frac{1.4PA^2}{V} \qquad \textbf{6.4(10)}$$

where:

A is the effective area of the actuator
V is the volume of trapped air in each actuator cavity
P is the absolute pressure in the actuator

The main contributors to the friction forces are the packing friction on the actuator stem, the valve stem and the effect of any valve internal balancing seals. The motion of the actuator is faster than the time it would take for the air to be exchanged on both sides of the diaphragm or piston. Therefore, the air pressure conditions at each point of travel can be evaluated in a static manner, and the air exchange dynamics can be ignored.

A number of observations can be made in connection with Equation 6.4(9). One such observation is that the dynamic or running friction (F_d) is always less than the static or breakaway friction (F_s). The difference usually is 25–35%. Another observation is that the friction forces for a PTFE (Teflon) seal are less than the friction forces generated by higher temperature seals made of fibrous graphite.

The size of these friction forces is much affected by the amount of extra torque applied to tightening packing box seals during installation. Too much compression of the seals will result in high friction forces and in stem travel oscillations.

The mechanical spring rate (K_s) is essentially constant. The air spring rate (K_a) can be increased by selecting a large effective area (A) in the actuator in combination with a small air volume (V). Because the air spring rate (K_a) is a function of the air volume and because the mechanical spring force changes with the stem movement, the resolution (R) will also vary with valve travel.

The relationship between resolution and stem travel for a variety of actuator designs is shown Figure 6.4i. In most designs the use of a spring tends to reduce the resolution. In spring-diaphragm combinations, the resolution is improved (reduced) when the spring opposes the direction of valve stem travel.

Good maintenance is essential to minimize the frictional forces in valve actuators. The positioner, which delivers or exhausts air to/from the actuator, is slower than the speed at which small changes in stem position occur.

Once the valve is installed the only means available to the user to change the resolution is to modify the supply air pressure, up to the limit of the design pressures. Because the air spring rate (K_a), which can be calculated by Equation 6.4(10), is small in comparison to the mechanical spring rate (K_s), an increase in the air supply pressure is not likely to have much impact on the resolution.

For reasons of competition, the valve manufacturers usually provide the smallest actuator they can for the particular application. Yet, for a small additional expense the user can usually obtain an actuator with a larger effective area and obtain a noticeable improvement in resolution and, therefore, in the controllability of the loop. By so doing, the continuous oscillation of the valve can often be stopped.

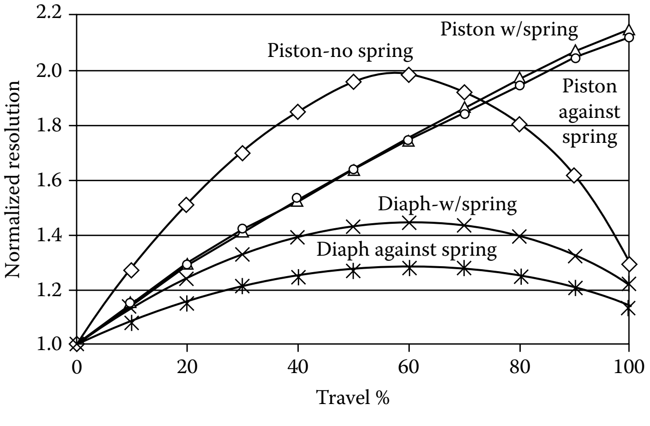

FIG. 6.4i
Actuator resolution curve vs. travel for a number of actuator designs.

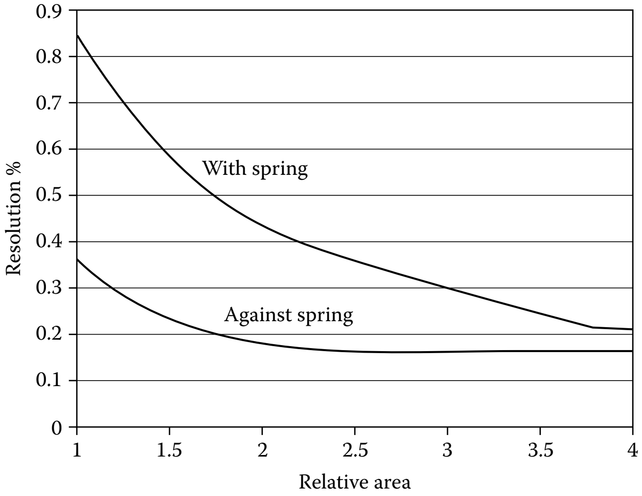

FIG. 6.4j
Resolution vs. diaphragm effective area.

As it is shown in Figure 6.4j, the valve resolution can be much reduced (improved) by using a larger actuator. As can be noted from the figure, a doubling of the effective area of a diaphragm actuator cut the actuator resolution nearly in half.

Safe Failure Position

The valve application engineer must choose between the two readily available fail-safe schemes for control valves, either fail open or fail closed. The choice will be based upon process safety considerations in the event of control valve air failure. Complete plant air failure, controller signal failure, and local air supply failure must all be considered. Local failure is significant when a valve positioner is being used and when piston actuators with cushion loading are used.

The choice must be based on detailed knowledge of the valve application in the overall process or system. Two generalizations are that in a heating application, the valve should fail closed, and in a cooling application it should fail open. There are certainly applications where either failure mode is equally safe; then, considerations of standardization may be used.

Fail-safe involves the selection of actions of actuator and inner valve. Both actuator and inner valve usually offer a choice of increasing air pressure to push the stem down or up, and pushing the stem down may open or close the inner valve. The proper choice of combinations may be made by fail-safe considerations. The process application of the valve must be investigated to determine whether, on instrument air failure, it would be better to have the valve go fully open, fully closed, or remain in its last position.

There may not be much flexibility in the inner valve action. For example, a single-seated top-guided valve must push down to close the plug. There is freedom of choice, however, in either single- or double-seated top- and bottom-guided valves. Other valve bodies, such as the Saunders and pinch valve styles, must be of the push-down-to-close type.

Rotary types, such as butterfly and ball valves, may be arranged either way.

The inner-valve flexibility leads to two cases: one in which either inner-valve action is permissible and one in which the inner-valve must be push-down-to-close.

When there is a choice of inner-valve action, overall valve action may be obtained by selecting the suitable inner-valve action and always using increasing air to push down the actuator. This is known as a direct actuator. A direct actuator is preferred because of economy reasons in spring-and-diaphragm actuators. The savings may be in purchase cost. It is also realized in maintenance costs, because there is no actuator stem seal to cause possible leakage and maintenance costs.

When the inner valve must be push-down-to-close, it is necessary to use both direct and reverse actuators to accomplish the desired fail-safe actions. Figure 6.4k summarizes the available diaphragm failure options.

The piston-type actuator is equally suitable for direct or reverse action. If it is the actuator to be used, the application engineer has complete freedom of the choice of selecting the valve action.

The Role of the Positioner The above description provides a "baseline" for safe valve failure if the actuators are not provided with positioners. By the addition of a positioner, the topic of safe valve failure becomes quite complex. This is because in this case not only the pneumatic signal to the actuator can fail, but also the air supply to the positioner. In order to satisfy these requirements and also to make available the "fail in place" configurations, it is necessary to provide various accessories to either exhaust or trap the actuator air pressure. These accessories include pneumatic pilot valves (see Section 6.2) that, if air pressure is lost, will trip to provide a safe valve action. As far as digital systems are concerned, as of this writing only one digital positioner manufacturer provides a tight shut-off positioner.

Valve failure (Overall)	*Fail Open*		*Fail Closed*	
Actuator	Direct	Reverse	Reverse	Direct
Inner Valve	Direct	Reverse	Direct	Reverse

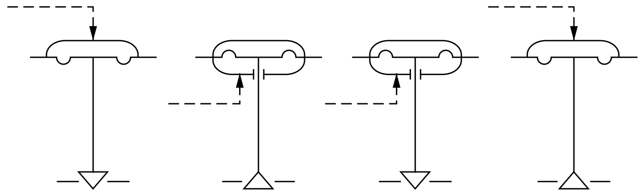

FIG. 6.4k

Overall valve failure positions, which can be achieved by various combinations of direct or reverse actuators and inner valves.

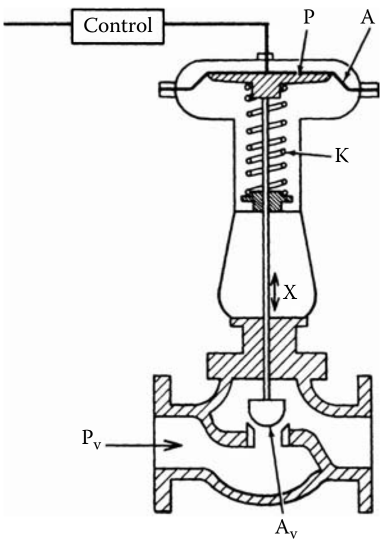

FIG. 6.4l

Forces acting on control valve with a spring-and-diaphragm type actuator.

In the cases where only the positioner can send an air signal to the valve actuator, the valve failure position is usually unaffected by the addition of the positioner. An exception to this statement is if a nonbleeding digital positioner is used.

Actually, it is questionable if a bleed can be considered as a means of providing positive failure position. This is because the time to bleed the air out through the positioner can be quite long. This long time that is required to reach a failure position is often unacceptable, and in such cases, one should provide pneumatic pilot valves to quickly trap or exhaust the air.

Pneumatic Response Times

An earlier discussion considered the transfer functions of the spring-and-diaphragm actuator between the actuator pressure to the resulting stem travel. Next we will consider the pneumatic transfer function of the air signal from the controller to the diaphragm actuator (Figure 6.4l).

A short tube behaves linearly as a pure resistance, and the air volume in the actuator above the diaphragm behaves as a capacitance. So the combination is a resistance-capacitance time constant. Some time constant values obtained from tests with very short tubing are given in Table 6.4m.

TABLE 6.4m

Time Constants for Short Tube Sections

Valve Size		*Time Constant*
(in.)	*(mm)*	*(sec)*
1	25	0.03
2	50	0.05
4	100	0.8

Performance is usually limited by the controller's or positioner's ability to supply the required air fast enough. The time constant values in Table 6.4l were obtained from tests in which the air supply was not limiting. These figures show that the valves are capable of fast response. Section 3.1 contains a more detailed discussion of transmission lags and methods of boosting.

PISTON ACTUATORS

Piston actuators are either single or double acting. The single-acting actuator, shown in Figure 6.4n, utilizes a fixed air pressure, known as the cushion, to oppose the controller signal. This valve does not have spring or diaphragm area nonlinearities, but it is of course subject to the same plug force nonlinearities (Figure 6.4f) as the spring-and-diaphragm actuator.

In order to use such an actuator for throttling purposes, it is necessary to have a positioner. The positioner senses the actuator motion and causes the valve to move accordingly. It cannot be used as a proportioning travel device without the positioner; consequently, its performance is that of the "ideal" curve in Figure 6.4g.

A double-acting piston actuator is one that eliminates the cushion regulator and uses a positioner with a built-in reversing relay. Thus, the positioner has two air pressure outputs, one connected above the piston and the other below. The positioner receives its signal and senses travel in the same manner as a single-acting positioner. The difference is in the outputs; one pressure increases and the other decreases to cause piston travel.

Table 6.4o provides typical actuator stroking times as a function of actuator sizes, stroking distances, and connecting tube sizes. For closed-loop control applications, the speed of response that is critical is not the full stroking time but rather the time it takes to move the valve about 5% of its full stroke, which is much faster than the values given in Table 6.4o. Therefore, velocity limiting of the loop usually occurs only when the valve is "slow" relative to the controlled variable and when the change in the controller signal to the valve is large.

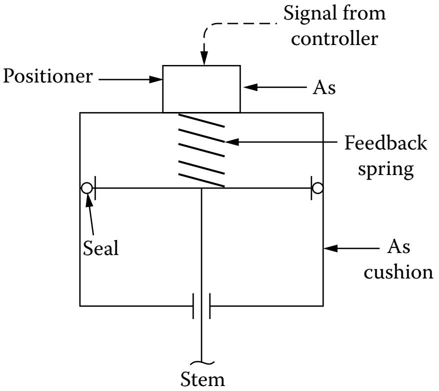

FIG. 6.4n
Single-acting piston actuator.

TABLE 6.4o
Spring-Loaded Piston Actuator Stroking Times for Linear Control Valves[*]

	Time (seconds) for Maximum Stroke[**]		
Actuator Size	*$^1/_4$ in. Tubing*	*$^3/_8$ in. Tubing*	*Stroke (inches)*
25	1.2	1.0	1.5
50	3.5	3.1	3

[**] Stroking time only (does not include time from receipt of signal and beginning of stem motion).

One advantage of the piston actuator is that higher pressures can be used for motive power. The higher pressure provides better stiffness and resolution. It also provides more force to keep the valve closed. The higher force between the valve plug and the seating surface ensures a tighter shutoff and helps to meet the leakage specifications of the original design.

The piston actuators can also generate longer strokes, because their stroke is limited only by the length of the cylinder used. Such longer strokes are required for many special valve designs that are used in services where cavitation, noise, or pipe vibration is a problem (see Section 6.14).

All of the failure modes are available with the piston actuator. A spring may be used inside or outside of the cylinder to cause the valve to fail in the desired position. The use of outside springs necessitates the use of additional seals and increases mechanical complexity. The use of an inside spring requires a larger cylinder volume that could impact the resolution of the valve.

To obtain a positive failure position without a spring requires a standby air tank to provide the needed power for moving the valve into the failure mode. It also requires control accessories to ensure proper exhaust or lock-up of the air pressures.

HIGH-SPEED ACTUATORS

In the past, high-speed actuation was usually provided by hydraulic actuators. Applications that require fast control valve motion include compressor recycle, turbine bypass, and pressure relief applications. Control valves used in starting up or shutting down a process may also require fast actuation

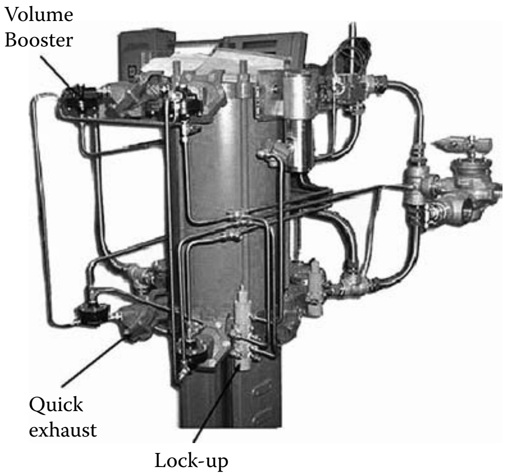

FIG. 6.4p
High speed pneumatic circuitry. (Courtesy of Control Components Inc.)

to protect equipment. Fast speed in these cases usually means full valve stroke in 1 to 2 sec.

In case of pneumatic actuators, the factor that is limiting the speed is the speed at which air can be fed or exhausted from the cylinder. This is accomplished by accessories that direct the air to the cylinder while bypassing the positioner and by increasing the air feed line sizes and the air supply pressure. Because of the increased pressure, the piston actuator is usually preferred in comparison with the diaphragm design, because of its higher pressure rating.

Diaphragm actuators are usually limited to 40 PSIG (275 kPa), with a few designs permitting 60 PSIG (410 kPa) operation. The high-pressure designs can operate with the usual plant air systems of 150 PSIG (1035 kPa) with normal operating pressures of 100 PSIG (690 kPa). This range of air supply pressures is readily available in most plants.

The high-speed pneumatic actuation can be achieved by the use of boosters to feed and exhaust air from the cylinders. These boosters are actuated when the control signal calls for a 10% or so change in valve opening. An actuator that is being fed by two boosters located above and below the piston is shown in Figure 6.4p.

In addition to the boosters, other accessories are also needed to guarantee the required failure positions. There are many disadvantages to these designs, including the difficulty of tuning and calibrating all of the component devices individually so as to maintain a stable operation. In addition, the tubing configuration requires a substantial amount of space around the actuator, and the accessories and tubing provide a lot of handhold and support points for operators, which can lead to damage. These systems can also be sensitive to vibration and to high temperatures radiating from a hot valve.

A newer development is shown in Figure 6.4q. This design required the development of high-capacity servo-valves that can be positioned to very close tolerance and of a programmable electronic controller. The controller can receive the HART or fieldbus protocol of the control system, can maintain the travel of the actuator so that there is no visible overshoot even during the fastest transients, and can calibrate the actuation system within seconds. The higher pressure and stiffness of the actuator allows positioning within 0.25% of the total travel. Dead time and hysteresis are also considerably lower than for the more conventional pneumatic actuators.

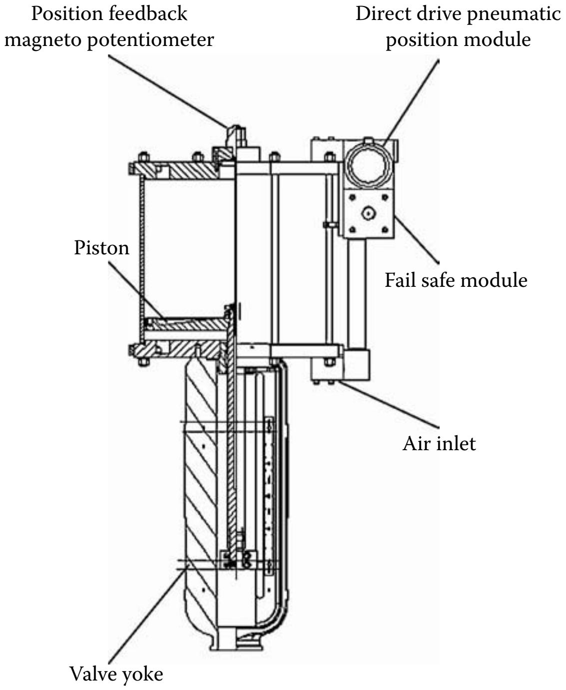

FIG. 6.4q
High-speed piston actuator without boosters. (Courtesy of Control Components Inc.)

Figure 6.4r shows a response curve for an actuator with a 14 in. (355 mm) travel in which full stroke is achieved in 1.3 sec. The dead time is less than 0.140 sec, and there is no visible overshoot when operating a relatively high friction valve. There are no mechanical linkages, tubing, or accessories

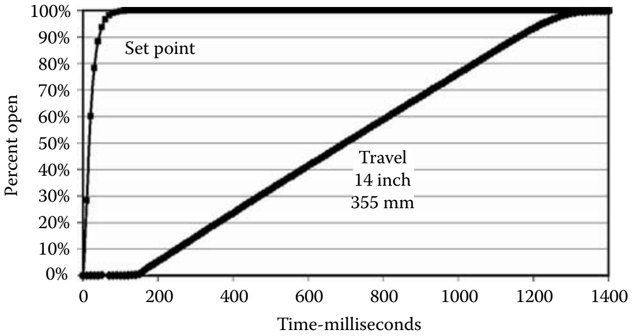

FIG. 6.4r
High speed actuator step change response. (Courtesy of Control Components Inc.)

to fail from vibration or from other environmental conditions. According to the supplier, all failure positions can be provided and diagnostic software is also available. (For more details, see Sections 6.8 on valve diagnostics, 6.11 on fieldbus interaction, and 6.12 on intelligent valves.)

The high-speed pneumatic actuators reduce the need to use hydraulic actuators, when the stroking time of a second or two is sufficient. One pneumatic actuator supplier feels that both electric and hydraulic high-speed actuators are more expensive than the pneumatic ones. (For a detailed discussion of hydraulic and electric actuators refer to Section 6.3.)

RELATIVE MERITS OF DIAPHRAGM AND PISTON ACTUATORS

Table 6.4a compared the features of diaphragm- and piston-type pneumatic actuators. When choosing between piston actuators and the spring-and-diaphragm type, the fail-safe consideration may be the reason for the final selection. If properly designed, the spring is the best way of achieving fail-closed action. Fail-open action is less critical.

Piston actuators may depend upon air lock systems to force the valve closed on air failure. Such systems may work well initially, but there are possibilities for leaks to develop in the interconnecting tubes, fittings, and check valves. Therefore, such piston actuator systems are not considered reliable by many. However, according to one manufacturer, field data on reliability shows the opposite to be true. Air lock systems also add to the actuator's cost. Piston actuators may also be specified with closure springs to provide positive failure positions.

Valve installation in the line is also a factor to consider. Flow over the plug assists in maintaining valve closure after air failure, but the considerations involving dynamic stability are more important. Therefore, the use of "flow-to-open" valves is recommended for most diaphragm actuators, as the actuator force is usually marginal.

Piston actuators are larger and require more space than do diaphragm actuators. This is particularly the case when the piston is provided with a spring to provide a positive failure position.

Both the diaphragm and piston actuators use manifolds and have become available in modular designs. This has somewhat reduced their costs and lowered their potential for leakage by reducing the number of connections that could leak. An example of the modular design of a linear actuator is shown in Figure 6.4s. The linear actuator includes a positioner, boosters, and adjustable quick exhaust.

Figure 6.4t illustrates the modular design of a rotary piston actuator. The rotary design is the balanced pinion type that can be provided with a plug-in positioner, which can be either the conventional or the smart design. The smart positioners also are available with bus communication options.

The modular designs provide flexibility, as they may be changed out in the field to accommodate process changes or upgrades or to correct errors in the original design. These modular designs are usually provided with position indicators, which are enclosed within the actuator housing. Because of these housings, reliability is better than in designs where the linkages are exposed. Most control modules will eventually include bus control communication and self-diagnostics capability.

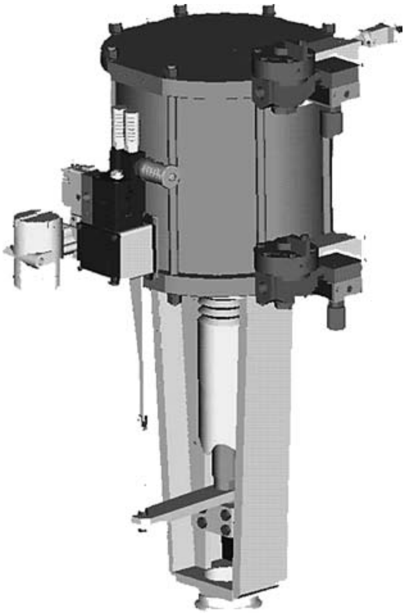

FIG. 6.4s
Piston actuator with modular manifolds. (Courtesy of Control Components Inc.)

Pneumatic vs. Hydraulic Actuators While the purpose of this section is to describe the features of pneumatic actuators and while a detailed discussion of hydraulic and electric actuator features is given in Section 4.3, a few comments

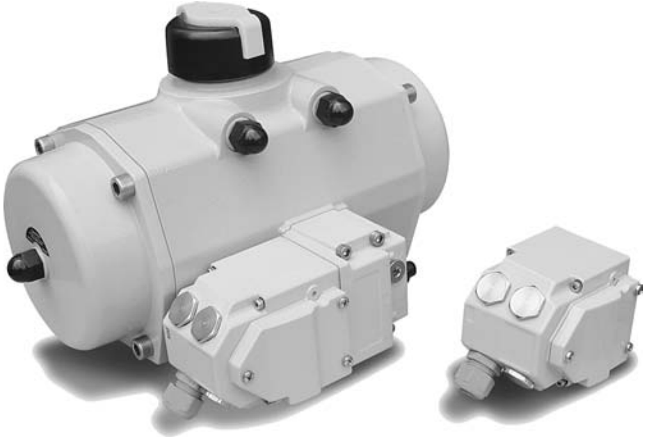

FIG. 6.4t
Rotary actuator provided with interchangeable control modules. (Courtesy of Emerson Process Management.)

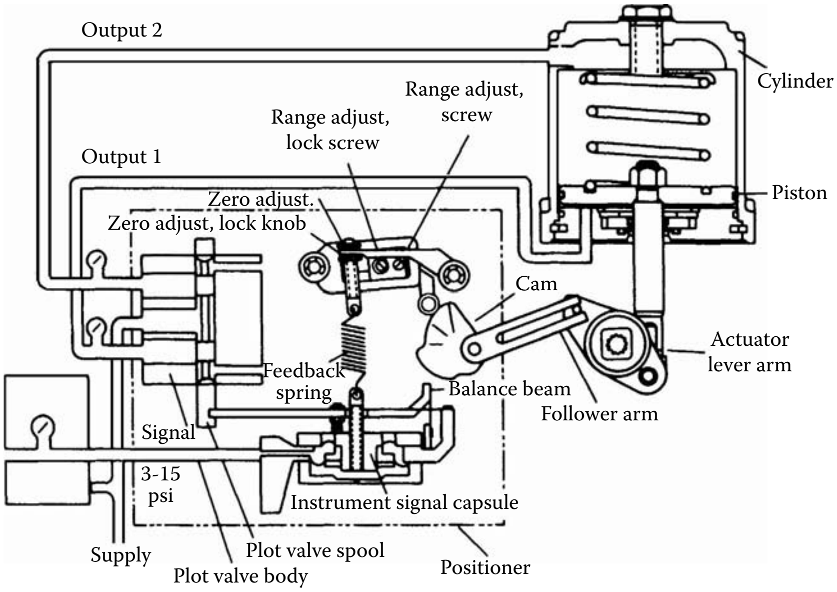

FIG. 6.4u
When linear actuators are used to operate rotary valves, a unit change in controller signal will not result in a unit change in rotation unless a positioner is used. (Courtesy of Flowserve Inc.)

from the perspective of a pneumatic piston actuator manufacturer is included here.

The main advantages of hydraulic actuators are speed and stiffness. This is the case because of the high density and the incompressibility of liquids in comparison to air. The speed difference between pneumatic and hydraulic actuators has been narrowed, as the stroking time of some pneumatic piston operators (particularly with dual pistons) is about 1 sec.

With the use of 100 PSIG (690 kPa) or higher air pressures, the piston actuator stiffness and stability have also improved and approach that of the hydraulic actuators. The stem forces provided by a pneumatic piston can equal or exceed those of the hydraulic cylinders, because the area of an oversized air piston can provide higher stem forces than a standard hydraulic actuator. For example, if the hydraulic cylinder area is one 50th of the air piston, while the air pressure is one 20th of the oil pressure, the stem force produced by the hydraulic actuator is actually less than that of the pneumatic actuator.

ROTARY VALVE ACTUATORS

When linear spring-and-diaphragm, piston, or cylinder actuators are used on rotary valves, their performance will not be linear unless a positioner is used (Figure 6.4u). By the addition of a positioner, one can guarantee that the ratio between a unit change in controller signal and the resulting rotation will be uniform. On the other hand, loose-fitting actuator lever and follower arms can still create dead play in the actuator, which will lower the responsiveness of the loop when the direction of change in the control signal reverses.

As can be seen in Figure 6.4v, the torques required to rotate ball, butterfly, or plug valves are not linear. These valves are usually used only for on/off applications. When considered for closed-loop throttling control, the nonlinear relationship between the air signal and the resulting rotation makes the use of a positioner essential.

Figure 6.4w shows the nonlinearity in the torque characteristics of double-acting and spring-loaded cylinder actuators.

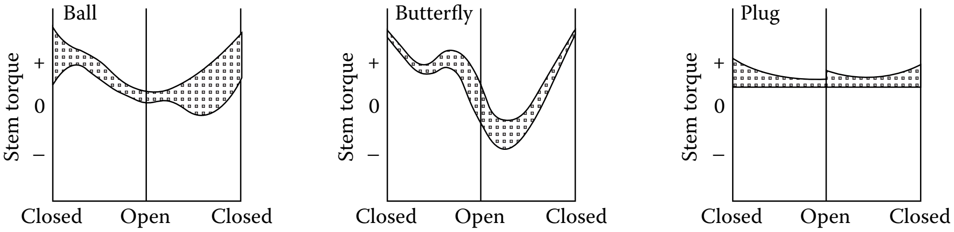

FIG. 6.4v
The torque characteristics of such rotary valves as ball, butterfly, and plug valves are not linear.

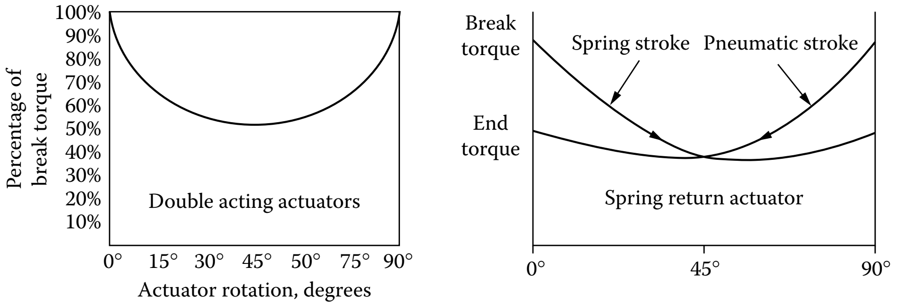

FIG. 6.4w
Torque characteristics of spring-return and double-acting cylinder actuators. (Courtesy of Rotork Controls Ltd.)

Naturally, the piston actuator should be so selected that its break torque exceeds the peak torque requirement of the valve, which occurs at the beginning and the end of the stroke (break torque).

The torque characteristics of the double-acting piston actuator of Figure 6.4x shows two maximums. One maximum occurs at the closed position and one near the 60–80° position, which corresponds to the peak of the dynamic torque for butterfly valves. Naturally, this actuator too should be so selected that its break torque exceeds the peak torque requirement of the valve, which occurs at the beginning (break torque) and near the end of the stroke.

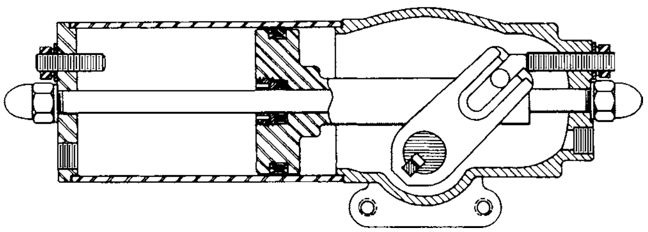

FIG. 6.4y
Pneumatic cylinder actuator with Scotch yoke.

Cylinder Type

Increased use of ball and butterfly valves or plug cocks for control has bred a variety of actuators and applications of existing actuators for powering these designs.

Positioning a quarter-turn valve with a linear output actuator using a lever arm on the valve resolves itself into a problem of mounting and linkages. The actuator can be stationary, with a bushing to restrain lateral movement of the stem. This requires a joint between the stem and a link pinned to the lever arm. The actuator can be mounted on a gimbal mechanism to allow required movement. The actuator can be hinged to allow free rotation to allow for the arc of the lever arm.

Various Scotch yoke designs, such as the one shown in Figure 6.4y, can be used with one, two, or four cylinders. Use of rollers in the slot of the lever arm utilizes the length of the lever arm of the valve opening or closing points.

A rack and pinion can be housed with the pinion on the valve shaft and the rack positioned by almost any linear valve actuator. The rack (Figure 6.4z) can be carried by a double-ended piston or by two separate pistons (Figure 6.4aa) in the same cylinder, where they move toward each other for counterclockwise rotation and away from each other for clockwise rotation.

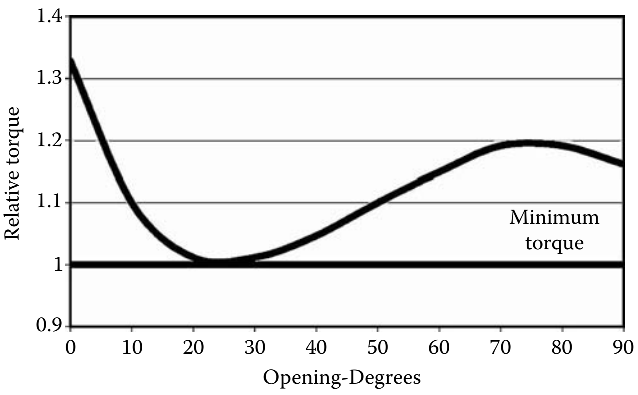

FIG. 6.4x

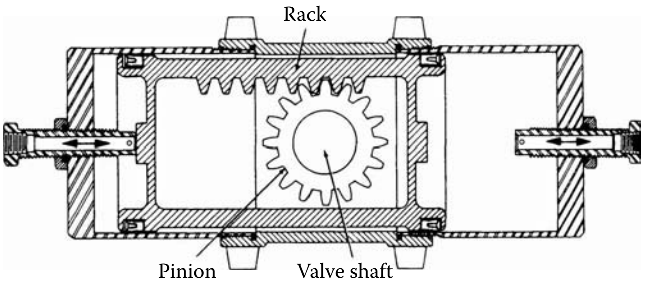

FIG. 6.4z
Rack and pinion actuator with dual-acting cylinder.

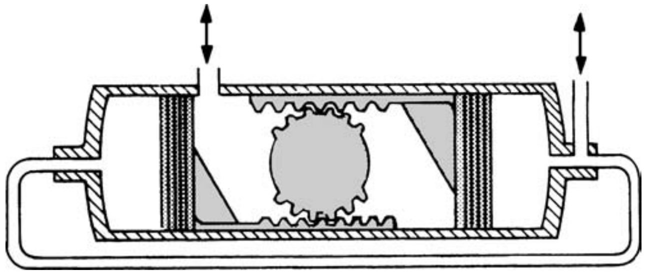

FIG. 6.4aa
Rack and pinion actuator operated by two separate pistons.

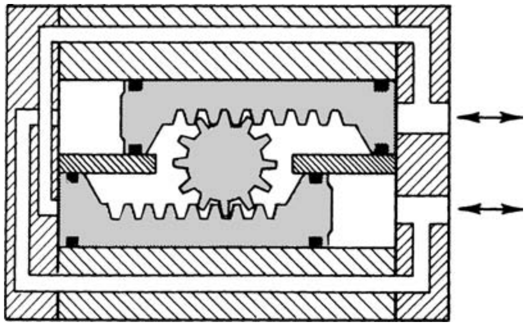

FIG. 6.4bb
Rack and pinion actuator operated by two parallel pistons.

Similar action is obtained (Figure 6.4bb) by two parallel pistons in separate cylinder bores. Dual cylinders are used in high-pressure actuators used to rotate ball valves as large as 16 in. (400 mm) in less than 0.5 sec.

An actuator similar to the one shown in Figure 6.4cc can be spring-loaded for emergency or positioning operation.

On/off operation of cylinders for quarter-turn valves requires solenoid or pneumatic pilots to inject pneumatic or hydraulic pressure into the cylinders. Open or closed position must be set by stops that limit shaft rotation or piston travel. Thereby the valve rotation is stopped and held in position until reverse action is initiated. Positioning action requires a calibrated spring in the piston or diaphragm actuator, a valve positioner, or a positioning valve system that loads and unloads each end of the cylinder.

Rotation of the valve must be translated to the positioner by gears, direct connection, cam, or linkage. The valve positioner must be the type that includes the four-way valve. The positioning valve system can be a four-way valve with a positioner for use with a pneumatic controller. The piston is sometimes positioned by a servo-system consisting of a servovalve that accepts an electronic signal, a four-way valve to amplify and control the pressure to the cylinder, and a feedback signal from a potentiometer or LVDT.

An electrohydraulic power pack or pneumatic pressure source may be used to furnish pressure to a pair of cylinders, one for each direction of rotation, as shown in Figure 6.4dd.

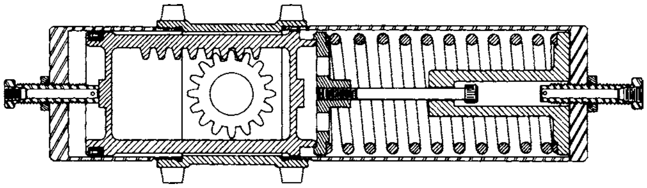

FIG. 6.4cc
Rack and pinion actuator with spring-loaded (fail-safe) cylinder.

Rotation by Spline or Helix

A multiple helical spline rotates through 90° as pressure below the piston (Figure 6.4ee) moves the assembly upward. A straight spline on the inside of this piston extension sleeve rotates the valve closure member through a mating spline. The cylinder is rated at 1500 PSIG (10 MPa). The actuator will rotate 1 in. (25 mm) and $1^1/_2$ in. (37.5 mm) valve stems. The mounting configuration is designed to adapt to many quarter-turn valves.

A nonrotating cylinder (Figure 6.4ff), with an internal helix to mate with a helix on a rotatable shaft, creates a form of rotating actuator. Hydraulic or pneumatic pressure in the drive end port (left) causes counterclockwise rotation; clockwise rotation is caused by pressure on the opposite side of the piston. There is a patented seal between the internal and the external bores of the cylinder and the external surface of the shaft. The unit is totally enclosed by seals to protect it from contaminated atmospheres. A hydraulic pump, reservoir, and necessary controls can be mounted integrally.

Vane Type

Injection of pressure on one side of a vane to obtain quarter-turn actuation is straightforward and obtainable with a minimum number of parts. A single vane (Figure 6.4gg) can be used for 400 to 30,000 in. lb_f (27 to 2060 N · m).

Units can be mounted together for double output, or a double-vane design (Figure 6.4hh) can also be used. The success of the vane actuator as a control device is dependent upon the control systems. By use of an auxiliary pneumatic pressure source, all types of fail-safe actions are possible, although not as positively as with spring loading. Use of line pressure to create hydraulic pressure on the vane is piloted by both manual and automatic methods. Use of a rotary potentiometer to sense position and complete a bridge circuit is necessary for proportional control.

Rotary Pneumatic Actuators

Pneumatic pressure is used to power a rotary motor to drive any of the large gear actuators. Control is by a four-way valve. The motor shown in Figure 6.4ii is running in one position. This will continue until the valve is repositioned or until a cam operates a shut-off valve at one end of the stroke. Reversal of the four-way valve causes reverse operation. An intermediate position causes the motor to stop. The four-way valve can be operated by pneumatic or electric actuators for remote automatic control. A position transmitter will allow adaptation to closed-loop proportional control.

OTHER PNEUMATIC ACTUATORS

Pneumohydraulic Actuators

An actuator with two double-acting cylinders uses an integrally designed pneumatic or electric powerpack (Figure 6.4jj). This has the advantage of furnishing a constant hydraulic pressure to the cylinders regardless of the power source to the prime mover. Few cylinder sizes are needed to cover a wide range of torque outputs. The prime movers are sized and selected to obtain the actuator speeds desired with the pneumatic pressures or electric voltages available. Multiple auxiliary switches, position transmitter, and positioning devices are adapted to the unit.

Gas pressure is used to create hydraulic pressure using two bottles (Figure 6.4kk). The stability of a hydraulically operated cylinder is utilized in this manner, using line gas pressure and the bottle size for amplification. The manual control valve can be replaced by a variety of electric or pneumatic pilot valves for automatic control. A hand pump is furnished that can take over the hydraulic operation in the absence of gas pressure or malfunction of the pilot controls. This self-sustaining approach to cylinder operation finds wide application for line break shut-off and for the various diverting and bypass operations of a compressor station.

A hydrostatic system consisting of a pneumatic prime mover (Figure 6.4ll) on the shaft of a hydraulic pump to run a hydraulic motor has interesting features. This actuator incorporates many of the features of other high-force geared actuators that rotate a drive sleeve. Torque control consists of a relief valve in the hydraulic line to the motor. This eliminates the reactive force of spring-loaded torque controls. Starting torque occurs

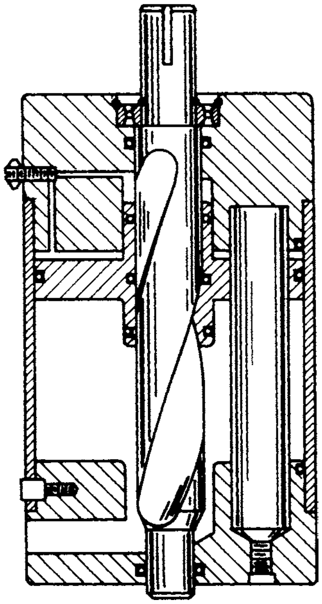

FIG. 6.4ee
Helical spline actuator.

because hydraulic slippage of the pump allows the motor to reach maximum speed.

Direction and deactivating control is attained with a four-way valve. As many as 16 auxiliary switches, settable at any position, are housed in the unit. Limit switches can be pneumatic or electric. A wide range of torque outputs and speeds is obtained by selection of prime mover, pump, and motor combinations. Initial success of the unit was partially due to its adaptability for retrofit to existing valves. The unit can be manually operated if required.

Electropneumatic Actuators

An actuator that defies classification, except that it is pneumatically powered and electrically controlled for proportional

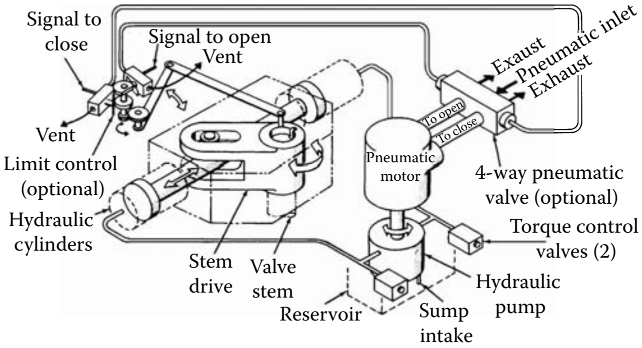

FIG. 6.4jj
Actuator with two double-acting cylinders and power pack.

application, is described at this point. Operation of a threaded drive sleeve occurs when spring-loaded pawls create a jogging action on a drive gear. Pressure introduced through one of the external lines selects the pawl to become active when the rocker arm is repetitively rocked by the pneumatic motor. A lead screw positions a sliding block to operate control switches, potentiometer, and position indicators. The lead screw is driven from a small spur gear and bevel gears.

Air is supplied from 60–140 PSIG (414–966 kPa) to give torque outputs up to 360 or 720 ft lb_f (25 or 50 Nm) using two actuators. Air consumption is from 0.75 SCF–1.70 SCF (0.021–0.048 m^3) per revolution at 140 PSIG (966 kPa). Maximum valve stem diameter that can be rotated is 2 in. (50 mm).

Numerous motivating combinations are used for control, including electropneumatic, electric, and fully pneumatic. A wide variety of components can be used to build up these systems, as shown in Figure 6.4mm.

RELIABILITY

Some of the reliability studies on the performance and reliability of pneumatically operated valves were done in the offshore oil industry[2] and in the power industry.[3,5] These studies did not evaluate only the actuator but the complete valve and actuator system combined.

The offshore study for pneumatically operated control valves was made in 1984 and reported the highest failure rate of 1 failure every 10,000 hours; or a little less than 1 failure per year. A 1990 study made for pneumatically operated control and on/off valves by the Institute of Nuclear Power Operation[4] (INPO) showed a failure rate of 116,000 hours.

In 1997 a summary on the reliability of air-operated valves by the electric power industry was published.[3] The sample consisted of 525 failures from 4,726 component years of operation. This would equate to a failure every 9 years or 79,000 hours of operation. The data covered all types of valves with both piston and diaphragm actuators from eight manufacturers. The study looked at what was called "high duty" (e.g., control valves) vs. "low duty" (e.g., shut-off valves) as well as the impact of intrusive maintenance. A summary of the results

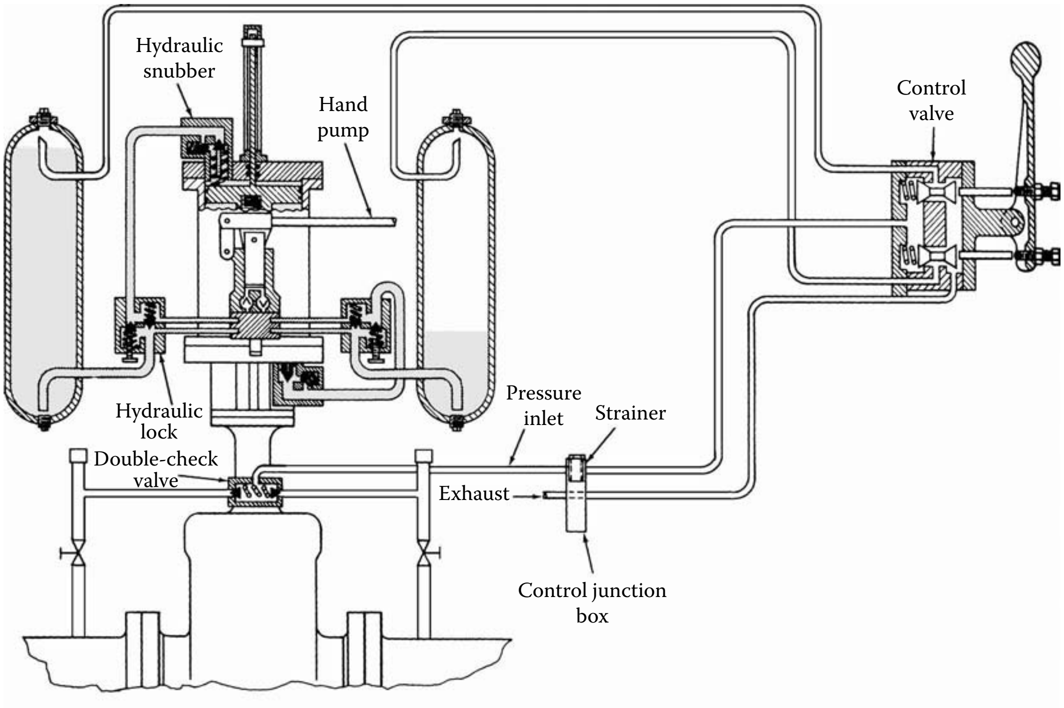

FIG. 6.4kk
Pneumohydraulic actuator powered by line pressure. (Courtesy of Shafer Value Co.)

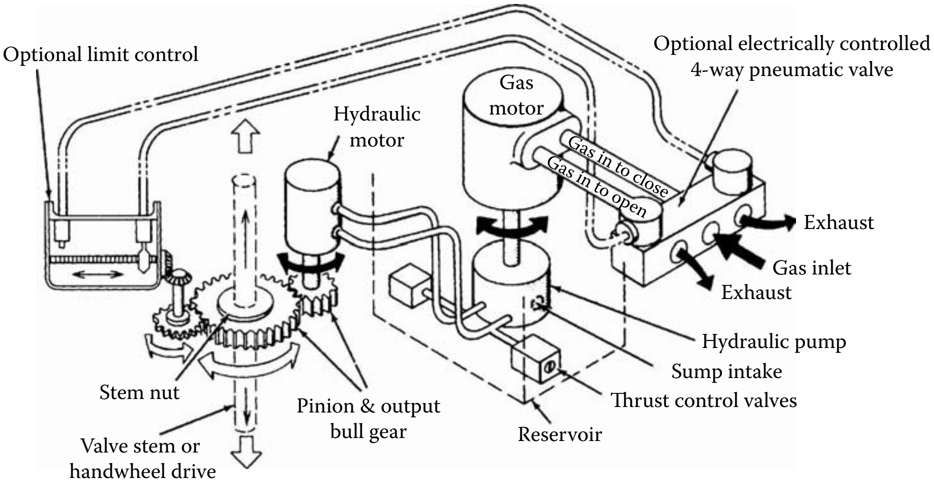

FIG. 6.4ll
Actuator system with pneumatically powered hydrostatic valve. (Courtesy of Ledeen Div. Textron.)

from this study is given below:

- High duty cycle valves exhibit up to 13 times lower reliability than low duty cycle valves.
- Intrusive preventive maintenance causes reliability to decrease by a factor of 6 times.
- The reliability of piston-type actuators was 4 times better than that of diaphragm-type actuators.
- The reliability of diaphragm-actuated valves was 6 times more likely to be impacted by duty cycle than were piston actuators.

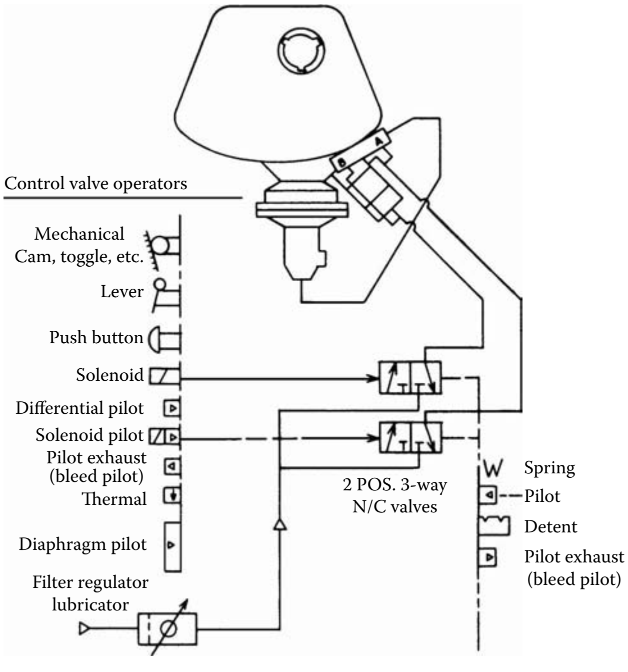

FIG. 6.4mm
Electropneumatic valve actuator. (Courtesy of OIC Corp.)

These results are a bit surprising because the common perception is that the diaphragm actuator is much more reliable that the piston actuator. It is also possible that by combining all types of valves (on/off and throttling) and by placing emphasis on duty cycle (opening and closing of the valves), the results of this evaluation would differ with one that evaluated only throttling control valves.

CONCLUSIONS

Before deciding on the type of control valve actuators to be used in a particular application, the reader is advised to also read Section 6.3, which discusses hydraulic, electric, and digital valve actuators, and to study Table 6.3a, which lists the advantages and disadvantages of electromechanical, electrohydraulic, and servo- or stepping-motor-operated electric actuators. Those who want to learn even more about the features and performance of available valve actuators are advised to study the test reports, books, and articles listed in the Bibliographies of both Sections 6.3 and 6.4.

As far as actuator trends are concerned, pneumatic actuators are still the technology favored by the users of valve actuators. Nevertheless, from 1998 to 2003, the market share of electric actuators increased from 11% to 45% and the market share of hydraulic and electrohydraulic actuators increased from near 0% to 28%. During the same period, use of solenoid valves has dropped by 42%.[6]

6.5 Advanced Stem Packing Designs

J. B. ARANT (2005)

Designs and Sizes:	Chevron or V-rings, and rectangular rings. All valve and stem sizes available commercially. Special packing can be designed for any and all rotary or linear valve sizes.
Design Pressures:	Up to 2500 PSIG ANSI
Design Temperatures:	–450 to 1000°F (–268 to 538°C), depending upon the materials of construction and configuration of the packing system, and valve design. Teflon with a cooling bonnet can be used up to 850°F (454°C).
Packing Materials:	Teflon®, Kalrez®, Zymaxx®, and Expanded Graphite®
Cost:	The costs of Teflon and Expanded Graphite packing sets and rings are moderate. The KVSP packing is more costly on first costs. However, they are more economical overall due to their greatly reduced maintenance needs, longevity, and overall performance, with regard to "fugitive emissions" and the resulting valve dynamics.
Partial List of Suppliers:	Teflon, Kalrez, Zymaxx, and KVSP are all registered trademarks of E.I. Du Pont Co. (now, Du Pont- Dow Elastomers); Expanded or Flexible Graphite is a registered trademark of Union Carbide Co.

INTRODUCTION

Similarly to most industrial products, control valve packing has also evolved over time. The two main requirements of control valve stem packing are that 1) it should seal the valve stem to eliminate or minimize leakage, and 2) it should not influence the performance or dynamics of the control valve.

The ability of a control valve to respond to small control signal changes without overshooting and cycling is inversely proportional to packing friction. Therefore, the ideal packing would be one that is as tight (as leakage free) as a bellows seal and yet completely friction free. Real packings do have some emissions (Figure 6.5g) and do have some friction. The lower the friction, the smaller the dead band (resolution) and the shorter the response time of the packing (Table 6.5h).

Prior to 1950, stem leakage was a constant problem with these older packing designs. Today, both of the above requirements can be met. Modern seals can be extremely tight, providing performance approaching that of a bellows seal, and they can also be low friction. This guarantees not only the good dynamic response of the control valve, but also low maintenance and a long service life.

Today's packing is no longer just a packing, but it is a well-engineered part of the control valve and its sealing systems. They can be installed to operate under wide temperature and pressure ranges. They can be used in applications involving temperatures from cryogenic to very high temperatures. They can also operate under process pressures from vacuum to several thousands of PSIG.

History

The early control valves were provided with only one type of packing, which consisted of braided asbestos rings. These rings were formulated with various braiding designs, utilizing various types of asbestos, binders, and lubricants. For control valves, the best versions were used, such as Blue African asbestos with premium binders and braid lubricants.

These rings were installed in a very smooth, finished well inside a valve bonnet. The valve stem was well polished. The valve bonnet was fitted with a lubricator assembly that included a shut-off isolation valve and a "ram screw." Depending on the process fluid, the appropriate choice of "grease sticks" was inserted and the lubricant was forced into the packing area by the ram. After this, the isolating valve was closed to prevent the pressurized process fluid from escaping.

By today's standards, this was system, yet it was very workable. All instrument maintenance mechanics, and many of the instrument engineers and supervisors, routinely carried

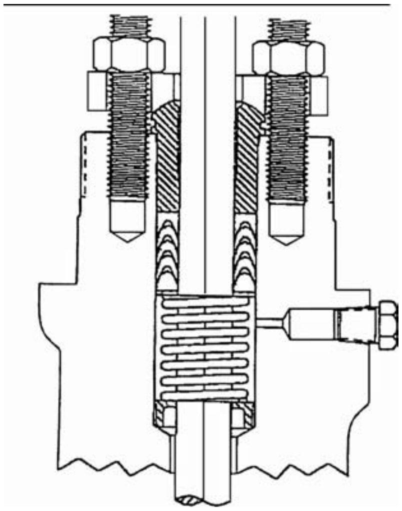

FIG. 6.5a
Valve stem packing made out of PTFE V-rings with internal coil spring located below the packing.

boxes of lubrication sticks in their pockets so as to be able to control stem leakage while guaranteeing a well-lubricated packing. It was a never-ending chore.

Teflon V-Rings In the mid- to late 1940s, the Du Pont Co. developed a fluorocarbon polymer, Teflon®, and it occurred to the control valve manufacturers that this material could be made into packing rings. These rings not only had the potential of providing a good seal, but were also inherently self-lubricating and resistant to essentially all process fluids. So the Teflon V-rings, or chevron rings, as they came to be known, were born (Figure 6.5a).

Because of its corrosion resistance to almost any process fluid, its self-lubrication, easy manufacturing via molding, and good temperature and pressure ratings, Teflon rapidly replaced asbestos as a packing material in many industries.

Essentially the only problem that arose was that this packing material was so "slick" and had such low friction that the control valve had a tendency to overshoot and oscillate at times. This was partially because these early valves were designed for use with the higher friction asbestos packing. The solution to this problem was to add some friction back into the Teflon packing. So, the packing gland was tightened a little, and the instrument mechanics learned when to do it.

Graphite Later, Union Carbide developed the Expanded Graphite®, or flexible carbon, materials that could be formed into shapes such as packing rings (Figure 6.5b). This increased the choice of packing.

Graphite can be used at higher operating pressures if the process fluids are the nonoxidizing-type fluids, although Teflon, by far, provided a superior control valve packing. Teflon could be used at temperatures up to 850°F, if the valve was provided with an extended cooling bonnet.

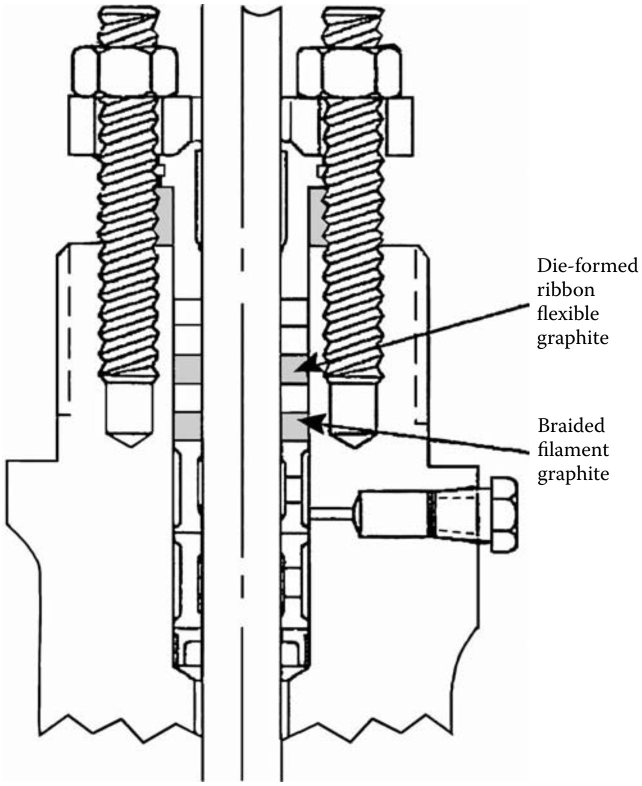

FIG. 6.5b
Graphite packing consisting of die-formed ribbons and braided filament graphite rings.

Graphite packing works very well with manually operated valves, but it gives poor performance on control valves, because it affects their dynamics and resolution. This happens because it tends to "plate out" on the valve stem. This further increases stem friction and necessitates increased loading of the packing in order to seal the stem. In addition, there can also be a fugitive emission problem with graphite packing.

The Enviro-Seal and the Dual Packing Another early development in the history of leak-resistant packing systems was one developed by Fisher Controls, using its Enviro-Seal® stem packing system (see Figures 6.5c and 6.5d).

While the development of the Enviro-Seal was a big step forward in valve stem sealing and in coping with leakage and fugitive emissions, it required about the same amount of packing seal maintenance as did the older packings. In addition its friction was much higher than that of Teflon, which negatively impacted its performance. This was reported in ISA (Instrumentation, Systems, and Automation Society) 75.25 Appendix A, which evaluated the link between packing friction and valve performance.

Nevertheless, the Enviro-Seal helped to "hold the fort" until better packing designs eventually came onto the marketplace.

Another interim and early improvement in the field of packing designs was the use of dual Teflon packing sets, with a lantern ring between the sets. The lantern ring could be

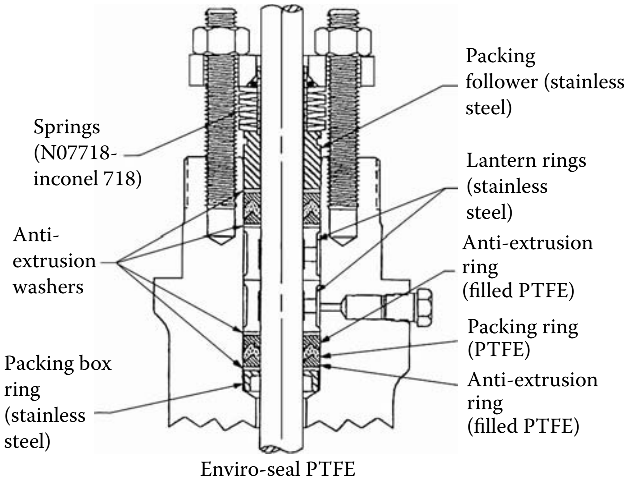

FIG. 6.5c
The Enviro-Seal was developed by Fisher Controls and included a PTFE packing ring and external Belleville disc springs.

used for sealing greases, or to allow piping to a leakage disposal system. While this design worked to some degree, it was also a somewhat clumsy and high maintenance system.

Industrial Practices In general, chemical and most other industries favored the Teflon packings, while the petroleum industry continued to favor asbestos and Expanded Graphite, because of their suitability for high-temperature and "fire safe" services, which are common in that industry. Their rationale was that "fire safety" should be their main concern, because they handled flammable fluids at high temperatures.

This logic was questionable, as the chemical industries also handled highly flammable fluids along with high temperatures and were just as vulnerable to fires. In the chemical industry a woven graphite ring was added at the top of the Teflon stack, with which these packings passed the API 607 valve fire test. With such packing designs, the chemical industry had years of experience with no particular problems.

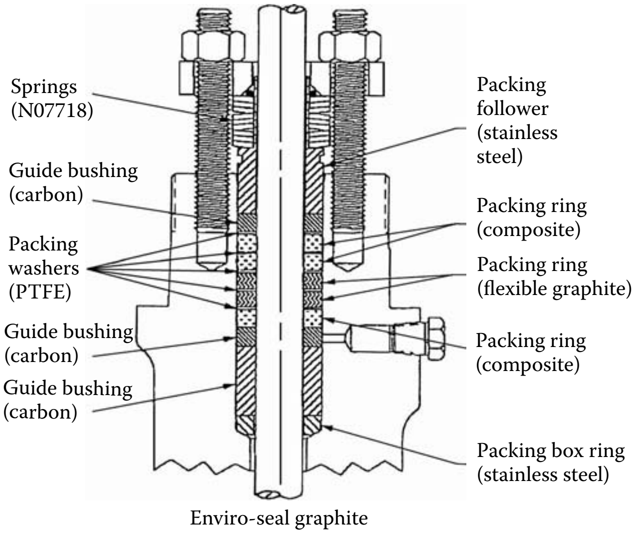

FIG. 6.5d
Fisher's Enviro-Seal provided with flexible graphite packing rings and external Belleville disc springs.

This difference in philosophies between the two industries persisted until recent years when the Federal Clean Air Act changed everything. Asbestos was phased out by the federal government as a "hazardous" material, and the petroleum industries were left with few packing options other than Expanded Graphite, plus some unsuccessful attempts at developing synthetic fibers as "asbestos substitutes."

Development of the KVSP Packing In the late 1980s, the Du Pont Co. and industry in general, came under pressure from the Federal Clean Air Act. The response was to again develop a new valve stem packing based on the use of forming chevron rings out of Kalrez®. This was a fluroelastomer material that had all of the corrosion-resistance properties of Teflon, plus a higher temperature rating along with the elastomeric characteristics. At that time, the primary use of Kalrez was in O-rings and other sealing shapes.

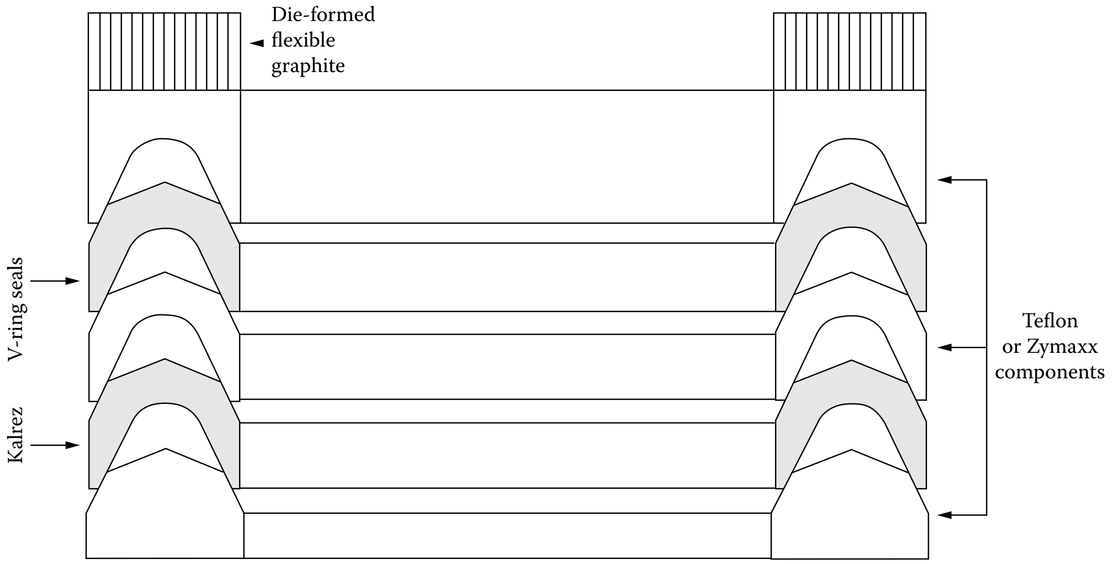
During these years, because of air pollution concerns, the federal government was trying to eliminate or to minimize more of the "fugitive emissions" from valve and pipe joint seals. Therefore, extensive tests were conducted and it was found that Kalrez Valve Stem Packing (KVSP), this new valve stem packing, did an excellent job in reducing emissions far below the levels of the federal and state (California) clean air standards. According to the testing per the Instrumentation, Systems, and Automation Society 75.25.01 and 75.25.02 KVSP performed essentially as well as Teflon. Thus was born the KVSP (Figure 6.5e).

After very extensive testing, using helium to simulate the most severe process plant leakage conditions, both the process industries and the control valve manufacturers started to use KVSP packing as a premium packing for solving their valve stem fugitive emission problems while still maintaining the dynamic response of Teflon packing. By replacing non-Teflon valve stem packing with KVSP, process plants and even California refineries in populated areas were able to meet EPA and Federal Clean Air Act fugitive emission standards.

Figure 6.5f illustrates the improvement that KVSP represents in terms of packing friction relative to graphite. As can be seen from the figure, the variability has been more than cut in half by using KVSP.

Further testing, development, and field experience with the KVSP packing led to the "fire-safe" design, per the API 607 Standard, in addition to the high-temperature (KVSP 500) and the creep- and extrusion-resistant (KVSP 400/500) variations. Specific combinations of Kalrez, Teflon, Zymaxx® (a high strength Teflon composite reinforced with long carbon fiber structural composites), and expanded woven graphite rings provided the solutions to many specific applications.

While Teflon and Expanded Graphite rings are still extensively used for control valve packing, KVSP packing is making



• KVSP 400 Series	Kalrez/Teflon
• KVSP 500 Series	Kalrez/Zymaxx
• KVSP Fire-Safe	Kalrez/Zymaxx/graphite

Note: consists of Kalrez and Teflon PTFE/Zymaxx
Maximum continuous temperature use 204°C (400°F)/288°C (550°F)

FIG. 6.5e
The KVSP packing system consists of Teflon or Zymaxx components and Kalrez V-ring seals below a flexible graphite ring.

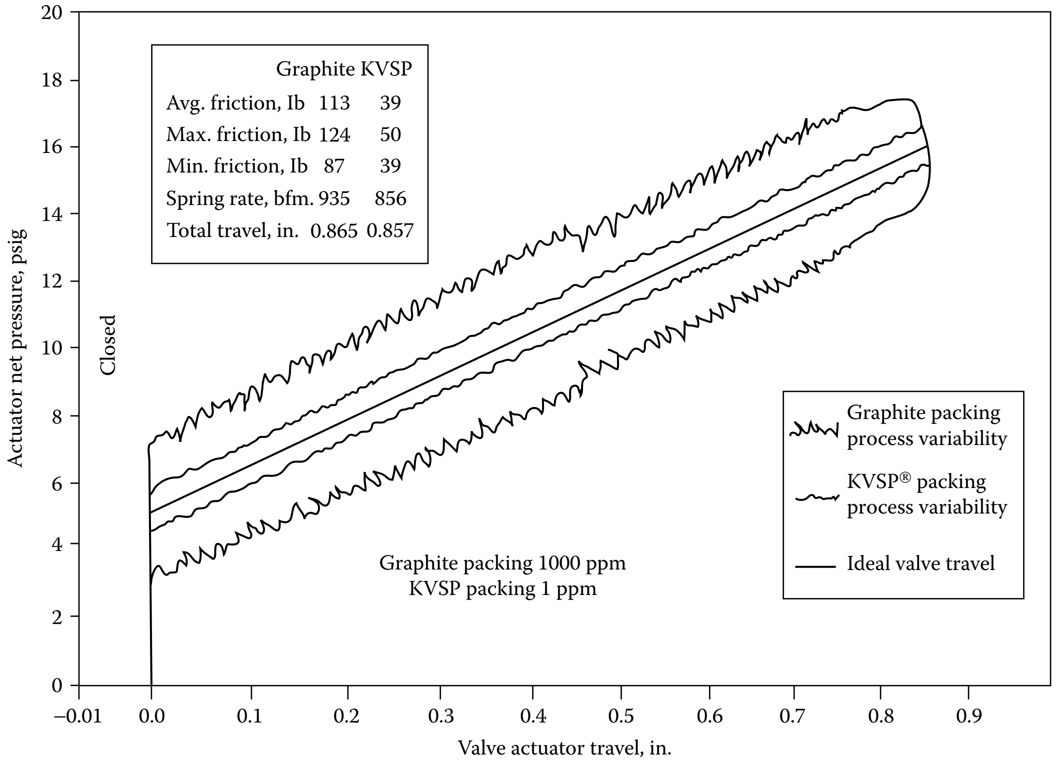


FIG. 6.5f
In addition to better controlling fugitive emissions, KVSP also reduces the packing friction effects on process control (variability). The curves compare the variability of the valve travel in response to increasing actuator pressure, when graphite and KVSP packing is used.

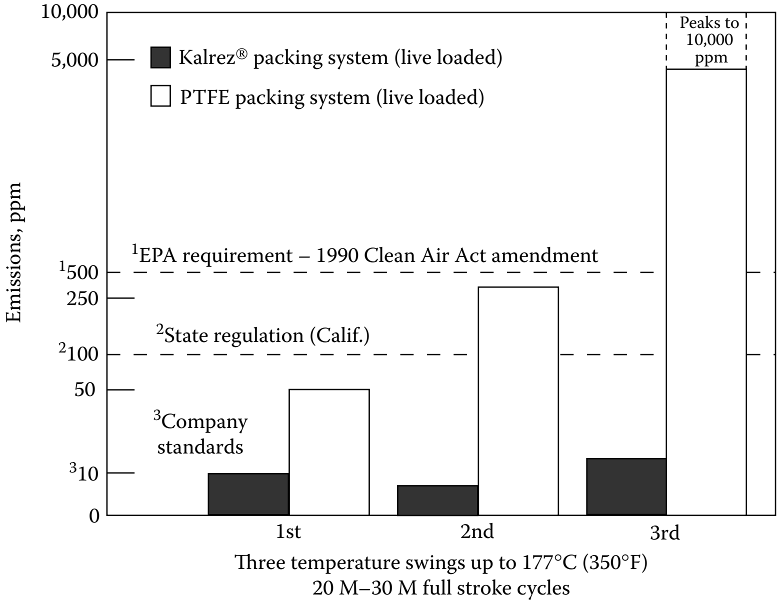

FIG. 6.5g
Emissions caused by creep and cold flow during temperature swings are much reduced when Kalrez packing is used instead of PTFE. These emissions satisfy both EPA's Clean Air Act and the California state regulations.

rapid inroads in many areas due to its superior capabilities and lower overall "ownership costs." One could say that KVSP is the nearest thing to a "universal" valve stem packing material today.

This packing works well on both linear and on rotary stem control valves, and is suitable to practically all process fluids. Some users have adopted it as their primary packing, which is used in all applications except for the more benign and innocuous ones such as water, where Teflon is more economical. Field retrofitting kits are available for valves to upgrade spring-loaded Teflon packings in existing valves with KVSP.

KVSP® Performance The major attributes of this packing, patented by Du Pont-Dow Elastomers, are as follows:

- When using it, the emissions are not measurable and exceed both the federal and California State Clean Air emission standards.
- Its resistance to HAPS and toxins is equivalent to that of Teflon.
- Its leakage containment is almost as good as that of a bellows.
- Its packing friction is very low.
- Its dynamic response is equivalent to that of Teflon.
- Its process variability of 0.1% is also equivalent to that of Teflon.
- When using it, the plant yield and throughput increases, because it has as little impact on process control dynamics and resolution as does Teflon.

A major performance advantage of KVSP over Teflon is that it is far less sensitive to leakage caused by thermal cycling at high temperatures. Figure 6.5g shows the emissions resulting from temperature swings when using KVSP and Teflon. It can be noted that because of creep and cold flow, the emissions using KVSP (Kalrez) are much reduced.

Table 6.5h provides a summary of the performance testing results that was published in Instrumentation, Systems, and Automation Society 75.25. From the table one can see that the ability of a control system to respond to small control signal changes is inversely proportional to packing friction, and the lower it is, the better control dynamics can be expected. This is because with lower packing friction, the valve's step response is faster and its dead band (resolution) is smaller.

Kalrez and PTFE V-rings are effective not only on control valves, but also for the stem packing of automatic on/off and manual valves, if fugitive emissions are to be minimized. As

TABLE 6.5h
Performance of Leading Packing Designs

Packing Type	*Dead Band or Resolution*	*Step Response Time*
Fisher's Graphite Enviro-Seal	0.6–1.2%	0.5–7.7 sec
Fisher's PTFE Enviro-Seal	0.2–0.4%	0.5–4.4 sec
PTFE V-Packing	0.0–0.1%	0.5–4.4 sec
KVSP Packing	0.1–0.2%	0.4–2.9 sec

Data Based on ISA 75.25 Control Valve Performance Testing Summary to the number of packing rings, five-ring packing sets are the norm. Three-ring packing can be used in many rotary stem valve applications, because the rotary stem movement is easier to seal against leakage than are the linear stems. Yet, for reasons of convenience and standardization, the five-ring design is the most often used.

6.6 Capacity Testing

(Copyright ISA 1996, reprinted with permission of ISA, The Instrumentation, Systems, and Automation Society. Standard formatted for publication in this handbook by A. Bálint, 2005)

INTRODUCTION

The "Control Valve Capacity Test Procedure" is covered by Instrumentation, Systems, and Automation Society's (ISA's) Standard S75.02-1996. The international equivalent of these U.S. standards are IEC 60534-2-1, "Industrial Process Control Valves, Part 2-1: Flow Capacity Sizing Equations for Fluid Flow under Installed Conditions," and IEC 60534-2-3, "Industrial Process Control Valves, Part 2-3, Flow Capacity Test Procedure." The equations in the international editions are essentially equivalent to those in the U.S. standards, with the exceptions of using metric units.

A revision of the ISA standard is anticipated in the near future, and for this reason only the front part of S75.02-1996 is reprinted below. The reader is advised to refer the revised standard (when published) for the test procedures and calculations. Meanwhile, Section 6.15 can be used for all valve sizing applications, while Section 6.14 provides all the information needed for valve noise calculations.

The reader should also note that in the ISA test procedure the pressure taps are not located at the in- and outlets of the control valve, but two pipe diameters upstream and six pipe diameters downstream. Therefore, the pressure differential measured during the test is the sum of the valve pressure drop (ΔP_v) and the drop through eight pipe diameters' length of straight piping (ΔP_p). This can introduce errors, if the pressure drop in the pipe exceeds 5–10% ($\Delta P_p / (\Delta P_p + \Delta P_v) > 0.1$).

This section is reprinted from "Control Valve Capacity Test Procedure," ANSI/ISA-S75.02-1996, with permission of the copyright holder, ISA, The Instrumentation, Systems, and Automation Society, 67 Alexander Drive, P.O. Box 12277, Research Triangle Park, NC 27709.

1. SCOPE

This test standard utilizes the mathematical equations outlined in ANSI/ISA-S75.01, "Flow Equations for Sizing Control Valves," in providing a test procedure for obtaining the following:

a. Valve flow coefficient, C_v
b. Liquid pressure recovery factors, F_L and F_{LF}
c. Reynolds number factor, F_R
d. Liquid critical pressure ratio factor, F_F
e. Piping geometry factor, F_P
f. Pressure drop ratio factor, X_T and X_{TP}

This standard is intended for control valves used in flow control of process fluids and is not intended to apply to fluid power components as defined in the National Fluid Power Association (NFPA) Standard T.3.5.28-1977.

2. PURPOSE

The purpose of this standard is to provide a procedure for testing control valve capacity and related flow coefficients for both compressible and incompressible fluids. This standard also provides a procedure to evaluate the major data.

3. NOMENCLATURE

(For the actual control valve sizing equations for both compressible and incompressible fluids, the reader should refer to Section 6.15)

4. TEST SYSTEM

4.1 General Description

A basic flow test system as shown in Figure 6.6a includes

a. Test specimen
b. Test section
c. Throttling valves
d. Flow-measuring device
e. Pressure taps
f. Temperature sensor

4.2 Test Specimen

The test specimen is any valve or combination of valve, pipe reducer, and expander or other devices attached to the valve body for which test data are required (Figure 6.6a). Modeling of valves to a smaller scale is an acceptable practice in this standard, although testing of full-size valves or models is preferable. Good practice in modeling requires attention to significant relationships such as Reynolds number, the Mach number where compressibility is important, and geometric similarity.

Symbol	*Description*
C_v	Valve flow coefficient
d	Value inlet diameter
D	Internal diameter of the pipe
F_d	Valve style modifier
F_F	Liquid critical pressure ratio factor, dimensionless
F_k	Ratio of specific heats factor, dimensionless
F_L	Liquid pressure recovery factor of a valve without attached fittings, dimensionless
F_{LP}	Product of the liquid pressure recovery factor of a valve with attached fittings (no symbol has been identified) and the piping geometry factor, dimensionless
F_P	Piping geometry factor, dimensionless
F_R	Reynolds number factor, dimensionless
G_f	Liquid specific gravity at upstream conditions (ratio of density of liquid at flowing temperature to density of water at 15.6°C [60°F]), dimensionless
G_g	Gas specific gravity (ratio of flowing gas to density of air with both at standard conditions, which is equal to the ratio of the molecular weight of gas to the molecular weight of air), dimensionless
K	Ratio of specific heats, dimensionless
m	The number of similar flow paths (i.e., $m = 1$ for single-ported valves, $m = 2$ for double-ported, etc.)
N_1, N_2, etc.	Numerical constants for units of measurement used
p_1	Upstream absolute static pressure, measured two nominal pipe diameters upstream of valve-fitting assembly
p_2	Downstream absolute static pressure, measured six nominal pipe diameters downstream of valve-fitting assembly
Δp	Pressure differential, $p_1 - p_2$
p_v	Absolute vapor pressure of liquid at inlet temperature
q	Volumetric flow rate
$q_{\max}$	Maximum flow rate (choked flow conditions) at a given upstream condition
Re_v	Valve Reynolds number, dimensionless
T_1	Absolute upstream temperature (in K or degrees R)
x	Ratio of pressure drop to absolute inlet pressure ($\Delta p/p_1$), dimensionless
x_T	Pressure drop ratio factor of the valve without attached fittings, dimensionless
x_{TP}	Value of x_T for valve-fitting assembly, dimensionless
Y	Expansion factor, ratio of flow coefficient for a gas to that for a liquid at the same Reynolds number, dimensionless
ν(nu)	Kinematic viscosity, centistokes

Subscripts:

1. Upstream conditions
2. Downstream conditions

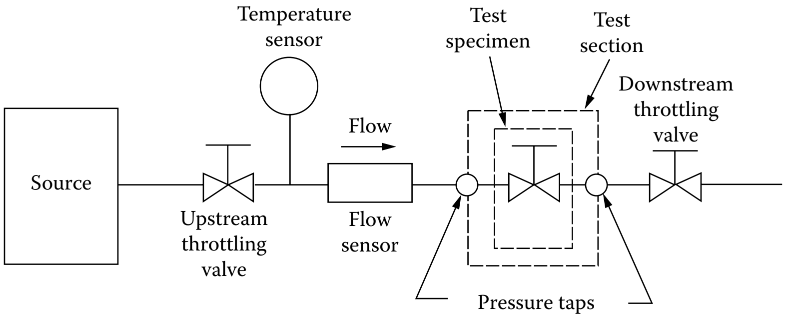

FIG. 6.6a
Basic flow test system.

TABLE 6.6b
Piping Requirements, Standard Test Section

A and ***	*B*	*C*	*D*	*Standard Test Section Configuration*
At least 18 nominal pipe diameters of straight pipe	2 nominal pipe diameters of straight pipe	6 nominal pipe diameters of straight pipe	At least 1 nominal pipe diameter of straight pipe	
*Dimension "A" may be reduced to 8 nominal diameters if straightening vanes are used. Information concerning the design of straightening vanes can be found in "ASME Performance Test Code PTC 19.5-1972, Applications, Part II of Fluid Meters, Interim Supplement on Instruments and Apparatus."

**If an upstream flow disturbance consists of two ells in series and they are in different planes Dimension "A" must exceed 18 nominal pipe diameters unless straightening vanes are used.

***See Section 4.2 for definition of the test specimen.

4.3 Test Section

The upstream and downstream piping adjacent to the test specimen shall conform to the nominal size of the test specimen connection and to the length requirements of Table 6.6b.

The piping on both sides of the test specimen shall be Schedule 40 pipe for valves through 250 mm (10 in.) size having a pressure rating up to and including ANSI Class 600. Pipe having 10 mm (0.375 in.) wall may be used for 300 mm (12 in.) through 600 mm (24 in.) sizes. An effort should be made to match the inside diameter at the inlet and outlet of the test specimen with the inside diameter of the adjacent piping for valves outside the above limits.

The inside surfaces shall be reasonably free of flaking rust or mill scale and without irregularities that could cause excessive fluid frictional losses.

4.4 Throttling Valves

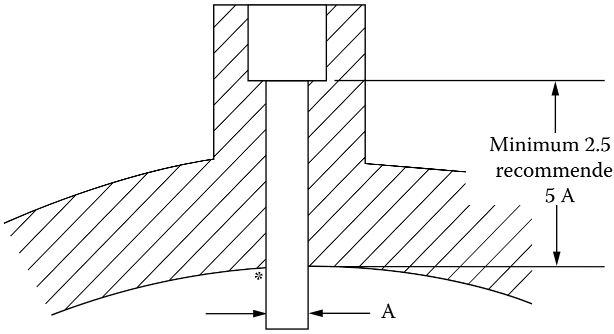
The upstream and downstream throttling valves are used to control the pressure differential across the test section pressure taps and to maintain a specific downstream pressure. There are no restrictions as to style of these valves. However, the downstream valve should be of sufficient capacity to ensure that choked flow can be achieved at the test specimen for both compressible and incompressible flow. Vaporization at the upstream valve must be avoided when testing with liquids.

4.5 Flow Measurement

The flow-measuring instrument may be any device that meets specified accuracy. This instrument will be used to determine the true time average flow rate within an error not exceeding ±2% of the actual value. The resolution and repeatability of the instrument shall be within ±0.5%. The measuring instrument shall be calibrated as frequently as necessary to maintain specified accuracy.

4.6 Pressure Taps

Pressure taps shall be provided on the test section piping in accordance with the requirements listed in Table 6.6b. These pressure taps shall conform to the construction illustrated in Figure 6.6c.



Size of pipe	A Not exceeding	A Not less than
Less than 50 mm (2 in.)	6 mm (1/4 in.)	3 mm (1/8 in.)
50 mm to 75 mm (2 to 3 in)	9 mm (3/8 in.)	3 mm (1/8 in.)
100 mm to 200 mm (4 to 8 in.)	13 mm (1/2 in.)	3 mm (1/8 in.)
250 mm and greater (10 in. and greater)	19 mm (3/4 in.)	3 mm (1/8 in.)

FIG. 6.6c
Recommended pressure connection.

* Edge of hole must be clean and sharp or slightly rounded, free from burrs, wire edges or other irregularities. In no case shall any fitting protrude inside the pipe. Any suitable method of making the physical connection is acceptable if above recommendations are adhered to. Reference: "ASME Performance Test Code PTC 19.5-1972. Applications, Part II of Fluid Meters, Interim Supplement on Instruments and Apparatus."

Orientation:

Incompressible fluids—Tap center lines shall be located horizontally to reduce the possibility of air entrapment or dirt collection in the pressure taps.

Compressible fluids—Tap center lines shall be oriented horizontally or vertically above pipe to reduce the possibility of dirt or condensate entrapment.

Multiple pressure taps can be used on each test section for averaging pressure measurements. Each tap must conform to the requirements in Figure 6.6c.

4.7 Pressure Measurement

All pressure and pressure differential measurements shall be made to an error not exceeding ±2% of actual value. Pressure-measuring devices shall be calibrated as frequently as necessary to maintain specified accuracy.

Pressure differential instruments are required in the measurement of the pressure differential across the test specimen to avoid additional inaccuracies resulting from taking the difference of two measurements. Exceptions to this are the procedures in Sections 6.2 and 8.2 for determining maximum flow rates for incompressible and compressible flow, respectively. (These sections are not included here, the reader is referred to ANSI/ISA-75.02-1996 for guidance in these procedures.)

4.8 Temperature Measurement

The fluid temperature shall be measured to an error not exceeding ±1°C (±2°F) of actual value.

The inlet fluid temperature shall remain constant within ±3°C (±5°F) during the test run to record data for each specific test point.

4.9 Installation of Test Specimen

The alignment between the centerline of the test section piping and the centerline of the inlet and outlet of the test specimen shall be as listed in Table 6.6d below:

When rotary valves are being tested, the valve shafts shall be aligned with test section pressure taps.

Each gasket shall be positioned so that it does not protrude in the flow stream.

4.10 Accuracy of Test

Valves having an N_3C_v/d^2 ratio of less than 30 will have a calculated flow coefficient, C_v, of the test specimen within a tolerance of ±5%.

TABLE 6.6d
Allowable Misalignment between the Centerlines of the Test Specimen and of the Test Section Piping

Pipe Size	*Allowable Misalignment*
15–25 mm	0.8 mm
($^1/_2$–1 in.)	($^1/_{32}$ in.)
32–150 mm	1.6 mm
($1^1/_4$–6 in.)	($^1/_{16}$ in.)
200 mm and larger 8 in. and larger)	1% of the diameter

5. TEST FLUIDS

5.1 Incompressible Fluids

Fresh water shall be the basic fluid used in this procedure. Inhibitors may be used to prevent or retard corrosion and to prevent the growth of organic matter. The effect of additives on density or viscosity shall be evaluated by computation using the equations in this standard. The sizing coefficient shall not be affected by more than 0.1%. Other test fluids may be required for obtaining F_R and F_F.

5.2 Compressible Fluids

Air or some other compressible fluid shall be used as the basic fluid in this test procedure. Vapors that may approach their condensation points at the vena contracta of the specimen are not acceptable as test fluids. Care shall be taken to avoid internal icing during the test.

SUMMARY

The international equivalent of this U.S. standard are IEC 60534-2-1, "Industrial Process Control Valves, Part 2-1: "Flow Capacity Sizing Equations for Fluid Flow under Installed Conditions," and IEC 60534-2-3, "Industrial Process Control Valves, Part 2-3, Flow Capacity Test Procedure."

A revision of the Instrumentation, Systems, and Automation Society standard is anticipated in the near future, and for this reason only the first five sections of S75.02-1996 were presented here. The reader is advised to refer the revised ANSI/ISA-75.02-1996 standard (when published) for Sections 6 to 10 for the test procedures and calculations. Meanwhile, Section 6.15 can be used for all valve sizing applications, while Section 6.14 provides all the information needed for valve noise calculations.

6.7 Characteristics and Rangeability

B. G. LIPTÁK (1995, 2005) **A. BÁLINT** (2005)

INTRODUCTION

The characteristics, gains, and rangeabilities of control valves are interrelated. The process control engineer should clearly understand these terms, because they describe the personality of the valve and as such play an important role in the closed-loop performance of the loop.

This section begins with a brief discussion of valve gains, followed by an explanation of the difference between theoretical and actual (installed) valve characteristics. The section ends with an explanation of valve rangeability.

VALVE GAIN AND LOOP GAIN

The gain of any device is its output divided by its input. For a linear (constant gain) valve, the valve gain (G_v) is the maximum flow divided by the valve stroke in percentage (Fmax/100%).

When a loop is tuned to provide quarter amplitude damping (Figure 6.7a), the controller gain (G_c = 100/%PB) is adjusted until the overall loop gain (the product of the gains of all the loop components) reaches 0.5. If a linear controller and a linear transmitter are used, their gains are constant. Therefore, if the process gain (G_p) is also constant, a linear (G_v = constant) valve is needed to keep the loop gain product constant at 0.5.

If the transmitter is nonlinear, such as a d/p cell without square root extraction, the transmitter gain will rise in proportion to flow, and therefore the loop will be unstable at high flows and sluggish at low flows. The usual solution is to install a square root extractor, which makes the transmitter linear (G_t = constant) with flow. One can also correct for the nonlinearity of the transmitter by using a nonlinear controller or a valve whose gain drops with flow (quick opening).

Nonlinear Processes

If the process is nonlinear (G_p varies with load) while the other loop gains are constant, a change in load will result in the loop gain's shifting away from 0.5. Therefore, if the total gain rises, the loop will become unstable; if it drops, the loop will become sluggish. Therefore, if the process gain changes with load (a nonlinear process), the loop can remain stable only if another gain component of the loop is also changing, and if that change is the inverse of the gain change of the process.

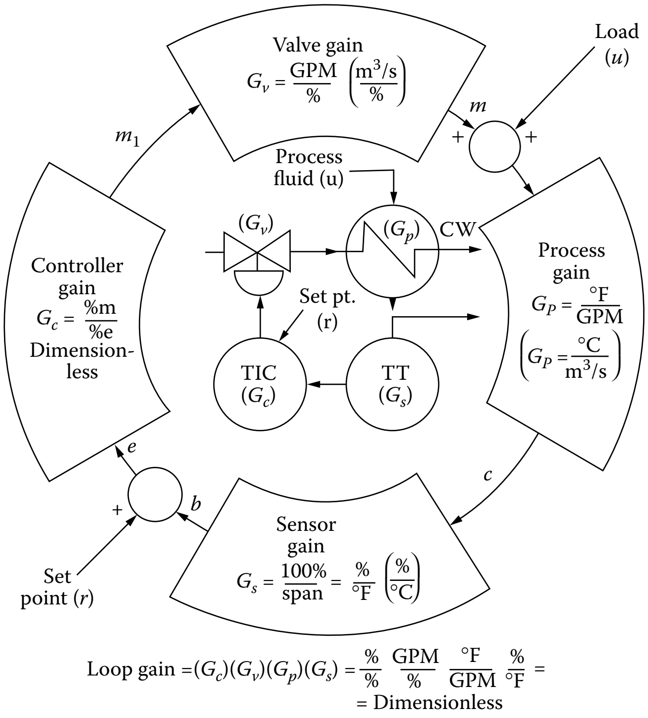


FIG. 6.7a
The loop gain is the product of the gains of the loop component. In a properly tuned loop (decay ratio of $^1/_4$), this gain product should be constant at 0.5.

Therefore, as the process gain (G_p) drops, this other gain must be rising, thereby keeping the loop gain constant at around 0.5. This other gain can either be the gain of the controller (G_c) or that of the control valve (G_v).

If the controller gain varies with load, the controller is called a nonlinear controller. When the control valve gain varies with load (flow), it is named according to the type of nonlinearity that exists between the flow through the valve and the valve stroke.

If, as the flow is increasing, the valve gain is also rising and that rate of rise is a constant rate with flow, the valve characteristic is called equal-percentage. If the valve gain is increasing at a variable rate with flow, it is named in accordance with the type of nonlinearity it provides (parabolic, hyperbolic, and so on). If the valve gain is dropping when the flow increases, it is called a quick-opening valve.

Some processes, such as the pH process, are highly nonlinear. In such applications as pH control, the variation in the process gain (G_p) is compensated by an inverse variation in the controller gain (G_c), which is selected to drop when G_p rises. Therefore, the controller of a pH process is a nonlinear controller.

In heat transfer processes, because the heat transfer area is constant, its efficiency of heat transfer drops as the load (the amount of heat to be transferred across that fixed area) rises. Therefore the process gain (G_p) drops with the heat load. To compensate for this drop, the valve gain (G_v) must rise with the load. Such a valve is called an equal-percentage valve, which should be the valve characteristic selected for all temperature control valve applications.

Installed Valve Gain

As will be discussed in more detail later, the inherent valve gain changes after the installation of the valve, if the valve pressure differential varies with load. This is the case in all mostly friction pumping systems, because as the load (flow) rises, the pressure drop in the piping system also increases, which leaves less pressure drop for the valve.

As the valve differential pressure drops with increasing flow rate, the valve gain (G_v) also drops. This tends to shift the installed gain of equal-percentage valves towards linear and the installed gain of linear valves towards quick opening. Therefore, on mostly friction pumping systems (Figure 6.1c), if it is desired to keep the valve gain relatively constant (linear characteristics), it is recommended to install an equal-percentage control valve.

An even more effective method of keeping the valve gain (G_v) constant is to replace the valve with a linear control loop (Figure 6.1h). The disadvantage of this cascade configuration (in addition to the higher cost) is that this will degrade the control quality if the controlled process is fast, because in each cascade system, the gain of the outer loop must be smaller than that of the inner loop. This will necessitate the detuning (lowering the gain, increasing the proportional band) of the master controller (outer loop), which generates the set point for the flow controller (FC) in Figure 6.1h.

THEORETICAL VALVE CHARACTERISTICS

Valve Testing

The standard methods of testing the capacity of valves are discussed in Section 6.6. It should be noted that the goal of this test is only to determine the valve C_v (K_v) within an error of 5%. What is important to note is that the valve characteristics (G_v characteristics) are neither tested nor defined by the standard.

It should also be noted that during the testing, the pressure drop through the valve itself is not measured, because the ΔP is detected across a pipe section, which includes the valve, plus a length of eight pipe diameters of straight pipe (Section 6.6).

The end result of such a test is a valve characteristic curve, which describes the flow through the valve as it is stroked from 0 to 100% of its stroke. The C_v (K_v) data provided by manufacturers is usually reliable within an error of about 10%, if the installation is identical to the test setup (usually it is not).

Valve Characteristics

The inherent characteristics of a control valve describes the relationship between the controller output signal received by the valve actuator and the flow through that valve, assuming that:

1. The actuator is linear (valve travel is proportional with controller output).
2. The pressure difference across the valve is constant.
3. The process fluid is not flashing, cavitating, or approaching sonic velocity (choked flow).

Some of the widely used inherent lift to flow rate relationships are illustrated in Figure 6.7b. For example, in a linear valve, travel is linearly proportional to capacity and therefore the theoretical gain is constant at all loads. (The actual gain is shown in Figure 6.7e.)

In equal-percentage valves, a unit change in lift will result in a change in flow rate, which is a fixed percentage of the flow rate at that lift. For example, in Figure 6.7b, each percentage increase in lift will increase the previous flow rate by about 3%. Therefore, the theoretical gain of equal-percentage valves is directly proportional to flow rate (actual gain shown in Figure 6.7e) and increases as the flow rate increases. On a logarithmic chart (left side of Figure 6.7b), the equal-percentage characteristics correspond to a straight line having a slope that corresponds to its fixed percentage.

In quick-opening valves, the gain decreases with increasing flow rates. Figure 6.7b shows the quick-opening valve characteristics with the same total lift as for the other plug types. If the travel of the quick-opening plug is restricted so that the distance of 100% lift travel corresponds to only $^1/_4$ of the seat diameter, then the valve characteristics will approach linear (if the hydraulic resistance is constant) with the gain being nearly constant.

Valve and Process Characteristics

Control loops are usually tuned at normal load levels (at normal flow rates through the control valve), and it is assumed that the total loop gain will not vary with process load. This assumption is seldom completely valid, because the process gain usually does change with load. Because one

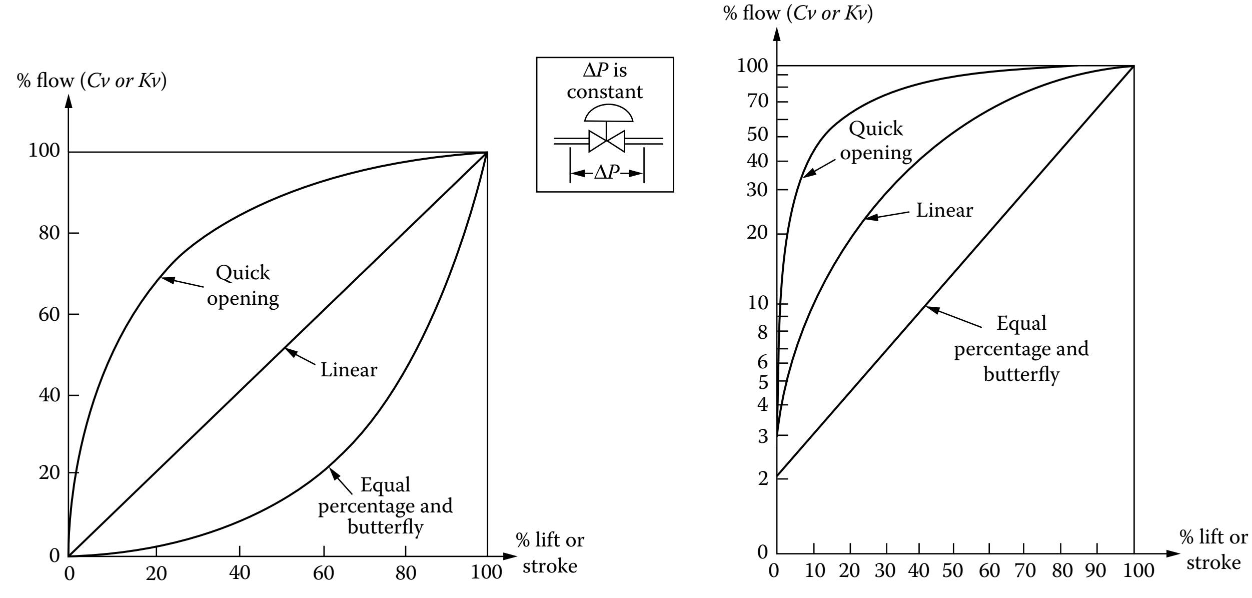

FIG. 6.7b
Inherent flow characteristics of quick-opening, linear, and equal-percentage control valves.

cannot afford to retune the controller for each new load, it is desirable to select control valves that will compensate for these load change effects.

For example, when a liquid-to-liquid heat exchanger is being controlled, the process gain and dead time (transportation lag) will both decrease as the load increases. Therefore, one should attempt to compensate for this inverse load-to-gain relationship by using a valve with a direct load-to-gain relationship, such as the equal-percentage valves. If one does that, as the heat-exchanger load increases and therefore the process gain drops, the valve gain will rise, thereby compensating for that effect and reducing the total change in the loop gain.

Equal-percentage valves are not ideal, though, if high turndown is required or if there are solids in the throttled process fluid.

An opposite example is a control loop whose sensor has an expanding scale, such as an orifice plate or a vapor-filled thermometer. With such detector, the loop gain is increasing with load, and therefore the gain of the selected valve should decrease with load. Therefore, a quick-opening control valve is often used.

In a fairly large number of cases, the choice of valve characteristics is of no serious consequence. Just about any characteristic is acceptable for the following applications:

1. Processes with short time constant, such as flow control, most pressure control loops, and temperature controls through mixing a cold and a hot stream
2. Control loops operated by narrow proportional band (high gain) controllers, such as most regulators
3. Processes with load variations of less than 2:1

In general it can be said that the quick-opening characteristics are used in regulators and on orifice-type measurements, if no square root extractors are provided. The equal-percentage characteristics are most often used on heat-transfer type temperature control applications and on pumping systems where the valve differential pressure varies more than 2:1 as the load (flow rate) changes. Linear characteristics are used in most other cases.

Selection Recommendations

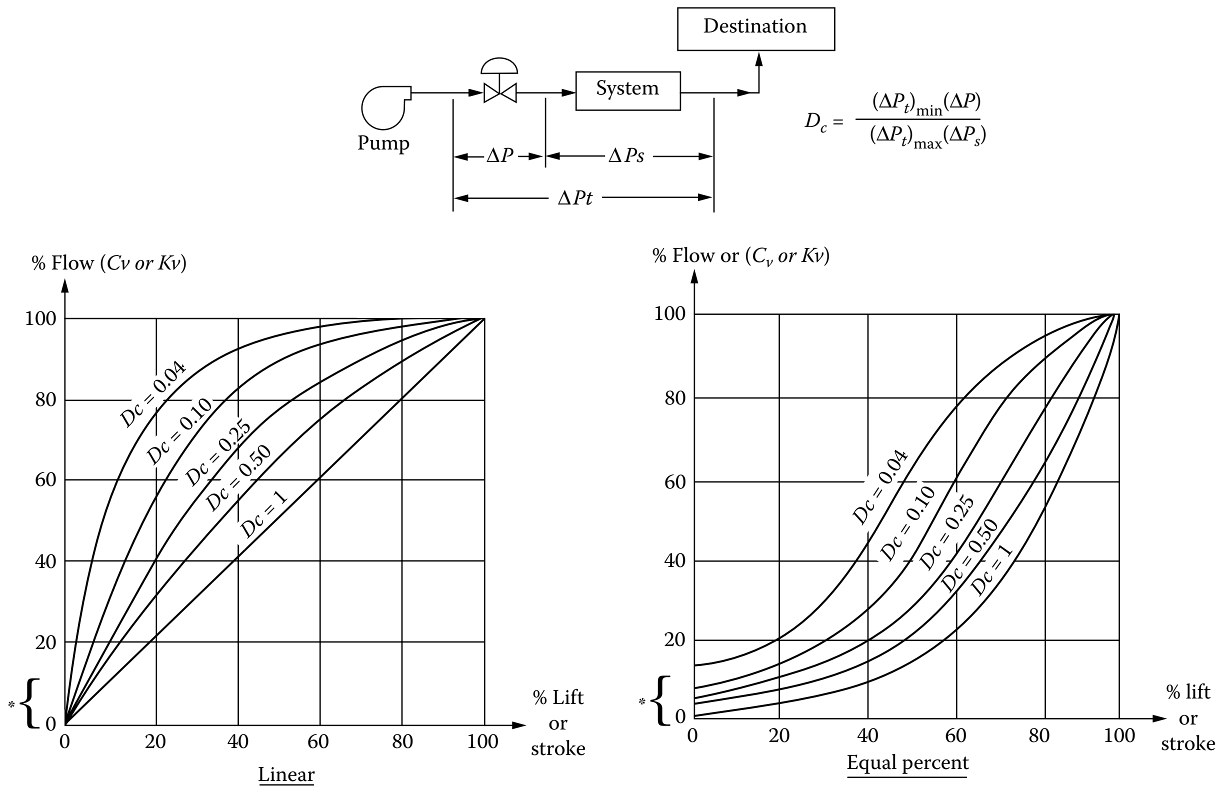
As was discussed in Section 6.1, different engineers have developed different rules of thumb in selecting valve characteristics for the various types of control loops. These recommendations vary in complexity.

Shinskey, for example, recommends the use of equal-percentage valves for heat-transfer control and the use of linear valves for all flow, level, and pressure control applications, except vapor pressure, for which he recommends equal-percentage valves.

Driskell suggests that for relatively constant valve differential pressures, quick-opening valves should be used for square root-type flow loops, equal-percentage valves for temperature and liquid pressure, and linear valves for all others. If the valve differential pressure varies with load, his quick-opening recommendation shifts to linear, and his linear recommendation shifts to equal-percentage.

Lytle's recommendations were summarized in Table 6.1g. They are even more involved, as they take into account more variables.

As will be shown in Sections 6.16 to 6.23, the inherent characteristics of ball and butterfly valves are similar to the



*Note that the minimum "controllable" flow increases as D_c drops.

FIG. 6.7c
These figures illustrates the effects of the distortion coefficient (D_c) on inherently linear (left) and on inherently equal-percentage valves (right), according to Boger.

equal-percentage, while the characteristics of Saunders and pinch valves are closer to the quick-opening.

Installation Causes Distortion

As was pointed out in connection with Figure 6.1c, in mostly friction-type pumping systems, the pressure drop available for the control valve is dropping, as the load (flow rate) is increasing (Figure 6.1e).

This is a different condition from the test conditions under which the valve C_v (K_v) was measured by the manufacturer, because on the manufacturers' test stand, the flow rate through a valve is measured under constant pressure drop conditions. Therefore, when such a valve is installed, its gain (characteristics) will shift as shown in Figure 6.7c. If that shift is substantial, one might obtain a "near linear" installed characteristic by installing a "theoretically" equal-percentage valve.

Different engineers have approached the shift between inherent and installed valve characteristics in different ways. One approach, that of the "old school," was to oversize the pump, so that the *ratio* between the "minimum" and "maximum" valve pressure drops (Figure 6.1c) will not be large, and therefore the gain of the process will not change much with load. This approach works, but it wastes pumping energy.

Distortion Coefficient

When the control valve is installed into the piping in a process plant, its flow characteristics are no longer independent of the rest of the system. This is because the flow through the valve will be subject to the frictional resistance, which is in series with the valve. The consequence is the type of distortion illustrated in Figure 6.7c.

From the curves in Figure 6.7c, one can conclude if a particular installation will have a very substantial effect on both flow characteristics and rangeability of the valve, or not. Under conditions of excessive distortion, clearance flow alone can increase as much as tenfold, and equal-percentage characteristics can be distorted toward linear or even quick opening.

It should be emphasized that Figure 6.7c assumes the use of a constant speed pump (Figure 6.1c). In variable-speed pumping systems, one might adjust the pump speed so as to keep the valve Δp constant, and therefore in such control systems the installed and theoretical valve characteristics are more similar, and less distortion is allowed to occur. Naturally, in variable-speed pumping systems one can completely eliminate the valve and just throttle the pump speed.

The predictability of installed valve behavior is reduced, not only because the inherent valve characteristics deviate

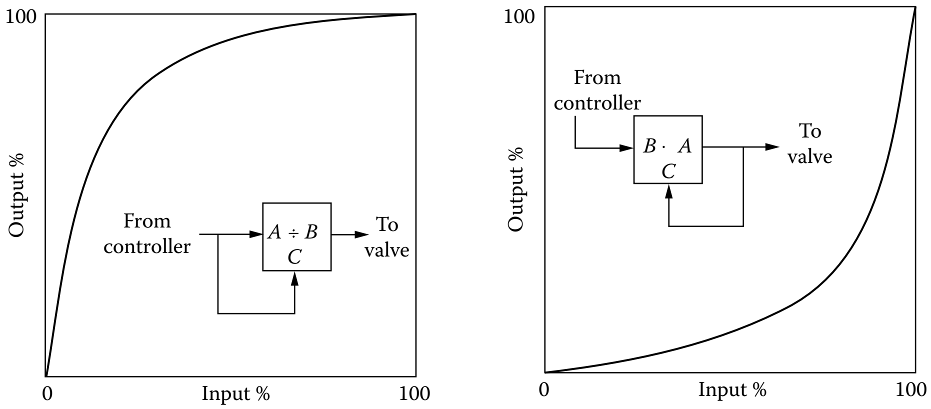


FIG. 6.7d
The valve characteristics can be modified by inserting a divider or multiplier relay into the controller output signal.

from their theoretically prescribed character, but also because:

1. Actuators without positioners will introduce nonlinearity.
2. Pump curves will also introduce nonlinearity.

It should also be recognized that in order to learn the true valve characteristics requirement, a full dynamic analysis of the process is required. Even if one took the trouble to perform such analysis, it would probably yield a valve characteristics requirement that is not commercially available in conventional air-operated control valves. For these reasons, one might consider any one of the following options:

1. Characteristics that are an intrinsic property of the valve construction, such as an equal-percentage ball or butterfly or a beveled (quick-opening) disc
2. Valves that are characterized by design, such as globe valves having linear or equal-percentage trims
3. Digital control valves that can be characterized by software
4. Characteristics that are superimposed through auxiliary hardware, such as function generators, characterized positioners, cams, and so on
5. Intelligent control valves (Section 6.12), which can electronically modify the control signal, which is received as a function of the inherent valve characteristics and of the desired valve gain

Correcting the Valve Characteristic

The linear valve has a constant gain at all flow rates, while the gain of the equal-percentage valve is directly proportional to flow. If the control loop tends to oscillate at low flow but is sluggish at high flow, one should switch the valve trim characteristics from linear to an equal-percentage.

If, on the other hand, oscillation is encountered at high flows and sluggishness at low flows, the equal-percentage valve trim should be replaced with a linear one.

Changing the valve characteristics can be done more easily by modifying the controller output signal or by inserting accessories into the control signal leading to the actuator than by replacing the valve.

One approach proposed by Fehérvári/Shinskey is to insert a divider or a multiplier into the control signal line, as illustrated in Figure 6.7d. By adjusting the zero and span at port C, a complete family of curves can be obtained. The divider is used to convert an air-to-open equal-percentage valve into a linear, or an air-to-close linear valve into an equal-percentage one.

The multiplier is used to convert an air-to-open linear valve into an equal-percentage, or an air-to-close equal-percentage valve into a linear.

According to Shinskey, both devices are perfectly standard, sensitive, stable, easy to calibrate, and “real lifesavers when one needs a linear butterfly valve.”

RANGEABILITY

The conventional definition of rangeability used by most manufacturers is the ratio between maximum and minimum “controllable” flow through the valve. Minimum controllable flow (Fmin) is defined as the flow below which the valve tends to close completely. In other words, this widely held definition of Fmin refers not to the leakage flow (which occurs when the valve is closed), but to the minimum flow that is controllable in the sense that it can be changed up or down as the valve stroke is changed.

Using this definition, manufacturers usually claim a 50:1 rangeability for equal-percentage valves, 33:1 for linear valves, and about 20:1 for quick-opening valves. These claims suggest that the flow through these valves can be controlled down to 2, 3, and 5% of the flow corresponding to their rated C_v (K_v).

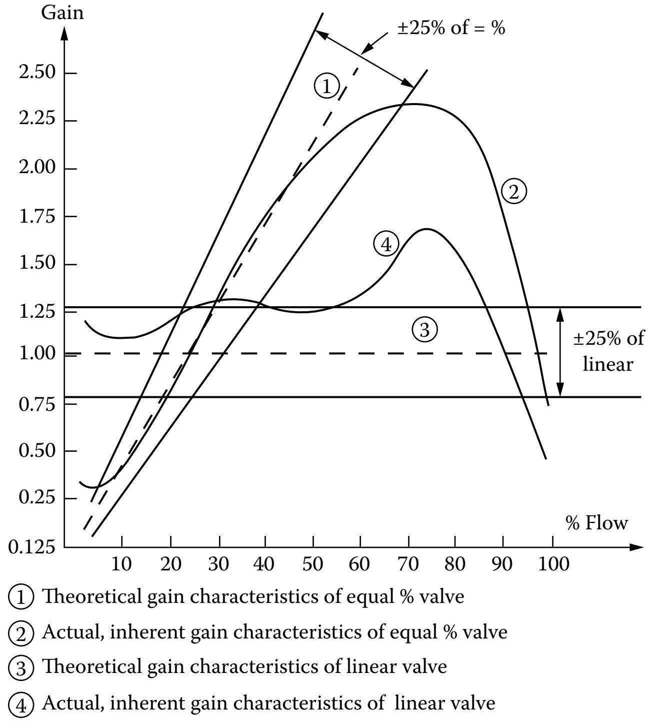

FIG. 6.7e

The theoretical vs. the actual characteristics of a 2 in. (50 mm) cage-guided globe valve, according to Driskell.

The above definition of rangeability is based on the inherent C_v (K_v) determined during testing. It can be seen in Figure 6.7c that the minimum controllable flow rises as the distortion coefficient (D_c) drops. At a D_c value of 0.1, for example, the 50:1 rangeability of an equal-percentage valve drops to close to 10:1.

This is because the valve pressure drop is much higher at low flows (Figure 6.1e), and therefore the minimum valve opening will pass much more flow. Thus, the required rangeability should be calculated as the ratio of the C_v (K_v) required at maximum flow (and minimum pressure drop) and the C_v (K_v) required at minimum flow (and maximum pressure drop).

Improved Definition of Rangeability

The decision on whether a particular control valve is capable of providing the required rangeability should not be evaluated on the basis described above. This is because a loop is uncontrollable not only when the valve cycles between closed and some minimum flow but also when the loop gain product shifts away from 0.5 (the tuning target for quarter amplitude damping).

Therefore, the acceptable flow range within which the valve can safely be used for closed-loop control must be based on a relationship between the theoretical and the actual valve gain. The valve rangeability should therefore be defined as the flow range over which the theoretical (inherent) valve gain and the actual installed valve gain will stay within preset limits.

Therefore, the rangeability of the valve can be defined as the ratio of the minimum and maximum C_vs (K_vs) bordering the region within which the actual valve gain is within ±25% of the theoretical valve gain.

This advanced definition of valve rangeability establishes the point at which the flow-lift characteristic starts to deviate from the expected by more than 25%. (Figure 6.7e shows the points where the actual gain's deviation from the theoretical starts to exceed 25%.)

If one defines "intrinsic rangeability" as that range of the ratios of C_v(max) to C_v(min) within which the values of the valve gain do not vary more than ±25% from the theoretical, then according to Figure 6.7e, the rangeability of a linear valve can be greater than that of an equal-percentage valve. Actually, if one uses this definition, the rangeability of equal-percentage valves is seldom more than 10:1.

The rangeability of some rotary valves can be higher because their clearance flow tends to be less than that of other valves, and their body losses near the wide open position tend to be lower than those of other valve designs.

Valve rangeability can also be limited by the sensitivity and accuracy of positioning.

Why Traditional Rangeability Is Wrong

The problem with traditional rangeability definitions is that they tend to overstate the range within which the control valve can be used. This results in poor control quality for the whole loop. The main reasons why the traditional definition for control valve rangeability is unacceptable are as follows:

1. The minimum "controllable" flow (F_{min}) is determined using a test during which the valve pressure differential is constant, while in most real-life installations the pressure differential is maximum when the flow is minimum. Therefore, the real value of F_{min} should be higher than the claimed values.
2. The valve should not only be "controllable" within its rangeability but should have a gain (G_v) that is close to its theoretical gain.
3. The traditional definition of rangeability is based on dividing the maximum flow (F_{max}) by F_{min}. This approach is also wrong, because while the flow through a nearly 100% open valve is "controllable," its gain is nowhere close to the theoretical value.

As was shown in Figure 6.7e, if the acceptable valve gain is defined as 1, which is within ±25% of the theoretical valve gain, F_{max} of the linear valve should not exceed 60% and F_{max} of the equal-percentage valve should not exceed 70% of the maximum flow through the valve. In terms of valve lift, these flow limits correspond to 85% lift for equal-percentage and 70% lift for linear valves.

CONCLUSIONS

It is time to realize that smart transmitters and sophisticated control algorithms alone cannot result in properly functioning control loops. Stable and responsive closed-loop control also requires that the gain of the final control element (the valve) be much more predictable and better controlled.

In many valve designs (digital valves excluded) this can only be achieved if the valve rangeabilities are redefined and thereby restricted (reduced). The manufacturers should contribute to the achievement of this improvement by publishing the characteristic curve for each valve showing its $F_{\min}$ and gain values at different distortion coefficients (D_c).

The user's contribution should be a better understanding of the role that the valve gain plays in process control and the realization that in most control valve designs the upper one third of the stroke is not usable for stable control.

6.8 Diagnostics and Predictive Valve Maintenance

K. BEATTY (2005)

Types of Predictive Maintenance:	a) Performance tests b) Valve characterization and signatures c) Valve response tests
Types of Diagnostic Systems:	a) Field testing using specially mounted sensors b) Smart positioners with integral sensors c) Host system tools that measure response d) Partial stroke test for safety-related valves
Special Features:	a) Actuator pressures, temperature, and position measurements b) Fully integrated with smart positioners, or field installed for individual tests c) Specially prepared valves for regular testing
Cost:	Premium for \$300–\$1000 for smart positioner, \$50–200 per test for field-mounted test systems
Partial List of Valve Diagnostics Suppliers:	ABB Inc. (www.abb.com/us/instrumentation) Dresser Flow Control, Masoneilan Operations (www.masoneilan.com) Fisher Controls International (www.fisher.com) Flowserve, Flow Control Div. (www.flowserve.com) Honeywell Industry Solutions (www.iac.honeywell.com) Invensys Flow Control (www.invensysflowcontrol.com) Metso Automation (www.jamesbury.com) Samson Controls Inc. INTRODUCTION

There is currently a major change in the approach taken to equipment maintenance due to longer times between turnarounds and a reduction in the available personnel. Valves are typically one of the higher maintenance pieces of equipment in a process. This is because, unlike measurement instrumentation that only monitors the process, valves are dynamic devices, and in order for them to function properly, their main components, such as their actuators, packings, positioners, and I/P converters, all need to be operational. If any of these components fail, the result is that the process can no longer be remotely controlled. For this reason, control valve testing should evaluate the condition of all of these components.

Valve diagnostics and predictive maintenance is relatively new. In the past, the approach to maintenance was to schedule the periodic rebuilding of critical valves based on the time that the valve has been in service and not on the basis of actual need. This type of preventative maintenance method has several drawbacks. One is that by using this approach, a lot of unnecessary maintenance is done. Secondly, if critical failures occur between maintenance intervals, they are overlooked. Finally, sometimes the act of maintenance itself causes problems in valves that had no problem before.

DIAGNOSTICS

Instrumentation Used

Diagnostic information can be obtained from smart positioners, local portable sensors, and the evaluation of process control signals. As discussed in more detail in Section 6.12, smart positioners are relatively inexpensive and easy to use. For these reasons, they are used most commonly.

The local sensors utilized in diagnosing the control valves are usually integrally mounted on the valve. In safety-related control valve systems (as discussed further in Section 6.10), specialized positioners are used to provide partial stroke tests, which can verify the operational status of the valve without interrupting the process.

When diagnosing existing installations, the testing is often performed by analyzing the past performance and records of the process instrumentation. When time permits, portable sensors can be installed in the field to monitor the performance of the valves and to provide the required data for diagnostic tests.

Intermediate signal control boxes can also be used, primarily in safety-related systems. These can partially stroke on/off safety and shut-off valves (Section 6.10) by briefly interrupting the signal to a solenoid. This way, the system can verify that the valve is operational, because it is beginning to operate. In order not to adversely affect the operating process, once the valve begins to respond, the solenoid is quickly re-energized. This way, the valve is tested without a need to shut down the process while testing.

Diagnostic Methods

Standards such as ISA-75.13-1996, “Method of Evaluating the Performance of Positioners with Analog Input Signals and Pneumatic Output,” or “ANSI/ISA-75.25.01-2000,” Test Procedure for Control Valve Response Measurement from Step Inputs,” are useful in evaluating the performance capabilities of control valves. These standards describe the performance tests required to determine HRL hysteresis, repeatability, and linearity (HRL) of control valves.

These tests provide very useful information on the performance of both the positioner and the valve actuator, but they do not provide much information that would be useful in predictive maintenance.

Many smart positioners have built-in diagnostics that can provide usage information and current status that is very useful in troubleshooting existing problems. Most of these positioners do not provide on-board predictive diagnostic information. In order to perform predictive diagnostic tests, the positioner usually has to be accessed through a digital interface and its data downloaded into a PC for analysis.

Many new host control systems can pass the information directly to a diagnostic PC over a network connection. Some positioners also have internal data historians that provide detailed information on the valve command, actual position, and actuator pressures that provide a level of detail not normally available in host historians for diagnosing transient problems.

Characteristics Tests

Another category of tests are the characteristic or signature tests, which are well suited for predictive diagnostics. They can be generated by a smart positioner or obtained by using a portable test rig.

Valve signatures are obtained by ramping the valve through a range of travel and capturing information concerning the position command, the valve travel, and the actuator pressure(s). This information can be analyzed independently, or over time to observe changes in the characteristics of the control valve.

For example, a signature can be the friction in a valve over a range of travel. Changes or abnormalities in the friction plot over the range of travel provide direct information related to seating problems or galling that may be occurring in the valve trim. A full travel signature can provide information on the travel calibration of pneumatic actuators or help to locate leaking or worn seals and fittings.

New software tools are also available for the historical analysis of valve command signals and of the corresponding process response. This method of analysis is nonintrusive and can be applied with both smart and traditional positioners.

Many of the analysis packages can access the required data directly from a historian in the DCS. This method of analysis involves the comparing of the controlled process measurement with the command signal received by the control valve. If the controlled process measurement is sensitive enough to respond to small changes in the valve opening, then this measurement can be correlated with the control signal received by the valve and, thereby, determine if there is sticking or lagging and quantify the magnitude of the problem. The main limitation with this type of analysis is that it provides an indication of the existence of a problem, but does not provide detailed information.

Some equipment suppliers now offer diagnostic services on a contractual basis. In providing these services, the suppliers utilize large databases that they have compiled over time, using various types of valve designs in a wide variety of process services. These services often include a review of the existing installation to see if other valve designs might not be better suited for the applications at hand.

Valve Signatures

A valve signature is obtained by running a reproducible test on a control valve. During such a test, a repeatable signal is sent to the control valve, and the response to that signal is captured and then analyzed to see if the control valve operates correctly.

The valve should be removed from the process and placed on a test stand while running the complete signature test. This is because during the test, the valve is forced to travel over a wide range, and if this was not done off-line, it could cause harm to equipment, personnel, or the process. For the signature of an emergency shutdown valve, refer to Figure 6.8a.

However, a partial stroke signature can sometimes be obtained on-line. If a valve signature is obtained near the end of the valve stem travel, or even beyond the end of travel, it still can be of some value. For example, if the behavior of a normally closed valve is tested with a control signal range of –5 to 0%, one can obtain diagnostic data on the response

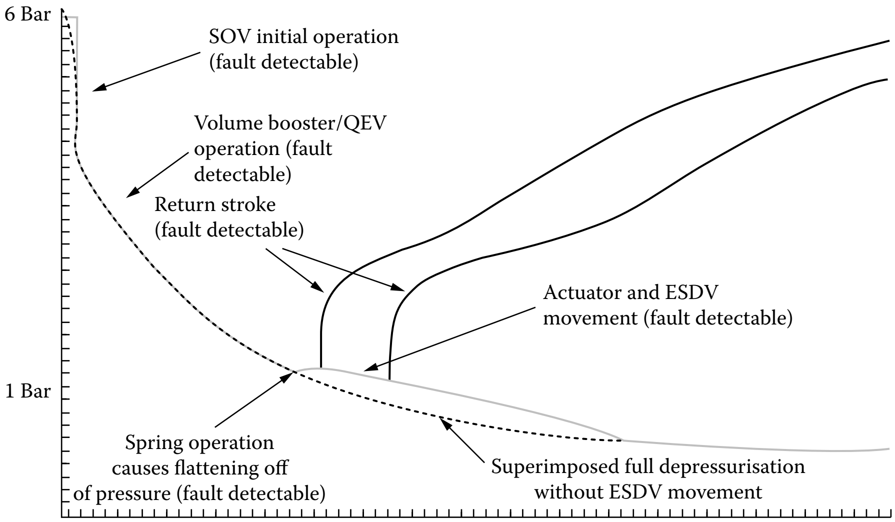

FIG. 6.8a
The signature of an emergency shutdown valve (ESDV). (Courtesy of Drallim Industries Ltd.)

of the pilot valve in the positioner without opening the valve (moving the valve stem) at all.

Similarly, limited signatures can be obtained, when control valves are in operation, by changing their control signals within a small range (1–2% of travel) around the required opening of the value.

Valve Signature Types There are four types of valve signatures. These are obtained by detecting the valve's response to steps, ramps, partial strokes, or internal operation. The step and ramp signatures can be performed in either the opening or closing directions. Figure 6.8b shows the *ramp test signature* of a control valve with a double-acting actuator, and Figure 6.8c shows the same signature for a valve provided with a spring-loaded, single-acting actuator.

When performing a ramp test, first the starting and ending valve positions are entered. The ramp rate and the sampling time is usually also entered. The data gathered at each sample point includes the value of the control command signal, the valve position, and actuator pressure.

In order to obtain a *step signature*, first the step size is defined by setting the starting and ending valve positions, and then the recording time period is set, where time zero is the time at which the step command is issued. The data gathered at each sample point include elapsed time and the values of the control command, valve position, and actuator

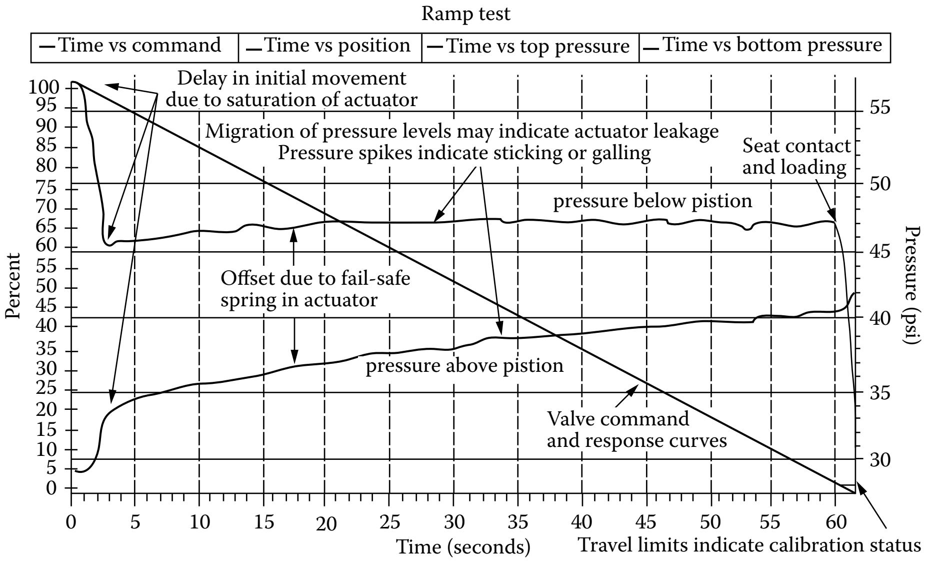

FIG. 6.8b
The ramp test signature of a control valve with a double-acting actuator. (Courtesy of Flowserve Corporation.)

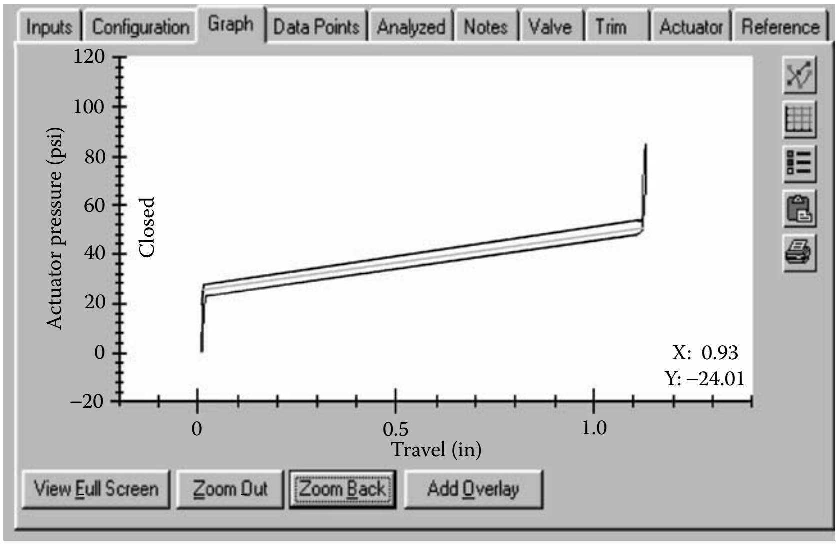

FIG. 6.8c
The ramp test signature of a control valve with a spring-loaded (single-acting) actuator. (Courtesy of Fisher Controls.)

pressure. The result is a graph that shows the response of the valve to a step in its control signal including the approach and stabilization of the valve at the new position.

A *partial stroke test* is similar to a step test, but it is based on a temporary and small change in the control signal. Instead of reaching and maintaining an end position, the test only lasts long enough for the valve to begin to move or sometimes not even that, but only begins to apply the necessary pressure to begin to move the valve stem before resuming normal operation.

Internal operation signatures are primarily positioner diagnostic tools, because they test the operation of the pneumatic relay.

Analyzing Valve Signatures

Most valve manufacturers provide information and guidance for interpreting the above-described signature tests. Interpretation of valve signatures considers two different factors: One is the characteristics of type of valve used, the second is the past history of valve performance.

In terms of valve characteristics, the control signal and valve travel relationship is a function of the type of valve used. Similarly, the minimum and maximum stem friction values depend on the type of packing used by the particular valve design (see Section 6.5 on packing designs). Other characteristics include the balancing pressure range of double-acting actuators and positioners, which, if it is outside the design range, is an indication of problems in the actuator. Also, there usually are inflection points in the valve signature, which indicate the particular seating and linkage characteristics of the valve.

The second basis for evaluating the signature of a valve is by making a historical comparison with past performance. The reference signatures can best be obtained when the valve is in good working order. Once a set of baseline signatures for each valve have been obtained, subsequent signatures can be directly compared against that baseline reference signature, which was taken under the same conditions as the existing ones. The differences between the reference and actual signatures can point to possible problem areas.

The Instrumentation, Systems, and Automation Society (ISA) committee "SP 75.26.01, Valve Diagnostic Data Acquisition and Reporting" is in the process of developing a standard for the methodology to be used in acquiring valve signatures. Their scope includes the defining of the test procedures to be used and the obtaining of reports that can be transferred from one diagnostic system to another.

CONCLUSIONS

The analyzing of valve diagnostic information is a new and evolving field. The diagnostic needs of a plant can depend on its age, on the type of control system being used, and also on the experience and attitude of the operating staff. Today, a variety of diagnostic services are offered by valve manufacturers, instrument suppliers, and service companies. With the passage of time, standardization is expected both in the methods of obtaining and in the interpretation of valve signature tests.

6.9 Dynamic Performance of Control Valves

C. G. LANGFORD (2005)

VALVE RESPONSE

This section first defines the terms associated with control valve mechanical response. It then explains how the speed and accuracy of the control valve response will determine the quality of control of the process. Then it provides suggestions for improving control valve response to achieve acceptable performance.

Improved data collection and analysis with modern control systems make the quality of process control more visible and quantifiable. The business requirements for profit and improved quality control require better control performance.

Modern control valve positioners, often incorporating computer technologies, can improve system performance (see Sections 6.2 and 6.12). See the Bibliography for test data from poorly behaving valves (see Figure 6.9a). The elimination of asbestos-based packings and the increased concerns over packing leakage had the result of improvements in packing design and materials. Developments in low-friction packing materials provide a powerful tool for improved control (see Section 6.5).

Some applications may have control response requirements that preclude the use of a conventional control valve. For these, a pressure or flow regulator may be the better choice. Regulators tend to be relatively fast and reasonably accurate. They lack the control options provided with a separate controller and the design and materials flexibility provided by a separate valve. Some regulators are available with a pressure receiver replacing the spring and screw top works. This provides for remote control of the loading pressure, and thus the set point. Many regulators use techniques that decrease the "droop," which is the normal pressure drop at high flows (see Section 7.7).

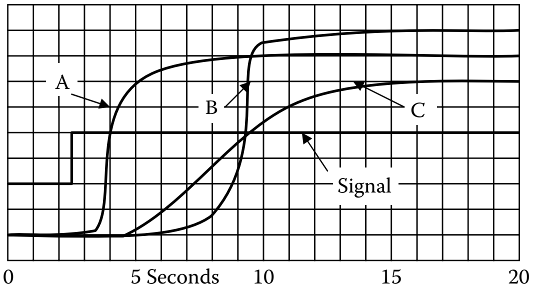

FIG. 6.9a
The responses to a step change in control signal by valves A, B and C.

Definitions

Valve: A valve is a device used for the control of fluid flow. It consists of a body that must satisfy the key requirement of containing the fluid with flow ports, and a moveable closure member, which opens, restricts, or closes the port(s) (see ANSI/ISA-75.05.01-2000, "Control Valve Terminology").

Actuator: An actuator is a device that supplies the force causing the movement of the valve closure member. Most commonly these are fluid or electrically powered (see ANSI/ISA-75.05.01-2000). Actuators most often use compressed air but may use electric, hydraulic, or electrohydraulic power.

Motion conversion mechanism: A mechanism installed between the valve and the power unit of the actuator to convert between linear and rotary motion where required. The conversion may be from linear actuator action to rotary valve operation or from rotary actuator action to linear valve operation.

Accessories: Additional devices used in the operation of the control valve. As described in ANSI/ISA-75.05.01-2000, typical examples include a positioner, transducer, signal booster relay, air set, and snubber (see also Section 6.2).

Dead band is the range through which an input signal may be varied, with reversal of direction, without initiating an observable change in output signal (ANSI/ISA-S51.1-1979 [R1993]). In standard ANSI/ISA-75.25.01-2000 it is defined in percentage of input span. Note that in some other literature this definition is used for dead zone. See Figures 6.9b and 6.9c. The input signal is shown here as a linear ramp for clarity.

Control valve response is the dynamic (considering time) relationship between the change in a control signal and the change in the valve stem position. The process operator is interested in the process response, not the valve stem position. It is important to remember the end purposes of the control valve functionality are business and safety. Process safety is easier if the process is under good control. Much of the discussion in this section uses the conventional globe style valve for the examples. However, the basic principles apply to all final control elements. The response of electric or air motors in a film windup, the performance of swirl vanes

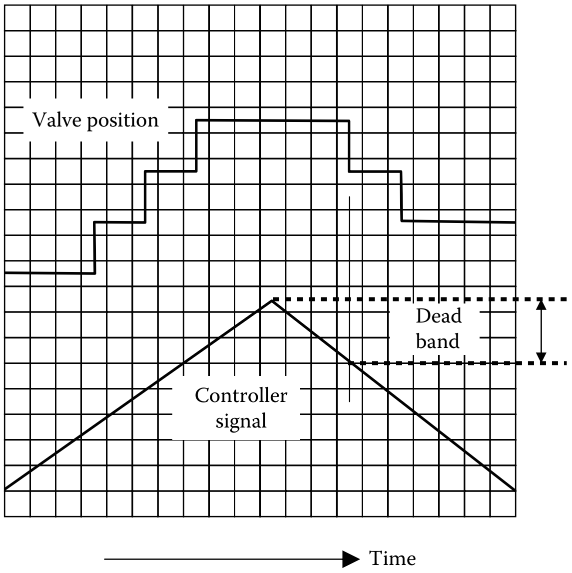

FIG. 6.9b
Dead band is defined as the amount by which the controller output signal has to drop, before the valve position changes. This figure illustrates the response of a valve with high packing friction.

used on the inlet of a blower, and variable speed pumps all have dynamic characteristics similar to valves.

DISCUSSION

The function of a control valve is to change the closure member ("trim") configuration in a way that the flow restriction coefficient, C_v, changes in a controlled and predicted manner. Bernoulli's law states that except for losses and energy taken from or added to the fluid, the sum of the pressure energy, the kinetic energy, and the internal energy within a system will remain constant.

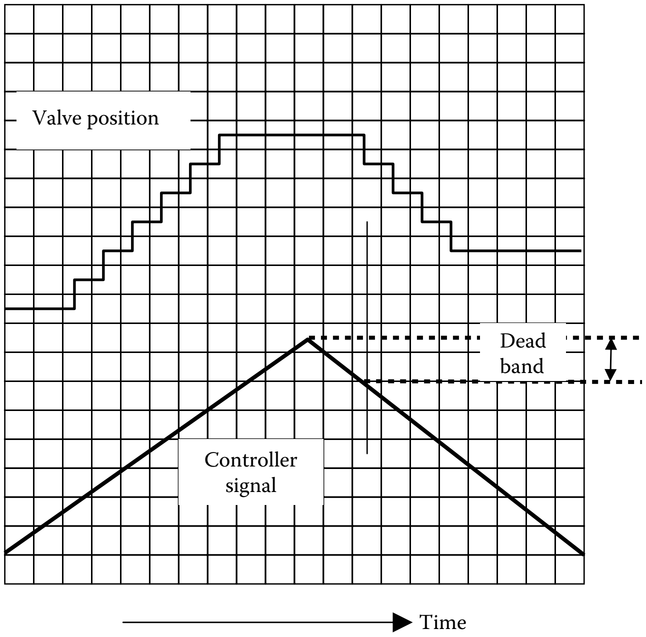

FIG. 6.9c
If the packing friction of the valve is reduced, the dead band required to initiate a change in valve position is also reduced.

The tortuous and varying fluid path in a control valve converts part of the pressure energy into kinetic energy, with a high-velocity jet and increased turbulence. Most of the turbulence dissipates into heat (internal) energy as the flow jet slows down into a more orderly velocity distribution downstream of the restriction. Some of the velocity energy will change back into pressure energy downstream of the flow jet at a lower pressure. The energy converted into heat will leave the valve with the flowing fluid or is lost through the piping wall. Except for inefficiencies, the quantity of energy lost is essentially equivalent to the energy required for a pump to increase fluid pressure by the same amount. The valve closure member connects to the actuator by way of a valve stem or shaft. The valve mechanical response is a function of the valve actuator and its various accessories and with the forces that act to cause or restrain the motion.

The response of the process is a function of the response of the valve and the relationship is normally not a simple one. For difficult or sensitive applications, the valve response requirements should be determined from actual or calculated knowledge of the process response requirements rather than from a simple specification based only on common practices or habit.

Valve System

The installed control valve is a system, consisting of the body and trim, the actuator, and all the accessories. Air pressure supplied by a pneumatic controller or current to pressure (I/P) relay causes flow in to, or out of, the actuator and increases or decreases the pressure on the diaphragm (see Figure 6.9d). Information about valves and accessories is available in this handbook (Sections 6.2 and 6.12) and from catalogs or from various computer programs (see Table 6.2n). The manufacturers' data can aid in developing practicable performance purchase specifications. There is no point in specifying an impossible valve or one that will require very special and expensive attention.

Typically, a spring provides the opposing force in an actuator to move the stem in the opposite direction when the actuator air pressure decreases. The force is proportional to the change in stem position; this is Hook's law. The diaphragm actuator in the typical diaphragm changes effective area with pressure and stroke position. This results in an imperfect conversion of pressure into force.

In the sliding stem valve, stem packing friction creates a force that opposes motion in either direction. This is often a large force, from hundreds to thousands of pounds. The result is to increase the pressure (mass of gas) required in the actuator to cause a change in stem position. Any source of friction will have a similar effect. With ball and plug valves, the friction of the liner and the seat is often much larger than stem packing

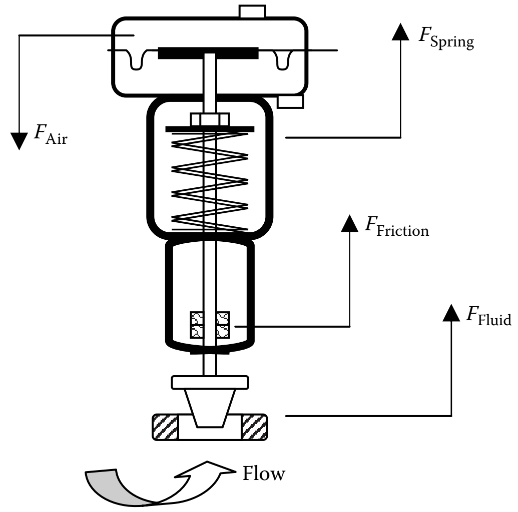

FIG. 6.9d
If both the process fluid and the valve spring are arranged to resist the closing of the valve, the air signal must generate a force, which will overcome these two, plus the force generated by the packing friction.

friction. In this case, appreciable valve shaft "windup" may occur with shaft distortion from the high torque. This windup might not be apparent from outside the valve. Any freedom of motion between the closure member and the shaft will increase the dead band. Valve design details all play a part in this.

Fluid forces on the closure member will vary with fluid conditions and the closure member design and position and may act in either direction. These forces are more significant in the larger valves. For valves smaller than $^1/_2$ in. (12 mm), fluid forces are small. Balanced trim reduces these forces.

Install Positioner

The valve closure member will move when the sum of the forces acting to move the stem exceeds the sum of the forces that act to oppose motion. Because static (nonmoving) friction is higher than dynamic (moving) friction, the valve stem will not move in a smooth manner but will jump to a new position and then stop, because the actuator force decreases when it moves and the pressure drops. This new position is only rarely perfectly, and exactly, the position represented by the control signal. This valve response will result in a flow response and, then after that, in a process response. The process value will result in a change in the control system output, and the cycle starts again. The word "cycle" used here makes the point that cycling is almost inevitable. It is almost certain that the stem will move in steps. This discussion is about the size and significance of those steps.

In the absence of other forces, the spring coefficient defines the stem position for a given actuator pressure. With other forces added in, the stem position will differ. Adding a positioner to the system reduces the effects of the other forces and raises the "stiffness" of the system as the positioner acts to oppose errors due to friction and fluid forces.

The flow of air into or out of the actuator is an integrating (summing) process and will always lag or follow the input signal change. The process under control will also have characteristics of lag and dead time. The control system adds more lag. Despite all the efforts of the finest minds, it is not yet possible to see accurately into the future. Sophisticated model-based control may help but nothing can be perfect. From this, it is clear that no real control system can control perfectly. The goal is to have something that is "good enough" to satisfy the system requirements. Valves, sensors, and the control system performance all together determine the quality of process control. Improvements from a base case will generally cost money, and the added costs must be justified and supported by the predicted desired improved performance. The relationship between these various times and magnitudes defines how well the process is controlled. Simply, a very fast process will require fast control response, and a process with high gain requires high accuracy.

The catalog listings for most positioners and pneumatic relays list the available air flow capacity in SCFM (SCMM) or other mass units at the specified supply pressure (see Table 6.2n), the air capacity of selected pneumatic components. The positioner is a narrow proportional (high gain) pneumatic relay. This sensor and amplifier with the actuator comprises a servomechanism, with the valve stem as the controlled device. The positioner compares the difference between an input signal defined in terms of the stroke of the valve and the actual stem position as measured with a mechanical linkage, and it controls air to the actuator. The early simple designs had the disadvantage of cycling if the gain was too high for the response time of the valve assembly. That is, because the system is an integrating controller, the inherent phase lag in the stem response requires that the gain be limited or a low-frequency cycle will result. If the valve is the slowest element in the control loop, or behaves poorly, then it is the limiting control device. If the positioner slows the valve response, then it becomes the limiting device. If the volume of the actuator is large compared to the air flow rate, then the air flow rate is the limiting element. During the 1960s, typical positioners were very simple, with few options, and they had limited air flow capacity.

In the early days of automatic control, special high-performance valves received special engineering attention. This led to papers that made the case that positioners could have a negative effect on control. The original positioners had a one-size-fits-all philosophy designed to work with any size of actuator. Price was a concern, and the possible improvement in control was not valuable enough to justify the extra costs, not only for purchase, but also for installation and operation. It is clear that in applications using larger valves, control improves with the use of positioners because of the servomechanism error correction. Concern with the speed of response led to higher air flow capacity. Later positioners were not linear in response, with low gain for a small position error and higher gain for larger errors. This also has the result that stem motion speed will differ with signal step size. Some modern positioners adjust to suit the specific application and may include adjustable gain and integral action. Digital devices can improve accuracy, be more repeatable, and include the flexibility of configuration for the specific application.

Positioners must have an air supply of 0.375 in. (10 mm) tubing as a minimum, and each positioner requires a separate adequate supply filter-regulator. Control valves use substantial amounts of air, and severe control interaction can occur if an inadequate air supply affects the air supply pressure to other valves and transmitters. The interactions can be very complex, and the oscillations are impossible to stop.

Increase Force

The second available significant improvement is to increase the actuator force. A larger actuator will provide a greater force but adds cost and increases the air consumption. Increasing air supply pressure, up to the safe actuator operating pressure, improves response. An undersized or marginal actuator will exhibit slow response because it requires a greater change in pressure to start motion, and as actuator pressure approaches supply pressure, the flow rate will decrease. Many diaphragm actuators commonly used at 25 PSIG (170 kPa) can safely operate at pressures to 30 or 60 PSIG (200 or 400 kPa). It is necessary only to increase the air supply pressure and modify the calibration or use a pressure amplifying relay. If the change in actuator pressure required to move the stem is reduced, then the jump in position is reduced. The analogy might be using a wrench with a longer handle to loosen a frozen bolt. Control of the wrench is much easier if it is not necessary to exert your full strength on the wrench handle. There are practical limits to actuator sizes for each valve body size and type. Some actuator schemes use stacked actuators in line to achieve greater forces.

Reduce Friction

Perfect alignment of the valve actuator system and stem will minimize friction. The very close tolerances between the valve stem and the stem guide can only tolerate a small misalignment without binding up (locking) the assembly and prevent any movement. Packing friction will increase with misalignment. Careful attention during maintenance is important. Any looseness or play in the assembly will cause unpredictable friction.

The proper tension on the packing follower bolts will prevent valve stem leakage without adding unnecessary friction. Careless overtightening may make the valve nearly inoperative and greatly reduce the life of the packing.

Packing selection and design are important (see Section 6.5). Graphite packing or packing with graphite content, typically specified for high-temperature operation, will substantially increase friction. Stem packing friction will vary over a range of 10:1 or even more, depending on packing materials and designs. It is necessary to remember that the packing temperature may differ considerably from the process temperature towards the ambient and will depend on the design and installation. Valve manufacturers have data to help in these decisions. Optional extended packing designs provide even greater thermal isolation from the process. The low-friction TFE packings popular in the chemical industry are limited to moderate temperatures. Modern elastomeric low-friction packings can serve at temperatures far higher than the temperature limits of fluorocarbon packings and have passed standard fire tests in some valves (see Section 6.5). Packing selection is no longer a simple task.

Defining Response

The ANSI/ISA-75.25.01 Standard, "Test Procedure for Control Valve Response Measurement from Step Inputs," defines step sizes for signal input step change in terms of the resulting response. It defines four step sizes. First is a signal step so small that there is no response. The next larger step size results in some response, but it does not match the required specifications in amplitude or time. The next larger step size results in a response satisfying the specifications used. The largest step size is large enough that the amplitude is within specifications but the time is longer than specified. In each case, the specification used is a function of the application.

As a useful definition for response time, the ISA (Instrumentation, Systems, and Automation Society) standard uses T_{86}, defined as the time for the valve to complete 86.5% of the final motion.

Measuring Response

Shop Test Valve testing "on the bench" at the factory or in a maintenance shop proves that the valve is mechanically functional, demonstrates valve response without fluid forces, and is much more convenient than field tests. A serious limitation is that there is no way to prove that the packing as installed will prevent stem leakage, and there is only a very limited ability to include fluid forces. (See Figure 6.9e.)

In Situ Test In situ (in place) testing has the advantage of providing the desired information about the valve and process response under actual service conditions. The packing is fully functional; the test fluid pressures and temperatures are the service conditions.

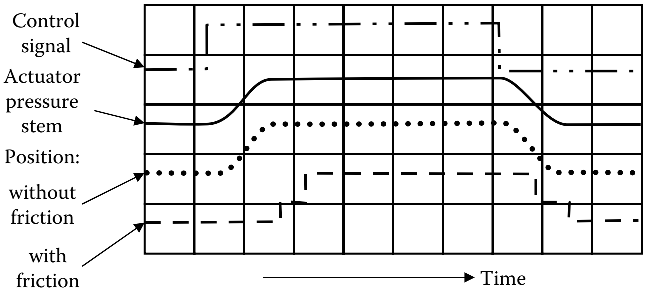

FIG. 6.9e

Response curves: On the top—step change in control air signal, second from top—air pressure inside the actuator, third from top—position of the (theoretical) valve stem w/o friction, fourth from top—position of an actual valve stem with friction.

There are two kinds of in situ tests. Normal operation with normal flows, temperatures, and pressures provides the "perfect model" and provides the required data. Operating constraints may limit the allowable range of valve opening and testing. The alternative is to take data from a shutdown unit. This can determine only the valve mechanical response and may not be completely representative of the operating situation. In either case, it may be necessary to add temporary or permanent instrumentation to gather all of the desired information. Valve manufacturers and service companies can provide add-on instrumentation. Data collection may be as simple as personal field observation of stem movement and positioner gauges. It is easy to identify large stem position jumps and slow action by observing the signal gauges and the valve. If this approach does not provide adequate information, it may be necessary to introduce precise signal step changes of various sizes as shown in the above referenced standard and to take measured data from the valve stem along with the related flow meter and other process sensors. There is a general opinion that the usual standard process instrumentation is rarely adequate to collect all of the desired data. The user will want to take advantage of all the available resources and to develop and justify a plan to quantify the problem and determine the solution.

Relationships

A 1% change in stem position does not translate into a 1% change in flow coefficient and result in a 1% change in the process variable. The engineering requirement is to determine the effect of flow changes on the process and then derive the required control valve specifications from that.

Determine Required Response Specifications

In situ testing should provide enough information to define the required valve response specifications. The valve manufacturer can provide guidance for sound decisions for improving the performance of a specific valve design.

The engineering analysis required to predict valve requirements is not difficult. For a number of reasons, the most common error in valve specifications is to oversize the valve. An oversized valve will increase the effective dead band by that same percentage. The definition of inherent rangeability of a control valve is: "Rangeability: The ratio of the largest flow coefficient (C_v) to the smallest flow coefficient (C_v) within which the deviation from the specified inherent flow characteristic does not exceed the stated limits" (Ref: ISA-75.05-1983). The ANSI/ISA-75.05.01-2000 Standard includes a definition for C_{vR} that is a calculated valve coefficient for the installed valve. This provides a way to quantify the real valve performance and to determine the effective rangeability.

The installed rangeability for an oversized valve may be much less than for a properly sized valve, because control is impossible at small valve openings due to the dead band and very high gain near the seat, and the excess capacity of the fully open valve has no effect on flow. Accurate service condition information is vital. It is far too common to add excessive contingency factors in sizing pumps and valves. A full process simulation will provide valuable data about process gain and valve gain and result in an understanding of how dead band will affect control. In the absence of the simulation, the user will need to estimate the valve gain at operating conditions and to estimate the response time needed. It is not economical to specify very tight control valve dynamics response specifications except where the process conditions justify this added cost.

Application Examples

Simple Tank Level Control Fluid enters the tank at a variable rate; an outlet valve controls level, and process considerations determine acceptable level limits. The analysis consists of considering the tank volume, the normal volume flow rates, and the allowable level deviation from set point. If the inlet flow can suddenly stop, calculate the required outlet valve response time from the rate of change in level. The required maximum allowable valve dead band is determined from the required precision for level. The allowable level dead band can be converted into flow dead band and then into the stem dead band at operating conditions in order to calculate the required valve dead band specification. A simple pressure control loop is a very similar problem.

Heat Exchanger One fluid exchanges its heat energy with another fluid in a heat exchanger. The process engineer should provide the range of flow rates and temperatures and the impact of a change in the heating/cooling flow rate. In most cases, the response time is not an issue. The sensitivity, or gain, of the temperature from the flow rate changes will determine the allowable dead band. Because this is a slow process, the dead band effects become very visible. The common attempt to conceal the dead band by reducing controller gain and lengthening reset time will only make the cycle time so long that everyone forgets it. Any reduction in dead band will improve control. Knowledge of the expected valve dead band will permit calculating the required controller settings.

Flow Control

Most flow measurements are inherently noisy; the associated controller has low gain and fast reset function to filter the higher frequency valve control signals and still bring the flow towards the set point. The valve speed of response must be adequate for the anticipated pressure upsets. Dead band is not an issue because the controller signal changes rapidly and often. Usually, the control is adequate with a standard valve. In compressible flow, the downstream volume provides some smoothing. Heavy filtering at the transmitter will make everything look nice but the system will respond slowly to upsets.

Reactor Mixing

A fast process reaction resulting when two fluids mix in a mixing volume is difficult to control. Downstream mixing will not make up for the errors. Past practice has been to make both flow measurements as similar as possible, and the control systems and valves as similar as possible, in order that the dynamics all are similar and, wishfully, all the dynamic errors will match and balance out. The process reaction is over and gone too quickly. The dead band must be very small, and the required precision of adjustment is very high. Special motor-operated small valves have satisfied these requirements. Process data is required to determine the allowable dead band.

Neutralizing Waste Water

This is another difficult control problem; flows and stream analysis may vary widely (see Section 8.32). The worst problem is that the neutralizing curve may have a very high gain over a narrow range, and this may vary with time. The region of very high gain is usually close to or at the set point value. The requirements are that the valve have enormously high precision and accuracy and then operate over a wide range. There are no real valves available to satisfy these specifications. The most popular solution is to use two valves in parallel. The small valve provides the precision and the larger bypass valve provides the bulk of the flow capacity. One reset-only controller adjusts the larger valve to cause the pH proportional-only controller to adjust the smaller valve to operate near 50% open. This solves both of the problems of precision and capacity. The natural dead band of the larger valve provides a gap action to allow the smaller valve to control over the small flow range. The price paid is a slow speed of response for large demand changes. Common practice is to use a downstream surge tank to mix and average the outflow pH. The design problem is to size the small valve large enough to be in control most of the time but to not oversize it and have too large a dead band. In real life, this means the study of the predicted neutralization curves and converting this information to the equivalent stem motion. For even greater rangeability, it is possible to extend this concept to a third valve. In each case, prediction of each dead band is valuable information.

Antisurge Valve

A centrifugal compressor requires a certain minimum mass flow through the machine in order to maintain a discharge pressure. If gas flow decreases below this value, then the compressor will lose flow and pressure and start to cycle internal flows and pressures. In larger machines, this surging puts excessive force on bearings and shafts and can quickly destroy the machine. Normal practice is to measure the gas mass flow into the machine and open an antisurge valve to discharge to atmosphere or to recycle enough gas around the machine to maintain the minimum flow. On a sudden decrease in gas demand, such as an interlock shutdown, the valve must open very quickly and then begin to throttle as needed in order to maintain stable operation. The compressor manufacturer can provide information on the required valve opening speed, or it is possible to estimate these values from the machine curve and knowledge of the pressurized volume. Adequate response may require the dead band high-volume booster relay described in Section 6.2. Other issues for these valves are associated with aerodynamic noise.

Delay or Slowdown Valve Action

There are a number of situations where it is desirable to delay or to slow valve action. For example, water hammer is the excessive pressure surge that is the result of a sudden change in fluid flow in a very long pipeline. Accurate control of the valve is still important; in some installations, the fluid flow will exert a high force and rapidly force the valve closed.

When flow suddenly changes, a pressure surge wave will travel through the fluid at the speed of sound (c) in the fluid. This pressure wave will reflect off the first solid surface (elbow or tee) and travel back and forth. This wave may shake or damage the valve and the piping. The situation is strongly dependent on the exact flow and piping situation. Even a few percentages of entrained air or gas bubbles in a liquid will increase the compressibility enough to make a considerable difference. Reported problems include pipe hangers broken in a 2-in. pipe line at a high flow rate and very fast shut-off valves. A 4-ft.-diameter fiberglass waste water pipe system collapsed when the upstream valve closed too quickly. Some hydraulic power plants use surge tanks to absorb the energy. Possibly the best scheme is to use a reset-only controller to get a predictable, linear delay. With a digital control system, a ramp function configuration will provide an accurate and dependable rate of closure or opening. If the valve is on/off, an equal percentage-type trim will provide some smoothing of flow. Some authors have suggested a fast-acting pressure control loop can override the control signal to slow the valve to limit the overpressure.

A very noisy process signal can lead to excessive valve or packing wear. The “inverse derivative” relay, which passes a fraction of a sudden input change immediately and the balance of the change later, will provide a low pass filtering effect (see Equation 1.2[14]). A needle valve, or restrictor, used with a volume chamber will provide a resistor/capacitor-type filter.

Safety Solenoid Valves

Emergency shutdown systems (ESDs) may use a solenoid valve piped between the positioner and the valve actuator installed to reduce the chance that the positioner could interfere with positive valve action. Consider that the air flow capacity (C_v) of the solenoid might limit air flow and valve response. See Section 6.2 for more details.

Troubleshoot Valve Response

Control valve response may be poor because of

- Oversize valve
- Incorrect trim
- Excessive packing friction
- Undersized actuator
- Loose linkage
- Inadequate mounting
- Inadequate air supply capacity or pressure, or plugged air filter
- Damaged or leaking tubing
- Leaking air lines or fittings
- Inadequate positioner flow capacity
- Broken actuator spring
- Incorrect calibration
- Leaking or damaged diaphragm or piston
- Positioner/actuator time constant equal to process time constant
- Manual valve handwheel or limit stops prevent free motion
- Bypass valve open
- Valve body plugged
- Broken valve stem
- Failed or plugged interlock solenoid valve

Some of these possibilities are unlikely depending on the situation history; that is, did it once work well? Did it have recent maintenance? Are there changes to the flow system? In all the above, once the cause is identified, the solution is usually clear. Identification may be as simple as from observing the positioner gauges and the valve action. As in any control situation, instability occurs when phase (time) lag causes the control loop to react too late. A valve actuator has capacitance; that is, the valve does not change position when air flow starts to enter but moves only when enough air accumulates to build up pressure and cause motion. The classic control oscillation problem occurs when the valve time constant is the same as the rest of the process. A positioner has a small input capacitance, but because it causes large flow amplification, it reduces the effective actuator capacitance. A control loop tuned with very little gain and a long reset time may have a cycle time of hours and hide the cycle. It is often very difficult to discover whether a given control loop is causing a cycle or is just responding to another loop.

6.10 Emergency Partial-Stroke Testing of Block Valves

A. S. SUMMERS (2005)

Features:	Discussion of partial-stroke testing of block valves
Purpose:	Enhanced diagnostics can be used to achieve higher safety integrity level using partial-stroke testing.
Codes, Standards, and Recommended Practices:	Instrumentation, Systems, and Automation Society (ISA), ANSI/ISA 84.00.01-2004, "Functional Safety: Electrical/Electronic/Programmable Electronic Safety-related Systems," Research Triangle Park, NC International Electrotechnical Commission (IEC), IEC 61508, "Functional Safety: Safety-Instrumented Systems for the Process Industry Sector," Geneva, Switzerland International Electrotechnical Commission (IEC), IEC 61511, "Functional Safety: Safety Instrumented Systems for the Process Industry Sector," Geneva, Switzerland

INTRODUCTION

ANSI/ISA 84.00.01-2004 (ISA 84) and IEC 61511 are new functional safety standards, covering the design, implementation, operation, maintenance, and testing of safety instrumented systems (SISs). Successful implementation of the safety life cycle model associated with these standards hinges on an essential design constraint: the safety integrity level (SIL). The SIL is a numerical benchmark, related to the probability of failure on demand (PFD). SIL is affected by the design quality, e.g., device integrity, voting, and common cause faults, and by the operation and maintenance strategy, e.g., diagnostics and testing interval.

For many operating companies, one of the most difficult parts of complying with the standards is the testing interval often required for final elements, such as emergency isolation valves or emergency block valves. Traditionally, these valves have been tested at unit turnaround, using an off-line, full-stroke test to demonstrate performance.

Thirty years ago, turnarounds were relatively frequent, occurring on average every 2–3 years. Due to successful mechanical reliability and preventive maintenance programs, many operating companies have been able to extend unit turnarounds. In some industries, it is now common to have turnaround intervals of 5–6 years. Extended turnaround intervals yield great economic returns through increased production. However, extended turnaround intervals also mean that block valves are expected to go longer between function tests, yet still achieve the same performance. This is simply not possible.

When SIL 2 or SIL 3 performance is required, 5-year function tests are inadequate. Consequently, it is necessary to supplement the off-line full-stroke test. This involves implementation of valve diagnostics, such as partial-stroke testing, or alternate testing strategies, such as on-line full-stroke testing.

Many users consider partial-stroke testing (PST) as a cost-effective alternative to on-line full-stroke testing (FST). The use of PST often eliminates the need for full flow bypasses, reducing engineering, capital, and installation costs, as well as potentially removing a bypass that could be inadvertently left open. Partial-stroke testing improves the block valve performance, as measured by the Average Probability of Failure on Demand (PFD_{AVG}). The amount of the reduction is dependent on the valve and its application environment.

This section will discuss the method of determining the actual impact of the partial-stroke test on PFD_{AVG}. It will also present a discussion of the three partial-stroke testing methodologies that are currently being evaluated and used by industry.

THE PARTIAL-STROKE TEST

There are three basic types of partial-stroke test equipment: mechanical limiting, position control, and solenoid valves. Each type involves different levels of sophistication and risk.

Mechanical Limiting

Mechanical limiting methods involve the installation of a mechanical device to limit the degree of valve travel. When mechanical limiting methods are used, the valve is not available for process shutdown.

The mechanical devices used for partial-stroke testing include collars, valve jacks, and jammers.

- Valve collars are slotted pipes that are placed around the valve stem of a rising stem valve. The collar prevents the valve from traveling any farther than the top of the collar. Any fabrication shop can build a valve collar, suitable for test use.
- A valve jack is a screw that is turned until it reaches a set position. The valve jack limits the actuator movement to the screw set position. The valve jack is ordered from the valve manufacturer when the valve is purchased. Valve jacks work with both rising stem valves and rotary valves.
- Mechanical jammers are integrated into the rotary valve design. They are essentially slotted rods that limit valve rotation when placed in position using an external key switch. Since the jammer is integrated into the rotary valve, the jammer must be purchased from a valve manufacturer. A contact can be provided for the key switch to allow annunciation in the control room whenever the key is used.

Mechanical limiting methods are inexpensive in terms of capital and installation costs. These methods are manually initiated in the field and are personnel-intensive.

A limit switch or visual inspection is used to confirm block valve movement. Successful test implementation and return of the block valve to normal operational status are completely procedure driven. For valve collars and jacks, bypass notification to the control room is entirely procedural. For the jammer, automatic notification using the key switch contact can be provided.

Two of the biggest drawbacks to these methods are the loss of protection that occurs during the test and the lack of assurance that the valve is in or has been returned to normal status. There is no way to know for certain that the jack or jammer has been completely retracted without actuating the valve. Furthermore, unauthorized use of the valve jack or jammer cannot be determined by casual inspection. This means that the valve could potentially be out of service, with operations personnel unaware of the situation.

These methods do not add to the normal operating spurious trip rate. However, there is the potential for a spurious trip during the partial-stroke test. For valve collars, the main culprit of spurious trips is improper installation, causing the collar to pop off the stem when the valve begins to move. Jacks and jammers must be placed in service by the technician; so procedural mistakes can result in the valve closing completely rather than just partially. Therefore, these methods are really only as good as the written procedures and technician training.

Position Control

Position control uses a positioner to move the valve to a predetermined point. This method can be used on rising stem and rotary valves. Because most emergency block valves are not installed with a positioner, this method does require installation of additional hardware. Consequently, cost is a major drawback for the position control method.

A limit switch or position transmitter can be used to determine and document the successful completion of the tests. If a smart positioner is used for the position control, a HART maintenance station can collect the test information and generate test documentation. Of course, the use of a smart positioner and maintenance station further increases the capital cost.

Some manufacturers have promoted the use of the positioner in lieu of a solenoid valve for valve actuation. However, most positioners do not have a large enough vent port (C_v) for rapid valve closure. Consequently, a solenoid valve should still be used for valve actuation. This solenoid valve must be installed between the positioner and the actuator.

The positioner does contribute to the spurious trip rate during normal operation, because the positioner can fail and vent the air from the valve. When a solenoid valve is installed between the positioner and the actuator, the safety functionality is never lost during the partial-stroke test. De-energizing the solenoid valve will shut the valve, regardless of the positioner action.

Solenoid Valve

A partial-stroke test can be accomplished by pulsing a solenoid valve. The solenoid valve can be the same as the one used for valve actuation, resulting in lower capital and installation costs for this method than other methods. If the actuation solenoid valve is used, this method will also test the solenoid valve's capability to execute safe shutdown.

Single Solenoid Valves The Minerals Management Service, which oversees safety for oil and gas operations for U.S. offshore waters, provides one method for partial-stroke testing. This method relies on the operator to pulse a single solenoid valve by turning a field-mounted switch, which de-energizes the solenoid coil for as long as the field operator holds the switch.

The field operator monitors the valve position and releases the button when the operator confirms valve movement. When the valve moves, it can be inferred that the solenoid valve successfully vented. Of course, the main risk is that the operator may hold the switch too long, allowing the valve to close sufficiently to disrupt the process, resulting in unit shutdown.

It is also possible to automate the single solenoid valve test using a pulse timer adjusted to achieve the desired valve travel. Valve travel confirmation is accomplished using a limit switch or position transmitter, allowing automatic documentation of test status. Because a failure of the solenoid valve or block valve may result in excessive block valve travel, the pulse timer should be voted with the limit switch or position transmitter. If the valve reaches its desired travel point before the pulse timer is finished, the solenoid valve is reset. The test can be programmed in the SIS logic solver with the test implemented automatically on a programmed cycle time or initiated by the operator per a maintenance schedule.

Another method is to measure the block valve position as related to air pressure in the actuator during the time of the solenoid pulse. This results in a "fingerprint" of the breakaway pressure for block valve closure, which can be compared with the original valve fingerprint. In order for this method to be effective, maintenance must have a specific procedure for examining the fingerprint to identify that the block valve is degraded and to respond with corrective action.

When a simplex solenoid valve is being used to PST the block valve, the solenoid is de-energized and then re-energized. If the solenoid valve does not reset, the test becomes a trip. Using redundant solenoid valves can essentially eliminate this problem.

Redundant Solenoid Valves When arranged in a two-out-of-two (2oo2) configuration, redundant solenoid valves provide improved reliability during normal operation and reduce the probability of a spurious trip during the PST. For processes that are sensitive to spurious trips, the reliability improvement is typically sufficient to justify the additional capital and installation costs.

There are commercially available solenoid valve packages that provide on-line diagnostics of solenoid coil failure, facilitate on-line solenoid valve testing, and perform on-line, partial-stroke testing of the block valve. One particular package (patent pending) operates in a one-out-of-one hot standby (1oo1HS) configuration. During normal operation, the air signal passes through the package from the signal source to the valve actuator. When a trip occurs, the solenoid package vents the air from the valve actuator and allows the valve to move to its fail-safe position.

With the 1oo1HS, one solenoid valve is used as the primary actuation solenoid and is confirmed on-line using a pressure switch. A secondary solenoid valve is off-line and confirmed in the vented state (off-line state) by a pressure switch. The safety logic solver is programmed so that if the primary solenoid valve goes to the vent state without being commanded (as detected by the pressure switch), the secondary solenoid valve is energized, preventing the spurious trip.

Solenoid valve testing is performed by cycling the solenoid and by verifying that each solenoid valve successfully vents and resets using the pressure switches. The 1oo1HS can be used for PST by incorporating a PLC timer to pulse the power to the solenoids for just long enough to achieve the partial stroke. To verify the movement of the valve, a position transmitter or limit switch is used.

The position indication is also used to prevent overstroking of the block valve; i.e., if the valve moves too far during the timed stroke, the solenoids are re-energized. For preventative maintenance activities, overstroke or understroke alarms can be configured to let maintenance know if the valve is moving too quickly or too slowly during the test.

TABLE 6.10a

The Relationship among the Safety Integrity Level (SIL), the Average Probability of Failure on Demand (PFD_{AVG}), and Risk Reduction

SIL	PFD_{AVG}	Risk Reduction
4	0.0001 to 0.00001	10,000 to 100,000
3	0.001 to 0.0001	1,000 to 10,000
2	0.01 to 0.001	100 to 1,000
1	0.1 to 0.01	10 to 100

Impact of PST on SIL

Safety integrity level (SIL) and MTTF are defined by the average probability of failure on demand for demand mode SIS. In Instrumentation, Systems, and Automation Society 84 and IEC 61511, there are four SIL classes. Each SIL class provides an additional order of magnitude risk reduction, as shown in Table 6.10a.

The SIS standards require an examination of the PFD_{AVG} to ensure that the risk reduction assigned to the SIS is met. It is important to note that SIL is not a property of a specific device. It is a SIS property, encompassing the field sensors through the logic solver to the final elements (e.g., solenoid valve, block valve, or pump motor control circuit).

SIL is an important concept for safe operation, but plant management demands that the process plant operate at a high utilization rate. If a SIS is installed that has a low Mean Time to Failure Spurious ($MTTF^{spurious}$), the project will be considered a failure, regardless of the SIL that the SIS achieves. Consequently, any SIS assessment should include an analysis of the $MTTF^{spurious}$.

Let's examine a typical SIS, including transmitters, a redundant logic solver, solenoid valves, and block valves. In order to perform the PFD_{avg} and $MTTF^{spurious}$ calculations, failure rate data is required. This data can be selected from various industry-published databases. The values used in this analysis are shown in Table 6.10b.

For illustration purposes, the analysis will be presented in two parts: 1) the impact of PST on block valve performance, and 2) the impact of PST on the SIS performance. For the latter case, a dual solenoid valve package (1oo1HS) will be used for block valve actuation and PST. Other PST methods can be assessed using similar techniques.

The results for other PST methods may provide very different results for PFD_{AVG} and $MTTF^{spurious}$. Consequently, the results presented in this section should not be generalized for all PST equipment. The reader is further cautioned to ensure that any data used during SIL verification is appropriate for their application. In other words, the results presented here may not be directly applicable to the reader's application.

TABLE 6.10b
Failure Rates Used in the Analysis

Device	*MTTF^D (Years)*	*$\text{MTTF}^{spurious}$ (Years)*	*Data Sources$^{(1)}$*
Transmitters	100	100	OREDA data for various transmitters
Redundant Logic Solver	5000	Not included in analysis	Vendor data for 1oo2D, 2oo3D, or 2oo4D logic solvers
Solenoid Valve	60	15	TR84.00.02 data
Pressure Switch	75	60	CCPS data
Block Valve	40	455	OREDA data

(1) Due to the nature of the analysis presented in this chapter, values were selected to represent generic devices rather than specific devices. For the evaluation of an actual SIF, failure rate values representing the specific devices should be used.

Block Valve Analysis

Block valve components can be examined to determine which failures potentially result in the valve not operating when a process demand occurs. The causes of failures and associated modes of failure are shown in Table 6.10c.

The PFD_{AVG} can be calculated using the dangerous failure rate (λ^D) and the testing interval (TI). The mathematical relationship, assuming that the mean time to repair is small compared to the testing interval and that $\lambda^D \times \text{TI}$ is much small than 0.1, is as follows:

$$\text{PFD} = \lambda^D \times \text{TI}/2 \qquad \textbf{6.10(1)}$$

TABLE 6.10c
Causes of Block Valve Failures and the Associated Modes of Failure

Cause of Failures	*Modes*
Actuator sizing insufficient for valve actuation	Valve fails to close (or open)
Valve packing is seized	Valve fails to close (or open)
Valve packing is tight	Valve is slow to move to closed or open position
Air line to actuator crimped	Valve is slow to move to closed or open position
Air line to actuator blocked	Valve fails to move to closed or open position
Valve stem sticks	Valve fails to close (or open)
Valve seat is scarred	Valve fails to seal off
Valve seat contains debris	Valve fails to seal off
Valve seat plugged due to deposition or polymerization	Valve fails to seal off

TABLE 6.10d
Average Probability of Failure on Demand of a Typical Block Valve Given as a Function of Testing Interval (Note: Does Not Include the Contribution of the Solenoid Valve)

Testing Interval	*PFD_{avg}*
1 year	1.25E–02
2 years	2.50E–02
3 years	3.75E–02
4 years	5.00E–02
5 years	6.25E–02

Thus, the relationship between PFD and TI is linear. Longer test intervals yield a larger PFD_{AVG}. The Offshore Reliability Data Handbook (OREDA) database has data for various valve types and sizes. For the purposes of illustration, a MTTF^D of 40 years will be used. The failure rate λ^D can be calculated from the MTTF^D using the simplified equation:

$$\lambda^D = \frac{1}{\text{MTTF}^D} \qquad \textbf{6.10(2)}$$

For a MTTF^D of 40 years, this yields a dangerous failure rate of 2.5e–02 failures per year. The valve failure rate varies with type, size, and operating environment (e.g., process chemicals, deposition, polymerization, etc.). The reader should determine the appropriate failure rate for the specific application.

The PFD, based on 2.5e–02 failures per year, is shown in Table 6.10d for various testing intervals. As expected, the valve performance at a 5-year testing interval is not the same as the valve performance at a 2-year testing interval. Due to the degraded performance at longer testing intervals, many companies have found that they must test the block valves on-line. Once facilities for on-line testing are installed, full-stroke testing can easily be performed. However, since a full-stroke test involves full contact of the valve seating members, frequent stroking can cause excessive wear to the block valve seat. This is a serious concern for soft-seated valves. Increased testing may achieve a higher integrity, but cause damage to the valve seat, leading to earlier valve failure.

Another major concern is that the plant is unprotected while the block valve is in bypass for testing. The fraction of the time that the valve is in bypass must be considered in the PFD calculation. If the valve is bypassed every 6 months for testing and the test takes 1 hour, the PFD is increased by 2.28^4. For longer bypass periods or more frequent testing, the impact on the PFD is even more significant. To maintain safety, operating procedures must include a list of the actions to be taken when the valve is in bypass, such as continuous monitoring of critical process variables and when manual shutdown should be initiated.

Partial-Stroke Testing An alternative option to a full-stroke testing is a partial-stroke test. The test involves moving the valve from the fully open position. This tests a portion of the valve failure modes. The remaining failure modes are

TABLE 6.10e
Dangerous Failures, Failure Modes, and Test Strategy

Failures	*Failure Modes*	*Test Strategy*
Actuator sizing is insufficient to actuate valve in emergency conditions	Valve fails to close (or open)	Not tested
Valve packing is seized	Valve fails to close (or open)	Partial- or full-stroke
Valve packing is tight	Valve is slow to move to closed or open position	Partial- or full-stroke, if speed of closure or resistance to closure is monitored
Air line to actuator crimped	Valve is slow to move to closed or open position	Partial- or full-stroke, if speed of closure or resistance to closure is monitored. Physical inspection
Air line to actuator blocked	Valve fails to move to closed or open position	Partial- or full-stroke
Valve stem sticks	Valve fails to close (or open)	Partial- or full-stroke
Valve seat is scarred	Valve fails to seal off	Full-stroke test with leak test
Valve seat contains debris	Valve fails to seal off	Full-stroke test
Valve seat plugged due to deposition or polymerization	Valve fails to seal off	Full-stroke test

tested using a full-stroke test. The main purpose of the partial-stroke test is to reduce the required full-stroke testing interval.

How does partial-stroke testing affect the PFD? The valve failures are modeled in two parts: 1) those failures that can be tested using the partial-stroke (PS), and 2) those failures that can only be tested using a full-stroke (FS). For the calculation, the dangerous failure rate, λ^D, must be divided into what can be tested at the partial-stroke ($\lambda^D{}_{\mathrm{PS}}$) and what can only be tested with a full-stroke ($\lambda^D{}_{\mathrm{FS}}$).

To determine the percentage of failures that could be detected using PST, the failure mode distributions for various valve types and sizes contained in the Offshore Reliability Data Handbook were examined. This evaluation can be done for any valve type, based on the application environment and the shut-off requirements.

Table 6.10e provides a listing of typical dangerous failures and failure modes for block valves. The test strategy indicates whether the failure mode can be detected by partial-stroke testing or only by full-stroke testing. Based on the OREDA data, the typical percentage of the failures that can be detected by a PST is 70% for many valve types and services. Additional analysis can be performed to justify a higher percentage of detected failures. However, it is very difficult to substantiate a percentage greater than 85% for process industry applications. Those failures that are not detected during the PST are tested using an FST.

An imperfect testing model is used for calculating the $\mathrm{PFD}_{\mathrm{AVG}}$ of the block valve when PST is utilized. The percentage of detected (PD) failures is used with the dangerous failure rate of the block valve (λ^D), testing interval (TI), and the mean time to repair (MTTR), as follows:

$$\mathrm{PFD}_{\mathrm{AVG}} = \mathrm{PD} \times \lambda^D \times \mathrm{TI}_{\mathrm{PST}}/2 + (1 - \mathrm{PD}) \times \lambda^D \times \mathrm{TI}_{\mathrm{FST}}/2 + \lambda^D \times \mathrm{MTTR} \qquad \mathbf{6.10(3)}$$

FST Supplemented by PST Table 6.10f provides a simple comparison of the $\mathrm{PFD}_{\mathrm{AVG}}$ for block valves tested using FST

TABLE 6.10f
Comparison of Average Probability of Failure on Demand (PFD_{avg}) for Block Valve(s) Undergoing Full-Stroke Testing (FST) Only or FST with Monthly Partial Stroke Testing (PST) (Note: Does Not Include Common Cause Failures or the Contribution of the Solenoid Valve)

	Single Block Valve		*Dual Block Valves*	
FST Interval (Years)	*FST only PFD_{AVG}*	*FST and Monthly PST PFD_{AVG}*	*FST only PFD_{AVG}*	*FST and Monthly PST PFD_{AVG}*
1	1.25^{2}	4.55^{3}	1.58^{4}	2.07^{5}
2	2.50^{2}	8.30^{3}	6.28^{4}	6.89^{5}
3	3.75^{2}	1.21^{2}	1.41^{3}	1.45^{4}
4	5.00^{2}	1.58^{2}	2.51^{3}	2.50^{4}
5	6.25^{2}	1.96^{2}	3.92^{3}	3.82^{4}

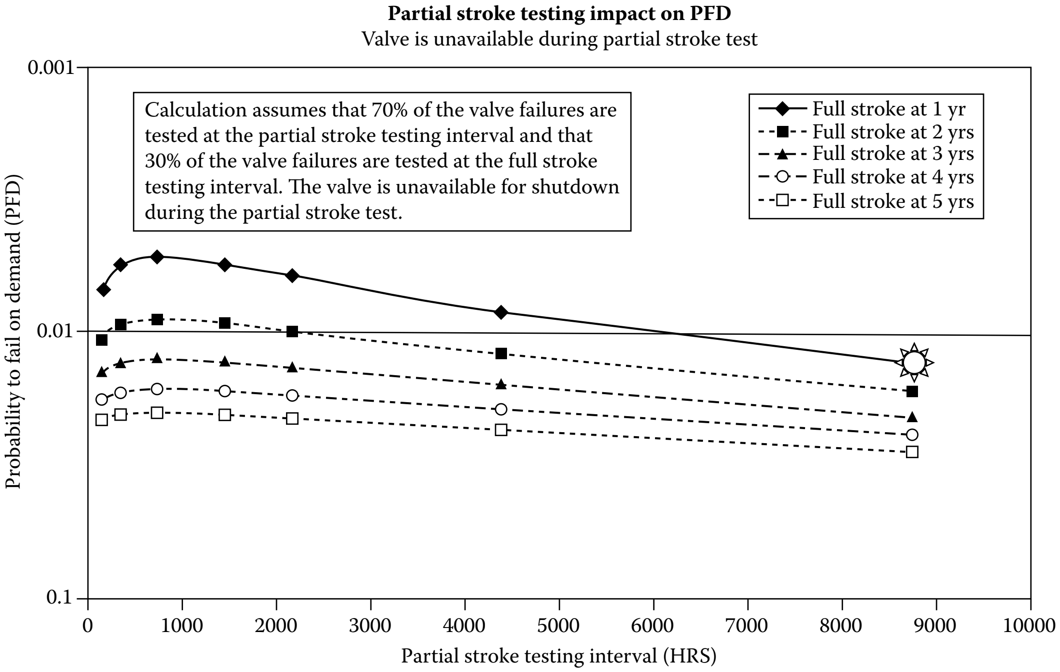

FIG. 6.10g
Relationship between the PST and PFD valves. Valve is unavailable during the test.

only and using FST supplemented with PST. The PFD_{AVG} is shown as a function of the full-stroke testing interval. For this illustration, the partial-stroke test is performed monthly. Similar calculations can be performed at other PST intervals. The results in Table 6.10f do not include the solenoid valve contribution to the PFD_{AVG}. The PFD_{AVG} for the single block valve is significantly reduced when PST is utilized. For double block valves, the PST lowers the PFD_{AVG} by nearly an order of magnitude.

The reader is cautioned that this breakdown is based on average valve performance and may not represent the breakdown for the reader's application. This evaluation should be done for each valve type, based on the application environment and the shut-off requirements.

If the service is erosive, corrosive, or plugging, the failure rate and failure mode breakdown will be different from that shown in this chapter. If the valve is specified as tight-shut-off, the contribution of minor seat deformation or scarring may be more significant than shown in this chapter.

Probability of Failure Using a dangerous failure rate of 2.5^2 failures per year, Figure 6.10g shows the PFD when the test procedure requires bypassing the valve during the test. As expected, the PST does improve the PFD_{AVG} performance of the valve. The star illustrates the point where the partial-stroke test and full-stroke test are both conducted at a 1-year interval. This corresponds to the result shown for a 1-year full-stroke test in Table 6.10a.

The downward trend of the curves for very frequent partial-stroke testing is due to the valve being bypassed during the test. This removal results in the valve not being available for the fraction of time that the valve is being tested. The calculation assumes that the total test time is 30 minutes. If the actual test time is longer, the effect will be more pronounced.

Figure 6.10h shows the PFD when the test procedure allows the valve to remain in service during the test. Very frequent partial-stroke tests improve the PFD substantially, because there is no loss of functionality during the test. Again, the star illustrates the point where the partial-stroke test and full-stroke test are both performed at a 1-year interval.

For both test procedures, partial-stroke testing does improve the valve performance. For example, 5-year full-stroke testing achieved a PFD of 6.25^2 (Table 6.10a). A 5-year full-stroke test supplemented with a 1-month (720 hours) partial stroke test achieved a PFD of 1.96^2, which is an approximately 30% reduction in PFD. In the cases of 1-year and 2-year full-stroke testing, a single block valve can potentially achieve SIL 2 performance when supplemented with frequent partial-stroke tests.

For longer full-stroke testing intervals, the valve performance can increase from low SIL 1 to high SIL 1, depending on the partial-stroke testing interval. From the graphs, it is easy to see that no amount of partial-stroke testing is going to allow a single valve to achieve high SIL 2 performance, let alone SIL 3 performance, at full-stroke testing intervals of 1 year or more.

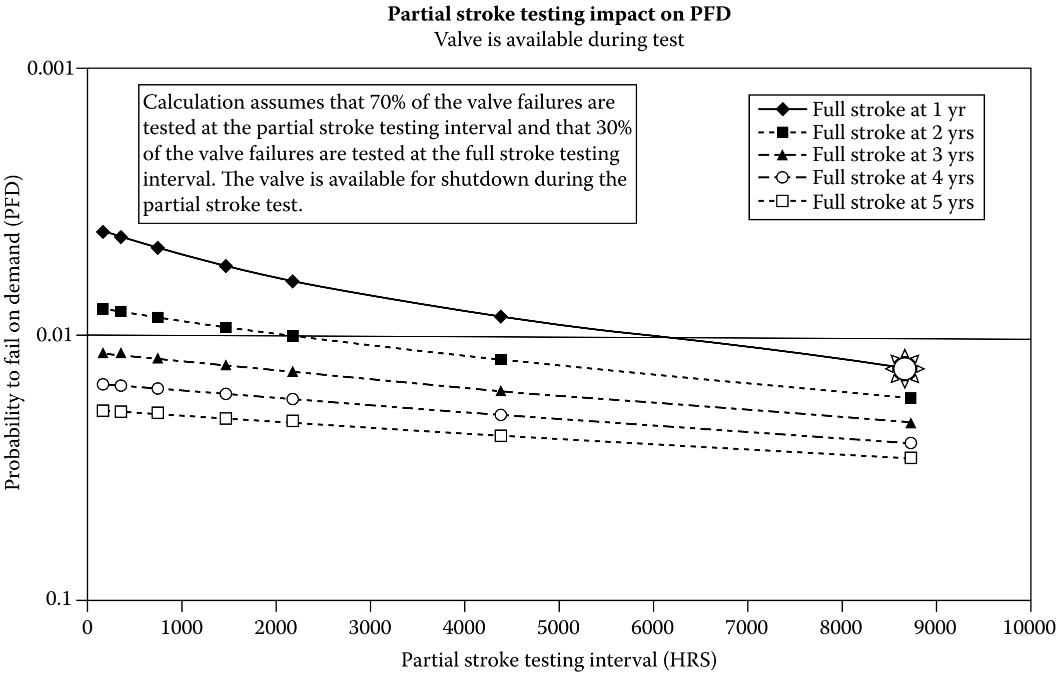

FIG. 6.10h

Relationship between PST interval and PFD. Valve is available during the test.

OVERALL SIS PERFORMANCE

Let's examine a typical SIS, including transmitters, a redundant logic solver, solenoid valves, and block valves. For the PFD_{avg} and $MTTF^{spurious}$ calculations, the failure rate data presented in Table 6.10b was used. In addition, the following assumptions were made:

- For redundant transmitters, it was assumed that analog signal comparison is performed and a fault alarm is initiated when the transmitters deviate unacceptably. "D" at the end of the voting architecture indicates the use of diagnostic coverage. The diagnostic coverage is assumed to be 80% for dual redundancy and 90% for triplicated redundancy.
- The PST can detect 70% of the valve dangerous failures.
- Common cause factor is assumed to be 2%.
- Mean time to repair is assumed to be 24 hours.

The results of the analysis were plotted using bar charts to illustrate the relative contribution of each device on the PFD_{AVG}.

Single Block Valve Case

For the simplex solenoid valve cases shown in Figure 6.10i, the SIS only achieved SIL 1 at annual function testing. When PST is used to supplement the full-stroke test, the SIS achieves very high SIL 1 to mid-range SIL 2. The individual bars can be examined to determine the major contributors to the PFD_{AVG}. For the 1oo1 and 2oo2D cases, the transmitter is the major contributing cause to the PFD_{AVG}. The impact of the transmitter can be decreased by changing the voting to 1oo2D or 2oo3D, which results in the single block valve being the major contributor.

For the spurious trip rate calculation, the logic solver was not included in the calculation, because the spurious failure rate can vary so much dependent on the specific architecture. Some logic solvers have high spurious trip rates, and their contribution to the overall $MTTF^{spurious}$ can overwhelm the other SIS components. For this illustration, the logic solver was not included in this calculation to allow the examination of the field devices. For actual installations, the logic solver must be included in the PFD_{AVG} calculation.

The benefit of using the 1oo1HS is evidenced in Figure 6.10j. In each case, the spurious trip rate was reduced significantly when the 1oo1HS was used instead of a simplex solenoid valve. The simplex solenoid valve cases had a spurious trip rate of 10 years for the 1oo2D transmitter case and 15 years for the other transmitter cases.

When the 1oo1HS is used, the $MTTF^{spurious}$ exceeds 45 years for the 1oo2D transmitter case and exceeds 420 years for the 2oo2D and 2oo3D transmitter cases. If the plant life is 20 years, the single solenoid valve cases yield an average of 1.5 trips during the life of the plant. Even if a spurious trip costs only $100,000, the simplex solenoid valve will result in the loss of $150,000 over the life of the plant. For the 1oo1HS cases, the $MTTF^{spurious}$ is greater than the plant life expectancy, yielding substantial savings.

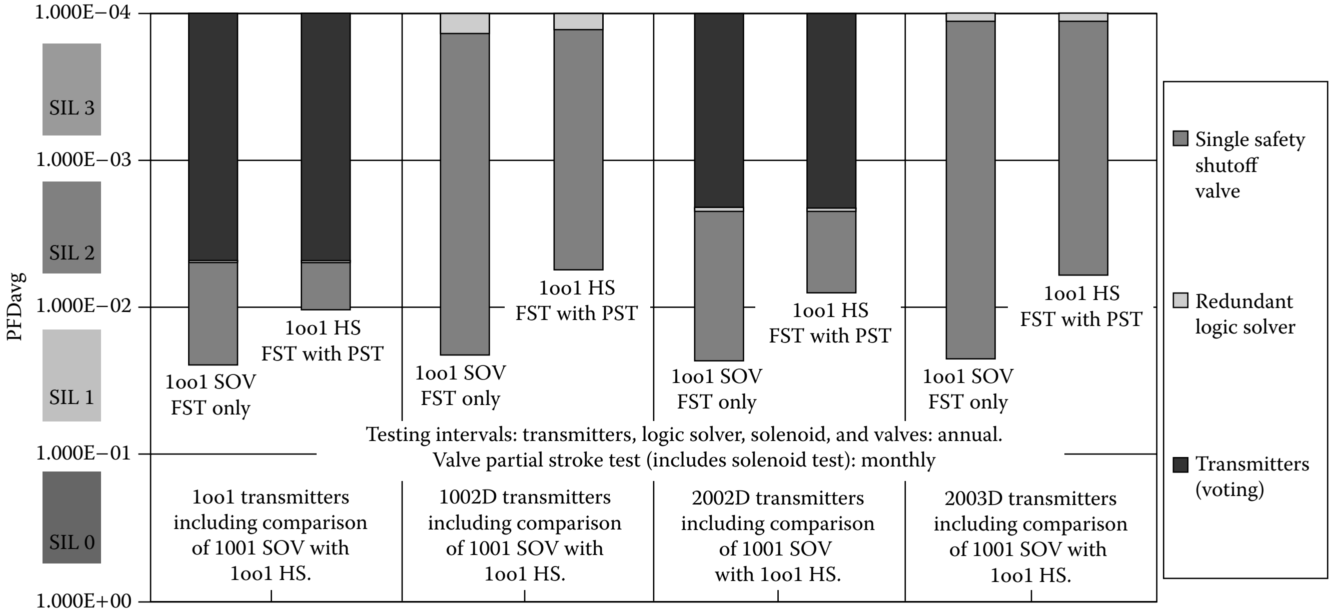

FIG. 6.10i
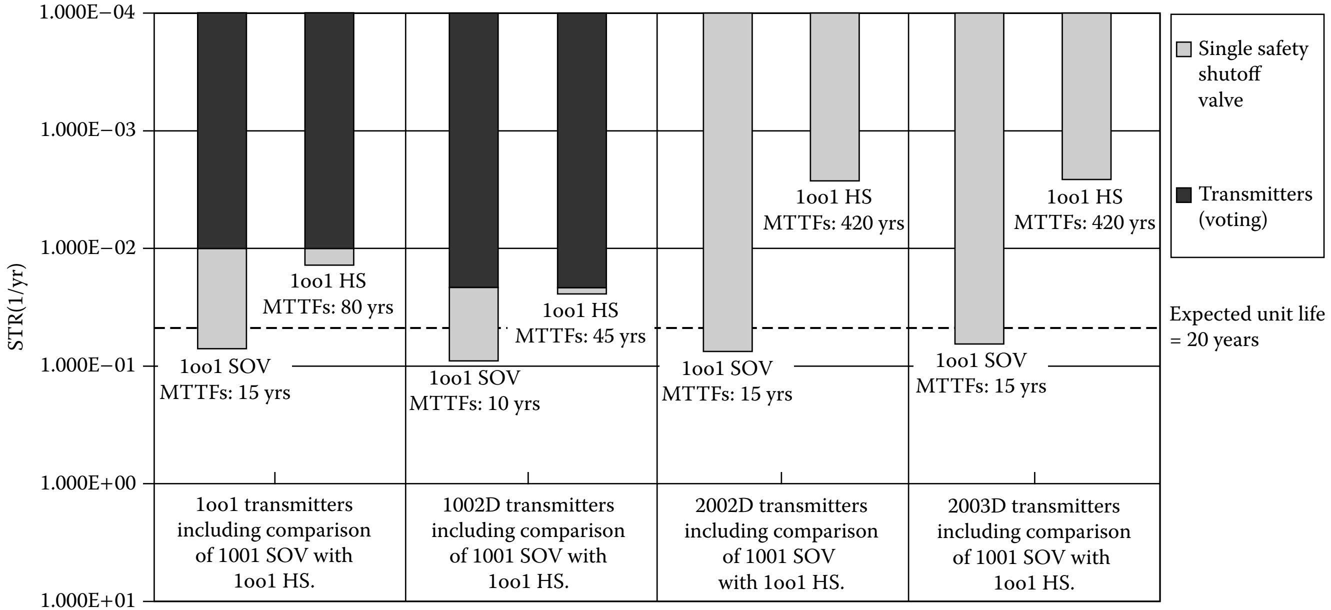
Plot of PFD_{AVG} showing the benefit of using PST of a single block valve.

Dual Block Valve Case

Dual block valves are used in many installations to provide greater assurance that the process is isolated. When dual block valves are used, it is common for test intervals to be extended to unit turnaround. Consequently, for the analysis, a 5-year full-stroke test was assumed for the logic solver, solenoid valves, and block valves, while annual testing was used for the transmitters.

For the simplex solenoid valve cases shown in Figure 6.10k, the SIS achieved high SIL 1 to the borderline between SIL 1 and SIL 2 at 1-year full-stroke testing. When PST is used to supplement the full-stroke test, the SIS achieves mid-range SIL 2 with 1oo1 and 2oo2D transmitter voting. For 1oo2D



This comparison includes field devices only. The contribution of the redundant logic solver to the spurious trip rate is not shown.

FIG. 6.10j
Plot of $MTTF^{spurious}$ showing the benefit of using PST of a single block valve.

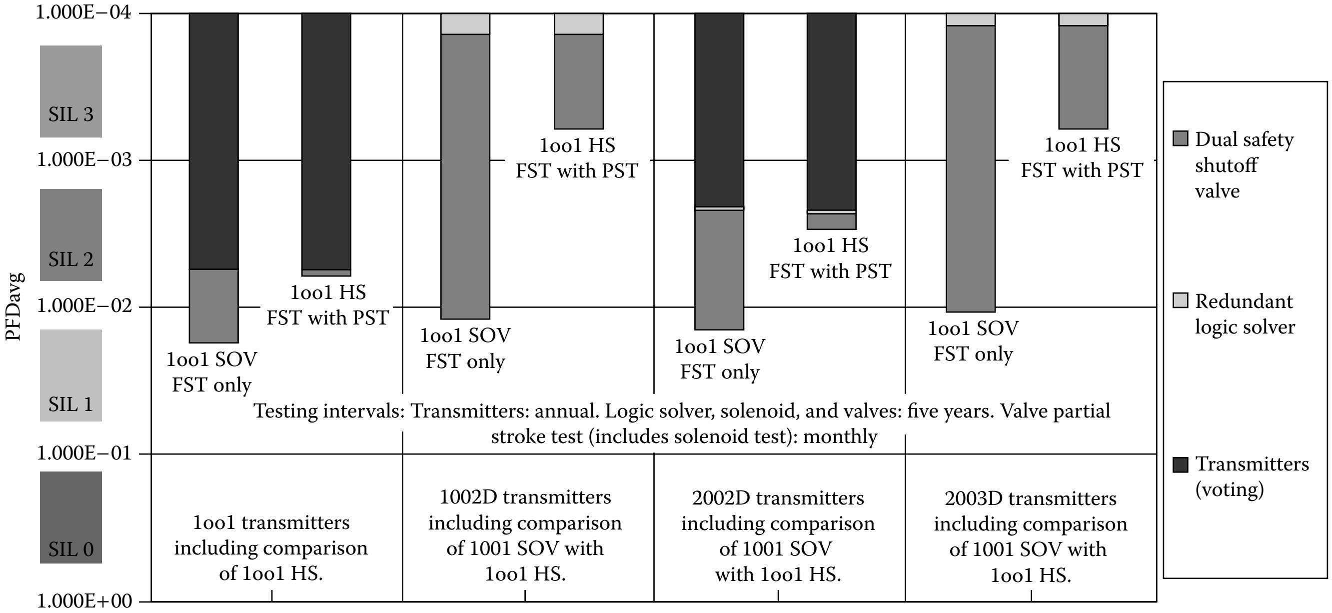


FIG. 6.10k
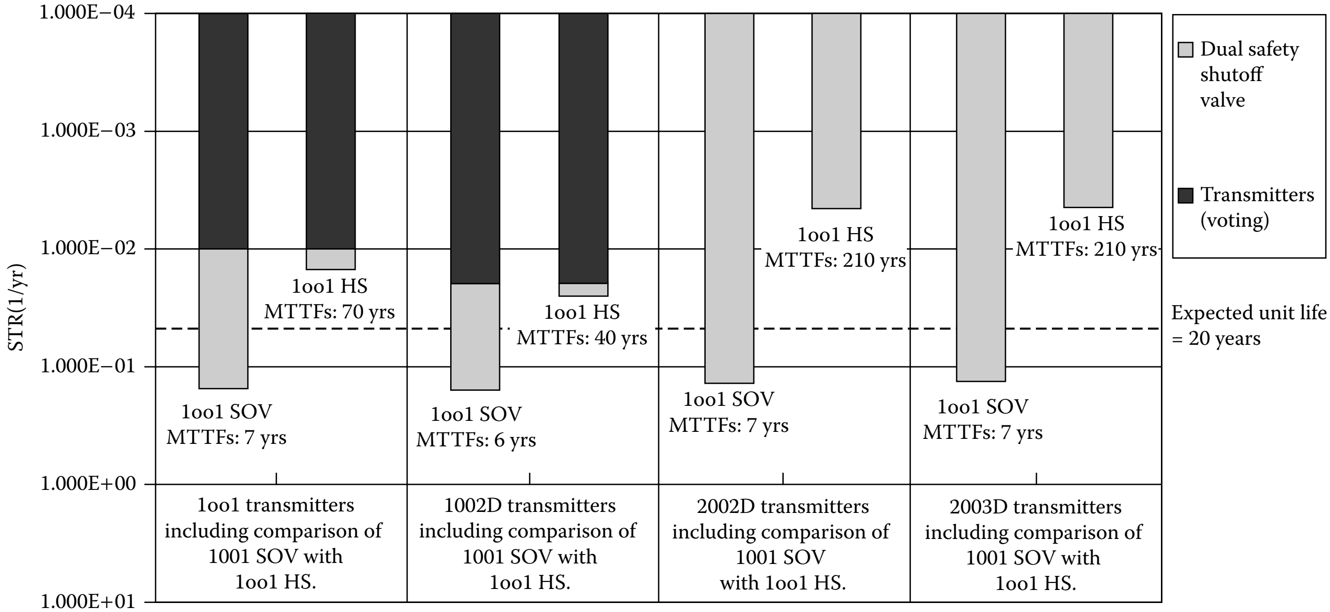
Plot of PFD$_{AVG}$ showing the benefit of using PST of a dual block valve.

and 2oo3D voting, the PST makes it possible to achieve SIL 3.

Again, the individual bars can be examined to determine the major contributors to the PFD$_{AVG}$. As seen in the simplex block valve SIS, the transmitter is the major contributing cause to the PFD$_{AVG}$ for the 1oo1 and 2oo2D transmitter cases. The contribution of the transmitter is seriously reduced when the voting is changed to either 1oo2D or 2oo3D. In these latter cases, the major contributors to the PFD$_{AVG}$ are the dual block valves.

The benefit of using the 1oo1HS is evidenced in Figure 6.10l. The MTTF^{spurious} for the simplex solenoid valve cases is an average of 7 years. When the 1oo1HS is used for valve actuation, the MTTF^{spurious} is more than 40 years for



This comparison includes field devices only. The contribution of the redundant logic solver to the spurious trip rate is not shown.

FIG. 6.10l
Plot of MTTF^{spurious} showing the benefit of using PST of a dual block valve.

the 1oo2D transmitter case and more than 210 years for 2oo2D and 2oo3D transmitter cases.

If the plant life is assumed to be 20 years, the simplex solenoid valve cases yield an average of 2.8 trips during the life of the plant. Again, if a spurious trip costs $100,000, the plant will lose more than $280,000 over the life of the plant due to spurious trips.

CONCLUSIONS

Partial-stroke testing does provide measurable improvement of the PFD over full-stroke testing alone. The amount of improvement is dependent on the specification, configuration, and application environment. The three partial-stroke testing methodologies offer choices between manual and automated testing.

It is important to remember that partial-stroke testing is used to achieve diagnostics on the valve in lieu of on-line, full-stroke testing. Some of these methods presented in this chapter have a higher potential for spurious block valve closure (e.g., on-line spurious actuation or unintentional actuation during test) than others. For processes that are sensitive to spurious trips, the selection of specific method should take into account not only the diagnostic capability, but also the reliability.

Whichever method is selected, procedures must be written to ensure that the block valve is not tripped during testing, the test is properly carried out, incorrect valve performance is documented, and maintenance is performed to return the valve to fully functional status. The primary issue is that partial stroke testing can reduce the full-stroke testing interval required to achieve the required SIL performance.

INTRODUCTION

The impact of fieldbus and smart technology on the design of control valves is profound. It changes how valves are installed, commissioned, set up, maintained, and operated. Ultimately, many benefits and savings can be achieved from using digital communication for valves.

The brains of an intelligent control valve are in the digital valve positioner. An intelligent control valve is therefore primarily an issue of using digital valve positioners. For a basic introduction on positioners please refer to Section 6.2, for a discussion of intelligent valves and positioners see Section 6.12, and for a discussion of valve diagnostics and predictive maintenance, refer to Section 6.8.

The brains of an on/off valve are in the discrete valve coupler (DVC). Therefore, using an intelligent on/off valve is an issue of using a discrete valve coupler. A Foundation™ Fieldbus or PROFIBUS-PA valve receives the command signal over the digital data highway or network.

A smart control valve receives the signal via 4–20 mA but also provides digital communication for auxiliary functions. Actually, in the case of Foundation Fieldbus more often the control is done in the positioner itself, and the positioner receives the process variable from the transmitter over the fieldbus.

Valve instrumentation based on HART, Foundation Fieldbus, and PROFIBUS-PA includes

Control valve positioner
Valve coupler
Electrical actuator
Fieldbus to current converter

Fieldbus to pneumatic signal converter
Fieldbus remote I/O
Position transmitter

BENEFITS AND SAVINGS

For valve users who spend too much effort and resources on maintenance, and see too much variability in product quality, network-enabled valves can significantly reduce the cost of operation. Unlike traditional hardwired valves, networked valve packages have microprocessors, which also allow for digital communication.

Networking of valves and microprocessors has enabled several technological breakthroughs that in turn can result in savings. This is because all information can be accessed remotely and because all functions are performed in device firmware instead of hardware: flow characterization, soft limit switch, feedback, and automatic setup.

HART, Foundation Fieldbus, and PROFIBUS-PA

In Foundation Fieldbus-based systems all valves have a permanent network connection to the engineering tool and to the asset management tool (Figure 6.11a). The digital communication works across the same single pair of wires that is used for the desired valve position. "Always on" communications means that interrogation for monitoring, parameterization, and diagnostics can conveniently be done any time.

Unlike in the past when smart valves, using HART communication, used temporarily connected handhelds, smart valves should have permanent communication with the control system in order to leverage the smart capabilities. A permanent communication link between valves and software enables on-line asset management. Operators can get on-line feedback of the control valve's true position and can monitor all critical parameters in real time without having to go into the field.

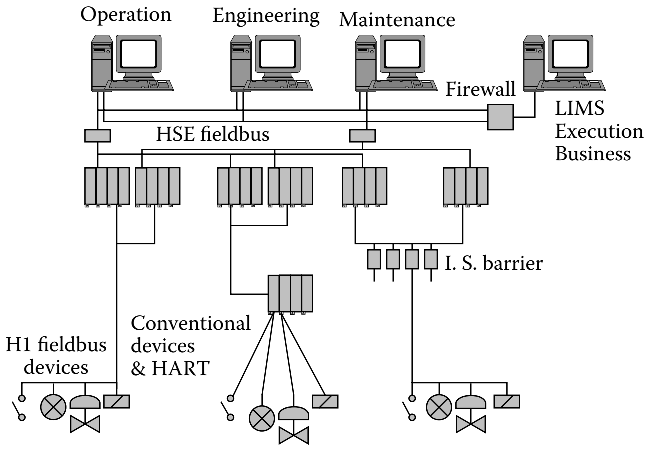

FIG. 6.11a
Illustration of a networked system architecture, which is "always on."

A fair amount of data can be accessed also from a smart HART-based valve positioner. However, fieldbus with its higher speed and standardized data formats enables positioners to provide more diagnostics, and faster. Fieldbus-based positioners therefore can bring more diagnostics to the user than their smart counterparts.

Digital valves can be configured remotely across the bus from a handheld or software tool. This makes it possible to adjust tuning, without having to leave the control room. A single type of digital valve positioner or discrete coupler can be configured for all control and on/off valves, respectively.

Self-Diagnostics Digital valves have internal self-diagnostics that can be interrogated remotely across the bus from a handheld or software tool without having to go into the field. Diagnostics to this level of detail was never possible before the introduction of microprocessors and digital communication. More sophisticated valve diagnostics can be done by using on-line asset management or by utilizing proprietary software tools using information tapped from the positioner.

In the case of Foundation Fieldbus the digital valve positioner or coupler can even issue alerts when failure is detected. The user can, from a single workstation, access all the positioners and other instruments using the engineering tools. The health of any device in the plant can thus be checked easily without having to venture into the field. In the past, valve diagnostics software was connected on a single unit basis. Diagnostics was performed after the valve had already failed, "post-mortem."

Additionally, digital valves internally collect operational statistics such as total travel and the number of reversals. The operational statistics are used for condition-based maintenance schemes.

Interoperability Digital valves can be monitored remotely to see variables such as actuator pressure or torque, and to feed back actual valve position. In the case of Foundation Fieldbus and PROFIBUS-PA, the actual position feedback provided by the digital valve positioner or coupler is fast enough to be used as part of the control loop. The feedback signal travels digitally on the same wire as the desired valve position from the controller or logic, i.e., without additional wiring or external proximity switches.

The HART, Foundation Fieldbus, and PROFIBUS-PA protocols are all developed and managed by independent organizations formed by several manufacturers. This means that many valve products, control systems, and other tools that communicate by using the same protocols are therefore compatible with them. It is possible to select valve positioners, couplers, and tools independent of the control system.

All three protocols support electronics device description (DD, a.k.a. EDDL) in some form. The DD files are loaded in the configuration tool, permitting the tool to communicate with the digital valve and make all its special features accessible.

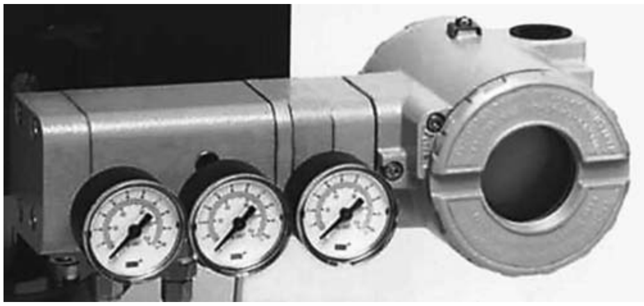

FIG. 6.11b
Digital valve positioner. (Courtesy of SMAR.)

DD for Foundation Fieldbus is very well supported in many control systems, while the DD for HART and PROFIBUS-PA is not so common. Thus better interoperability is achieved with Foundation Fieldbus, as the full set of information can be accessed from virtually any fieldbus system.

PROFIBUS-PA is also taking two other approaches to interoperability; one is device profile, which defines a common basic set of functionality providing some degree of interoperability, and the other is FDT/DTM (field device tool/device type manager). Although FDT/DTM is also not widely supported in control systems, it does have some potential advantages when it comes to sophisticated valve diagnostics. Future enhanced versions of DD may also address this capability.

Control Algorithm in Positioner A defining characteristic of Foundation Fieldbus is that it also is a standard function block diagram programming language to build the control strategy. In a modern network-based control system architecture control is often done in the field instrument (Figure 6.11b), and therefore it is possible to reduce or eliminate the number of control cards usually found in a DCS or PLC system.

Fieldbus positioners perform control in the field by executing the PID control function block. Other blocks perform functions such as split-range, flow characterization, and the positioning servo itself. It is possible to adopt decentralized control using Foundation Fieldbus programming language instead of central controllers and proprietary languages.

The failure of the electronics in the valve affects only a single loop. Diagnostics in the positioner and coupler detect loss of signal from the controller and subsequently bring the valve to its fail-safe position.

Foundation Fieldbus and PROFIBUS-PA completely do away with 4–20 mA. Valves, transmitters, and other devices are multidropped on a network. Typically up to 16 devices are connected to the same pair of wires. Theoretically it is also possible to multidrop HART devices, but the communication speed is too slow for valve applications.

Wiring Costs Using digital valves, the total installed cost can be reduced, achieving savings before the valve is even put into operation. Digital communications reduce installation cost in new construction and also in revamps.

Networked control valve positioners require less wiring than their hardwired counterparts. For example, if actual position feedback is required from an analog positioner, it is necessary to run a second pair of wires back into the control room, where the DCS or PLC will also require an analog input point (on the left side of Figure 6.11c).

For Foundation Fieldbus and PROFIBUS-PA no additional wiring is required because the feedback value is communicated on the bus together with the other values (at the center of Figure 6.11c). HART positioners also do not require an additional wire to run back into the control room. If the control system does not have native support for HART, it is possible to add a HART-to-current converter in the control room instead (Figure 6.11c right).

The converter connects to the same two wires used for the positioner to receive the desired valve position signal from the DCS or PLC, and then it uses HART to poll the positioner to get the actual position digitally (Figure 6.11d).

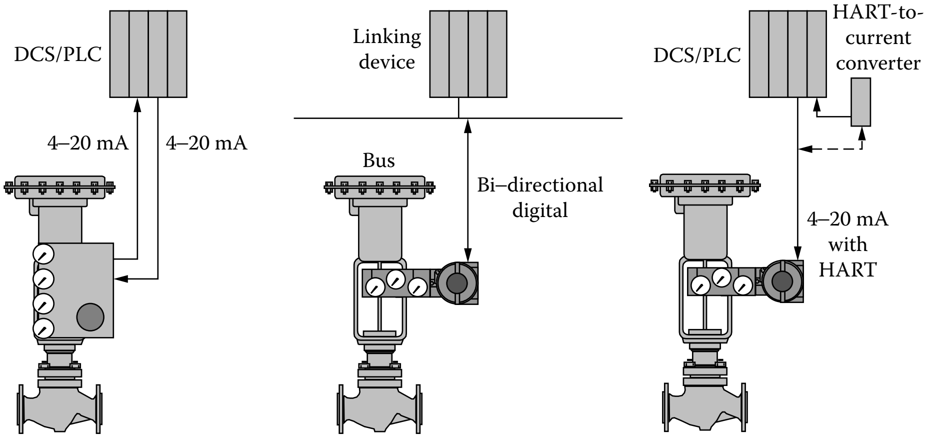

FIG. 6.11c
Wiring requirements of providing position feedback in analog (left), Fieldbus (center), and HART (right) systems.

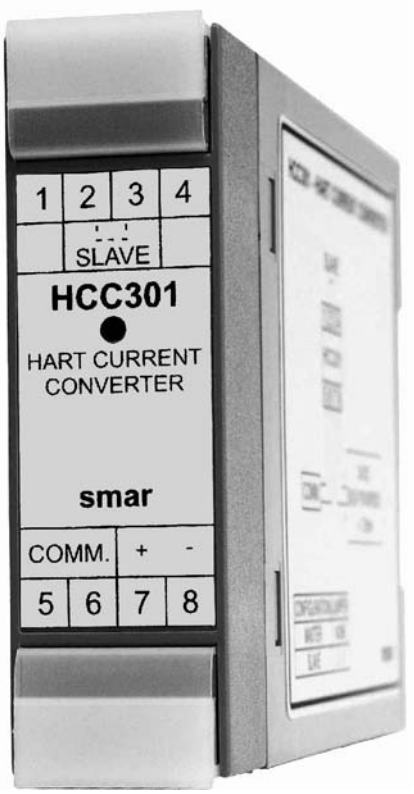

FIG. 6.11d
HART-to-current converter. (Courtesy of SMAR.)

The converter generates an analog signal accepted by the analog input card in any control system or single loop controller. Additional safety barriers are also eliminated. If discrete open/close statuses are required, these are simply detected as alarms in the control system using the actual position signal.

Similarly, networked discrete valve couplers require less wiring than their hardwired counterparts. For example, if open/close statuses are required from a hardwired valve, it is necessary to run two additional pairs of wires back into the control room, where the DCS or PLC will also require two discrete input points. However, the discrete valve coupler provides it on the same bus (Figure 6.11e).

An electric actuator may be even more extreme because the need for signals such as open/stop/close or desired valve position, shut-down, open/close statuses or actual position, local/remote, opening/closing, torque switch or torque value, and failures is not uncommon (Figure 6.11f). Using a bus, a lot of hardwire and I/O modules are eliminated.

In this case, using bus technology, it is possible to reduce by anywhere from two to ten pairs of wires per valve even if one is only considering the auxiliary functions. Needless to say, the savings in cable and controller I/O cards and all the associated costs of engineering and installation is significant.

Both Foundation Fieldbus and PROFIBUS-PA permit several devices to be connected on the same pair of wires together with other devices. Moreover, an interface module can handle as many as 64 devices, thus eliminating the need for a large number of conventional I/O modules. Significant savings in wiring and installation costs are therefore possible as compared to hardwired valves. In intrinsically safe installations the savings are even greater, because as many as four or eight devices share the same single safety barrier, depending on the scheme used. This too is a significant cost saver.

To really benefit from Foundation Fieldbus and PROFIBUS-PA multidrop wiring, the valve electronics shall draw as little power from the bus as possible. Pneumatic valve positioners that use piezo technology to drive the flapper have significantly lower power consumption than the solenoid type. Lower current draw means lower voltage drop along the wires, which translates into more devices, longer wires, and fewer barriers. Therefore, by using lower power consumption positioners, such as 12 mA, further savings are possible.

Positioners, couplers, and actuators based on HART, Foundation Fieldbus, and PROFIBUS-PA are available from multiple competing vendors. The competition among interoperable products brings prices down lower than for units using proprietary communication.

Valve Calibration and Configuration

Configuring and calibrating valves in the past required tedious mechanical adjustments. Using handheld terminal or computer software to access the valve, these tasks require less time and resources and thus result in savings (Figure 6.11g). For more detail on the subject of configuring intelligent devices, refer to Section 1.6 in Volume 1 of this handbook.

Valve instrumentation without microprocessor and communication requires mechanical and electronics adjustments at the valve in order to change the way it operates. For example, the modification of flow characteristics previously had to be done by changing mechanical cams and springs. Using digital communication it can now be done remotely through software, thereby significantly reducing cost and time, particularly during commissioning.

Other valve parameters, such as the opening and closing time of the valve, can also be set.

To align mechanical feedback systems based on leavers, cams, and potentiometers in older positioners was tedious and time consuming, especially in the field. Using digital communication, a setup command can simply be sent from a handheld terminal or software in the control system to auto-calibrate the positioner. This significantly shortens the setup time, as stroking need not be done manually, achieving reduced installation cost. Once the setup is initiated the valve automatically finds its own fully opened and fully closed positions.

A key advantage of Foundation Fieldbus is that control is also done in the field devices, typically in the valve. The decentralized architecture where control can be done in the field instruments is called Field Control System (FCS). Because control is done in the valve the number of loops in centralized controllers is reduced, and the number of

FIG. 6.11e
Discrete valve coupler incorporates solenoid and position feedback. (Courtesy of TopWorx.)

centralized controls can subsequently also be reduced. The savings achieved from the reduction in very expensive controllers are tremendous.

To enjoy maximum flexibility, the positioner can have dynamically instantiable function blocks. This allows the user to freely select from more than a dozen blocks in a library containing scores of blocks including PID, splitter, and arithmetic.

Valve Cycling and Stiction An inadequately functioning control valve will still degrade the overall loop performance and may cause the valve to wear out prematurely. Conversely, a healthy positioner ensures better control and less maintenance. The greatest savings potential for applying networked digital valves is in long-term operational costs such as maintenance and improved performance.

The push for higher valve performance has been seen particularly in the pulp and paper industries, because of their need for increasing product uniformity. Digital valve solutions have higher performance than their analog counterparts, resulting in lower process variability, which in turn translates into higher quality, less rejects, higher yield and productivity, and lower raw material and fuel consumption. Information from the digital valve may be used to fine-tune the loop for optimum production output and tighter product uniformity. The higher valve performance ultimately results in savings because of the resulting boost in production and yield.

Because aligning and calibrating analog positioners is tedious, this is often not done properly or not checked regularly. Automatic setup invoked through the fieldbus network makes sure it is done accurately, every time, so that positioning is precise. It is possible to remotely calibrate the positioner when conditions allow, e.g., while the process is down for any reason. As the valve seat and other parts wear and tear during operation, one can calibrate the valve to make sure that it operates and shuts off properly.

It is commonly seen that control valve cycling can cause the control loops to cycle and that this can destabilize production. Studies show that as many as two out of three control loops are oscillating due to the dead band of control valves. The operational statistics such as total valve travel and number of cycles that now are provided by the positioners are extremely helpful in detecting oscillation problems and enable one to eliminate them (Figure 6.11h).

FIG. 6.11f
Fieldbus electrical actuator. (Courtesy of Rotork.)

One can eliminate the sources of variability one by one. A hunting valve is easy to catch because one can see a great number of reversals counted in the positioner or coupler and communicated over the fieldbus. If this occurs, one knows that either the positioner or loop is poorly tuned. The servo gains and other parameters like the time required for opening and closing the valve can be set from a handheld or by a software tool to optimize positioner response to different valve sizes.

For good control loop performance a control valve must be able to respond to small steps in the control signal by matching it accurately with its stem within 1% or less. If not, a problem called “backlash” or “stiction” will occur. It is typically caused by packing friction (Section 6.5), which in turn may be a result of wear and tear.

In addition to being able to predict wear based on operational statistics, software is now available to analyze the valve’s performance thanks to the improved communications capabilities to obtain data for such plots. The operational statistics may be used to more accurately predict the packing wear, as to strike the right balance of downtime due to replacement, and greater performance as a result of more frequent packing change.

Position Feedback Fieldbus positioners provide an actual position feedback value over the communication network that is fast enough to be used as part of advanced control strategies and also for true bumpless transfer and true reset windup protection based on actual valve excursion end points. Because the valve position is available over the communication network, the actual position can be put into use at a later stage, without having to modify the valve positioner, running wires, or adding any AI points to the control system, as was the case in the days of analog feedback.

Foundation Fieldbus thus makes actual position feedback possible for every control loop. This makes it feasible to provide true bumpless transfer back to the automatic control mode after the valve has been switched to manual control and was operated locally. Similarly, true integral windup protection can be provided when the valve has reached its endpoints or is unable to move. In the past this was done for some loops in conventional systems, but was not realistic for all. In fieldbus systems, this feature has no extra cost and therefore it is viable to optimize every loop and obtain the corresponding savings.

Lastly, systems and devices using Foundation Fieldbus or PROFIBUS-PA eliminate the need for D/A and A/D conversions in the transmission path, as no analog signals are used. This results in higher accuracy. Because the actual valve position is transmitted back to the workstation using digital communication, inaccuracies caused by conversion to analog are eliminated. Additional points of calibration are also eliminated.

Proactive or Predictive Maintenance For further details on valve diagnostics and predictive maintenance, refer to Section 6.8. Self-diagnostics done in the digital valves as well as using other information make it is possible to move to a proactive condition-based maintenance scheme that can lower maintenance expenses as compared to reactive or preventive maintenance schemes.

Operational statistics, such as listed here, is easily reviewed and can trigger alarms notifying the operators that the valve is due for service. (Screenshot is courtesy of SMAR Syscon.)

Asset management software can continuously poll digital valves over the network to find out their health immediately. This means that failed valves can be found faster and problems pinpointed with greater accuracy, making repair quicker and easier. Fewer resources spent means savings. For example, if the supply air to the positioner is lost, the operator is immediately notified.

The operational statistics such as total valve travel and number of cycles that now are provided by the positioners are leading indicators of wear and tear. The operational statistics are used for proactive maintenance to determine the optimum time for valve overhaul. Based on valve manufacturer recommendation for stem packing change, alarm limits for these statistics can be set, notifying the technicians that maintenance is due. Spares can be ordered in advance, several valves can be fixed all in one shutdown, and maintenance can be done before the valve fails. Fewer unscheduled shutdowns mean higher productivity. Major maintenance savings are possible.

In the past, many valves were removed, brought to the workshop, and torn down only to find nothing was wrong. Remote diagnostics reduce such unnecessary work by allowing the technicians to check the general health of the valve from the host before even going into the field. Valve instrumentation can be managed without having to leave the workstation. The cost that can be saved by not having to bring one valve into the workshop is substantial. Users can instead target their maintenance resources to the valves that really need attention.

It primarily is the asset management software that allows technicians to find out what is really wrong, and based on the valve condition it is possible to schedule maintenance only when really necessary, prioritizing the most immediate needs. Rather than running until essential equipment fails, maintenance can be carried out when needed, and only when needed. Maintenance efforts can be focused on problem valves, not the healthy ones.

Spare Parts and Flexibility The interoperability of HART, Foundation Fieldbus, and PROFIBUS-PA means that plants have many alternative third parties from which to obtain their replacement positioners and couplers. This ensures that spare prices will be market based, and not inflated, as was the case when proprietary protocols were used.

To achieve maximum flexibility and enable the same positioner or coupler to be used with any pneumatic control valve or actuator in a plant, more and more functions are performed in software as opposed to hardware, making it easier to adjust and adapt to the application. Users can standardize on one positioner or discrete valve coupler for all different kinds of control valves, keeping spares and training to a minimum.

Safety and Pollution

Apart from the direct economical benefits, digital technology can also enhance safety and protect the environment. An important part about the actual position interlocks in Foundation Fieldbus is that they are handled by the PID and AO blocks, without the user having to configure separate logic for interlocks and reset windup protection on actual position, as was done in old DCSs.

This is different from the old days, when some valves were connected to the DCS using 4–20 mA analog signals from the controller to the positioners. The DCS had no way of knowing the actual position of the valve. If the valve failed, nobody knew about it because there was no feedback or diagnostics. If somebody operated the valve by hand, nobody knew. This was very dangerous, because the operator was under the impression that automatic control was in operation, when it was not. Under these conditions, the controller can change its output, but the valve does not change, so the DCS still attempted to control even though there was no actuation.

Also, if the output of the automatic controller was 50% (12 mA), while some technician in the field has been operating the valve by hand and opened it to 75%, when the loop was switched back to the automatic controller, the valve has to jump 25% (from 75 to 50%). To avoid this, some critical loops had a 4–20 mA feedback of actual valve position from the positioner to the DCS AI module. In the DCS, then, one had to program logic to detect the deviation and in this case put the PID in manual and make sure the PID output follows the actual position feedback from the valve. That is very complex logic, but for Foundation Fieldbus valves it is all automatically taken care of.

Failure Detection Diagnostics from networked positioners and couplers detect failure in positioner, actuator, and valve including loss of supply air. Foundation Fieldbus communication will inform the operator of such events and will stop control. This allows for corrective action to be taken sooner, which might protect from dangerous situations and production loss. Thereby, Foundation Fieldbus makes systems safer.

Another example is a thermocouple failure detected by a temperature transmitter propagated to the positioner, which in response shuts the loop down to a predetermined safe state without the need for any central control action.

Another important form of diagnostics is partial stroke testing (Section 6.10). It verifies that the valve is not stuck, increasing the probability of a successful movement if called upon. This reduces the problem of valves stuck in one position.

Digital communication in conjunction with asset management software can ensure that the installed base of digital valves is maintained well and is experiencing fewer surprise failures. Thus, asset management enables plants to run uninterrupted for longer periods of time, subsequently increasing productivity, keeping costs down. Diagnostics provide an early warning for abnormal conditions and may be used as an indication of problems to come, allowing technicians to solve problems before they adversely affect the process. Users can switch to a proactive maintenance program, thereby minimizing plant downtime.

On-line Plant Asset Management

An inadequately functioning control valve will upset the overall loop performance or may cause the valve to wear out prematurely. Conversely, a healthy positioner ensures better control and less maintenance. A fieldbus control valve positioner takes a total life cycle view of the valve and is designed to enable a longer life for the valve package.

Positioners now come with built-in pressure sensors continuously monitoring the pressure at both the air supply input and the actuator chambers. This enhances simple text-based diagnostics such as loss of supply air with sophisticated chart- and graph-based analysis, such as valve signature. Thus, the valve is provided with additional on-board sensors, which determine its condition, the ambient conditions, and such external factors as the loss of supply air, and gives this information to the microprocessor.

The diagnostics is communicated to the on-line plant asset management tool using HART, Foundation Fieldbus, or PROFIBUS-PA communication. Asset management software takes the vast amount of diagnostics data in the positioner and turns it into information, which is useful to maintenance technicians. Together the asset management software and the positioners make it is easier to determine valve health and estimate their remaining life spans (Figure 6.11i).

Valve Signature The Valve Signature plot traces the actuator pressure required to put the valve in a desired position (Figure 6.11j). As was shown in Section 6.8, comparing changes in this behavior over time helps identify problem areas. Other charts include Hysteresis (a.k.a. “Positioner Signature” or “Dynamic Error Band”), step response (Section 6.9), and drive signal. It is a good idea to capture a “base line” signature for the valve package as it is new, and compare future signatures against this benchmark (Figures 6.8b and 6.10j).

By using the above described techniques, maintenance can be done before the valves fail.

DIGITAL VALVE INSTRUMENTATION

The first generation of digital valve instrumentation was an electropneumatic device enhanced with a CPU and HART communication. Few other things changed. These devices still relied on the old lever and potentiometer for the actual valve position sensing for the feedback. They had the same old pneumatic gauges. High-current-consumption solenoids were used for flapper actuation. There was not much diagnostics to speak of. However, in the second generation the technology went beyond the mere incorporation of a CPU.

Second Generation

completely controls the valve. For example, instead of cam and spring mechanics on the feedback to apply flow characterization, these instruments do the characterization in software. Error due to mechanical imprecision is avoided, further improving performance. Likewise, split-range operation, digital display, and local operation are all provided using software.

Position sensing is a key aspect of valve control and is an important means to acquire the data for sophisticated diagnostics and to tap the full potential of digital instrumentation.

A valve signature. (Screenshot is courtesy of SMAR AssetView.)

See Section 7. 10 in Volume 1 of this handbook ("Linear and Angular Position Detection") for details on position sensing. Noncontact position sensing technologies such as Hall-effect eliminates linkages that can stick and gall; they are also less sensitive to vibration, thus improving hysteresis and reliability. Accurate position sensing allows the valve to be able to respond to very small demands in position change as required for tight control.

Power consumption is a key issue for digital valve instrumentation, and it is their only disadvantage as compared to analog instrumentation. For example, a traditional electropneumatic positioner has a voltage drop of only a few volts,

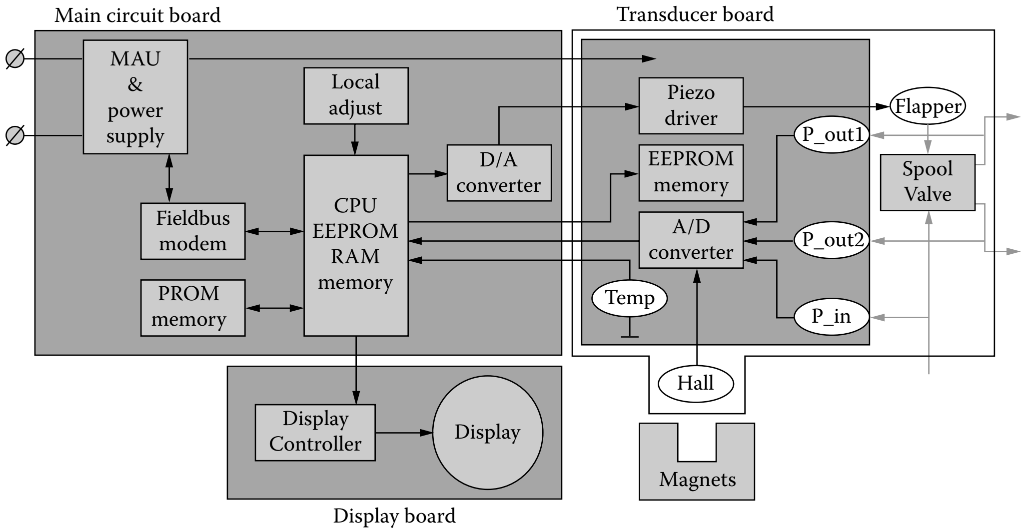

FIG. 6.11k
Block diagram of a Fieldbus pneumatic control valve positioner. (Courtesy of SMAR.)

permitting the positioner to be driven from a regular controller output over very long wires. It is even possible to put two analog positioners in a split-range scheme in series without concern.

However, smart positioners using HART typically have a voltage drop of 11 V or more and therefore Ohm's Law is putting a restriction on cable length, as controller open loop voltage may not be sufficient to drive the signal through the positioners plus cable resistance. Split-range applications generally require signal amplifiers. Current consumption is a concern in fieldbus installations where several devices are connected on the same network, causing voltage drops and restricting the number of devices on a safety barrier. Valve instrumentation that has I/P sections based on piezo technology typically have lower power consumption, making this less of a consideration.

Additional auxiliary sensors can be included in digital valve instrumentation in order to provide inputs for more advanced diagnostics. For example, they might include internal ambient temperature sensing as well as built-in pressure sensors to continuously monitor the pressure at the air supply input and at the two pneumatic outputs. The on-board sensors are dedicated to providing continuous information to the microprocessor, so that it can determine the condition of the valve assembly and ambient conditions.

CONCLUSIONS

The market for digital valve positioners in general, and for fieldbus in particular, looks very promising and is perhaps the single most important event that has occurred in the control valve industry during the past several decades.

Standards and flexible software have made it possible for users to choose third-party positioners when the positioners being offered by the control valve manufacturers cannot meet their performance requirement. With the right positioners it is very easy to upgrade an existing control valve to make it smart or fieldbus-compatible. Even when an old DCS system is converted into a fieldbus system, all the user needs to do is to remove the old 4–20 mA positioner and place a Fieldbus-compatible positioner in its place.

INTRODUCTION

The reader is advised that various aspects of valve and positioner intelligence have also been discussed in the previous four sections, where control valve diagnostics (Section 6.8), dynamics (Section 6.9), safety (Section 6.10), and fieldbus interaction (Section 6.11) have been covered.

Intelligent positioners are primarily used to control the position of the control valve stem in relation to the process control signal. They are also known as “smart” or “digital” positioners. In case of most designs, the “digital” designation is somewhat of a misnomer, because in most cases, it is only the signal processing portion of the positioner that is digital, while most of the input signals are still analog (4–20 mA) and most output signals are either electrical or pneumatic.

Digital positioners arrived on the scene in the mid 1980s and thereafter rapidly replaced the former electronic, i.e., analog, positioners. Similarly to their analog predecessors, these intelligent devices also use air as their source of actuating power, and because of their enhanced electronics, they are about one third more expensive than their predecessors.

Advantages of Intelligent Positioners

Most intelligent positioners can be adapted to both sliding and rotary stem valves. On existing control valves, if built in conformance with IEC Standard 60534-4-1, these intelligent positioners can replace pneumatic or analog electronic positioners of the same supplier. Conformance to a new

FIG. 6.12a
Typical digital positioner with explosionproof housing meeting FM and CSA approval requirements. (Courtesy of the Dresser Valve Group, Inc. Masoneilan.)

German VDI/VDE Standard 3847 would even guarantee interchangeability between positioners made by different manufacturers.

The control signals into the smart positioners can be analog (4–20 mA) or digital (via bus systems), among which Foundation Fieldbus® predominates in the United States, while Prifibus® is more commonly used in Europe.

Similarly to electronic analog positioners, the digital units are also available in "intrinsic safe" designs or with explosionproof housings (see Figure 6.12a) and are protected from EMC interference. They typically meet U.S./CSA as well as CENELEC (European) and CESI (Japanese) standards.

In Figure 6.12a, one should note the presence of the explosionproof pushbuttons, which, in conjunction with the display window, enable the operator to perform on-site calibration and configuration. This is a feature that may not be available on all positioner models. In the illustrated design, calibration is done over the signal wires via HART protocol.

Listed below are some of the advantages of digital positioners and other field devices relative to their analog counterparts:[1]

Increased accuracy, 0.1–1% vs. 0.3–2% for analog
Improved stability, about 0.1% compared to 0.175%
Wider rangeability (without sacrificing accuracy) up to 50:1 compared to 10:1
Capable of performing multifunctions
Diagnostic and self-testing capability
Ability for miniaturization
Ability to be calibrated and adjusted without physical access to the instrument
Utilize information that could not be measured or accessed by analog means

Typical Performance Specifications

Analog input signal: 4–20 mA DC (4–12 or 12–20 mA split-range optional)
Signal voltage for HART communication: 11 V
Minimum current input: 3.5 mA
Load: 300 Ohm
Max. voltage: 30 V
Power source: extra-low voltage (SELV)
Reverse polarity protection
Actions: Single-direct or single-reverse (double acting, optional)
Hazardous area classifications: as required
Temperature limits: −40–85°C (−4–185°F)
Typical pneumatic supply pressures: 0.3 bar (5 PSIG) to 8 bar (120 PSIG)
Steady-state air consumption: 400 sL/hr (14 scfh) at 1.4 bar (20 PSIG)
Max. output capacity: 10,600 sL/hr (375 scfh) at 1.4 bar (20 PSIG)
Min. dead band: 0.2% of output span
Independent linearity: ±0.75% of output span.

Generating the Pneumatic Output

There are basically two ways to control the pneumatic output signal to the valve actuator. The first is to use a conventional I/P transducer coupled with an amplifying relay to increase the air flow to the valve actuator. The second is to generate the pneumatic output signal by pulsing either two piezoelectric valves, or two miniature solenoid valves (one for each stroke direction), and then amplify this output by a relay.

The advantage of the pulsed system is that there is less air consumption, at least when the valve is not moving. Other advantages include that the valve travel time (time constant) can be changed quite easily by varying the pulse rate of the miniature valves. This could improve the stability of the valve and the control loop's performance. Another advantage is a more compact positioner size.

A disadvantage is that these devices can have a larger dead band than their I/P-controlled cousins. This is necessary to keep the miniature valve from continuously pulsing if the signal is noisy. Unintended continuous pulsing can also happen, if there is a small air leak in the actuator or in the joints of the connecting air tubing. This could lead to an early failure of the "on/off" micro valves, which have a lifetime of about 10^8–10^9 pulses. In a worst-case scenario, this lifetime limit could be reached in a little over a year, in case of sustained high frequency instability!

Smart positioners offer a number of functional advantages, which are easily obtainable by digital processing and which could not be obtained from analog electronic positioners. Some of these features will be discussed in the following paragraphs.

Valve Performance Monitoring

As was discussed in Section 6.8, the ability to monitor the performance of the control valve is a widely advertised feature of intelligent positioners. Valve performance is monitored by checking some of the basic valve calibration parameters, which include the "zero" position and the travel span of the valve. Additional tests can monitor the air pressure in the actuator against travel. This "signature" is compared against data obtained when the valve was newly installed.

A major deviation from the "desired" characteristic could indicate potential problems such as the valve stuffing box being too tight, the valve stem being corroded, or the actuator spring being damaged. When such conditions evolve, they can cause an increase in the dead band and the dead time of the valve, thereby creating a potential for instability and cycling of the control loop.

This test data can be called up via HART protocol and can be a vital part of the plant's asset management system (also discussed in Section 6.11). Some believe such data could also be transmitted to a computer via a fieldbus digital signal while the valve is actively controlling the process. Others argue that in order to measure the valve's performance, one has to provide an artificial offset to the control signal. Therefore, some plant operators are understandably reluctant to utilize this feature, because they fear that this offset to the control signal would create too much disturbance in the control loop.

As a result, one typically has to wait until the valve is out of service (process is shut down) in order to perform functionality tests.

It also has to be realized that continuous monitoring of valve performances can create an information overload for the engineer or technician who may be responsible for up to 600 control loops! It therefore may make more sense to monitor the quality of the control signal (against preset limit values) at the controller. Any significant deviation could then be used to trigger a check of the control valve and its positioner.

Otherwise, such "call-up" of the valve's performance data, perhaps with a handheld HART, has to wait until it is time for the regular scheduled maintenance.

Future Trends and Tasks Future uses of the intelligent positioner as "data transmitter" will no longer be restricted to the monitoring of the condition of the valve actuator but may include

1. Monitoring the leakage of the valve's packing box or stem bellows using the "binary" output of suitably placed pressure sensors, or by "sniffing" the ambient air around the valve stem to detect toxic substances by means of a miniaturized chemical analyzer.
2. Checking for fluid leakage between plug and seat by feeding the signal of a sound pressure transducer the sound frequency within the valve housing against a known frequency profile to the positioner.
3. Another method of indirectly discovering excessive seat leakage is by comparing the controller output signal at "low flow" conditions with the same signal, which was measured for the same low flow rate when the valve was new. Excessive leakage would result in such a signal change, which will show less travel (less opening) to compensate for the increase in leakage.

An important feature of all positioners is the time they take to either evacuate all the air from the actuator (if the valve is "air-to-open"), or to deliver the maximum air pressure to the actuator (if the valve is "air-to-close") whenever the control signal calls for the valve to be closed. When this occurs, in order to avoid seat leakage, the positioner output signal must change rapidly to apply the maximum actuator force onto the valve plug.

Some digital positioners offer memory-embedded data such as serial number, date purchased, vendor, tag number, and valve size. These are all useful for asset management purposes and especially handy when the original valve serial plate is corroded and has become unreadable.

Future intelligent positioners may be able to receive their control signal via radio transmission. The difficulties with such a schema include reliability, path loss, RF interference, multipath radio echoes, and the required transmission power. Most of all, these positioner will still require sufficient electrical power to operate their pneumatic and electronic components. Consequently, the valve positioners will never be truly "wireless."

CONTROLLING THE PROCESS

Embedding the control algorithm (usually PID) inside the digital heart of the positioner transforms the control valve package into a dominant part of a "distributed control system." Such a smart control valve requires only an input from a process sensor/transmitter and a supervisory (adaptive, feedforward, and so on)or set point signal from a central computer.

Such imbedded algorithms initially tend to involve PID control only but may later include more advanced features to serve self-tuning or fuzzy logic functions.

Changing the Valve's Characteristics

Another common feature of digital positioners is their ability to modify the relationship between the controller's output signal and the pneumatic output signal to the valve actuator. The effect of this relationship is to alter the valve's inherent flow characteristic. Choices include "quick opening," "linear," "equal percentage" (Figure 6.7b), and a variety of "user-defined" characteristics that must be custom programmed.

Such a modification of the valve's inherent characteristic is similar to placing a mechanical cam in the travel feedback linkage of a pneumatic positioner. For example, it can convert

FIG. 6.12b
Typical intrinsically safe digital positioner that can provide single- or double-acting pneumatic output (note pneumatic pressure gauges). (Courtesy EMERSON Process Management–Fisher.)

the static flow characteristic of a butterfly valve, which has a nearly linear characteristic (C_v vs. travel is linear), into an equalpercentage one (C_v varies exponentially with controller signal).

The trouble is that the travel vs. flow coefficient (C_v) of a butterfly valve is still linear. The result is that the signal resolution at low flow becomes very poor, because with an equal percentage output signal at low flows, the valve travel is very small per given signal change. Therefore, in such cases the valve's dead band becomes high compared to its signal resolution.

Valve Gain and Time Constant The purpose of changing the flow characteristic is to make the "gain" (rate of flow change vs. signal change) of the control valve such that the loop gain will be more constant, in order to aid in maintaining the stability of the loop control (Figure 6.7a). This can be accomplished, at least in theory, by the above-described modification of the control signal.

In practice, this approach works only in applications where the time constants of the valve and of the process differ by at least a factor of five. The reason is that the "static" signal modification performed by the positioner results in vastly different stem travel speed requirements at low and at high flow rates. This in turn results in a continuous variation of the valve's time constant,^{3} which makes controller tuning very difficult.

It is hoped that future positioner designs will provide algorithms that will change the rate of output signal change in proportion to the rate of signal modification. This would mean that the travel speed of the actuator is changed so that the change in flow through the valve becomes proportional to the change in the controller's output signal. This way one would have not only a constant control valve gain but also a constant control valve time constant!

Another problem caused by the changing of the flow characteristic has to do with the dead band of the valve. For example, if one changes the inherent "linear" valve characteristic to "equal percentage," the valve travel for say the first 10% of signal range (0–10%) will be very small (typically 0–3%). This means that the apparent dead band of the valve stem will increase three times, and this can cause oscillation in the control loop.

OPERATION OF SMART POSITIONERS

From the outside there appears to be little difference between smart digital and analog electronic positioners (Figure 6.12b), other than a digital monitoring window on the outside of some smart positioners.

The real difference lies inside. As can be seen in Figure 6.12c, all communication as well as power supply travel through a single pair of wires from the controller or computer to the printed wiring board containing all the functional electronics. This signal may be in the form of a 4–20 mA analog, or in a digital form according to the selected fieldbus protocol.

The controlling electronic portion is usually encapsulated and field-replaceable. This printed wiring board receives feedback from a motion transmitter, which is sensing the position of the valve stem.

Any deviation from the desired valve stem position will be detected, and a correcting signal is sent (in this case) to an I/P transducer that converts the electronic signal into a

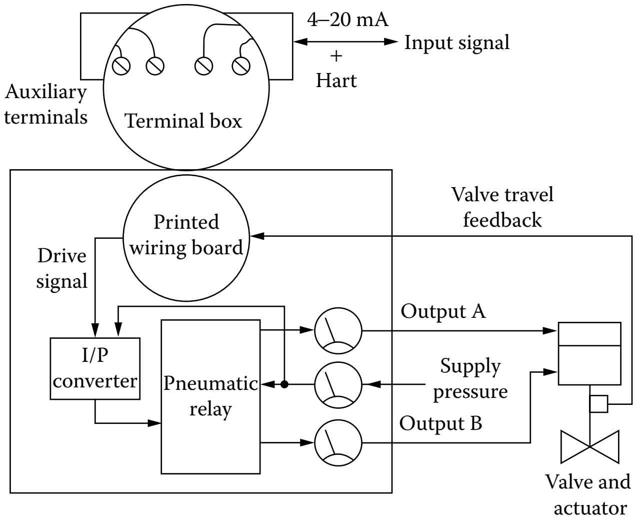

FIG. 6.12c
Schematic view of a digital valve positioner that is sending an electronic analog output signal into an I/P transducer, which in turn is generating a corresponding pneumatic output signal.

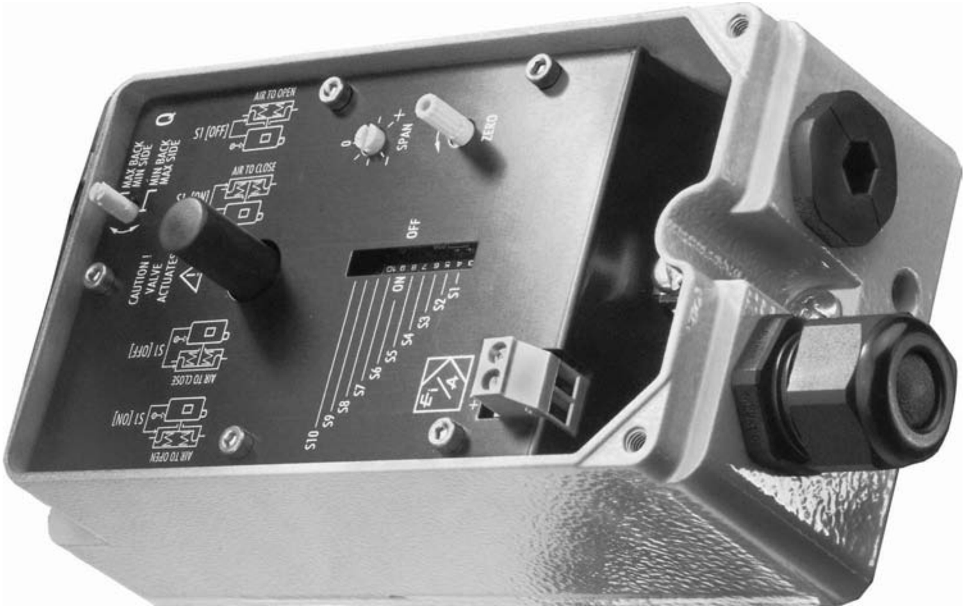

FIG. 6.12d
Digital valve postioner with cover removed. It shows the adjustment knobs for "zero," for "span" (travel), and for the type of action as "direct: air to open" or "reverse air to close." Finally, there is a setting for the low voltage internal limit switch. (Courtesy of SAMSON A.G.)

corresponding pneumatic one. This air signal is then amplified by a relay and fed to the valve's actuator.

Maintenance and Calibration

An additional pressure sensor (measuring the output of the air relay) can give additional feedback to the circuit board in order to aid in maintaining the stability of the loop. This pressure sensor also monitors the valve's performance by comparing the relationship between the air signal and travel with a stored relationship that was taken when the valve was new. As is illustrated in Figure 6.8c and discussed in Section 6.8, a major difference between the two relationships signals the need for maintenance.

After the positioner is mounted on the valve, its initial calibration can be done by a remote device such as a computer via a HART protocol, or alternatively by using internal adjustment knobs as shown in Figure 6.12d.

ACCESSORIES

The most common built-in accessories available as options in intelligent positioners are micro-switches, which typically operate on low-voltage levels (24 V). These switches provide the capability of a "safety shutdown" of the valve, which is initiated independently from the control signal. Other accessory options include analog or digital valve travel position transmitters.

In addition one also requires software, which is needed for the intelligent positioner to perform the desired diagnostic and remote calibration functions. Listed below are some of the capabilities that such a software package should support:

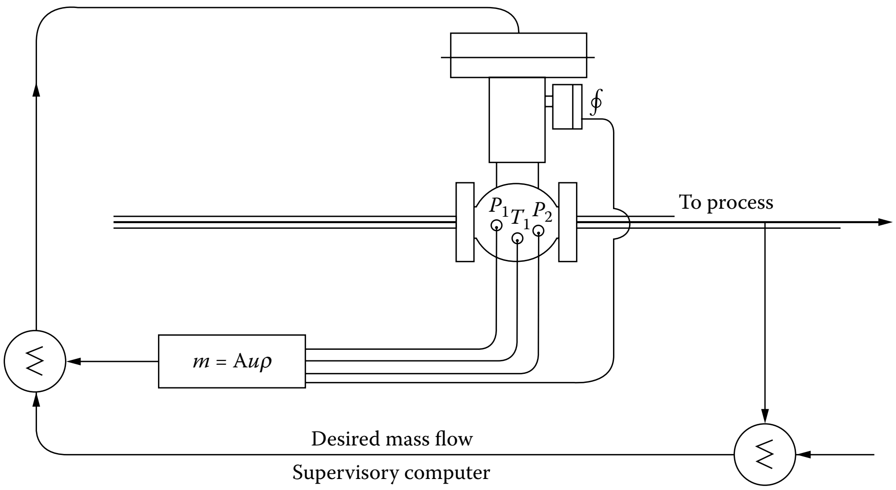
Reading of valve diagnostic data
Supporting the graphical diagnostic trends window displays
Valve configuration, and valve configuration database
Monitoring device variables
Configuration of valve characteristic
General process and valve database
Security levels for users
Diagnostic database

FLOW CONTROL BY SMART VALVE

It is possible to integrate a whole flow control loop into a control valve that is a self-contained part of a distributed control system. Such a device would include the valve, the flow sensor, the valve positioner. and the controller, all incorporated into a single entity.[4]

As shown schematically in Figure 6.12e, it includes a temperature sensor and a flow detector, which consists of two piezoelectric pressure sensors embedded within the valve housing and located up- and downstream of the valve orifice.

The mass flow through the valve is measured by detecting the differential pressure across the valve orifice and by applying a density correction to that differential on the basis of the detected temperature. This product is then multiplied by the known area of the vena contracta between orifice and valve plug at the prevailing inner valve travel position, and thereby



$$A = N_3C_v\phi(\text{ ft}^2);\ U = N_2\sqrt{P_1 - P_2}\ (\text{ ft/s});\ \rho = N_1\gamma P_1P_2/T_1\ (\text{lbs/ft}^3)$$

A = Area of valve opening
C_v = Valve capacity coefficient
m = Mass flow, lbs/s
N_1, N_2, N_3 = Numerical constants
P_1 = Absolute inlet pressure, lbs/ft^2
P_2 = Absolute outlet pressure, lbs/ft^2

T_1 = Inlet temperature, °R
U = Orifical velocity, ft/s
γ = Specific weight, lbs/ft^3 @ 70°F and 14.7 psia
ϕ = Fractional valve travel
ρ = Density of flowing gas (lb/ft^3)

FIG. 6.12e
Schematic view of a complete flow control loop built around an intelligent control valve.[4]

the on-board computer calculates the mass flow passing through the valve. Flow control is provided by a PID algorithm that compares the measured flow with a desired set point and adjusts the valve opening as needed to meet that set point.

Limitations

In order to make this type of flow measurement reasonably acceptable, one must locate the pressure sensors in a long and narrow channel in the body cavity to eliminate the effects of flow turbulence disturbances. While not an accurate flow sensor, it can detect a "deviation" from a desired flow rate and correct the flowing quantity.

Such a device can be used in temperature cascade loops, where this intelligent valve may control the flow rate of steam, while a temperature controlling cascade master adjusts the set point of this intelligent valve-based flow-controlling slave.

Such an intelligent valve provides ease of installation, space savings, and the elimination of extra wiring. While the price is higher than that of a conventional control valve, it is less than the combined cost of the components of a mass flow control loop.

INTRODUCTION

This section consists of two distinct parts. In the first part, a number of control valve designs are described, which are different in that they are neither linear nor rotary in their operation. These miscellaneous valve designs utilize the energy content of the flowing fluid for their operation. They depend on fluid interaction or the static pressure of the process fluid and use flexible elements to throttle gas pressure regulators and other control valves. These valves are used in specialized services, such as in sensitive level control, in gas pressure or flow regulation, and in toxic services.

In the second part of this section some of the special valve trim designs used in the traditional globe control valves are discussed in terms of their suitability for specialized applications. These applications include applications where noise; cavitation; flashing; high and low temperatures or pressures; or viscous, dirty, or slurry flows are involved.

Such trim designs and applications have already been discussed in Sections 6.1, 6.7, 6.14, and 6.15.

MISCELLANEOUS VALVE DESIGNS

Dynamically Balanced Plug Valves

This family of control valves has been developed for pressure and flow control applications where no external power is available to operate the valve, and therefore the static pressure of the process fluid is utilized to achieve throttling. Figure 6.13a illustrates an installation for upstream (back) pressure control.

Here, the upstream pressure is sent to the control pilot through port D. If the controlled upstream pressure drops, this lowers the pressure in the pilot chamber and the pilot spring moves the pilot poppet valve to the right. This opens port B and thereby upstream pressure is applied inside the plug chamber. This equalizes the pressure acting on the plug and allows the spring to move the plug to the left, to close the valve.

These valves provide nearly linear characteristics (Figure 6.13b) and high flow capacities ($C_v = 30d^2$). They are available in sizes up to 12 in. (300 mm), and special units

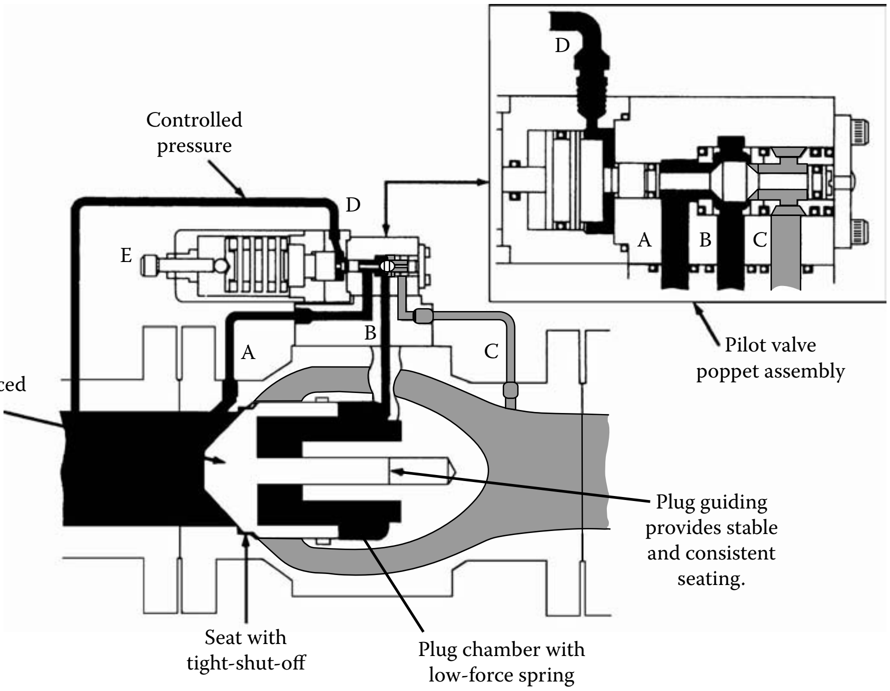

FIG. 6.13a

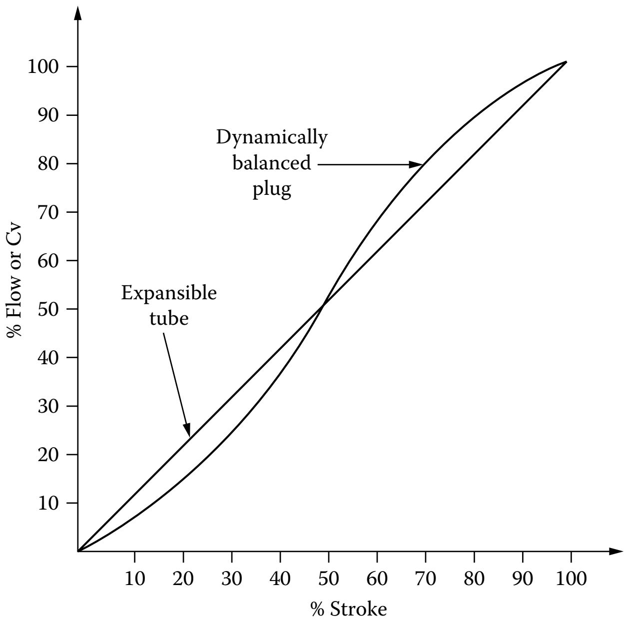

FIG. 6.13b
The characteristics of expansible tube and dynamically balanced plug valves are nearly linear.

have been made in up to 24 in. (600 mm) sizes. The valves can be provided with up to ANSI Class 1500 rating and with pressure control settings up to 3000 PSIG (205 bar).

The advantages of this design include its erosion and corrosion resistance, due to the hard facing of the plug; its good pressure recovery characteristics, due to the large and smooth annular flow area through the valve; its fast speed of response; and its bubble-tight seating.

Positioned Plug In-Line Valves

The positioned plug in-line valve, excluding control units, resembles a pipe spool. It is only necessary to inject pressure into its ports for positioning the valve plug. This simple design (Figure 6.13c) requires only three pressure seals. The plug is carried on a cylinder that also includes the piston. Pressure in one port causes closing, while the opposite port is used for opening. The valve has only one moving part and is available in sizes from 2–8 in. (50–200 mm) for use to 350 PSIG at 400°F (2.4 MPa at 204°C). Control quality is dependent upon the pilot valves and auxiliary units employed.

Another in-line valve available in small sizes (Figure 6.13c) carries the valve plug on a bridge in the operating cylinder, with the seat as part of a split body.

A spring-loaded version of this design uses the beveled end of the moving cylinder to seat on a replaceable soft seat, retained in a dam, held in position by struts from the inside wall of the valve body. The spring loading may cause fail-close or fail-open actions, as illustrated in Figure 6.13e. The unit can be powered with line fluid or by an external pressure source. A double-bleed feature can be incorporated to eliminate the possibility of actuation and line fluids combining if one of the dynamic seals should fail. All seats and seals are replaceable by separation at the body flange.

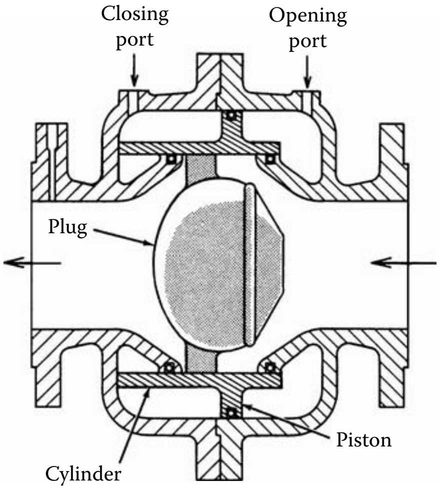

FIG. 6.13c
Positioned plug valve in its fully open position. (Courtesy of Eisenwerk Heinrich Schilling.)

The unit is particularly adaptable to fluids that are toxic or difficult to contain, such as nitrogen tetroxide, hydrogen, and others used in the aerospace industry. The unit is furnished in sizes from $1^1/_2$–18 in. (37.5–450 mm), with ratings to 2500 PSIG (17.3 MPa). All types of end connections are available, and control is dependent upon the auxiliary control components selected for the application. An explosionproof limit switch can be furnished for position indication.

Diaphragm-Operated Cylinder In-Line Valves An in-line valve using a low convolution diaphragm for positive sealing and long travel (Figure 6.13f) is designed particularly for gas regulation. The low level of vibration, turbulence, and noise of this in-line design makes it suitable for high-pressure gas service.

Fail closed design

Fail open design

FIG. 6.13e
Spring-loaded positioned plug valve.

Inlet pressures to 1400 PSIG (9.7 MPa) and outlet pressures to 600 PSIG (4 MPa) are possible in the 2 in. (50 mm) size. It is a high-capacity valve, as expressed by $C_v = 23\ d^2$. As a gas regulator the unit is supplied with a two-stage pilot to accept full line pressure. This pilot resists freeze-up and serves as a differential limiting valve. All portions of the pilot and line valve will withstand a full body rating of 600 PSIG (4 MPa).

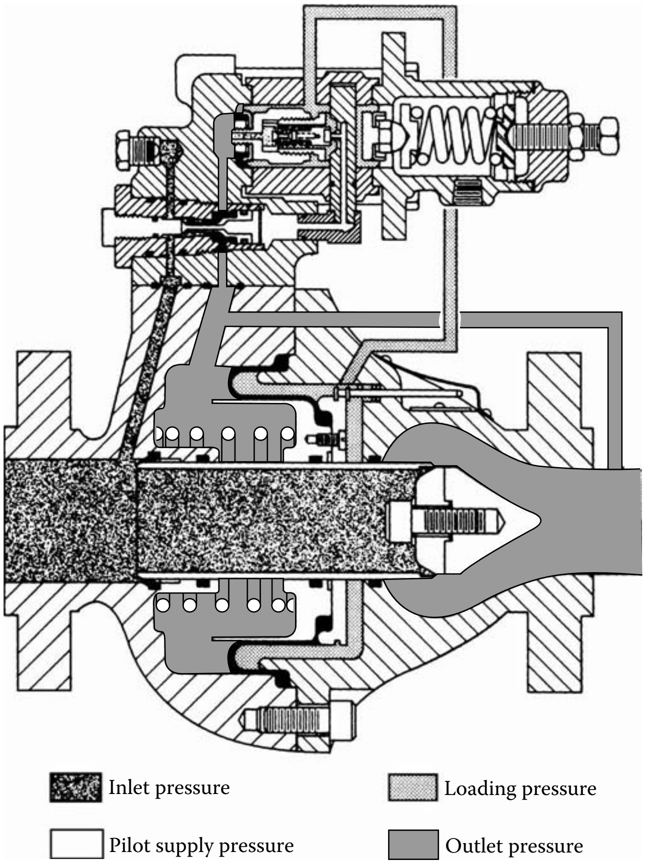

FIG. 6.13f
Diaphragm-operated cylinder-type in-line valve used in high-pressure gas regulation services.

Expansible Valve Designs

The expansible element in these valve designs can be a rubber cylinder, an expansible tube, or an expansible diaphragm. The common feature of all of these designs is that they utilize the process pressure to provide tight shut-off of gas flows.

Expansible Element In-Line Valves Streamlined flow of gas occurs in a valve in which a solid rubber cylinder is expanded or contracted to change the area of an annular space (Figure 6.13g). A stationary inlet nose and discharge bullet allow hydraulic pressure to force a slave cylinder against the rubber cylinder to vary its expansion. Control is from a diaphragm actuator, with the diaphragm plate carrying a piston. The piston acts as a pump to supply hydraulic pressure to the slave cylinder.

The rubber cylinder offers the seating ability of a soft seat valve. It has the capability of closing over foreign matter, and

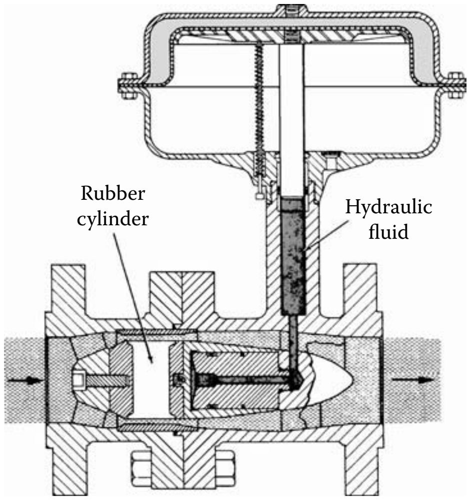

FIG. 6.13g
A rubber cylinder provides the soft seat in this low-noise, expandable element, pressure regulator in-line valve.

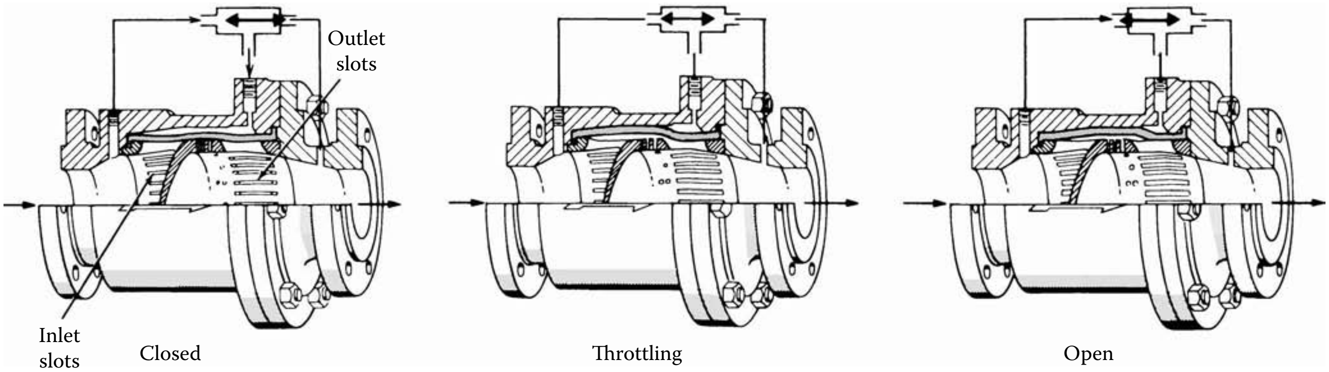

FIG. 6.13h
An expansible tube valve utilizes the process pressure for its operation, while being controlled by a three-way pilot that determines if the valve is to be closed (left), throttling (center), or open (right).

the design allows for the use of a restricted throat for reduced capacity. With this design, pressure drops as high as 1200 psid (8.3 MPa) have been handled with a low noise level. The valve may be utilized as a pressure reducer or for back-pressure control, depending upon the system requirements.

Available sizes are 1–6 in. (25–150 mm). The 1 in. (25 mm) valve can have screwed connections, while all sizes can be flanged. The body is steel with flange ratings to 600 PSIG (4 MPa).

A valve positioner can be used, if the stem position is calibrated as a function of the annular space reduction. If such calibration is provided, a controller output can throttle the valve to obtain accurate flow control.

Expansible Tube Valves Control of flow is obtained by use of an expansible tube that is slipped over a cylindrical metal core containing a series of longitudinal slots at each end and a separating barrier in between. The characteristics of such a valve were shown in Figure 6.13b.

A cylindrical, in-line jacket surrounds the tube so that the process pressure can be introduced between the jacket and the sleeve to cause the sleeve to envelope the slots. This valve will open if the space between the jacket and the sleeve is connected to the downstream (lower) pressure and will open if that space in connected to the upstream (higher) pressure.

With pressure connected to the downstream line (Figure 6.13h, right), the line pressure in the valve body will cause the valve to open fully. Control of the pressure on the sleeve creates a throttled flow condition by first uncovering the inlet slots and then progressively opening the outlet slots (Figure 6.13h, center). A continuous dynamic balance between fluid pressure on each side of the sleeve makes it possible to obtain wide rangeability between a no-flow and a full flow (fully open) condition.

The basic operation of the valve can be accomplished with a three-way pilot valve positioned from a remote location. A variety of automatic pilots give versatility to the basic valve. For reduced pressure control, a pilot is used to modulate the jacket pressure in response to the sensed pressure in the downstream pipeline.

As downstream pressure falls below the set point, the double-acting pilot positions itself to reduce the jacket pressure. This allows the valve to open to a throttling position. Therefore, downstream pressure increases to the set pressure, with attendant change in flow rate to maintain the set pressure. The static sensing line is separate from the pilot discharge line, in order to eliminate the pressure drop effect in the sensing line.

Another form simulates a conventional regulator, in that system gas is bled into the jacket annular space through a fixed orifice and bled off through the pilot regulator. In this form, the static sensing line and pilot output are common. Double-acting pilot systems use seven control ranges from 2 to 1200 PSIG (0.02–8.3 MPa) with corresponding inlet pressures up to 1500 PSIG (10.4 MPa). The fixed orifice design is available for control from 2 oz–600 PSIG (0.86 kPa–4 MPa).

Pilot Design Variations Back-pressure control and pressure relief are obtained in the same manner as pressure reduction is, except they sense the upstream pressure. By using a separate sensing and bleed port, a build-up from cracking to fully open can be varied from 3 to 14% of the set pressure. Return to normal operation causes the valve to create absolute shut-off. Emergency shut-off service may use an external pressure source piloted to obtain immediate shut-off upon abnormal conditions.

A diaphragm-operated, three-way slide valve may also control jacket pressure by proportioning the inlet and outlet pressures. In this design, the controller output signal is sent to the diaphragm actuator of the three-way slide valve, which causes the sleeve valve to open proportionally, in a manner similar to that of a conventional diaphragm control valve. In this manner, the valve becomes a throttling control valve (Figure 6.13i).

Differential pressure or flow control is accomplished by using a pilot valve in which the diaphragm is positioned by both upstream and downstream pressures. The differential

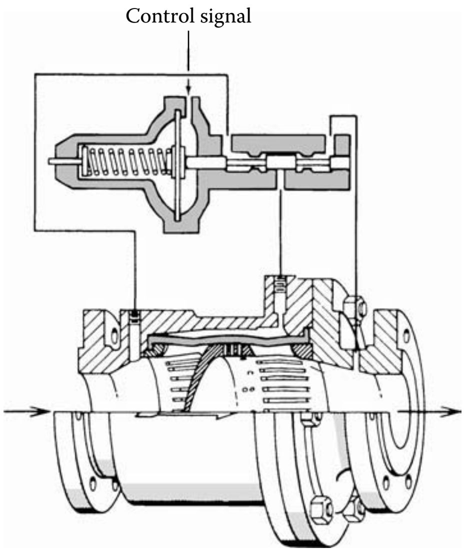

FIG. 6.13i
The expansible tube valve becomes a throttling control valve if it is provided with a three-way slide-valve-type control pilot.

static lines may be taken at the inlet and outlet of the line valve or, for flow control, across an orifice plate in the line.

Pressure Boosting A practically unlimited variety of pressure and flow regulators can be configured with the range of pilots that are available. One important application is in pressure boosting in gas distribution systems. By these boosters, the line pressure losses due to increased consumption can be counteracted automatically by increasing the set pressure of the distribution control valve.

In such a design, there can be as many as three pilots controlling the gas distribution control valve. In Figure 6.13j, the normal pressure is controlled by pilot #1. An increase in flow is sensed by the flow element (orifice, or flow tube), which opens a high-differential pilot to cut in a boost-pressure-control regulator (pilot #2), which has a higher set point than pilot #1. Return to normal flow cuts out the boost pressure control regulator and reinstates the normal control pilot.

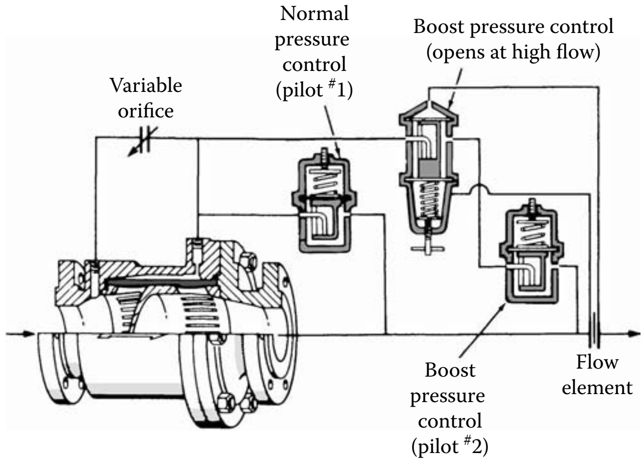

FIG. 6.13j
Expansible tube-type gas distribution control valve can automatically boost the distribution pressure, when the demand for gas increases.

The expansible tube valve is made in sizes from 1–12 in. (25–300 mm) with pressure rating from 200 PSIG (1.4 MPa) in iron to 1500 PSIG (10.3 MPa) in steel construction. It is made flanged or flangeless for insertion between line flanges. The flangeless body is cradled in the studs between the line flanges. Removal of the body is made easier by expanding the flanges about $^1/_8$ in. (3 mm) using nuts on the studs inside the flanges.

Tight shut-off or throttling requires a differential between the line pressure or external source used for closure and the downstream pressure sensed on the inside surface of the sleeve that is exposed to this pressure. This differential requirement for a special low-pressure 2 in. (50 mm) valve is 3.6 psid (24.8 kPa) and is 1.6 psid (11 kPa) for a 4 in. (100 mm) valve. The low-pressure series requires from 21 psid (145 kPa) for the 1 in. (25 mm) size to 4.6 psid (32 kPa) for the 10 and 12 in. sizes (250 and 300 mm). High-pressure models require from 58 psid (400 kPa) for the 1 in. (25 mm) size to 11 psid (76 kPa) for the 10 and 12 in. sizes (250 and 300 mm).

The body design allows tight shut-off, even with comparatively large particles in the flow stream. Freezing of the pilot by hydrates is not common because the intermittent and small bleed occurs only to open the valve and as such is not conducive to freezing.

The pilot may be heated or housed, or even located in a protected area close to the warm line. With its only moving part a flexible sleeve, this type of valve has no vibration to contribute to noise. The flow pattern also helps make this valve from 5 to 30 db more silent than most regulators. Flow capacities are comparable to those of single-seated as well as many double-seated regulators.

Expansible Diaphragm Design In an expansible diaphragm-type regulator, an expansible element (Figure 6.13k) is stretched down over a dome-shaped grid causing shut-off of the valve when pressure above this resilient member overcomes the line pressure under the element. Line pressure is evenly directed over the expansible area by a series of pressure channels.

Selection of the correct action on a pilot that supplies line or external pressure to the exterior of the expansible element causes the valve to control as a back-pressure or as a reducing control valve. For back-pressure control, or pressure relief, the static line is taken upstream of the valve. Increase in line pressure will increase the bleed from the annular space between the expansible element and the metal housing. Reducing regulation is accomplished by restricting the bleed upon increase in downstream pressure and increasing it upon decrease in downstream pressure.

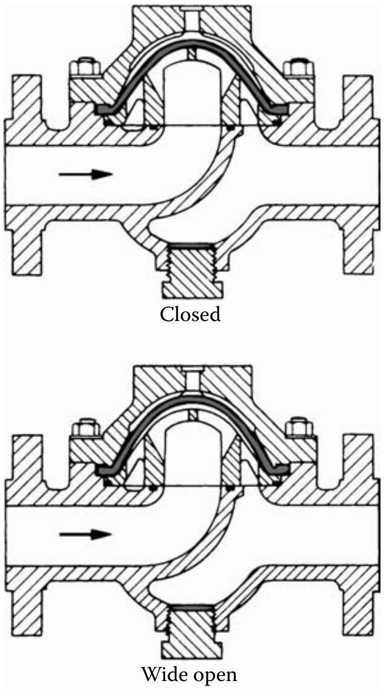

FIG. 6.13k
The expansible diaphragm valve can be used as either a pressure regulator or as a back-pressure relief valve.

The valve is available in iron or steel with ratings to 600 PSIG (4 MPa). Models are available from −10–150°F (−23–66°C), using a molded, Buna-N diaphragm. Relief valve pressures are from 30–300 PSIG (0.21–2.1 MPa), while reducing service varies from 5–150 PSIG (0.03–1 MPa). Capacity factors vary from $C_v = 11\ d^2$ in smaller sizes to $C_v = 14\ d^2$ in larger valves.

Fluid Interaction Valves

The Coanda effect, the basis of fluidics, is used in diverting valves from $^1/_2$–4 in. sizes (12.5–100 mm). The Coanda effect means the attachment of a fluid stream to a nearby side-wall of a flow passage. This effect can be used in a so-called “flip-flop” valve for diverting a stream from one discharge port to another.

Figure 6.13l shows the flow through the right-hand port due to both control ports being closed. Opening the right-hand port, to allow air or liquid to enter, will shift the flow. The industrial valve has rectangular diverting tubes, but the end connections may be circular. Control is maintained by opening or closing the control port or by injecting low-pressure air or liquid through a solenoid or other pilot valve.

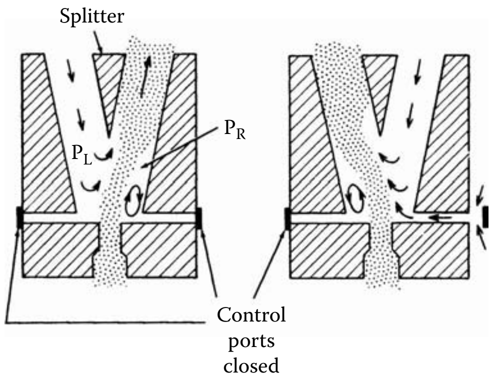

FIG. 6.13l
The Coanda effect is used in the “flip-flop” diversion of flow in the fluid interaction valves.

In this valve, with stream flowing in one diversion tube, the flow at the inlet contains some potential (pressure) energy and some kinetic (flowing) energy. Much of the potential energy is converted to kinetic energy at the nozzle. Up to 70% recovery of potential energy occurs in a diffuser section. Fifty percent recovery is guaranteed for commercial valves, and somewhat less for gases above critical flow and for viscous fluids ($\Delta P \sim P_1/2$).

Installation must allow the recovered pressure to create the desired flow against friction effects of piping or fittings. An uninhibited flow will create some aspirating effects in the open outlet; restriction causes blocking, while excessive restriction will cause a leak or diversion to the open port.

Fast Level Control Industrial valves, with their ability to divert in less than 100 ms, fill a wide variety of uses. The primary one is for level control in which the effluent not required for filling may be returned to storage. It is necessary only to use a dip tube set at the control point, as shown in Figure 6.13m. Lack of moving parts or of detrimental effects due to fast diversion action allows the system to provide close control.

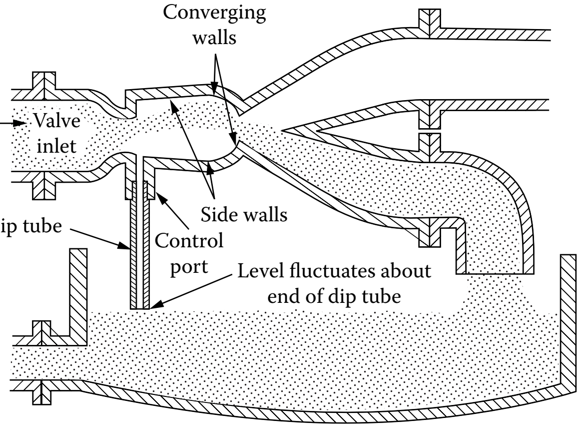

FIG. 6.13m
The response of level control with fluid interaction diverting valves can be very fast.

Numerous uses of diversion valves exist, such as tank filling, which is accomplished by using an external signal. Diversion of a process stream upon contamination, sensed by a pH or other analyzer, is important in paper mills and in chemical plants.

The ability to divert rapidly makes this valve applicable to oscillating flows. The valve may be used for space conditioning, if the total bypassing of a heating or cooling medium is adequate for space temperature control.

Fluidic valves can also be used for the diversion of engine exhaust gases from tailpipe propulsion nozzles to wing-mounted lift fans with ambient control flow. Other unique applications include a four-ported fluidic valve, which has been used for direction control of a missile. It seems that all the potential uses of this valve design have not been exploited yet.

SPECIAL VALVE APPLICATION

In the following paragraphs, the capabilities of one control valve manufacturer (Fisher Controls) are discussed in handling such demanding services as cavitation and sludge. This is somewhat redundant, because Section 6.1 has already covered all the special control valve applications. These included the products of all valve manufacturers and covered noise, cavitation, flashing, high and low temperature or pressure services, and viscous, dirty, or slurry flows.

Yet, the editor believes that this "manufacturer's perspective" that follows is still a valuable addition to the overall picture. The reader is reminded that Sections 6.14 and 6.15 provide in-depth information on control valve noise and on valve sizing aspects of the various special applications. For these reasons, the reader is advised to refer to the above-mentioned sections for an in-depth treatment of the subject matters that are discussed below.

Cavitation and Flashing

As it was already discussed in Section 6.1, a fluid will flash when the downstream pressure is below the vapor pressure of the flowing process fluid. The vapor bubbles that form when the pressure falls below the vapor pressure continue to grow as long as the pressure keeps dropping, and eventually the liquid changes or flashes to a vapor.

In connection with Figure 6.1w, cavitation has been also explained as it was also shown how vapor bubbles can be formed at the vena contracta and how these bubbles can implode and release powerful microjets that will damage any metallic surface, as the pressure rises downstream. In addition, the options available to the process control engineer to eliminate cavitation were also shown in connection with Figure 6.1x.

There are a number of ways to protect against cavitation. As was shown in Figure 6.1aa, one of the most common is to expose the fluid to a series of restrictions as opposed to a single restriction. Each subsequent restriction dissipates a certain amount of the available energy and reduces the inlet pressure to the next stage.

As was shown in Figure 6.1x, a well-designed pressure-staging device prevents cavitation by taking a large pressure differential and by maintaining the vena contracta pressure above the vapor pressure of the liquid, which prevents the liquid from cavitating.

The expanding flow area concept of damage control is closely related to the pressure drop staging approach (Figure 6.13n). Figure 6.13n shows a pressure vs. distance curve for flow through a series of fixed restrictions where the area of each succeeding restriction is larger than the previous. Notice that the first restriction takes the bulk of the pressure drop, and the pressure drop through successive sections decreases.

In the last restriction, where cavitation is most likely to occur, the pressure drop is only a small percentage of the total drop, and the pressure recovery is substantially lower. The expanding flow area concept requires fewer pressure drop stages to provide the same cavitation protection as does the concept that utilizes nearly identical areas for staging.

The most common approach to cavitation protection employs a drilled-hole cage that incorporates both pressure staging and expanding flow area concepts. Each drilled hole has a significant impact on the overall pressure recovery of the valve.

Drilled Trim and Multistage Designs Figure 6.13o shows the cross-section of three types of drilled holes that could be used in an anticavitation cage. The thin plate design is a very inefficient flow device, but it does provide a high F_L^2 value and therefore a low pressure recovery. The thick plate design is not only more efficient, but it also provides a high pressure recovery as denoted by its low F_L^2 value.

The Cavitrol® trim hole, designed by Fisher Controls, is a balance between the thick plate and the thin plate hole designs. It provides relatively high flow efficiency while still maintaining a high F_L^2 value, which results in a low pressure recovery. This design represents the optimal choice between capacity and cavitation control.

Figure 6.13p shows the cross-section of a three-stage, anticavitation trim. This particular design prevents the formation of damaging cavitation at pressure drops up to 3000 psid (207 bar) by utilizing a unique expanding flow area design, meaning that each stage has successively larger flow area.

When a series of drilled holes are used to control cavitation, it is also easy to characterize the trim. In the trim illustrated in Figure 6.13p, as the valve plug travels through the cage, the cage design changes. It begins as a pressure-staging device and transitions to a straight-through, low-restriction flow design. Consequently, the cavitation control ability of

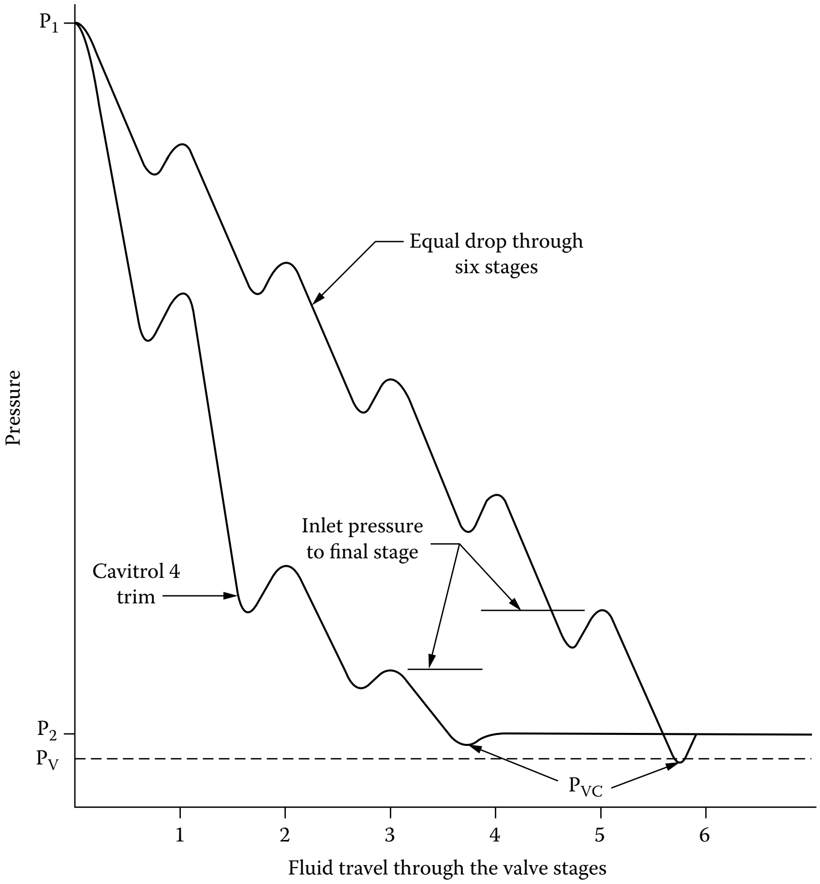

FIG. 6.13n
Comparison of staged pressure drops to prevent cavitation. (Courtesy of Fisher Controls.)

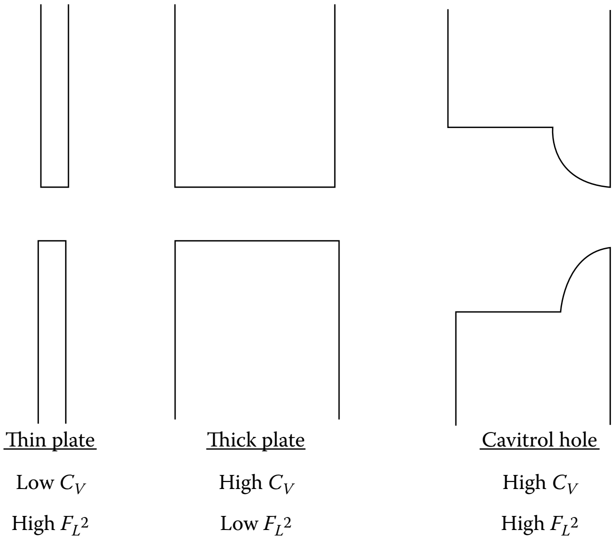

FIG. 6.13o
Comparing various drilled-hole-type anticavitation trim designs. (Courtesy of Fisher Controls.)

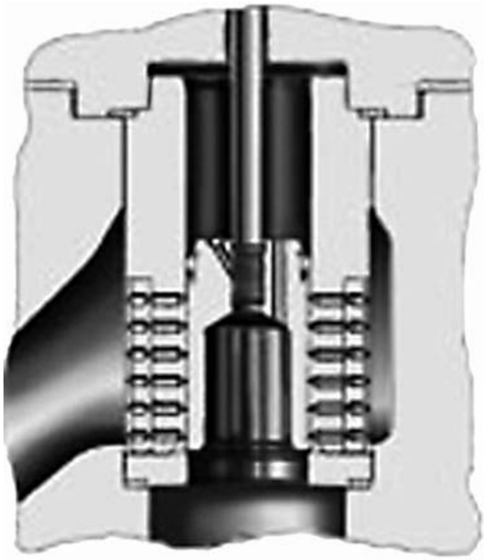

FIG. 6.13p
The cross-section of a three-stage anticavitation trim. (Courtesy of Fisher Controls.)

this trim design is the greatest at low travels and decreases as the valve plug travel increases.

In Figure 6.1y, a large number of anticavitation valve designs are shown. One disadvantage of most anticavitation trims is their potential for plugging. The flowing media often contains small particulate matter (e.g., sand) that can plug the passages, restricting or totally stopping flow through the valve. If this potential exists, the particles must be removed from the flow stream (e.g., by filtration), or an alternative approach to cavitation prevention should be taken.

In situations where it is impossible to remove the particulates via filtration or separation, valve designs that can pass the particulate and still resist cavitation and erosion should be considered. The next paragraph describes some of the control valves that can be considered for sludge or slurry services.

Dirty Process Services

In Section 6.1, Figure 6.1ee shows a number of control valve designs that can be considered for sludge and slurry services. These applications involving entrained particulates are some of the most challenging and can be found in all industries where entrained particulates are present in the process stream, which can cause extensive erosion to the valve trim and valve body.

Often these applications also involve high pressure drops that create the added potential for cavitation, flashing, and excessive noise and vibration. It is important to address all of these damage mechanisms in combination.

The most common valve selection for process streams containing entrained particulates is a rugged valve design utilizing erosion-resistant body materials and internal valve body liners. This brute force approach often does not incorporate any method of staging the pressure drop and therefore can cause valve and pipe vibration, if cavitating conditions exist.

Sweep-Angle and Rotary Ball Valves Figure 6.13q is an example of a valve that relies on "brute force" in being able to operate under dirty service conditions. This valve was initially designed for liquid asphalt service, but has also been successfully applied in separator let-down and slurry let-down applications.

This valve utilizes a venturi-type throat design that directs the fluid into the center of the valve and downstream piping. This prevents impingement of the fluid on the valve body and downstream piping. The expanded valve outlet reduces the velocity of the exiting fluid, thereby reducing any associated erosion effects. This is especially important in applications that experience flashing or out-gassing, where there may be some areas of high velocity.

The cylinder-guided valve plug ensures excellent controllability by providing plug stability, which results in better, more controlled flow of the fluid through the valve and reduced wear of the trim components.

FIG. 6.13q
Type 461 Sweep-Flo Valve by Fisher Controls.

For high-temperature applications, up to 1100°F (593°C), the valve body can be specified with an extension bonnet to reduce conduction of heat to the valve packing and the actuator. Connections on the side of the bonnet are available to flush particulate out of the extension bonnet cavity and back into the flowstream as the valve opens.

Another brute force selection for applications with lower pressure drops is to install a rotary ball valve. The plug in the rotary valve should be facing towards the downstream side of the valve body, so that the pressure drop will occur downstream of the valve body. However, with this approach it is important to provide either a durable downstream pipe liner or a sacrificial pipe section.

As rugged as these sweep-angle and ball valve designs are, they still can be exposed to conditions that cause excessive noise and vibration. This is because the process fluid is not staged through the valve trim in a manner that prevents the onset of damaging cavitation and the resultant noise and vibration.

Dirty Service Trim Another valve design that is available for dirty service applications (but not for heavy sludge, slurry services, or particle sizes exceeding 0.5 in., because of plugging) incorporates an axial flow path through a series of restrictions. These restrictions divide the pressure drop into stages, reducing the potential for cavitation and subsequent noise generation. Figure 6.13r shows one axial flow multistage trim design.

The dirty service trim (DST) trim eliminates damaging cavitation and resultant noise and vibration by staging the pressure across a properly determined number of stages. The

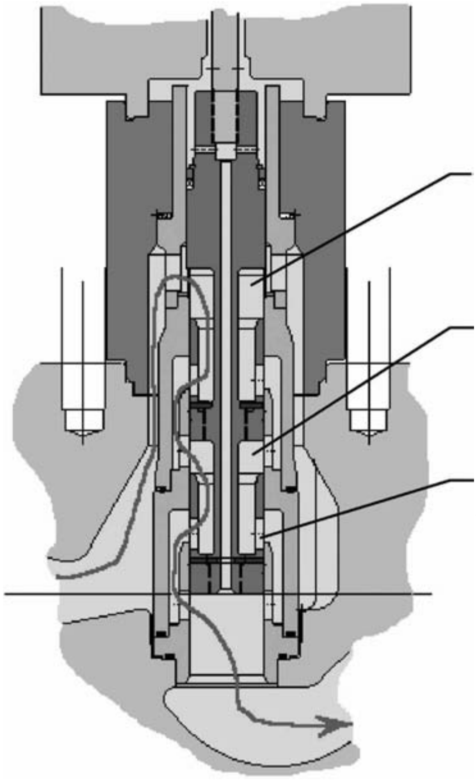

FIG. 6.13r
Dirty service trim (DST) design of Fisher Controls.

number of stages selected is dependent upon the pressure drop of the application and is designed in the same manner as was shown in Figure 6.13n.

The higher the pressure drop, the more stages become necessary. This trim design can pass particulates up to $^3/_4$ in. in diameter without plugging. The large open flow paths and expanded area staging design also compensate for volumetric expansion in flashing fluids, thus reducing velocities in the trim and the downstream piping.

Also included in this DST design is a protected seat, because the shut-off function of the trim is separate from its throttling areas. This separation is accomplished by not allowing any significant pressure drop to be taken until the fluid is downstream of the seating surface. This type of design also ensures that all clearance flow is subjected to a staged pressure drop. Unlike in linear cage-style, anticavitation trim sets, here no segment of the process flow can drop directly from the upstream (P1) to the downstream (P2) pressure after the valve.

High Noise

Section 6.14 covers all aspects of control valve noise, and Figures 6.14o to 6.14s show some low noise control valve designs from a variety of suppliers.

In many cases when the process fluid remains contained by the valve and piping, the noise generated becomes airborne only by its transmission through the valves and the adjacent piping. The sound field in the flow stream forces these solid boundaries to vibrate. These vibrations cause disturbances in the ambient atmosphere that are propagated as sound waves.

FIG. 6.13s
WhisperFlo noise abatement trim by Fisher Controls.

There are several ways to eliminate excessive valve noise (see Section 6.14), but this section will focus mainly on source treatment methods, which are obtained through specially designed control valve trim. There are many types of control valve trims that were designed to reduce valve noise, but there are only two ways to accomplish this reduction.

One method is referred to as frequency shifting, while the other is velocity control. The former approach, which has been used for many years, incorporates small, properly sized and spaced passages that raise the frequency of the fluid exiting the trim. The higher frequency reduces acoustic energy in the audible range by relying on the transmission loss of the piping. The latter approach (velocity control) can be accomplished in many ways, and the highest level of noise attenuation is usually accomplished by incorporating both methods.

Figure 6.13s shows the cross-section of a multistage noise reduction trim that utilizes a combination of noise reduction strategies and reduces valve noise by up to 40 dB.

Some of the features of this design include

- Unique passage shape reduces the conversion of total stream power generated by the valve into noise power.
- Multistage pressure reduction divides the stream power between stages and further reduces the acoustic conversion efficiency.
- Frequency spectrum shifting reduces acoustic energy in the audible range by capitalizing on the transmission loss of the piping system.
- Exit jet independence avoids noise regeneration due to jet coalescence.
- Velocity management is accomplished with expanding areas to accommodate the expanding gas.
- Complementary body designs avoid flow impingement on the body wall and secondary noise sources.

As explained in detail in Section 6.14, the amount of noise that will be generated by a control valve can be predicted quickly and reasonably by use of industry-standard methods. In order to obtain accurate noise predictions, it is important to utilize the standards described in Section 6.14.

High-Capacity Valves

Globe-style valves larger than 12-in., ball valves over 24-in., and high-performance butterfly valves larger than 48 in. are considered to be special valves. As valve sizes increase, shut-off static pressure loads also increase. Consequently, shaft strength, bearing loads, unbalance forces, and available actuator thrusts all become more significant with increasing valve size.

Noise levels must also be carefully considered in all large-flow installations because sound pressure levels increase in direct proportion to the magnitude of flow. To keep valve noise within tolerable limits, large cast or fabricated valve body designs have been developed. These bodies, which are normally cage-style constructions, use very long plug travel, a great number of small flow openings through the wall of the cage, and an expanded outlet line connection to minimize noise generation and to reduce fluid velocity.

With the increase in valve plug travels, the selection of the actuator used becomes more important. Typically, long-stroke, double-acting pneumatic piston actuators are selected. With these types of actuators, the accessories required to move the actuator also become more complex.

Cryogenic Valves

Cryogenic applications are those with temperatures that fall below –150°F (–110°C). Globe-style valves in cryogenic services are used in both cold box applications and non-cold box applications.

Cold boxes are commonly found in the air separation industry. Valves used in these applications feature bodies with welded extension necks and standard length bonnets to allow in-place trim maintenance from outside the cold box. For non-cold box applications, a cryogenic valve with an extension bonnet is used.

For control valves in cryogenic service, the correct selection of plastic and elastomeric components are important, because they often cease to function properly at temperatures below 0°F (–18°C). In these low-temperature ranges, components such as packing and plug seals require special consideration. For plug seals, a standard soft seal will become very hard and less pliable, thus not providing the shut-off that is required. Special elastomers have been applied in these temperatures, but require special loading to achieve a tight seal.

Packing is a concern in cryogenic applications because of the frost that may form on valves. Moisture from the atmosphere condenses on surfaces where the temperature is below freezing and will freeze into a layer of frost. As this frost and ice forms on the bonnet and stem areas of control valves and as the stem is stroked by the actuator, this layer of frost is drawn through the packing, causing tears and a loss of seal.

The solution is to use an extension bonnet (Figures 6.1t, 6.1u, 6.13t, 6.19p, and 6.19q) that allows the packing box area of the control valve to be warmed by ambient temperatures, thus preventing frost from forming on the stem and packing box areas. The length of the extension bonnet depends upon the operating process temperature and on the insulation requirements.

FIG. 6.13t
The construction of a cryogenic valve with extended bonnet. (Courtesy of Fisher Controls.)

When testing cryogenic valves for shut-off or in hydrostatic tests, the use of water-based tests should be avoided. If water tests are conducted, it is possible that moisture can be trapped inside the body or extension bonnet, which could ultimately form ice in the valve after it is cooled down. For these types of applications, in order to prevent freezing, the proper test medium is usually helium.

High-Temperature Valves

Valves that operate at temperatures above 450°F (232°C) experience many of the same limitations as do cryogenic valves. At elevated temperatures, the standard materials of control valve construction might be inadequate. For instance, plastics, elastomers, and standard gaskets generally prove unsuitable and must be replaced by more durable materials. Metal-to-metal seating materials are always used. Semimetallic or laminated flexible graphite packing materials are commonly employed, and spiral-wound stainless steel and flexible graphite gaskets are necessary.

It is important to select the trim materials and valve designs that will not experience sticking and gasket failure due to thermal expansion. If dissimilar trim materials are used, it is possible that one part will react to the high temperature faster than another, causing the components to gall. It is also important to allow the trim to grow axially in the valve body. Hanging the cage element from the top of the valve body does this. Some designs also incorporate internal springs or load rings to allow for the thermal expansion of the trim.

Similar to cryogenic applications, extension bonnets are used to protect the packing box parts from extremely high temperatures. For the selection of metallic and packing materials (Figure 6.1o) and the use of jacketed valve designs (Figures 6.1p to 6.1r), refer to Section 6.1.

Steam Conditioning Valves

Steam conditioning applications are examples of services where valves are exposed to high temperatures. These valves serve the function of simultaneously reducing the steam pressure and temperature to the level required for a given application. Frequently, these applications deal with high inlet pressures and temperatures and require significant reduction of both. They are, therefore, best manufactured as a forged or a fabricated body that can better withstand steam loads at elevated pressures and temperatures.

Forged materials permit higher design stresses, improve grain structure, and offer an inherent material integrity that is superior to cast valve bodies. The forged construction also allows the manufacturer to provide up to ANSI Class 4500, as well as intermediate and special class ratings, with greater ease vs. cast bodies.

Due to frequent extreme changes in steam properties as a result of the temperature and pressure reduction, the forged and fabricated valve body design allows for the addition of an expanded outlet to control outlet steam velocity at the lower outlet pressure. Similarly, with reduced outlet pressure, the forged and fabricated design allows the manufacturer to provide different pressure class ratings for the inlet and outlet connections to more closely match the adjacent piping.

Other advantages of combining the pressure reduction and desuperheating functions in the same valve versus two separate devices include:

- Improved spraywater mixing due to the optimum utilization of the turbulent expansion zone downstream of the pressure reduction element
- Improved rangeability
- Ease of installation and servicing of only one device

The manifold steam conditioning valve design (Figure 6.13u) is the most common form of steam conditioning valve available. This valve design offers all of the benefits of a combined valve, but features the ability to provide multipoint water injection utilizing an externally mounted manifold around the valve outlet. With this manifold, large quantities of water can be injected with a homogeneous distribution throughout the steam outlet flow.

Positioning of the valve plug within the control cage controls the steam pressure and flow. A signal from the pressure control loop to the valve actuator moves the valve plug within the control cage to increase or decrease the amount of free flow area. As the plug is lifted from the seat, steam passes into the center of the cage and out through the cage element.

The outlet section is outfitted with a water supply manifold. The manifold provides cooling water to a number of individual spray nozzles installed in the outlet section, which provide a fine spray mist that is injected radially into the highly turbulent stream of flowing steam.

FIG. 6.13u
The design of a steam conditioning valve, which is provided with an integral cooling manifold. (Courtesy of Fisher Controls.)

The combination of having a large surface area contacting the water and the high turbulence makes the mixing efficient and the vaporization rapid. For this control system an external water control valve is required, which is throttled by a downstream temperature controller to provide the required fine-tuning of the temperature control.

These types of valves are most commonly used in power (utility, cogeneration, and industrial) plant applications, which include the start-up of steam turbines, and the bypassing, dumping, venting, and exporting of steam.

Tank-Mounted Valves

Tank-mounted control valves are commonly found in the chemical industry. These are reverse acting (push down to open) control valves designed for handling corrosive fluids. The throttling element of the valve is positioned at the valve outlet and is placed inside the receiving tank so that flow exits directly into the vessel. In flashing applications or those with entrained gas, the erosion potential is greatly reduced.

H. D. BAUMANN (1970) **J. B. ARANT** (1985) **B. G. LIPTÁK** (1995) **F. M. CAIN** (2005)

Valve Noise Types:	Mechanical vibration (usually below 100 dBA); hydrodynamic caused by liquid turbulence, cavitation, or flashing (usually below 110 dBA); aerodynamic (can reach 150 dBA)
Sizes:	1 to 24 in. (25 to 600 mm) in standard bodies; sizes above 24 in. in special castings or weldment fabrications
Design Pressure:	Up to ANSI Class 2500 (PN 420) standard; above Class 2500 in special designs
Materials of Construction:	Any machinable wrought or cast metal for body and trim approved for use in valves or pressure vessels
Special Features:	Balanced plugs, special seal designs, hard facings, piloted inner valve, characterized flow, dual (high/low) operating conditions, multistage trims
Cost:	Highly variable depending upon type of design, size, metallurgy, special features. Range may be from 2 to 10 times equivalent standard valve

INTRODUCTION

This section begins with an overview of general noise principles, followed by a description of the types of noise produced by fluid flow through control valves. The discussion of control valve noise mitigation includes both the treatment of the noise source (modifying the valve) and the treatment of the noise path (providing downstream insulation or silencers). Other options include protection of the receiver (by personal protective equipment such as earplugs or earmuffs) or the removal of the receiver (by placing a barrier or distance between the noise source and personnel). The section ends with a discussion about recent improvements in predicting and calculating probable noise levels.

Because most valve noise calculation standards avoid excessive detail, only the SI system of units will be used in this section. Users of U.S. Customary units should refer to Appendix A.1 and A.2 for the proper conversion factors, including gravitational units conversions (i.e., g_c) when necessary.

SOUND AND NOISE

A weed has been defined as an unwanted plant or flower. As an environmental analogy, noise may be considered as an unpleasant or unwanted sound. Sound, in the context of this discussion, is defined as pressure fluctuations generated in the air or other medium, which are capable of stimulating the physiological hearing response of the human ear and brain. For ease of understanding, we will hereafter refer to *sound* and *noise* as equivalent terms.

Most common sounds are a complex mixture of many frequencies at varying magnitudes. Pure tones have discrete frequencies. It is customary to model sound as pressure waves with sinusoidal characteristics such as frequency (f), magnitude (p), wavelength (λ), and speed (c). Of course, sound waves possess other more complex characteristics that are beyond the scope of this topic.

Frequency is expressed in cycles per second (cps) or Hertz (Hz), where cps and Hz are equivalent units. The magnitude of sound pressure is measured in units of pressure (Pascal in the SI system). The range of sound pressures that humans can discern from the threshold of hearing to the threshold of pain spans over 12 orders of magnitude! Therefore, it is more convenient to use a logarithmic comparison of an actual sound pressure to a standard pressure reference at the threshold of hearing and to define this comparison as a *sound pressure level*, L_p, expressed by Equation 6.14(1) in decibels (dB).

$$L_p = 10\log_{10}\left(\frac{p}{p_o}\right)^2 = 20\log_{10}\left(\frac{p}{p_o}\right) \qquad \mathbf{6.14(1)}$$

where p is the actual sound pressure, and the reference sound pressure, p_o, is defined as 2×10^{-5} Pascal (2×10^{-4} microbar or 29×10^{-8} psi.). Because the decibel is a logarithmic function, for every 10 dB increase, there is a tenfold increase in sound intensity. Thus, a 100 dB sound is 10 times as intense as 90 dB and 100 times as intense as 80 dB. However, the human ear perceives each 10 dB increase as an approximate doubling of loudness.

The sound pressure fluctuations must be generated by some energy source that transfers power into the air or other wave-conducting medium. (Sound waves cannot travel in a vacuum.) The total acoustic power created by the noise source is defined as sound power, W_a, usually expressed in watts (W).

The calculation of sound power will be used in this section to predict sound pressure levels in valve applications. It is worth remembering that, while sound is produced by a power source, it is sound pressure that the ear perceives. Sound power can also be presented as a sound power level, L_w, in decibels by logarithmic comparison with the standard reference level, W_o, of 10^{-12} W.

$$L_w = 10\log_{10}\left(\frac{W_a}{W_o}\right) \qquad \mathbf{6.14(2)}$$

Wavelength, λ, is the distance required for one complete pressure cycle.

Speed of Sound

The speed of sound, c, in any medium is a function of its mass density and elastic properties.

For a solid:

$$c = \sqrt{E/\rho} \qquad \mathbf{6.14(3)}$$

where E is the elastic modulus and ρ is the mass density.

For carbon steel pipe at 100°C, E = 198 GPa, ρ = 7.86 g/cm^3, and c = 5020 m/s. For CrMo steel alloy pipe at 100°C, E = 207 GPa, ρ = 7.84 g/cm3, and c = 5140 m/s. Austenitic stainless steel pipe (UNS S30400) at 100°C with E = 190 GPa and ρ = 8.03 g/cm^3 has c = 4860 m/s. So, for purposes of estimating the speed of sound in steel pipe, using 5000 m/s usually produces satisfactory results.[1]

For a liquid:

$$c = \sqrt{E_s/\rho} \qquad \mathbf{6.14(4)}$$

where E_s is the isentropic bulk modulus. It can be shown that at 20°C, speed of sound in fresh water is 1481 m/s, in seawater 1521 m/s, and in machine oil (sp. gr. = 0.90) 1297 m/s.

For a gas or vapor:

$$c = \sqrt{\frac{\gamma p}{\rho}} = \sqrt{\frac{\gamma RT}{M}} \qquad \mathbf{6.14(5)}$$

where γ is the ratio of specific heats, R is the universal gas constant (8 × 314 J/kmol × K), T is absolute temperature (Kelvin), and M is molecular mass of the fluid. Using this relationship, we find that the speed of sound in air at 0°C (273°K) is 331 m/s.

Wavelength, frequency, and speed of sound are related as shown in Equation 6.14(6).

$$c = \lambda f \qquad \mathbf{6.14(6)}$$

THE HUMAN EAR

The human ear is an intricate acoustic instrument that is described here in only general terms. The anatomy of the ear is divided into three major regions, each with unique functions: the outer ear, middle ear, and inner ear. The outer ear consists of the pinna, ear canal, and outer layer of the eardrum. It channels sound waves to the eardrum, where sound pressure waves are converted into mechanical energy by vibrating the eardrum.

---

[1] The most recent valve noise calculation standard and the field of acoustics in general use SI units. Users of U.S. Customary Units are cautioned to use the proper gravitational units conversions (i.e., g_c) when necessary. To avoid excessive detail, only the SI system of units will be used in this section.

The middle ear is an air-filled cavity containing the ossicles (bones) that connect to the oval window to the inner ear. The middle ear cavity is also connected to the Eustachian tube, which equalizes static pressure across the eardrum. The middle ear mechanism acts as an impedance-matching transformer. It is matching the impedance of the air in the ear canal to the impedance of the liquid of the inner ear.

The inner ear vestibule leads to the semicircular canals (providing sense of balance) and the "snail-shaped" cochlea, where the final energy transformation occurs. In the cochlea, mechanical energy is conducted through a traveling wave pattern on the basilar membrane, causing a shearing of the cilia of the outer and inner hair cells of the Organ of Corti. The design and stiffness gradient of the basilar membrane allow more efficient response to higher frequencies at the basal end, and progressively lower frequencies are detected along the membrane toward its apex.

The Organ of Corti is the sense organ that changes vibration energy into neural energy. This conversion takes place as shearing stress on hair cells induces a depolarization that generates neural impulses. The neural impulses are conducted by the auditory nerve to the brain, where they are processed and interpreted as sound. Damage to the hair cells connecting the basilar membrane and Organ of Corti usually produces permanent loss of hearing. Damage or deterioration can occur from sudden, loud noise (explosions), excessive exposure to moderately loud noise (industrial environments, loud music), physical injury (head trauma), advancing age, infections, or disease.

Loudness Perception

A healthy, young adult human is able to perceive sound over a wide range of frequencies from approximately 20 to 18,000 Hz, which is generally accepted as the audible range. The human ear, however, does not give equal weight (loudness perception) to the same sound pressure level across the frequency spectrum.

Studies of apparent loudness by many human subjects over the frequency spectrum when compared to a pure tone of 1000 Hz frequency has resulted in mapping the ear response. The loudness level in phons represents the pressure level in dB of a 1 kHz tone that a typical hearer feels is as loud as the sound in question. Figure 6.14a shows the loudness level map as function of frequency.

We can see from Figure 6.14a that a sound at 1000 Hz and 50 dB sounds equally loud as 67 dB at 100 Hz or 62 dB at 10 kHz. The resulting correction numbers, which are approximating the response of the human ear, are called "A" weighting. The corresponding decibel level is indicated as dBA, as shown in Figure 6.14b.

There are other weighting schemes for various purposes, but A weighting is used in governmental regulations on noise pollution. Hence, for the discussion of valve noise levels and environmental noise reduction, we will use the dBA scale. Noise levels of some common environmental sounds are compared in Table 6.14c.

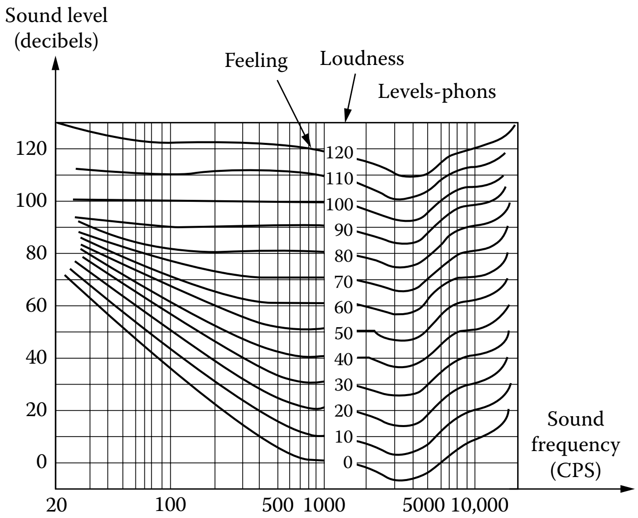

FIG. 6.14a
Apparent loudness contours for human hearing.

Limiting Valve Noise

There are several important reasons to limit the noise levels emitted by valves and piping. One of them is to prevent the harmful effects of environmental noise pollution, which includes hearing loss in people. As was noted earlier, we can tolerate much louder sounds at low and at very high frequencies than we can in the middle of the spectrum. This is represented in the A-weighting curve of Figure 6.14b.

Note that in the 500–7000 Hz range, the human ear is most responsive, and this is the area where high noise level exposure can do the most damage. For this reason, the U.S. government enacted the Occupational Safety and Health Act of 1970 (amended in 1998), establishing the Occupational Safety and Health Administration (OSHA). OSHA regulations limit a

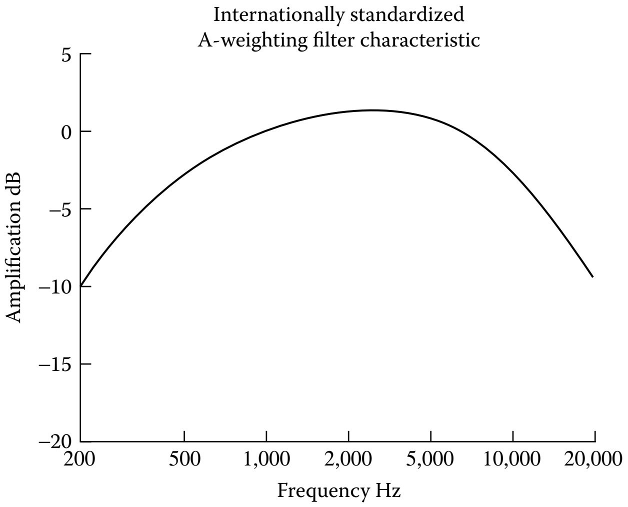

FIG. 6.14b
The A-weighting filter characteristic approximates the human ear's response to different sound frequencies.

TABLE 6.14c
Approximate Sound Pressures Levels of Typical Sounds

Source of Sound	*L_p (dBA)*
Near jet engine; artillery fire	140
50 hp victory siren at 30 m; threshold of pain	130
Rock-and-roll band; threshold of feeling	120
Jet flying overhead at 300 m	110
Air chisel; high pressure gas leak	100
Motorcycle at 15 m; subway train at 6 m; symphony	90
Inside sports car (100 km/h)	80

weighted 90 dBA maximum level exposure to 8 hours per day. Table 6.14d below shows general exposure time limits established by OSHA.

Figure 6.14e shows a typical frequency octave band noise level contour that will meet this limit. Note that if the predominant noise frequency exposure is in the critical middle frequency range of 1000–5000 Hz, the allowable weighted noise level over 8 hours would be considerably less than 90 dBA.

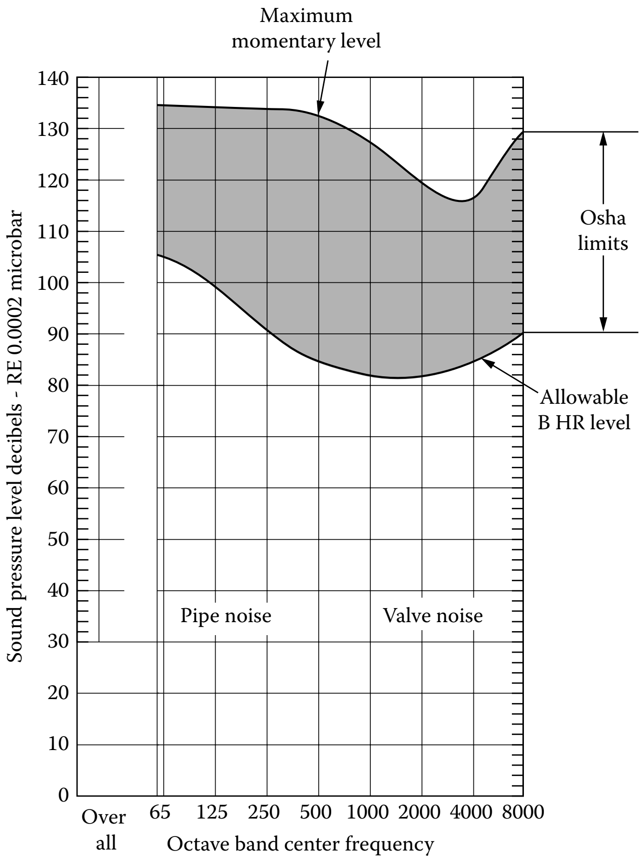

Fig. 6.14e
Frequency octave band noise level contours, which will result in the weighted average exposure to meet OSHA limits.

VALVE NOISE

While there are many noise sources in industrial and process plants, some of the main contributors can be control valves operating under conditions of high pressure drop. These are one of the few and sometimes the only sources of over 100 dBA sound levels found in process plants. To gain some perspective of how loud 100 dBA actually is, refer to Table 6.14c for a comparison of common environmental sounds.

However, even if people are removed from areas with high noise levels, other hazards are still created by excessive noise. High intensity noise can produce vibrations in structures, which become magnified when the natural (resonant) frequencies within the structure are close to the dominant frequency of the noise.

TABLE 6.14d
OSHA Exposure Time Limits for Various Noise Levels

Hours per Day	*dBA*
8	90
4	95
2	100
1	105
$^1/_2$	110
$^1/_4$	115 (max.)

Even without resonance, studies by Fagerlund have shown that the sound power that is produced downstream of valves can cause fatigue failures in valves and piping systems. This can occur when noise levels outside the pipe (1 m downstream of a valve and 1 m away from the pipe wall) exceed 110–115 dBA depending on pipe size.

Table 6.14f provides a summary of the likely causes of noise in valves and of their frequencies.

The five major sources of noise generated by control valves are as follows:

- Mechanical vibration
- Control element instability
- Resonant vibration
- Hydrodynamic noise
- Aerodynamic noise

Mechanical Vibration Mechanical vibration of valve internal parts is caused by unsteady flow and turbulence within the valve. It is usually unpredictable and is really a design

TABLE 6.14f
Sound Frequencies and Sources in Valves

Frequency (Hz)	*Octave Band Number*	*Sound Description*	*Typical Noise Source in Valves*
20–75	1	Rumble	Vertical plug oscillation
75–150	2		Cavitation*
150–300	3	Rattle	
300–600	4	Howl	Horizontal plug vibration
600–1200	5		
1200–2400	6	Hiss	Flowing gas
2400–4800	7	Whistle	
4800–7000	8	Squeal	Natural frequency vibration
20,000 and up		Ultrasonic	

* Cavitation frequencies vary widely from about 100 Hz to 15 kHz depending on valve and trim design.

problem for the manufacturer. Noise levels are typically low, usually well under 90 dBA, and in the 50 and 1500 Hz frequency range.

The problem is often not the noise, but the progressively worsening vibration as guides and parts wear. The solution can be in improving the valve design by adding heavy-duty stems and guides. Improvements in design may also include small changes in the flow path geometry of the trim, which can also eliminate some vibration problems.

Control Element Instability

Control element instability is usually due to mass flow turbulence impingement on the valve plug. The relationship between velocity and static pressure forces acting across the plug or disc face and the actuator force balance varies over time. Without sufficient stiffness in the actuator, valve, and mechanical connections, fluid buffeting forces may produce vertical stem oscillations in linear valves and torsional shaft oscillations in rotary valves, resulting in low-level rattle noise usually under 100 Hz. This instability is detrimental to control.

Correction requires changing the damping characteristics of the valve and actuator combination. This is done by providing a stiffer valve actuator or eliminating mechanical backlash. If the actuator is a spring-and-diaphragm type, then one can increase the nominal spring rate from 20–100 kPa (3–15 PSIG) to 40–200 kPa (6–30 PSIG).

For single-acting piston actuators, the cushion air loading can be increased. If these changes do not solve the problem, then either actuator can be replaced with double-acting air piston actuators, which are generally stiffer and allow use of higher air pressures. In extreme cases, a hydraulic snubber, an all-hydraulic actuator, or electromechanical actuator may be required.

Resonant Vibration

Resonant noise is characterized by a discrete tone and possibly a few harmonic multiples. Resonance can involve merely an acoustic interaction within the valve and piping geometry, with certain frequencies of the flow turbulence. Resonant frequencies from 200 Hz to 10 kHz can be excited acoustically by the flow in the same way that tones are produced in musical instruments.

Localized metal fretting or wear is likely on internal valve parts. In some cases, turbulence and acoustic resonance excites mechanical or structural natural frequencies, producing severe vibration capable of causing damage to piping, equipment, and supporting structures. Resonant noise levels exceed calculated predictions based on current prediction standards and may be in the 90–125 dBA range.

Work by Glenn refers to this discrete resonance as *screech*, and his research shows that screech is possible at pressure drops lower than required to produce sonic flow in gases or cavitation in liquids. It is possible for conditions to exist that produce screech-type resonance in virtually any valve type and brand. Glenn identifies several possible causes of screech in valves:

Higher than expected velocities in the valve, due to uncertainties in the pressure recovery characteristics as a function of valve opening. (Refer to the discussion of the pressure recovery factor F_L in Section 6.15.)
Excitation of harmonic pipe modes of vibration
Flow instabilities, due to
- Vortex shedding
- Tollmien-Schlichting waves in the laminar-to-turbulent flow transition
- Bi-stable flow separation
- Unstable shock waves
- Unstable vapor-liquid interface

Two approaches to solving these problems include 1) modifying the design of the flow path to change the characteristics of the turbulence, or 2) changing the stiffness and resonant frequencies of the valve trim.

Valve trims can often be modified by a change in stem diameter, change in the plug mass, or method of guiding. Flow paths can be modified sometimes by reversal of flow direction through the valve or by minor design changes to seats, plugs, or cages. These changes shift the natural frequency of the plug and stem out of the excitation range of the flow turbulence, or vice versa.

Valve manufacturers and users should collaborate to implement effective solutions in valves and piping when these problems arise. For example, one investigation identified the source of serious screech noise as a gap between valve and pipe flanges created by an oversized inside diameter of the gasket. Filling the gap with a properly sized gasket eliminated the problem.

Hydrodynamic Noise

Hydrodynamic noise is generally less troublesome and less severe than aerodynamic noise and usually only becomes excessive when accompanied by cavitation or flashing (discussed in Sections 6.1 and 6.15). Severe cavitation can produce noise in the range of 90–100 dBA or higher.

Problems with cavitation or flashing are usually avoided by use of a suitable trim or valve type with low-pressure recovery characteristics (high F_L). Noise caused by cavitation is the result of imploding vapor bubbles in the liquid stream. This noise can vary from a low-frequency rumble or rattling to a high-frequency squeal. This latter condition is due to acoustic or pipe resonance with cavitating fluid.

In most cases, the problem is not so much with noise as it is the destruction of the valve trim and piping from erosion and pitting by the imploding vapor bubbles. Reducing or eliminating the cavitation and its damage also eliminates the noise. Single-stage multiorifice valves (see Figure 6.1z) and multistage valves (see Figures 6.1y and 6.1aa) are typical solutions to cavitation erosion and noise.

The sizing of any liquid service control valve should include an evaluation of the cavitation potential, with emphasis on eliminating or mitigating the cavitation. Section 6.15 outlines methods for predicting the onset of cavitation. The standards VDMA 24422 and IEC 60534-8-4 include methods for calculating hydrodynamic noise, but these methods have been shown by Kiesbauer and Baumann to predict lower than actual noise in many cases. At the time of this writing, work is under way in the International Electrotechnical Commission (IEC) to improve the accuracy of hydrodynamic noise prediction.

Flashing is rarely a significant source of valve noise, although it can cause valve trim erosion damage in some cases. Flashing produces increasing valve exit velocity and downstream piping velocity as a result of the higher specific volume of the two-phase flow. In cases where sonic flow and shock cells develop in downstream piping, excessive noise can result. Expanded outlet valves and larger downstream piping will be required under conditions where a large percentage of the liquid undergoes flashing. At this time there is not a standard method for predicting noise from flashing.

Aerodynamic Noise

In control valve design, aerodynamic noise can be a major problem. It is a category of valve noise capable of generating noise levels of 120 dBA or greater. Noise produced by fluid turbulence in liquids is almost negligible as compared to the noise generated by the turbulence and shock cells due to the high velocity of gases and vapors passing through the valve orifice.

The mechanisms of noise generation in valves and transmission through pipe walls are highly complex and are still not completely predictable. As a result of the many variables influencing noise generation and the need for simplifying assumptions in calculations, predicting the noise levels from valves or atmospheric exhaust vents is an inexact science. However, universities, manufacturers, and interested technical societies have made much progress, which has resulted in better noise prediction methods based on scientific fundamentals, which will be discussed in the section on Noise Calculations.

Aerodynamic noise generation, in general, is a function of mass flow rate and the pressure ratio (p_1/p_2) across the valve. The point at which sonic speed is reached in the valve vena contracta is a function of the valve design and its pressure recovery coefficient, F_L, combined with the ratio of upstream to downstream absolute pressure (p_1/p_2). For example, valves with F_L values of 0.5 and 0.95 require pressure ratios of 1.15 and 1.80, respectively, to generate sonic flow in the valve.

When sonic velocity is reached at the vena contracta, the valves are said to be *choked*, because their capacity does not increase if the pressure ratio is increased while the upstream pressure is kept constant. Generally, choked valves are the sources of the highest noise levels, but subsonic flows can also generate high noise levels. Valves that are not choked operate in a subsonic flow regime. For a given mass flow, they are less noisy than choked valves, but the noise level will increase as the pressure ratio approaches the sonic level.

Velocity of the flow in downstream pipe can also generate significant noise starting at pipe velocities of about Mach 0.4 to Mach 1.0 (sonic). Noisy gas or vapor control valves can have acoustically induced and turbulence-induced vibration damage, trim wear, and control instabilities. High-intensity noise can produce vibration-related stresses at very high cycle rates (1,000–10,000 cps). Hence, noise-induced damage can drastically reduce valve service life, and in some cases, it can cause valve or piping failures in a matter of minutes or hours.

CONTROLLING NOISE

The transmission of a noise requires a source of sound, a medium through which the sound is transmitted, and a receiver. Each of these can be changed to reduce the noise level. In cases when the noise is from vibrating control valve components, the vibrations must be eliminated or they might result in valve failure. In cases when the source of noise is the hiss of a gas-reducing station, the acoustical treatment of the noise is sufficient.

Depending upon the magnitude of the aerodynamic noise and assuming that massive valve damage is not a factor, valve noise treatment can be accomplished either by path treatment or source treatment. Valve damage can only be reduced or eliminated by source treatment, which minimizes or eliminates the damage mechanism.

There is no absolute rule that will enable one to choose between path or source treatment. However, in general, if the noise is under 100 dBA, then either a path or source treatment is a possible solution. Noise above 100 dBA almost always requires source treatment to successfully solve the noise problem.

The proper choice of noise treatment method is not always easy to select, but with the help of improved noise predictions through frequency spectrum evaluation and with expertise based on experience it can be obtained. Conservative solutions are preferred, because reworking or retrofitting in case of poor design is often very expensive.

Path Treatment

Path treatment, as its name implies, does not focus on changing the noise source. The intent of path treatment is to attenuate the noise transmission from the source to the receiver (ear). There are several common path treatments: the use of heavy wall pipe; installation of diffusers, mufflers, or silencers; and application of acoustical insulation.

Path treatment is not always a more economical solution than source treatment, and economics must be evaluated for individual applications. For existing installations, path treatment may be used, not because it is the best solution, but because it may be the only feasible one.

Pipe Wall Thickness Heavy wall pipe reduces noise by increasing the transmission loss through the pipe wall. The amount of attenuation depends on the stiffness and mass of the pipe. The mechanisms are complex and beyond the scope of this text. However, as a simple rule for rough estimation, each doubling of pipe wall thickness results in approximately 6 dBA more attenuation depending upon pipe size (attenuation increases with pipe size).

Refer to the works of Fagerlund and Chow (1981) and Reethof and Ward (1986) for important foundation in calculating transmission losses through pipe walls. Sample calculations will be introduced in the Noise Prediction section.

Insulation and Absorption Another method of increasing transmission loss at the pipe wall is the use of acoustic insulation. Even thermal insulation can add 3–5 dBA attenuation. Proper selection and application of 1–2 in. (25–50 mm) of a good acoustic insulation can reduce the noise level by roughly 10 dBA.

Certain types of insulation are more effective at specific frequency bands, so this information is important for proper selection. Because sound travels down the pipeline with very little attenuation over long distances, increasing the pipe wall thickness or applying acoustical insulation can be a very expensive solution. This approach is most useful when downstream piping runs are short.

The higher the frequency of vibration, the more effective are the commercially available sound absorption materials. Figure 6.14g gives an example of acoustical treatment for the outside of a pipe.

It is often beneficial to cover the inside walls of the building with sound-absorbing materials to prevent the reflection and radiation of the sound waves from process equipment. If a valve is installed close to a single reflective surface (e.g., a hard floor or wall), the apparent noise increases by 3 dBA; with two reflective surfaces, noise increases by 6 dBA; and for three nearby reflective surfaces, noise increases by 9 dBA. A valve installed in a small room with all reflective surfaces can elevate noise levels by 30–40 dBA. When using walls as sound barriers, it is important to seal all openings.

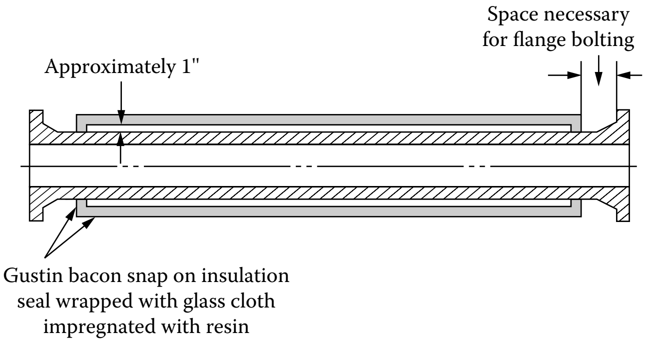

FIG. 6.14g
Acoustical treatment of pipe walls.

Isolation Locating a potentially noisy valve installation at a substantial distance from normal working areas may be effective and economical. If the valve can be located on top of a structure or pipe bridge, the distance attenuation can minimize the noise treatment required at the valve source and downstream pipe.

For example, instead of a control valve with a noise specification of 85 dBA, it may be possible to relax this to 90 or 95 dBA, which can considerably reduce the cost of the valve or noise treatment system. It is important to note that very little noise actually radiates from the valve itself, due to generally heavy wall thickness and rigidity of most valve bodies; downstream piping radiates the great majority of noise produced in the valve to the surroundings.

As a general rule, each doubling of a person's distance from the piping downstream of a valve will reduce the sound level by 3 dBA in a nonreflective environment. For example, the sound level that a person hears at 8 m from a valve will be 9 dBA quieter than the sound level at 1 m, and at 16 m it will be 12 dBA quieter than at 1 m.

Diffusers, Mufflers Diffusers located downstream of the valves (Figure 6.14h) can be helpful in both original installations and retrofit situations. These devices can aid in reducing exit flow turbulence or shock. Another important function of the multiple-hole design of diffusers depends on the fact that sound frequency increases as the size of the flow passage decreases. Using many small holes forces the dominant frequency of the turbulence into a higher range to which human hearing is less sensitive.

Diffusers can be designed to serve as pressure drop devices to reduce the pressure drop across the control valve

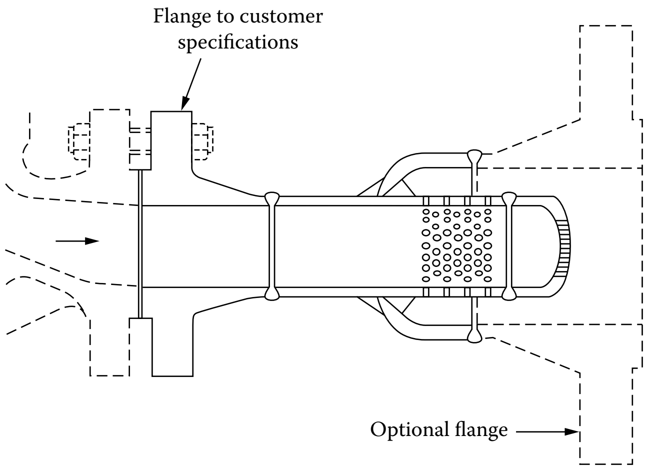

FIG. 6.14h
Acoustical diffusers are used to reduce the exit turbulence downstream of the valve. (Courtesy of Emerson Process Management.)

and thus reduce its noise generation. The valve and diffuser system works best in a situation when the flow rate is substantially constant or at least does not vary over a wide range. As a restrictor, the diffuser's effectiveness in generating backpressure on the valve decreases substantially as the flow rate drops. However, this shift of pressure drop back to the control valve does not necessarily increase noise, because when this occurs, the lower mass flow produces less noise.

Figure 6.14i illustrates a silencer design that can be installed downstream of a gas-regulating valve. Due to the resulting acoustical attenuation, it can reduce the sound pressure by a factor of five (e.g., from 96 to 82 dBA).

Mufflers or silencers (Figure 6.14j) can be used for in-line path treatment or for atmospheric vents. These are usually expensive devices, with the cost escalating dramatically with size.

Dissipative or dissipative/reactive silencers are most commonly used, but a comprehensive discussion of these devices is beyond the scope of this text. However, there are some rough guidelines for application. Inlet velocity must be subsonic, and the silencer cannot be sized to serve as a pressure reducer. An inlet diffuser (as shown in Figure 6.14j) can be helpful, because it breaks up turbulence or shock cell oscillations that often occur in downstream sound fields and reduce the effectiveness of the unit. The outer shell should have a thick enough wall to prevent resonance. Materials of construction are selected to meet process conditions and to retain absorptive materials.

Source Treatment

Source treatments reduce noise by limiting sound power generated at the source. In most cases, treatment consists of a special control valve and trim design, sometimes combined with a special diffuser or back-pressure element. While they may differ in concept, design, and manufacturing technologies, these special systems are designed for one or more of the following objectives:

- Reduce pressure drop in stages
- Limit fluid velocity to subsonic levels
- Reduce or eliminate the formation of high turbulence and shock cells
- Shift as much sound power as possible into higher frequency bands that have greater transmission losses in the pipe wall and have reduced response by human hearing

Depending upon the particular design, noise can be reduced with relatively inexpensive, simple elements by 7–10 dBA, whereas the more sophisticated valve designs or multielement systems can accomplish as much as 30–40 dBA attenuation from an untreated configuration.

Specification of source treatment valves or systems is not a simple matter. There are a number of design considerations, including the following:

- Application: in-line or vent
- Noise reduction required or maximum SPL allowed (dBA)

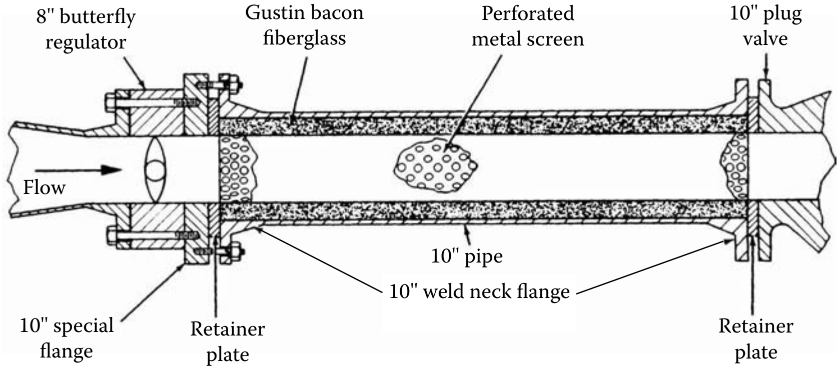

FIG. 6.14i
Silencer for gas regulating stations. (From King, C. F., "Control Valve Noise," Emerson Process Management.)

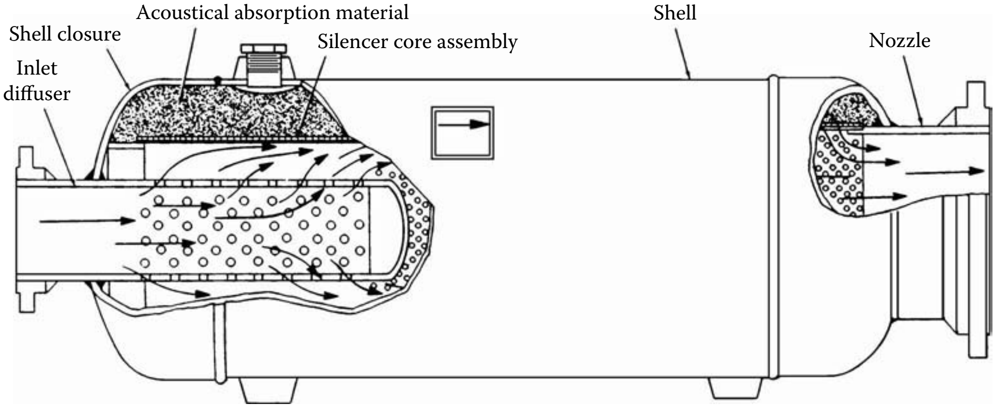

FIG. 6.14j
Silencers are installed in the flow path to dissipate the sound energy by absorbing it in an acoustical pack. They are designed to cause less than 1 PSI pressure drop. In-line silencers are often the most economical means of noise control in applications where the mass flow rate is high and the pressure drop is low. These units are normally installed immediately downstream of control valves, but in some cases they may also be required upstream of the valves. (Courtesy of Emerson Process Management.)

- Valve absolute pressure ratio: p_1/p_2 or $\Delta p/p_1$
- Pressure drop, Δp
- Fluid properties
- Temperature operating level and range
- Mass flow rate and turndown
- Metallurgy and mechanical design considerations
- Other potential velocity-induced problems
- Valve shut-off requirements
- Valve service life
- Valve location and orientation, piping arrangement, valve support, and maintenance access
- Actuation and control requirements
- Economics, including purchase, installation, and maintenance costs

The importance of each factor is a matter of judgment and experience, understanding all aspects of the application and plant operation. Thus it is up to the user to carefully weigh and evaluate all vendor proposals. If a vendor is using one of the standardized noise prediction methods, the user should verify that accurate input values were specified and used for the calculations. Vendors that offer proprietary noise prediction calculations should also offer empirical justification to support their noise prediction.

While initial cost is one factor, this is not the only consideration; it may be that the more expensive equipment is the most economical solution in the long run. Plant downtime and retrofit costs for deficient valve noise solutions are usually very expensive. With these caveats, there is much good equipment available, and vendor expertise and experience can be very valuable to the user with limited experience in controlling valve noise.

Basically, source treatment control valve designs fall into three categories: multipath, multistage, and combination of multipath/multistage. These designs are listed in order of sophistication and capability for noise reduction under severe operating conditions. As might be expected, cost also increases. The cost of these special designs tends to range from 2–20 times the cost of a standard valve with the same flow capacity.

Multipath Valves The multipath valve (Figure 6.14k) provides multiple orifices in parallel. A cylindrical plug to vary the flow rate through the valve uncovers these orifices. Although the path shape may vary by manufacturer, the principle consists of splitting the single-path flow into a large number of small paths. (See also the designs in Figures 6.1y and 6.1z.)

The noise radiated outside the pipe from the combined flow through multiple small paths is much less than that from the same flow rate through a single path restriction. Typical attenuation levels are 7–10 dBA but may reach 12–15 dBA in some applications. Variations of the multipath design are used for both hydrodynamic and aerodynamic valve noise with damage potential of low to moderate severity. Typically, compressible fluid pressure ratios (p_1/p_2) of 1.5–5 with valve exit velocities below Mach 0.33 are good candidates for this design.

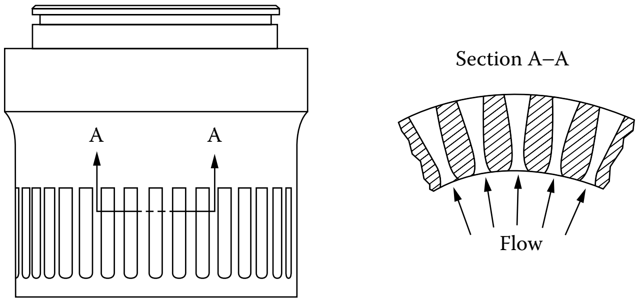

FIG. 6.14k
A multipath valve design, which can provide moderate noise reduction. (Courtesy of Emerson Process Management.)

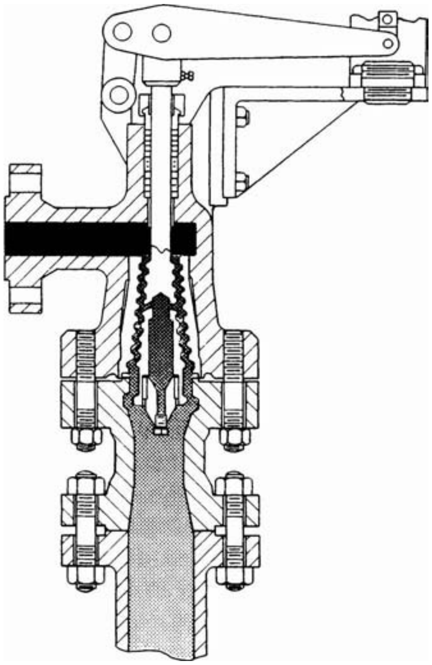

FIG. 6.14l
Multistage step trim valve for use on compressible fluids. Outlet is expanded to compensate for volume change. (Courtesy of Dresser Flow Solutions.)

Multistage Valves Pure multistage valves force the flow through a single path of two or more restrictions in series. (Figure 6.1y gives some examples.) An example of this design is shown in Figure 6.14l. The multiple orifices in series divide the total valve system pressure drop over several stages (typically three to nine). Thus, the reduced pressure drop per stage results in greater friction loss, reduced local velocities, and reduced noise.

The shape of the trim element allows an increasing effective flow area between the inlet and the outlet to compensate for the change in gas density and increase in specific volume. Thus, the outlet flange size is often larger than the inlet to limit the exit velocity to a level that will not regenerate excessive noise. Typically, these valves can provide noise attenuation up to 25 dBA, depending on pressure ratio and exit Mach number.

Resistor Elements In addition to diffusers, other special designs of multiple orifice restrictors are available (Figure 6.14m). These devices are built in a wafer design for installing between flanges and can be used in single- or in multistage configurations.

Such resistor elements can be installed in series, as shown in Figure 6.14n. These resistor plates are designed to work in series with the control valve to share the total pressure drop in a way that reduces pressure ratios on each element, thereby reducing the potential to generate noise.

The design of some of these devices forces the fluid through multiple changes in direction, acting like friction elements with noise attenuation capability of several dBA. These multiple orifice restrictors are very useful in valve noise control work, but like diffusers, they lose effectiveness with flow turndown.

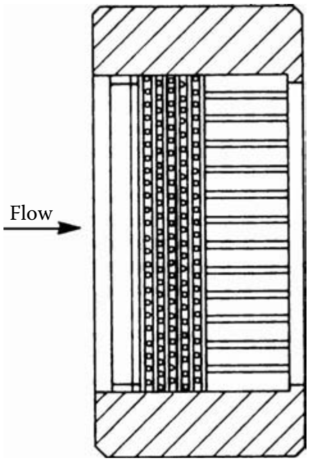

FIG. 6.14m
Resistor element used for valve back-pressure and noise reduction. (Courtesy of Dresser Flow Solutions.)

Combination Valves Combination multipath and multistage valves are usually required for the more severe and high noise producing services. These are the workhorse designs for the really tough applications, especially those that can cause extensive valve trim damage due to erosion or cavitation or noise levels in excess of 100 dBA. Various manufacturers have taken different approaches to the design of this type of valve.

Many are based upon multiple orifices in series and parallel with the flow controlled by a close-fitting cylindrical plug inside the cage for throttling (Figure 6.14o).

A variation of this design also incorporates a secondary diffuser element built into the valve (Figure 6.14p).

One manufacturer has designed a valve for moderate pressure drops using a standard valve trim assembly that eliminates the close-fitting cylindrical plug and uses a noise attenuator element ranging from one to seven stages (Figures 6.14q and 6.14r).

Another design utilizes the pressure loss producing effects of a fluid passing through a series of sharp turns

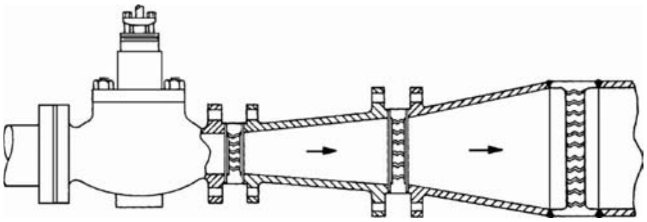

FIG. 6.14n
Noise can be reduced by resistor elements that are installed in series. (Courtesy of Dresser Flow Solutions.)

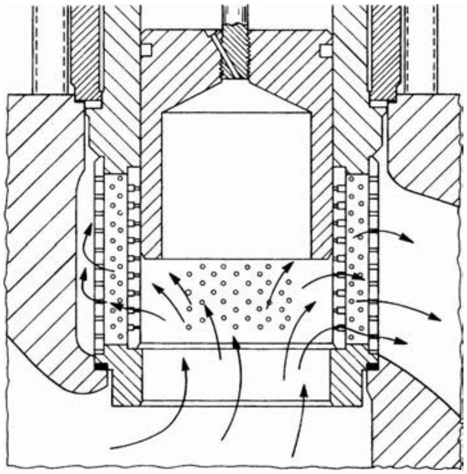

FIG. 6.14o
Multipath and multistage valve with shaped first stage holes. (Courtesy of Emerson Process Management.)

machined into a set of stacked disks (Figure 6.14s). Other similar designs are illustrated in Figure 6.1y and 6.1aa.

Depending upon the manufacturer and design, multistage, multiorifice valves will typically have 2–7 stages, although some might use 20 or more. However, the number of stages required by any specific design for a given application depends on the design principles employed and their effectiveness in the application. In other words, having more stages does not necessarily make a valve quieter than another design with fewer stages. Inexperienced users are advised to require some validation of manufacturers' claims of noise reduction for these critical service valves in addition to their noise calculations.

AERODYNAMIC NOISE PREDICTION

Valve noise prediction is an inexact science because of the complex nature of noise generation by the control valve and the transmission of this noise through the pipe wall. So it is not surprising that a number of different prediction methods are used by manufacturers and others. What is surprising is that the various methods can give answers for the same application that differ by up to 20 dBA.

The subject of valve noise prediction is still subject to continuing research and evaluation. So what should we do?

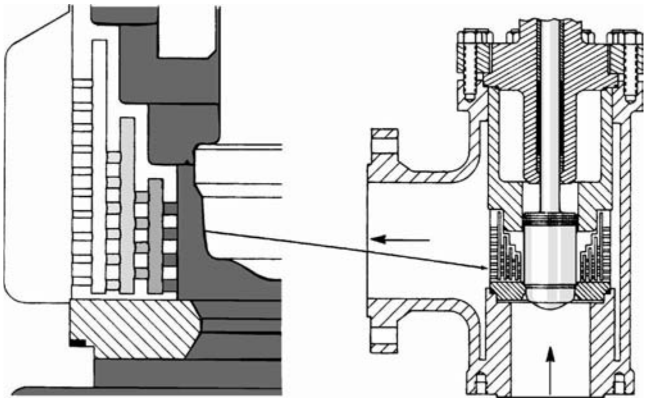

FIG. 6.14r
Multistage noise attenuator (and detail of that attenuator) in a valve, which was designed for use with a standard trim assembly with pressure balance. (Courtesy of Flowserve Corporation.)

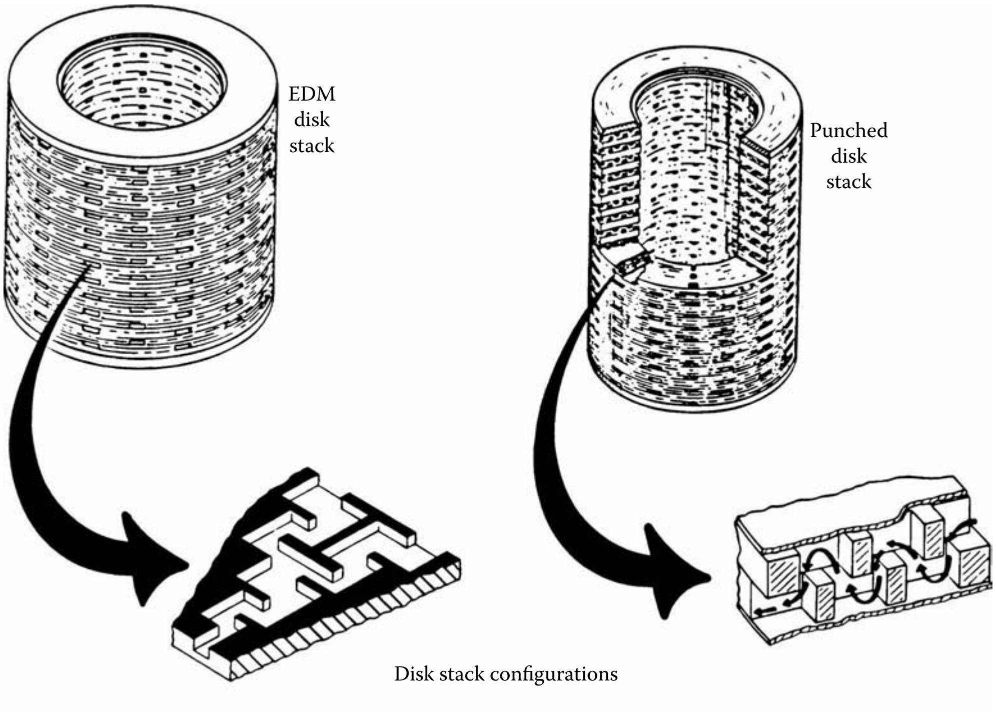

FIG. 6.14s
Special noise element design using labyrinth passages incorporated on plates. (Courtesy of Control Components Inc.)

Each manufacturer claims to be able to predict the valve noise level and provide a valve design solution. It finally falls upon the user to obtain the best possible process data, carefully evaluate all proposals, ask questions and resolve marked differences, and finally use good engineering judgment and experience in selecting the vendor for each application.

It is wise to err on the conservative side when making a final selection, because the cost of mistakes and of the required retrofit may far outweigh valve cost differentials. Fortunately, the noise prediction standards of the various standards organizations have helped to make comparisons of noise predictions somewhat easier for users and manufacturers alike.

Standards

The past quarter-century has seen continuous improvements in the standardized methods and in the industrial acceptance of noise prediction standards for valves. In 1979 the Verband Deutcher Maschinen- und Anlagenbau e.V. (VDMA) published the first standardized method of calculating the sound level for valves as Standard VDMA 24422, which addressed both hydrodynamic and aerodynamic noise. VDMA revised 24422 in 1989 to include calculations of the frequency domain.

The weakness of the VDMA method was that key valve noise parameters had to be determined experimentally; when testing was not practical, prediction accuracy was unsatisfactory. Meanwhile, other organizations were developing prediction methods based on free jet turbulence theories.

The Instrumentation, Systems, and Automation Society (ISA) published standard ISA-75.17 in 1989, and the International Electrotechnical Commission published the first edition of IEC 534-8-3 in 1995 and the second edition IEC 60534-8-3 in 2000. The basic methods in these standards are essentially the same. They both are based on the published works by Lighthill, Powell, Fowcs and Hawkins, Reethof and Ward, Shea, Fagerlund, Baumann, and the contributions of many others. These organizations update their respective standards when new information is validated.

The author has selected the more recent IEC Standard 60534-8-3 (2000) to demonstrate the basic calculation process. This standard and the field of acoustics in general use SI units. For conversion factors to U.S. Customary units, the reader should refer to Appendices A.1 and A.2 and is cautioned to use the proper gravitational unit conversions (i.e., g_c). To avoid excessive detail, only the SI system of units will be shown in this section.

Calculations

IEC 60534-8-3 The intent of this section is to familiarize the reader with the nomenclature and illustrate the basic procedure of the IEC 60534-8-3 aerodynamic noise prediction method. However, the standard covers additional special cases and details that are too extensive for coverage here. Like all theoretical methods, it is based on assumptions and limitations that must be applied with appropriate engineering skill and judgment to practical applications. Some of the stated assumptions and limitations of IEC 60534-8-3 include

- The valve is installed with steel or alloy steel piping upstream and downstream, possibly with pipe expanders, and that "the downstream piping is straight for a length of at least 2 m from the point where the noise measurement is made."
- The method assumes that the fluid properties can be modeled on the perfect gas laws.
- The method can be used for most valve types. However, it is not applicable for full-bore ball valves where the product F_pC (for the operating condition) exceeds 50% of the valve's rated flow coefficient.
- The method shown for standard single-stage trims in this section applies only for valve outlet and downstream pipe velocities with Mach numbers up to 0.3. Refer to IEC 60534-8-3 for multistage trims and higher velocities.
- Transmission loss of noise through the pipe wall is based on a simplified method due to the wide tolerances in pipe wall thickness for commercial steel pipe.
- The calculated sound pressure level assumes a location 1 m downstream from the valve or expander and 1 m from the outside of the pipe wall in an acoustic free field.
- The prediction does not guarantee actual results in the field. Validation tests were conducted with low pressure air and steam in laboratory tests, and the majority of test results were within 5 dBA of the predicted sound pressure level.

Nomenclature The following list of symbols, definitions, and units is a partial set of those used in IEC 60534-8-3.

Symbol	*Description*	*Unit*
A	Area of a single flow passage	m^2
A_n	Total flow area of last stage of multistage trim with n stages at given travel	m^2
C	Flow coefficient (K_v and C_v) (see IEC 60534-2-1)	Various (see IEC 60534-1)
c_{vc}	Speed of sound in the vena contracta at subsonic flow conditions	m/s
c_{vcc}	Speed of sound in the vena contacta at critical flow conditions	m/s
c_2	Speed of sound at downstream conditions	m/s
D	Valve outlet diameter	m
d	Diameter of a circular flow passage	m
d_H	Hydraulic diameter of a single flow passage	m
d_i	Smaller of valve outlet or expander inlet internal diameters	m
D_i	Internal downstream pipe diameter	m
D_j	Jet diameter at the vena contracta	m
d_o	Diameter of a circular orifice, the area of which equals the sum of areas of all flow passages at a given travel	m
F_d	Valve style modifier = d_H/d_o	Dimensionless
F_L	Liquid pressure recovery factor of a valve without attached fittings (see note 4)	Dimensionless
F_{LP}	Combined liquid pressure recovery factor and piping geometry factor of a control valve with attached fittings (see note 4)	Dimensionless
F_P	Piping geometry factor	Dimensionless
f_g	External coincidence frequency	Hz
f_o	Internal coincidence pipe frequency	Hz
f_p	Generated peak frequency	Hz
f_{pR}	Generated peak frequency in valve outlet or reduced diameter of expander	Hz
f_r	Ring frequency	Hz
l	Length of a radial flow passage	m
l_w	Wetted perimeter of a single flow passage	m
L_g	Correction for Mach number	dB (ref p_o)
L_{pAe}	A-weighted sound pressure level external of pipe	dBA (ref p_o)
$L_{pAe,1m}$	A-weighted sound pressure level 1 m from pipe wall	dBA (ref p_o)
L_{pi}	Internal sound pressure level at pipe wall	dB (ref p_o)
L_{wi}	Total internal sound power level	dB (ref W_o)
M	Molecular mass of flowing fluid	kg/kmol
M_j	Freely expanded jet Mach number in regimes II to IV	Dimensionless
M_{j5}	Freely expanded jet Mach number in regime V	Dimensionless
M_o	Mach number at valve outlet	Dimensionless
M_{vc}	Mach number at the vena contracta	Dimensionless
M_2	Mach number in downstream pipe	Dimensionless
$\dot{m}$	Mass flow rate	kg/s
$\dot{m}_s$	Mass flow rate at sonic velocity	kg/s
N	Numerical constants (see Table 6.14v)	Various
N_o	Number of independent and identical flow passages in valve trim	Dimensionless
p_a	Actual atmospheric pressure outside pipe	Pa (see note 3)
p_o	Reference sound pressure = 2×10^{-5} (see note 5)	Pa

p_s	Standard atmospheric pressure (see note 1)	Pa
p_{vc}	Absolute vena contracta pressure at subsonic flow conditions	Pa
p_{vcc}	Absolute vena contracta pressure at critical flow conditions	Pa
p_1	Valve inlet absolute pressure	Pa
p_2	Valve outlet absolute pressure	Pa
p_{2B}	Valve outlet absolute pressure at break point	Pa
p_{2C}	Valve outlet absolute pressure at critical flow conditions	Pa
p_{2CE}	Valve outlet absolute pressure where region of constant acoustical efficiency begins	Pa
R	Universal gas constant = 8314	J/kmol × K
r_w	Acoustic power ratio (see Table 6.14w)	Dimensionless
T_{vc}	Vena contracta absolute temperature at subsonic flow conditions	K
T_{vcc}	Vena contracta absolute temperature at critical flow conditions	K
T_1	Inlet absolute temperature	K
T_2	Outlet absolute temperature	K
TL	Transmission loss	dB
t_p	Pipe wall thickness	m
U_p	Gas velocity in downstream pipe	m/s
U_{vc}	Vena contracta velocity at subsonic flow conditions	m/s
W_a	Sound power	W
W_m	Stream power of mass flow	W
W_{ms}	Stream power of mass flow rate at sonic velocity	W
W_o	Reference sound power = 10^{-12} (see note 5)	W
α	Recovery correction factor	Dimensionless
β	Contraction coefficient for valve outlet or expander inlet	Dimensionless
γ	Specific heat ratio	Dimensionless
η	Acoustical efficiency factor (see note 2)	Dimensionless
ρ_1	Density of fluid at p_1 and T_1	kg/m^3
ρ_2	Density of fluid at p_2 and T_2	kg/m^3
Φ	Relative flow coefficient	Dimensionless

Note 1. Standard atmospheric pressure is 101.325 kPa or 1.01325 bar.

Note 2. Subscripts 1, 2, 3, 4, and 5 denote regimes I, II, III, IV, and V, respectively.

Note 3. 1 bar = 10^2 kPa = 10^5 Pa.

Note 4. For the purpose of calculating the vena contracta pressure, and therefore velocity, in this standard, pressure recovery for gases is assumed to be identical to that of liquids.

Note 5. Sound power and sound pressure are customarily expressed using the logarithmic scale known as the decibel scale. This scale relates the quantity logarithmically to some standard reference. This reference is 2×10^{-5} Pa for sound pressure and 10^{-12} W for sound power.

Method Outline Numerous equations are involved in the calculation procedure, but a brief outline of the five general steps will ensure continuity in the procedures.

1. Gather the necessary input data
    - Valve sizing data and dimensions of trim and body ports
    - Configuration and dimensions of adjacent piping
    - Service conditions and fluid properties
2. Calculate key pressures and pressure ratios, and determine the noise regime
3. Calculate the effective jet diameter
4. Calculate jet conditions, acoustic efficiency, sound power, peak frequency for the noise, and internal sound pressure level
5. Calculate pipe natural frequencies, pipe transmission loss, and external sound pressure level

Noise Regimes There are five key noise regimes identified in IEC 60534-8-3, which have different mechanisms governing the generation and transmission of sound. In order to determine which regime applies to a given set of conditions, several important pressures and pressure ratios must be calculated and compared with the actual downstream pressure, p_2.

The vena contracta is the region of flow constriction with maximum velocity and minimum pressure, p_{vc}, given in Equation 6.14(7).

$$p_{vc} = p_1 - \frac{p_1 - p_2}{F_L^2} \qquad \textbf{6.14(7)}^2$$

If the valve has attached fittings, F_L is replaced by the value of F_{LP}/F_P. At critical flow conditions, the vena contracta pressure is p_{vcc}.

$$p_{vcc} = p_1\left(\frac{2}{\gamma+1}\right)^{\gamma/(\gamma-1)} \qquad \textbf{6.14(8)}$$

The downstream pressure at the critical pressure drop where sonic flow begins at the vena contracta is P_{2C}.

$$p_{2C} = p_1 - F_L^2(p_1 - p_{vcc}) \qquad \textbf{6.14(9)}$$

At the break point pressure, P_{2B}, shock cell turbulent interaction begins to dominate noise generation. For downstream pressures greater than p_{2B}, turbulent shear flow generates most of the sound power.

$$p_{2B} = \frac{p_1}{\alpha}\left(\frac{1}{\gamma}\right)^{\gamma/(\gamma-1)} \qquad \textbf{6.14(10)}$$

where α is a correction factor defined as

---

[2] Equations 6.14(7)–(46) and 6.14(48)–(53) are used here by permission of IEC. Copyright © 2000, IEC, Geneva, Switzerland.www.iec.ch.

$$\alpha \equiv \frac{\left(\dfrac{p_1}{p_{2C}}\right)}{\left(\dfrac{p_1}{p_{\text{vcc}}}\right)} = \frac{p_{\text{vcc}}}{p_{2C}} \qquad \textbf{6.14(11)}$$

Regime V begins when downstream pressure drops to $P_{2\text{CE}}$ and is where acoustical efficiency becomes constant. Further reductions in downstream pressure will not increase the sound pressure level.

$$p_{2\text{CE}} = \frac{p_1}{22\alpha} \qquad \textbf{6.14(12)}$$

Table 6.14t summarizes the boundaries and characteristics of Regimes I through V.

Calculate Jet Diameter Determining the jet diameter requires information about the valve trim dimensions in order to calculate the valve-style modifier F_d, which is the ratio of hydraulic diameter, d_H, of a single flow passage to the circle diameter, d_o, corresponding to the total flow area.

$$F_d = \frac{d_H}{d_o} \qquad \textbf{6.14(13)}$$

$$d_H = \frac{4A}{l_w} \qquad \textbf{6.14(14)}$$

$$d_o = \sqrt{\frac{4N_oA}{\pi}} \qquad \textbf{6.14(15)}$$

TABLE 6.14t
Characteristics of IEC Noise Regimes

Regime	*Downstream Pressure*	*Description*
I	$p_1 > p_2 \geq p_{2C}$	Subsonic flow; isentropic recompression; turbulent shear noise
II	$p_{2C} > p_2 \geq p_{\text{vcc}}$	Sonic flow at vena contracta; isentropic recompression; turbulent shear noise
III	$p_{\text{vcc}} > p_2 \geq p_{2B}$	Supersonic flow past the vena contracta; no recompression; noise from shock turbulence and shear turbulence
IV	$p_{2B} > p_2 \geq p_{2\text{CE}}$	Sonic flow at vena contracta; supersonic Mach cone terminates in Mach disk at outlet; shock interaction dominates noise
V	$p_{2\text{CE}} > p_2$	Supersonic Mach cone reaches maximum Mach number; acoustical efficiency and noise level are constant

Lacking specific dimensions, approximate values of F_d are given in Table 6.14u.

The jet diameter, D_j, is calculated from Equation 6.14(16).

$$D_j = N_{14}F_d\sqrt{CF_L} \qquad \textbf{6.14(16)}$$

where units conversion factor N_{14} is found in Table 6.14v and depends on whether the required flow coefficient, C, is given as C_v or K_v. (Refer to Section 6.15 in this chapter for information about flow coefficients.)

TABLE 6.14u
Typical Values of Valve-Style Modifier F_d (Full-Size Trim)

	Relative Flow Coefficient Φ

TABLE 6.14v
Numerical Constants N

	Flow Coefficient	
Constant	K_v	C_v
N_{14}	4.9×10^{-3}	4.6×10^{-3}
N_{16}	4.23×10^{4}	4.89×10^{4}

Note: Unlisted numerical constants are not used in this standard

Regime I Calculations Calculate the following subsonic parameters for the vena contracta.

Gas velocity:

$$U_{\mathrm{vc}} = \sqrt{2\left(\frac{\gamma}{\gamma-1}\right)\left[1-\left(\frac{p_{\mathrm{vc}}}{p_1}\right)^{(\gamma-1)/\gamma}\right]\frac{p_1}{\rho_1}} \qquad \textbf{6.14(17)}$$

Stream power:

$$W_m = \frac{\dot{m}(U_{\mathrm{vc}})^2}{2} \qquad \textbf{6.14(18)}$$

Absolute temperature:

$$T_{\mathrm{vc}} = T_1\left(\frac{p_{\mathrm{vc}}}{p_1}\right)^{(\gamma-1)/\gamma} \qquad \textbf{6.14(19)}$$

Speed of sound:

$$c_{\mathrm{vc}} = \sqrt{\frac{\gamma R T_{\mathrm{vc}}}{M}} \qquad \textbf{6.14(20)}$$

Mach number:

$$M_{\mathrm{vc}} = \frac{U_{\mathrm{vc}}}{c_{\mathrm{vc}}} \qquad \textbf{6.14(21)}$$

With this information, calculate the acoustical efficiency factor, η_1, sound power, W_a, and peak frequency, f_p.

$$\eta_1 = (1\times 10^{-4})M_{\mathrm{vc}}^{3.6} \qquad \textbf{6.14(22)}$$

$$W_a = \eta_1 r_w W_m F_L^2 \qquad \textbf{6.14(23)}$$

where r_w is the acoustic power ratio taken from Table 6.14w.

TABLE 6.14w
Acoustic Power Ratio r_w

Valve or Fitting	r_w
Globe, parabolic plug	0.25
Globe, 3 V-port plug	0.25
Globe, 4 V-port plug	0.25
Globe, 6 V-port plug	0.25
Globe, 60 equal diameter hole drilled cage	0.25
Globe, 120 equal diameter hole drilled cage	0.25
Butterfly, swing-through (centered shaft), to 70°	0.5
Butterfly, fluted vane, to 70°	0.5
Butterfly, 60° flat disk	0.5
Eccentric rotary plug	0.25
Segmented ball 90°	0.25
Expanders	1

Peak frequencies in Regimes I and II are based on Strouhal's equation with the Strouhal number = 0.2.

$$f_p = \frac{0.2U_{\mathrm{vc}}}{D_j} \qquad \textbf{6.14(24)}$$

Common Calculations for Regimes II–V For sonic conditions in the vena contracta, calculate the following parameters.

Vena contracta temperature:

$$T_{\mathrm{vcc}} = \frac{2T_1}{\gamma+1} \qquad \textbf{6.14(25)}$$

Velocity of sound:

$$c_{\mathrm{vcc}} = \sqrt{\frac{\gamma R T_{\mathrm{vcc}}}{M}} \qquad \textbf{6.14(26)}$$

Stream power:

$$W_{\mathrm{ms}} = \frac{\dot{m}c_{\mathrm{vcc}}^2}{2} \qquad \textbf{6.14(27)}$$

Mach number in the freely expanding jet:

$$M_j = \sqrt{\frac{2}{\gamma-1}\left[\left(\frac{p_1}{\alpha p_2}\right)^{(\gamma-1)/\gamma}-1\right]} \qquad \textbf{6.14(28)}$$

Next, the acoustical efficiency factors, sound power, and peak frequency are calculated for the regime in question.

Regime II Acoustical efficiency factor:

$$\eta_2 = (1\times10^{-4})M_j^{6.6F_L^2} \qquad \textbf{6.14(29)}$$

Sound power:

$$W_a = \eta_2 r_w W_{\text{ms}}\left(\frac{p_1 - p_2}{p_1 - p_{\text{vcc}}}\right) \qquad \textbf{6.14(30)}$$

Peak frequency:

$$f_p = \frac{0.2M_j\, c_{\text{vcc}}}{D_j} \qquad \textbf{6.14(31)}$$

Regime III Acoustical efficiency factor:

$$\eta_3 = (1\times10^{-4})M_j^{6.6F_L^2} \qquad \textbf{6.14(32)}$$

Sound power:

$$W_a = \eta_2 r_w W_{\text{ms}} \qquad \textbf{6.14(33)}$$

Peak frequency is calculated from Equation 6.14(31).

Regime IV Acoustical efficiency factor:

$$\eta_4 = (1\times10^{-4})\left(\frac{M_j^2}{2}\right)\left(\sqrt{2}\right)^{6.6F_L^2} \qquad \textbf{6.14(34)}$$

Sound power:

$$W_a = \eta_4 r_w W_{\text{ms}} \qquad \textbf{6.14(35)}$$

Peak frequency:

$$f_p = \frac{0.35c_{\text{vcc}}}{1.25D_j\sqrt{M_j^2 - 1}} \qquad \textbf{6.14(36)}$$

Regime V Jet Mach number reaches it maximum:

$$M_{j5} = \sqrt{\frac{2}{\gamma - 1}[(22)^{(\gamma-1)/\gamma} - 1]} \qquad \textbf{6.14(37)}$$

The acoustical efficiency factor becomes constant:

$$\eta_5 = (1\times10^{-4})\left(\frac{M_{j5}^2}{2}\right)\left(\sqrt{2}\right)^{6.6F_L^2} \qquad \textbf{6.14(38)}$$

Sound power generated in this regime that radiates into downstream pipe is

$$W_a = \eta_5 r_w W_{\text{ms}} \qquad \textbf{6.14(39)}$$

Peak frequency:

$$f_p = \frac{0.35c_{\text{vcc}}}{1.25D_j\sqrt{M_{j5}^2 - 1}} \qquad \textbf{6.14(40)}$$

Noise Calculations The following calculations are used for all regimes.

Downstream mass density:

$$\rho_2 = \rho_1\left(\frac{p_2}{p_1}\right) \qquad \textbf{6.14(41)}$$

Downstream sonic velocity:

$$c_2 = \sqrt{\frac{\gamma R T_2}{M}} \qquad \textbf{6.14(42)}$$

where T_2 may be found from thermodynamic isenthalpic relationships. If fluid properties are not known, reasonable results can be obtained by assuming T_2 is approximately equal to T_1.

Mach number at valve outlet:

$$M_o = \frac{4\dot{m}}{\pi D^2 \rho_2 c_2} \qquad \textbf{6.14(43)}$$

If the outlet Mach number M_o is above 0.3, accuracy of this method diminishes. IEC 60534-8-3 clause 7 provides further procedures for high Mach number applications, which is outside the discussion of this basic process.

The internal sound pressure level, L_{pi}, referenced to 2×10^{-5} Pa is calculated in dB from the following:

$$L_{pi} = 10\log_{10}\left[\frac{(3.2\times10^9)W_a\rho_2 c_2}{D_i^2}\right] \qquad \textbf{6.14(44)}$$

Transmission through the Pipe The pipe wall must be made to vibrate in order for noise inside the pipe to radiate into the air outside the pipe. The mode of pipe vibration, for the purpose of this prediction method, is determined from the peak frequency of the noise source and the natural frequencies of the pipe.

The assumption is made that the shape of the sound frequency spectrum is an arc or "haystack"-shaped curve that reaches a pronounced maximum level at peak frequency, f_p. Although this is true for most valves, some configurations can possess "flatter" broadband spectra that could radiate more noise than the simplified model predicts.

Pipe natural frequencies are functions of the pipe diameter, wall thickness, and density. The transmission loss model used by the IEC standard is based on the work of Fagerlund and Chow. The important characteristic frequencies are explained in detail by Singleton and are summarized below.

Ring frequency, f_r, has a wavelength exactly equal to the circumference of the pipe, which produces a resonant stress wave around the circumference.

$$f_r = \frac{5000}{\pi D_i} \qquad \textbf{6.14(45)}$$

External coincidence frequency, f_g, corresponds to the external acoustic wave speed that matches the speed of a flexural wave in pipe wall. Assuming the speed of sound in steel is 5000 m/s and 343 m/s in air,

$$f_g = \frac{\sqrt{3}(343)^2}{\pi t_p(5000)} \qquad \textbf{6.14(46)}$$

First internal coincidence frequency, f_o, is the lowest natural frequency of the pipe wall and produces a longitudinal flexural wave that spirals along the length of the pipe.

$$f_o = \frac{1250}{\pi D_i}\left(\frac{c_2}{c_o}\right) = \frac{f_r}{4}\left(\frac{c_2}{343}\right) \qquad \textbf{6.14(47)}$$

Cutoff frequency, f_c, though not part of the IEC standard, is significant because at the cutoff frequency and below, the wavelengths are too long to reflect off the internal pipe wall, making them incapable of vibrating the pipe.

$$f_c = 0.586\frac{c_2}{D_i} \qquad \textbf{6.14(48)}$$

The relationship of the peak frequency in the flow stream to the pipe natural frequencies is used to calculate the frequency factors used in the transmission loss calculation. Table 6.14x, taken from IEC 60534-8-3, shows how frequency factors G_x and G_y are determined.

TABLE 6.14x
Frequency Factors G_x and G_y

$f_p < f_o$	$f_p \geq f_o$
$G_x = \left(\frac{f_o}{f_r}\right)^{2/3}\left(\frac{f_p}{f_o}\right)^4$	$G_x = \left(\frac{f_p}{f_r}\right)^{2/3}$ for $f_p < f_r$
	$G_x = 1$ for $f_p \geq f_r$
$G_y = \left(\frac{f_o}{f_g}\right)$ for $f_o < f_g$	$G_y = \left(\frac{f_p}{f_g}\right)$ for $f_p < f_g$
$G_y = 1$ for $f_o \geq f_g$	$G_y = 1$ for $f_p \geq f_g$

The transmission loss across the pipe wall is calculated from Equation 6.14(49).

$$TL = 10\log_{10}\left[(7.6\times10^{-7})\left(\frac{c_2}{t_p f_p}\right)^2 \frac{G_x}{\left(\frac{\rho_2 c_2}{415 G_y}+1\right)}\left(\frac{p_a}{p_s}\right)\right] \qquad \textbf{6.14(49)}$$

Next, calculate the downstream pipe velocity correction factor, L_g.

$$L_g = 16\log_{10}\left(\frac{1}{1-M_2}\right) \qquad \textbf{6.14(50)}$$

where M_2 should not exceed 0.3 and is calculated by

$$M_2 = \frac{4\dot{m}}{\pi D_i^2 \rho_2 c_2} \qquad \textbf{6.14(51)}$$

The A-weighted sound pressure level radiated from the outside surface of the pipe is given a 5 dB correction to account for all frequency peaks and is calculated below.

$$L_{\mathrm{pAe}} = 5 + L_{pi} + TL + L_g \qquad \textbf{6.14(52)}$$

Finally, a distance adjustment is made to calculate the sound pressure level in dBA at 1 m from the pipe wall.

$$L_{\mathrm{pAe,1m}} = L_{\mathrm{pAe}} - 10\log_{10}\left[\frac{D_i + 2t_p + 2}{D_i + 2t_p}\right] \qquad \textbf{6.14(53)}$$

Noise Calculation Example

These calculations are typically carried out with computer software and presented as part of the sizing calculations done by valve manufacturers. For a thorough understanding, a simple calculation example is tabulated below.

Example 1. Steam Valve

Inputs

Valve: NPS 4-in. (DN 100)	Fluid: Steam
Trim: Parabolic plug	$M = 18.02$ kg/kmol
$C = C_v = 152$ required (from sizing calculations)	$T_1 = 260$ °C $= 533$ K
$F_L = 0.90$	$p_1 = 2.5$ MPa
$\Phi = 0.60$	$p_2 = 1.7$ MPa
$F_d = 0.31$	$\dot{m} = 9.10$ kg/s
Maximum allowable noise level: 90 dBA	$\gamma = 1.32$
	From steam tables:
Pipe: NPS 4-in. (DN 100) Schedule 40 carbon steel	$\rho_1 = 11.17$ kg/m^3
$D_i = 0.102$ m	$T_2 = 247$ °C $= 520$ K
$t_p = 0.00602$ m	$\rho_2 = 7.58$ kg/m^3

Preliminary Calculations

Variable	*Equation*	*Results*

TL	6.14(49)	$10\log\left[(7.6\times10^{-7})\left(\frac{563}{(0.00602)(5509)}\right)^{2}\left(\frac{0.303}{\frac{(7.58)(563)}{(415)(1)}+1}\right)(1)\right]=-52.3\text{ dB}$
M_2	6.14(51)	$4(9.1)/[\pi(0.102)^2(7.58)(563)] = 0.261$
L_g	6.14(50)	$16\log[1/(1-0.261)] = 2.10$ dB
L_{pAe}	6.14(52)	$5 + 162.6 - 52.3 + 2.1 = 117.4$ dBA
$L_{\text{pAe,1m}}$	6.14(53)	$117.4 - 10\log\{[0.102 + 2(0.00602) + 2]/[0.102 + 2(0.00602)]\} = 105$ dBA

Conclusion: Noise level exceeds desired maximum; consider noise reduction trim; consult manufacturer.

Applying Distance Corrections

Placing extra distance between noisy equipment and people is sometimes a viable alternative to expensive noise reduction treatment, if there are no other detrimental effects of the noise at the source.

If a noise source can be treated as a point in the acoustic far field, the sound radiates in a spherical pattern. Atmospheric vents can be treated this way. The reduced sound pressure level at some distance, *r*, from the center of a point source can be determined from a measured or calculated sound pressure level taken at a reference distance of r_o from the center (typically r_o = 1 m + pipe OD/2) using Equation 6.14(54) below.

$$L_{\text{pAe,r}} = L_{\text{pAe,1m}} - 20\log_{10}\left(\frac{r}{r_o}\right) \qquad \textbf{6.14(54)}$$

Because noise produced by valves radiates to the environment largely through the pipe for great distances downstream of a valve, this type of noise source is generally treated as a line source. Line sources radiate noise in a cylindrical pattern. The reduced sound-pressure level at distance, *r*, from a line source is

$$L_{\text{pAe,r}} = L_{\text{pAe,1m}} - 10\log_{10}\left(\frac{r}{r_o}\right) \qquad \textbf{6.14(55)}$$

Example 2. Valve Noise at a Distance Problem: Using the same valve and conditions from Example 1, what would be the sound pressure level for a worker 30 m away from the downstream pipe (centerline)?

Solution: From Example 1, $L_{\text{pAe,1m}}$ = 105 dBA, and pipe OD = 0.114 m. Use Equation 6.14(55).

$$L_{\text{pAe,30m}} = 105 - 10\log_{10}\left(\frac{30m}{1m + 0.114m/2}\right)$$

$$= 105 - 15 = 90\text{ dBA}$$

HYDRODYNAMIC NOISE PREDICTION

Noise prediction for liquid flow through valves should consider three major flow regimes. 1) Turbulent flow, which, without cavitation, rarely produces noise levels high enough to create dangerous structural vibration or noise pollution. 2) Cavitating flow, which produces noise from vapor cavity formation and collapse as well as from turbulence, and it frequently causes excessive vibration and noise in addition to erosion of valve and piping materials. 3) Flashing of liquid into vapor across a valve sometimes causes high levels of noise and vibration, if vapor velocities in the downstream piping approach sonic velocities. Piping systems should be so sized as to avoid vapor or two-phase velocities, which are high enough to cause noise and erosion.

Hydrodynamic noise prediction is currently in a state of development. Noise prediction Standards VDMA 24422 (1989) and IEC 60534-8-4 (1994) have been shown by Kiesbauer and Baumann to predict lower than actual noise in many cases. A more accurate method of hydrodynamic noise prediction has been proposed (Kiesbauer, J. and Baumann, H. D., "Recent Developments in the Prediction of Hydrodynamic Noise of Control Valves," *Valve World*, February 2004), which is being considered by the IEC as a revision to Standard 60534-8-4 at the time of this writing. This method includes calculations for turbulent flow and cavitating flow regimes. There are no standards or generally accepted methods at this time for predicting noise under flashing conditions. For calculation of noise, the reader is advised to study the Kiesbauer-Baumann method or later revisions of IEC Standard 60534-8-4.

Hydrodynamic noise predictions use a differential pressure ratio, x_F, to identify noise regimes.

$$x_F = \frac{p_1 - p_2}{p_1 - p_v} \qquad \textbf{6.14(56)}$$

The incipient cavitation index, x_{Fz}, corresponds to the differential pressure ratio at which cavitation in a valve begins and should be determined from cavitation tests, although some of the methods include ways of estimating x_{Fz}. This is the index that separates the turbulent flow regime from the cavitating flow regime. (If $x_F \geq 1.0$, the liquid is flashing.) Each of the methods discussed above follows a general process similar to that for aerodynamic noise prediction:

1. Gather the necessary input data
   - Valve sizing data and dimensions of trim and body ports
   - Configuration and dimensions of adjacent piping
   - Service conditions and fluid properties
2. Calculate key pressures and pressure ratios, and determine the noise regime.
3. Calculate the effective jet diameter and stream power.
4. Calculate acoustic efficiency and internal sound-pressure level.
5. Calculate pipe natural frequencies, pipe transmission loss, and external sound-pressure level.

INTRODUCTION

The control valve is an important component of the total process control loop, and proper valve sizing is essential for this final control element to fulfill its role. There are two important prerequisites for the control valve to be able to fulfill its role: First is to have the correct process data. This includes the accurate knowledge of the maximum and the minimum flow conditions, the available pressure drops across the valve at the various flow conditions, the maximum inlet pressure and inlet temperature, the viscosity of the fluid, and whether or not the fluid is two-phased. Correct selection of the valve's pressure drop, for example, depends on the head loss in the piping system or the characteristic of a pump, to name just two system variables (Figure 6.1b). As the reader will notice, just the selection of the process conditions involves considerable uncertainties.

The second criterion is the selection of the correct valve sizing equation for the prevailing operating conditions. Therefore, before starting the process of sizing, the process control engineer has to determine which of the following sizing basis are applicable. For liquid flow sizing, they include 1) turbulent non-choked, 2) turbulent, choked, 3) saturated, 4) laminar (viscous), 5) non-Newtonian, and 6) two-phase. For gas flows, the sizing conditions can be: 1) turbulent non-choked, 2) choked, and 3) laminar (small flow valves).

The Standard IEC 60534-2-1 and the Instrumentation, Systems, and Automation Society equivalent Standard S 75.01 have improved the accuracy of valve sizing over the years, lowering the sizing errors to less than 5% except for two-phase flow and for non-Newtonian flow conditions.

ABOUT THIS SECTION

For the definition of all the terms used in this section, refer to the "Nomenclature" listing provided at the end of this section. For capacity testing procedures see Section 6.6. The subjects of control valve characteristics and rangeability are discussed in Section 6.7, and the subject of control valve noise and its calculation is covered in Section 6.14. The engineering units used in this section are the U.S. Customary units. Use the numerical constants listed in Tables 6.15l and 6.15p for conversion to metric units.

This section begins with a definition of the valve coefficients (C_v and C_d) and with a brief description of fluid behavior during flashing, cavitation, and under turbulent or laminar flow conditions. After this general discussion the various liquid sizing factors (F_L, F_F, F_P, F_{LP}, and F_R) are defined, and then the liquid sizing equations are provided, as well as some examples. Some of the examples deal with viscous (laminar flow), sizing applications and pipe expander losses, and generalized approaches to liquid sizing. This is followed with a more detailed discussion of cavitation and flashing.

The second half of this section begins with a discussion of valve sizing for gas and vapor services. After the sizing equations are described, an example outlines a generalized approach to gas/vapor sizing. The section is concluded with a description of sizing for two-phase flow applications.

STANDARDS

The study of control valve sizing is based on the science of fluid dynamics. The information in this chapter is an overview of current knowledge, which is continually growing. This know-how has been developed, in large measure, from the following two standards of the Instrumentation, Systems, and Automation Society (ISA): S75.01-2000, "Control Valve Sizing Equations," and S75.02-1996, "Control Valve Capacity Test Procedure." The author is grateful to ISA for its permission to copy and adopt portions of these standards for this section.

The international equivalent of these U.S. standards are IEC 60534-2-1, "Industrial Process Control Valves, Part 2-1: Flow Capacity Sizing Equations for Fluid Flow under Installed Conditions," and IEC 60534-2-3, "Industrial Process Control Valves, Part 2-3, Flow Capacity Test Procedure." The equations in the international editions are essentially equivalent to those in the U.S. standards with the exception of using metric units.

The user is cautioned that the calculations are not perfectly accurate for all conditions. Accuracy is best for water, air, or steam applications using conventional valve designs, which are installed in straight piping. For non-Newtonian fluids or high-viscosity or low Reynolds number flows, these calculations are less accurate. In all cases, reliable calculations require reliable information about the characteristics of the valve and the process fluid, including the fluid's flow rates and pressures at normal and unusual operating conditions.

The English units are used in the various sample calculations and also in the "Nomenclature" listing at the end of the section. While this was necessary because conversion constants are embedded in the working equations, other units can be substituted with appropriate conversions found in Tables 6.15i and 6.15n. The notations used in this section are those used in the ISA standards.

General Principles

The earliest control valves were manual globe valves. Sizing was easy: a 4 in. (100 mm) valve "belonged" in a 4 in. (100 mm) line. Later it became obvious that at higher pressure drops such a valve had too much capacity for good control. Thus evolved the next rule-of-thumb practice, which was to make the control valve one size smaller than line size.

The limitations of such rule-of-thumb methods of valve sizing led to the development of a sizing coefficient based on Bernoulli's theorem for the conservation of energy, and the continuity equation for the conservation of mass. These equations can be combined to express the ideal flow rate through a pipe restriction such as a control valve:

$$Q = A_2 \sqrt{\frac{2g(\Delta H)}{1-(A_2/A_1)^2}} \qquad \textbf{6.15(1)}$$

Calculating the actual flow rate requires the introduction of a discharge coefficient, *C*, which accounts for the real losses in the specific valve. The head loss (ΔH) may also be expressed as pressure drop divided by weight density (γ). Thus,

$$Q = CA_2 \sqrt{\frac{2g(\Delta p/\gamma)}{1-(A_2/A_1)^2}} \qquad \textbf{6.15(2)}$$

By combining the area terms and discharge coefficient (*C*) with the other constants and expressing density in terms of specific gravity, G_f, the flow equation can be written as a function of a capacity parameter, C_v, which is a generally accepted valve capacity parameter called the valve coefficient.

$$Q = C_v \sqrt{\frac{\Delta p}{G_f}} \qquad \textbf{6.15(3)}$$

It should be noted that Equation 6.15(3) is only valid for turbulent and nonchoked (low pressure drop) liquid flows in sizing control valves.

It is important to note that C_v is not a dimensionless coefficient, and in the SI system K_v is used. The conversion between engineering units is covered in later paragraphs of this section. Table 6.15i provides the conversion constants for liquid and Table 6.15n for gas and vapor sizing equations. The C_v valve coefficient, which is based on English units, is widely used in the United States, while K_v, based on the SI system, is the preferred unit in Europe.

The Flow Coefficient

Prior to about 1946 control valves were sized using the flow area of the valve's orifice in square inches together with some, usually proprietary equations in order to estimate the amount of liquid or gas passing through the valve. Thereafter, a new coefficient was introduced called *Cv*, which started standardization in this field. This coefficient denotes the number of (U.S.) gallons of water that a valve would pass when the pressure drop across it is 1 lb/in.^{2}

Under turbulent flow conditions the water velocity is related to the square root of the pressure drop (inlet pressure minus outlet pressure). Therefore, one can multiply this quantity with the C_v number of the valve to obtain the expected flow of cold water in gallons per minute. Later in this section it will be shown how this simple definition of the C_v can be expanded to liquids having specific gravity other than cold water and with the use of conversion factors, for gases as well.

Correction Factors Yet, the turbulent C_v alone turned out to be inaccurate. Using it, occasionally there appeared to be severe sizing errors (up to 50%) that nobody could explain. This problem was resolved in 1963 by the introduction of a Critical Flow Factor.[1] This factor was later renamed the Liquid Pressure Recovery Factor and designated as F_L.

What this factor describes is the amount of pressure recovery, which is occurring downstream of the throttling orifice. A low F_L factor, which is usually the case with streamlined valves, will promote vaporization in liquid streams or cause the development of sonic velocity in gas streams. These effects tend to "choke' the flow and consequently, the valve will pass less than would be predicted if the F_L factor was not considered.

In 1983 two additional factors were introduced. One is called *Xt*, the Pressure Differential Factor of a Control Valve at Choked Flow.[2] The other is called the Expansion Factor *Y*, which enables the calculation of the correct gas density at the valve's orifice.

Yet another, albeit less serious, sizing error source has been noticed in applications where a valve, smaller than line size, was installed between reducers. The error was caused by the pressure drops across the reducers, which lowered the pressure drop available for the valve. In 1968, this problem was overcome by the introduction of a Piping Geometry Factor,[3] F_p.

One more factor was introduced for viscous fluid services, which is called the Reynolds Number Factor,[4] F_R. In 1993, this factor was redefined and its accuracy was improved.[5]

Finally, the Liquid Pressure Ratio Factor, F_F (based on the original work of Allen[6] and others), was introduced for boiling or flashing liquid applications.

Table 6.15a tabulates the various sizing equations for the overall orientation of the reader. The equations listed in this table will be derived in the following paragraphs. In this section, the equations are numbered consecutively, so the

TABLE 6.15a
Orientation Table: Summary of Valve Sizing Equations (for U.S. Customary Units: gpm, SCFH, psi, °F, lbm/hr, lb/ft^3, etc.)

Selection Basis		Fluid State	
		Liquid	Gas or Vapor
Nonchoked, turbulent flow in liquids: $\Delta p < F_L^2\ (P_1 - F_F P_v)$	Volumetric flow in gpm or SCFH	Eq. 6.15(35) $C_v = \frac{q}{F_P}\sqrt{\frac{G_f}{\Delta p}}$	Eq. 6.15(78) $C_v = \frac{Q}{1360 F_P P_l Y}\sqrt{\frac{G_g T_l Z}{x}}$ $Y = 1 - \frac{x}{3 F_k x_T};\ x = \frac{\Delta p}{P_l};\ F_k = \frac{k}{1.4}$
Nonchoked vapors and gases: $\Delta p / P_1 < x_T$	Mass flow in lbm/h	Eq. 6.15(36) $C_v = \frac{w}{63.3 F_P \sqrt{(\Delta p)\gamma_1}}$	Eq. 6.15(77) $C_v = \frac{w}{63.3\ F_P Y \sqrt{x P_l \gamma_l}}$
Choked flow due to cavitation or flashing liquids in liquids, or choked flow in gases	Volumetric flow in gpm or SCFM	Eq 6.15(31) $C_v = \frac{q_{\max}}{F_{LP}}\sqrt{\frac{G_f}{P_1 - F_F P_v}}$ $F_F = 0.96 - 0.28(P_v/P_c)^{1/2}$	Eq. 6.15(80) $C_v = \frac{Q_{\max}}{7320\ F_P P_l Y}\sqrt{\frac{M T_1 Z}{F_K x_T}}$
Choked flow due to sonic velocity in gases or vapors, or choked flow in liquids	Mass flow in lbm/h	Eq. 6.15(32) $C_v = \frac{w_{\max}}{63.3\ F_{LP}\ \sqrt{(P_l - F_F P_v)\gamma_l}}$	Eq. 6.15(79) $C_v = \frac{w_{\max}}{19.3\ F_P P_l Y}\sqrt{\frac{T_1 Z}{F_K x_T M}}$
Piping effect for above equations	Not choked	Eq. 6.15(22) $F_P = \left[1 + \frac{(\sum K) C_d^2}{890}\right]^{-1/2}$ ΣK See Eq. 6.15(21)	
	Choked	Eq. 6.15(23) $F_{LP} = \left[\frac{1}{F_L^2} + \frac{K_i C_d^2}{890}\right]^{-1/2}$ K_i See Eq. 6.15(20)	
Nonturbulent (viscous) flow	Volumetric flow in gpm	Eq. 6.15(63) $C_v = \frac{q}{F_R}\sqrt{\frac{G_f}{\Delta p}}$ where F_R is from Figure 6.15m and is a function of Re_v from Eq. 6.15(64 or 69)	Laminar, i.e., nonturbulent, conditions generally do not occur in gases or vapors except for small flow valves.
	Mass flow in lbm/h	Eq. 6.15(39) $C_v = \frac{w}{63.3\ F_R \sqrt{(\Delta p)\gamma_l}}$	

reader can easily find the derivation of any of the equations listed in the table.

Units In that part of the world where the SI system is used, the valve coefficient is called K_v and it is defined as the flow of cold water in cubic meter per hour units, when the a pressure drop across the valve is one bar. The conversion between C_v and K_v is

$$K_v = 1.17 C_v \qquad \textbf{6.15(4)}$$

The flow coefficient can be converted into an area that is the area of the vena contracta, or the net flow area inside a single stage valve orifice, in accordance with Equation 6.15(5):

$$A_v = C_v \times F_L \times 0.026 \text{ in square inches} \qquad \textbf{6.15(5)}$$

More refined equations are applicable for multistage valves but are not yet standardized.[7] Here the reader may refer to their respective vendors for assistance.

There has been substantial progress in increasing the accuracy of valve sizing, yet additional research is needed in the areas of mixed phase and non-Newtonian flows.

LIQUID SIZING

Fluid flowing through a control valve obeys the basic laws of the conservation of mass and energy. As the fluid stream approaches the valve restriction, fluid velocity increases in order to pass the same amount of flow through the restricted area. The restriction inside the valve is the result of moving a closure member (e.g., plug, disk, ball) closer to the valve seat.

Energy to accelerate the fluid comes from a corresponding decrease in static pressure, as illustrated in Figure 6.15b. Maximum velocity and minimum static pressure occur immediately downstream from the minimum area of valve restriction (the throttling point), the most constricted area of the flow stream. This minimum pressure point downstream from the throttling point is known as the vena contracta.

Figure 6.15b shows that as the velocity decreases after the vena contracta, some of the kinetic energy is converted back into static pressure. This conversion is called the pressure recovery of the valve, and its amount is equal to $P_2 - P_{vc}$. Valves with large pressure recovery relative to $P_1 - P_2$ are called high recovery valves. Such valves include most rotary and gate valves. The net pressure loss ($P_1 - P_2$) between the valve inlet and outlet is due to frictional effects (turbulence) and represents the permanent pressure loss.

Relative Valve Capacity Coefficient (C_d)

The valve capacity coefficient, C_v, increases as valve size increases, but valve geometry is also a major factor in the magnitude of the pressure loss for a given flow rate. It is therefore useful to define the relative valve capacity (C_d) in order to compare the effects of geometry of different valve designs. C_d is defined as

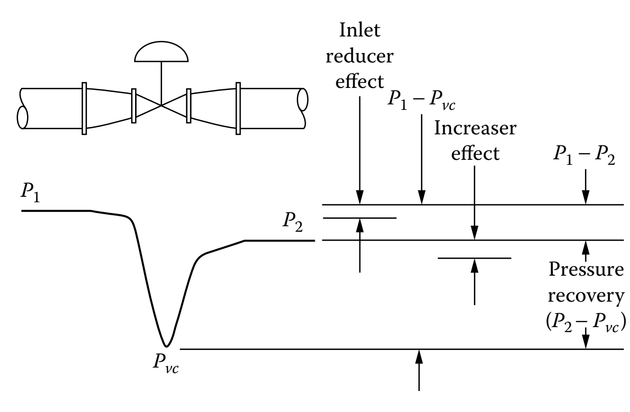

FIG. 6.15b
Pressure profile through a valve.

$$C_d = C_v / d^2 \qquad \textbf{6.15(6)}$$

Representative values of C_d for various valve styles (at full capacity) may be found in Table 6.15c.

C_d can also be useful for evaluating the relative magnitude of pressure recovery. Generally, the valve types with larger C_d values are also more likely to have higher pressure recovery ($P_2 - P_{vc}$); that is, they have a lower F_L factor and therefore tend to "choke" or have liquids evaporate at lower pressure drops ($P_1 - P_2$). The significance of this will become clearer in the discussions of sizing factors for choked flow.

Caution: The published C_v data from manufacturers is based on standard testing methods that include the friction losses associated with the test manifold pipe between the pressure taps (Section 6.6). When the C_d is under 20, the friction loss from eight diameters of this pipe adjacent to the valve is relatively insignificant. However, as the C_d increases above 20, the manifold pressure drop rises exponentially relative to the losses from the valve alone. Therefore, for valves with $C_d > 20$, one must also consider the pressure drop in the valve test manifold piping to avoid significant errors.

In the majority of valve applications the flow is turbulent, and the velocity profile across the restrictive (throttling) area of the valve is relatively uniform. Turbulent flow occurs when the Reynolds number is high (typically above 10,000). This occurs when the velocity is high and the viscosity is low [$\text{Re} = (\gamma U d/\mu)$]. In the turbulent range, the incompressible fluid flow is proportional to the square root of the pressure drop across the valve, as was shown in Equation 6.15(3). This proportionality is shown by the straight line on the left side of Figure 6.15d.

Factors F_L, F_F, F_P, and F_{LP}

Pressure Recovery Factor (F_L) F_L is the pressure recovery factor, which indicates the size of the pressure recovery relative to the valve pressure drop (Figure 6.15b). F_L is defined as

$$F_L = [(P_1 - P_2)/(P_1 - P_{vc})]^{1/2} \qquad \textbf{6.15(7)}$$

Note: F_L can also be used to calculate the pressure drop that causes sonic velocity in the valve orifice. As it has been discussed in Section 6.14, this is important for noise calculations, where

$$\Delta p_{\text{sonc}} = 0.5 \times F_L^2 \times P_1 \qquad \textbf{6.15(8)}$$

The values of F_L for various valve designs are listed in Table 6.15c.

TABLE 6.15c

Representative Values of Relative Valve Capacity Coefficients (C_d) and of Other Sizing Factors for a Variety of Valve Designs. The Cd Values Listed are for Valves with Full Area Trims, When the Valve is Fully Open

Valve Type	*Trim Type*	*Flow Direction**	X_T	F_L	F_d	F_s	$C_d = C_v/d^2$**	K_c

Liquid Critical Pressure Ratio Factor (F_F) The complex geometry of most valves makes experimental measurement of the pressure at the vena contracta (P_{vc}) impossible. The ISA sizing equations[9] use the liquid critical pressure ratio factor, F_F, for approximating P_{vc} used for saturated liquid flow conditions.

$$P_{\text{vc}} = F_F P_v \tag{6.15(9)}$$

where F_F can be approximated by

$$F_F \cong 0.96 - 0.28\,(P_v/P_c)^{1/2} \tag{6.15(10)}$$

A graph of this relationship is plotted in Figure 6.15e. Equation 6.15(10) is based on the assumption that the fluid is always in thermodynamic equilibrium. However, a liquid does not remain in thermodynamic equilibrium as it flashes across the valve restriction; therefore, the actual flow rate can be greater than that predicted by Equation 6.15(10). Estimating P_{vc} by using F_F is not fully agreed upon by experts but it is accepted by the valve sizing standard (ISA S75.01) and is in common use in the control valve industry.

The pressure drop required to cause choked flow in liquids is given by the following equation:

$$\Delta P_{\text{choked}} = F_L^2\ (P_1 - F_F P_v) \tag{6.15(11)}$$

Piping Geometry Factor (F_P and F_{LP}) By convention, valve tests and calculations have included a portion of piping adjacent to the valve. P_1 is measured upstream of the pipe reducer,

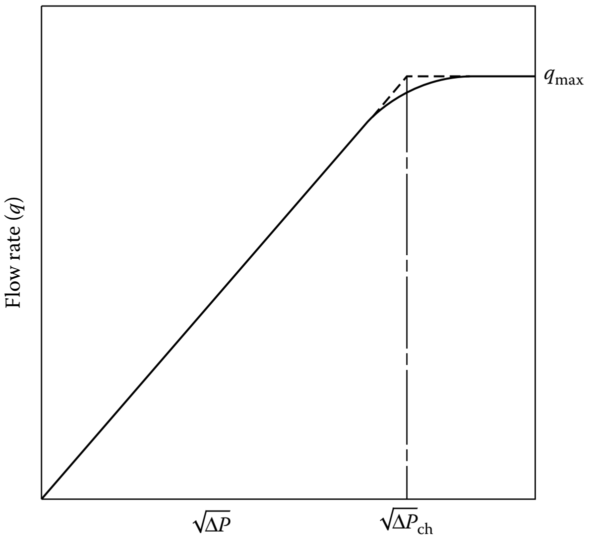

FIG. 6.15d
Typical flow rate vs. $\sqrt{\Delta p}$ *curve for liquid at constant upstream pressure and vapor pressure. The straight line segment on the left shows the behavior of turbulent liquid flow. As the pressure drop rises the pressure at the vena contracta drops and when it reached the vapor pressure of the liquid, vaporization starts. From this point on (right side of figure) the relationship is no longer linear, until at* q_{max} *the choked flow condition is reached.*

if used, and P_2 is downstream of the increaser. Some manufacturers supply tables for C_v for valves with standard pipe reducers. Where this data is based on actual test data, it should be used in preference to the approximations shown below. Elbows and block valves installed near the valve will upset the flow profile and cause some reduction in capacity. No procedure is available to predict these losses.

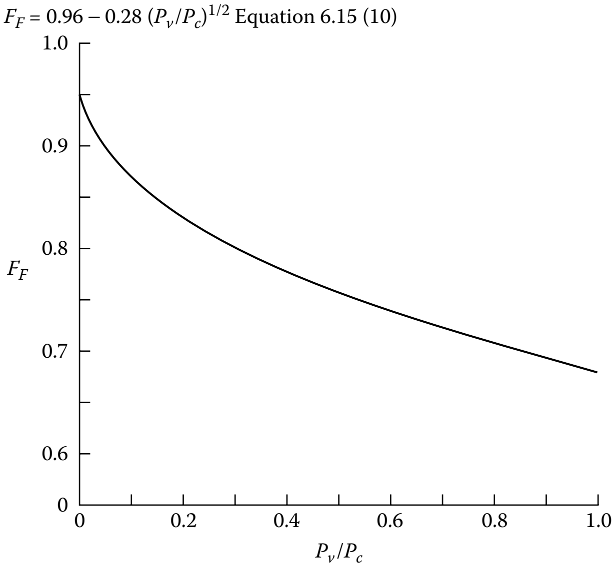

FIG. 6.15e
Liquid critical pressure ratio factor F_F*, plotted as a function of the* P_v/P_c *ratio.*

The standard reducer and increaser fittings result in an abrupt change in size. As a result of the change in cross-section, first there is an irreversible energy loss due to turbulence (friction loss), and second there is the conversion between pressure energy and velocity energy. If the control valve is smaller than the line size, the pressure at the valve inlet is reduced by the friction loss and is also reduced because the smaller flow area requires acceleration to a higher velocity.

If the downstream piping is the same size as the inlet piping, then the velocity-energy/pressure-energy exchange at the outlet is reversed and it cancels the effect at the inlet. Friction losses are always additives. For a reducer at the valve inlet, the ISA standard determines the inlet fitting friction loss coefficient:

$$K_1 = 0.5(1-(d/D_1)^2)^2 \qquad \textbf{6.15(12)}$$

For an increaser at the valve outlet the ISA standard defines the outlet fitting friction loss coefficient:

$$K_2 = (1-(d/D_2)^2)^2 \qquad \textbf{6.15(13)}$$

Although not explicitly stated by ISA S75.01, an analysis of the references shows that for the unusual case where an increase might exist at the valve inlet, K_1 is calculated as

$$K_1 = (1-(D_1/d)^2)^2 \qquad \textbf{6.15(14)}$$

and for a reducer at the outlet, K_2 is found as

$$K_2 = 0.5(1-(D_2/d)^2)^2 \qquad \textbf{6.15(15)}$$

For the velocity-pressure exchange (Bernoulli effect) for the usual case:

$$\text{reducer at inlet } K_{B1} = 1-(d/D_1)^4 \qquad \textbf{6.15(16)}$$

$$\text{increaser at outlet } K_{B2} = (d/D_2)^4 - 1 \qquad \textbf{6.15(17)}$$

It can also be shown from the same basic fluid mechanics for the unusual case:

$$\text{increaser at inlet } K_{B1} = (D_1/d)^4 - 1 \qquad \textbf{6.15(18)}$$

$$\text{reducer at outlet } K_{B2} = 1-(D_2/d)^4 \qquad \textbf{6.15(19)}$$

Certain combinations of these coefficients are used in calculations:

$$K_i = K_1 + K_{B1} \text{ (inlet combination)} \qquad \textbf{6.15(20)}$$

$$K = K_i + K_2 + K_{B2} \qquad \textbf{6.15(21)}$$

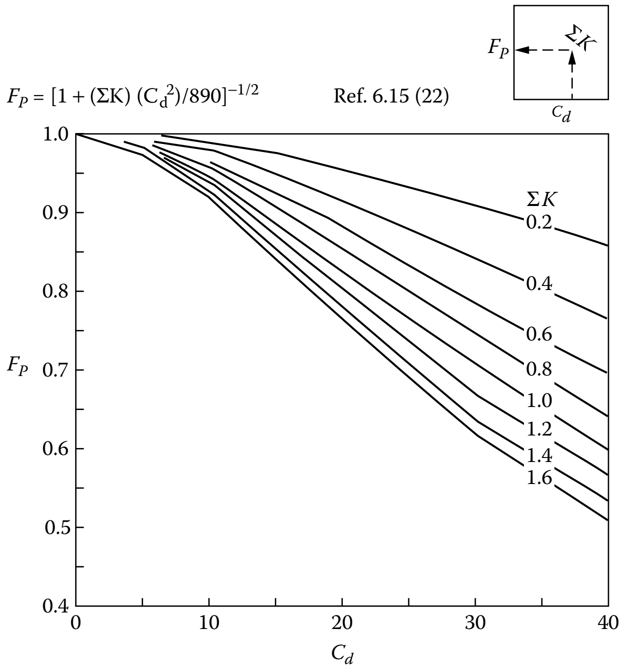

FIG. 6.15f
Piping geometry factor as a function of C_d and K.

A piping geometry factor is defined as:

$$F_P = [1 + (\sum K)(C_d^2)/890]^{-1/2} \qquad \mathbf{6.15(22)}$$

Valve flow capacity is directly proportional to this F_P factor (see Figure 6.15f).

Note that capacity is reduced for high values of ΣK combined with high C_d. Because the inlet fittings also affect the valve inlet pressure, a combination of F_L and F_P is used to predict choking or cavitation (see Figure 6.15g):

$$F_{LP} = [1/F_L^2 + (K_i)(C_d^2)/890]^{-1/2} \qquad \mathbf{6.15(23)}$$

Again note the large loss in capacity caused by reducers on valves with high C_d. This equation provides only an estimate. The actual point where choking starts is preferred to be determined by test.

$$(P_1 - P_{vc})(F_{LP}/F_P)^2 = \Delta p \text{ critical} \qquad \mathbf{6.15(24)}$$

For all practical purposes, the flow at rated valve capacity is always turbulent (otherwise the outlet velocity would be too high). This makes correcting for F_p much simpler and avoids most iterations. Figure 6.15h provides the piping configuration factor (F_p) for two pipe-to-valve diameter ratios. The curve on the left is for a $D/d = 2$, and on the right for a $D/d = 1.5$.

Installing a valve between reducers and expanders can lead to the distortion of the valve's inherent flow characteristic. This in turn can alter the gain of the valve (the percentage change in flow resulting from 1% change in control signal).

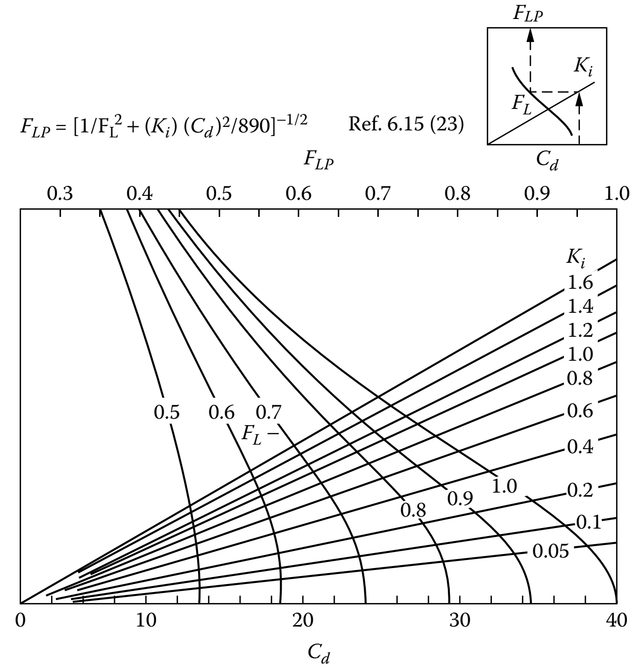

FIG. 6.15g
Combined factor (F_{LP}) for liquids as a function of C_d, K_i, and F_L.

F_p Correction Shortcut The correction to the required C_v for reducer and expander losses can also be obtained by the following steps: 1) Calculate the C_v for nonchoked liquid or gas flows. 2) Estimate the valve size d (inches) by determining the required C_d (dividing the calculated C_v by d^2). 3) Make sure that this required C_d is at least 40% smaller than the typical values listed in Table 6.15c. 4) Divide the pipe diameter by the chosen valve diameter to obtain the D/d ratio. 5) Select the applicable curve on Figure 6.15h. 6) Read F_p from the applicable graph using the calculated C_d (required C_v/valve size squared). 7) Divide the required system C_v by F_p. This then gives the required and corrected valve C_v. 8)

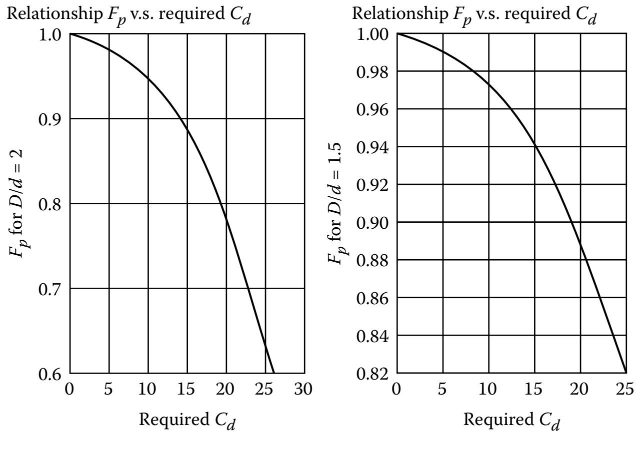

FIG. 6.15h
Correction factor for pipe reducers and expanders. The curve on the left is for a pipe to valve diameter ratio (D/d) of 2 and on the right, the curve is for D/d = 1.5.

Check the manufacturer's literature to make sure that the C_v of the chosen valve size is sufficient.

EXAMPLE

Assume that the required valve C_v was calculated from the flow data as 70 and the pipe size is 4 in. If a line size valve is assumed, the corresponding $C_d = 70/4^2 = 4.4$. This then could result in the selection of a 3– or 4-in. globe valve.

However, one might consider a less costly 2-in. ball valve. In that case the required $C_d = 70/2^2 = 17.5$. Consulting Figure 6.15h for a $D/d = 2$ (curve on the left), the factor F_p for a C_d of 17.5 is 0.84. Therefore, the required operating $C_v = 70/0.84 = 83.3$. For such a requirement, one needs to select a valve with a catalog C_v of 100 or more. Based on Table 6.15c, a 2-in. segmented ball valve can provide that, so the choice is acceptable.

Units Used in Valve Sizing

USA Units The valve sizing equations described here are based on Instrumentation, Systems, and Automation Society Standard S75.01, "Flow Equations for Sizing Control Valves."[9] For turbulent, nonvaporizing flow conditions, the flow rate in gallons per minute is calculated in accordance with Equation 6.15(25):

$$q = F_P C_v \sqrt{\frac{P_1 - P_2}{G_f}} \qquad \textbf{6.15(25)}$$

The valve coefficient may be calculated as

$$C_v = \frac{q}{F_P}\sqrt{\frac{G_f}{P_1 - P_2}} \qquad \textbf{6.15(26)}$$

where

P_1 and P_2 are in units of lb/in.^{2} absolute.

If flow rate, w, is given in lbm/hr and specific weight, γ_1, is in lbm/ft^3, then

$$w = 63.3\, F_P C_v \sqrt{(P_1 - P_2)\gamma_1} \qquad \textbf{6.15(27)}$$

or if solved for C_v:

$$C_v = \frac{w}{63.3\, F_P \sqrt{(P_1 - P_2)\gamma_1}} \qquad \textbf{6.15(28)}$$

Under choked flow conditions, the maximum flow rate is no longer dependent on the pressure drop but rather on the pressure drop at the onset of choking (Δp_{ch} in Figure 6.15d). See Equation 6.15(9). Therefore, the maximum volumetric flow rate, q, under choked conditions, in gallons/minute is

$$q_{\max} = F_L C_v \sqrt{\frac{P_1 - F_F P_v}{G_f}} \qquad \textbf{6.15(29)}$$

The maximum mass flow rate, w, in lbm/hr is

$$w_{\max} = 63.3\, F_L C_v \sqrt{(P_1 - F_F P_v)\gamma_1} \qquad \textbf{6.15(30)}$$

When reducers, increasers, or other fittings are installed between the pipe and the valve, a combined liquid pressure recovery factor, F_{LP}, is used. See the discussion on liquid sizing factors in connection with Equation 6.15(23).The volumetric flow rate becomes

$$\left.\begin{aligned} q_{\max} &= F_{LP} C_v \sqrt{\frac{P_1 - F_F P_v}{G_f}} \\ \text{or if solved for } C_v\text{:}\quad C_v &= \frac{q_{\max}}{F_{LP}}\sqrt{\frac{G_f}{P_1 - F_F P_v}} \end{aligned}\right\} \qquad \textbf{6.15(31)}$$

The mass flow rate is calculated by

$$\left.\begin{aligned} w_{\max} &= 63.3\, F_L C_v \sqrt{(P_1 - F_F P_v)\gamma_1} \\ \text{or if solved for } C_v\text{:}\quad C_v &= \frac{w_{\max}}{63.3\, F_{LP} \sqrt{(P_1 - F_F P_v)\gamma_1}} \end{aligned}\right\} \qquad \textbf{6.15(32)}$$

The pressure drop at the onset of choking (Δp_{ch}) must always be calculated to check if choking will occur. It is convenient to write the above Equations 6.15(25–32) using the allowable sizing pressure drop, Δp_a, which is defined as the smaller value of the actual pressure drop, $P_1 - P_2$, and the pressure drop at the onset choking, Δp_{ch}.

The Reynolds number factor, F_R, may also be included in the equation. Refer to the discussion on liquid sizing factors for nonturbulent in the later paragraphs discussing laminar and viscous flow. Thus, the following set of simplified equations can be written for volumetric flow rate (gpm):

$$q = F_P F_R C_v \sqrt{\frac{\Delta p_a}{G_f}} \qquad \textbf{6.15(33)}$$

and if solved for C_v:

$$C_v = \frac{q}{F_R F_P}\sqrt{\frac{G_f}{\Delta p_a}} \qquad \textbf{6.15(34)}$$

Other Engineering Units The equations presented previously were derived using U.S. Customary Units. In these equations C_v is not a dimensionless coefficient. Therefore, it is helpful to develop units conversion constants that will permit the use of these equations with other systems of units. ISA has chosen to write the equations using numerical constants (N_1, N_2, etc.) that take on unique values for specific

TABLE 6.15i

combinations of units. Equations 6.15(35–41) and Table 6.15i are from ISA S75.01.*

$$\left.\begin{aligned} q &= N_1 F_P C_v \sqrt{\frac{P_1 - P_2}{G_f}} \\ \text{or} \\ C_v &= \frac{q}{N_1 F_p}\sqrt{\frac{G_f}{P_1 - P_2}} \end{aligned}\right\} \qquad \textbf{6.15(35)}$$

$$\left.\begin{aligned} w &= N_6 F_P C_v \sqrt{(P_1 - P_2)\gamma_1} \\ \text{or} \\ C_v &= \frac{w}{N_6 F_P \sqrt{(P_1 - P_2)\gamma_1}} \end{aligned}\right\} \qquad \textbf{6.15(36)}$$

where:

$$F_P = \left[\frac{(\Sigma K)C_v^2}{N_2 d^4} + 1\right]^{-1/2} \qquad \textbf{6.15(37)}$$

The corresponding nonturbulent equations* are

$$\left.\begin{aligned} q &= N_1 F_R C_v \sqrt{\frac{P_1 - P_2}{G_f}} \\ \text{or} \\ C_v &= \frac{q}{N_1 F_R}\sqrt{\frac{G_f}{P_1 - P_2}} \end{aligned}\right\} \qquad \textbf{6.15(38)}$$

$$\left.\begin{aligned} w &= N_6 F_R C_v \sqrt{(P_1 - P_2)\gamma_1} \\ \text{or} \\ C_v &= \frac{w}{N_6 F_R \sqrt{(P_1 - P_2)\gamma_1}} \end{aligned}\right\} \qquad \textbf{6.15(39)}$$

The valve Reynolds number is defined* as

$$\text{Re}_v = \frac{N_4 F_d q}{\nu F_L^{1/2} C_v^{1/2}}\left(\frac{F_L^2 C_v^2}{N_2 d^4} + 1\right)^{1/4} \qquad \textbf{6.15(40)}$$

The equations* for determining maximum flow rate of a liquid under choked conditions for valves in straight pipes of the same size as the valve are as follows:

$$\left.\begin{aligned} q_{\max} &= N_1 F_L C_v \sqrt{\frac{P_1 - F_F P_v}{G_f}} \\ \text{or} \\ C_v &= \frac{q_{\max}}{N_1 F_L}\sqrt{\frac{G_f}{P_1 - F_F P_v}} \end{aligned}\right\} \qquad \textbf{6.15(41)}$$

Metric Capacity Coefficients, K_v and A_v Valve capacity coefficients, which have been derived in a similar manner as was the C_v but which have their basis in the metric or SI system of units, can be easily converted to their equivalent C_v values. If units for volumetric flow rate (q) are in cubic meters per hour (m^3/h) and the pressure drop (Δp), is given in bars (1 bar = 100 kPa), then the capacity coefficient K_v is

$$K_v = q(G_f/\Delta p)^{1/2} \qquad \textbf{6.15(42)}$$

---

* Reprinted by permission. Copyright © 1985, Instrumentation, Systems, and Automation Society. From ANSI/ISA-S75.01, "Flow Equations for Sizing Control Valves."

Simple units conversions lead to the following relationship between K_v and C_v:

$$K_v = 0.865C_v \qquad \textbf{6.15(43)}$$

The derivation of the capacity coefficient, A_v, yields an equivalent area in square meters (m^2) that is related to C_v by the conversion

$$A_v = 24 \times 10^{-6} C_v \qquad \textbf{6.15(44)}$$

It should be noted that valve capacity or sizing coefficients are defined in terms of a flow test with pressure taps located in straight pipe of the same nominal size as the valve and at specific distances upstream and downstream of the valve. The test configuration for determining C_v is well defined in ISA Standard S75.02[10] and is discussed in Section 6.6. The above conversions are valid only if K_v or A_v are determined using the same test manifold configuration and method as those specified in ISA-S75.02.

Sizing Example for Liquids

The above working equations can be used in a logical sequence to determine the required valve capacity for a given application. The following example illustrates the basic steps. However, there are other considerations when selecting a valve, such as noise, cavitation, corrosion, and actuator sizing, that are discussed in other sections of this chapter.

Example 1 Determine the required valve capacity coefficient (C_v) and valve size for the following application:

Liquid: Water
Critical pressure (P_c): 3206.2 psia
Temperature: 250°F
Upstream pressure (P_1): 314.7 psia
Downstream pressure (P_2): 204.7 psia
Flow direction (relative to valve plug): Flow-under-to-open
Line size/class: 4 in., ANSI Class 600
Flow rate (q): 500 gpm
Liquid vapor pressure (P_v): 30 psia
Kinematic viscosity (v): 0.014 centistokes
Valve characteristics: Equal percentage

Step 1: Calculate actual Δp.

$$\Delta p = P_1 - P_2 = 314.7 - 204.7 = 110 \text{ psi}$$

Step 2: Calculate choked pressure drop Δp_{ch} and determine allowable sizing pressure drop Δp_a. From Equation 6.15(10):

$$\begin{aligned} F_F &= 0.96 - 0.28\,(P_v/P_c)^{1/2} \\ &= 0.96 - 0.28(30/3206.2)^{1/2} = 0.93 \end{aligned}$$

In order to determine the Δp_{ch}, a preliminary valve-type selection must be made in order to establish the liquid pressure recovery coefficient F_L to be used in the calculation. Assume the use of a single-ported globe valve, which has an F_L equal to 0.9 (Table 6.15c). Solving for Δp_{ch} from Equation 6.15(11):

$$\Delta p_{\text{ch}} = F_L^2[P_1 - F_F P_v] = 0.9^2[314.7 - (0.93)(30)] = 232.3 \text{ psi}$$

The allowable sizing drop Δp_a is the smaller of Δp and Δp_{ch}. Therefore, we have determined that $\Delta p_a = 110$ psi, and the flow is not choked.

Step 3: Determine the specific gravity, G_f. The Instrumentation, Systems, and Automation Society sizing equations are based on water at 60°F with a density of 62.37 lb/ft^3. From water properties data we find the density of water at 250°F is 58.8 lb/ft^3.

$$G_f = 58.80/62.37 = 0.94$$

Step 4: Calculate the approximate required C_v assuming F_P and F_R equal 1.0. From Equation 6.15(34):

$$C_v = \frac{q}{F_R F_P}\sqrt{\frac{G_f}{\Delta p_a}} = 500(0.94/110)^{1/2} = 46.2$$

Step 5: Select the approximate body size based on the approximate C_v from Step 4. From manufacturers' catalogs it can be determined that the smallest globe valve body size that will accommodate C_v 46.2 is a 2 in. size with a maximum valve capacity coefficient of C_v51.

Step 6: Determine the piping geometry factor F_P. If manufacturer's test data are not available for the selected valve type, F_p may be estimated using Equations 6.15(12–22) or Figure 6.15f.

$$d = 2.0,\, D_1 = D_2 = 4.0, \quad \text{and} \quad d/D_1 = 0.50$$

Therefore, in Figure 6.15h, the left side ($D/d = 2$) curve should be used. For a reducer on the inlet and an increaser on the valve outlet the following values are calculated:

$$K_1 = 0.5[1-(0.5)^2]^2 = 0.2813$$

$$K_2 = [1-(0.5)^2]^2 = 0.5625$$

$$K_{B1} = 1-(0.5)^4 = 0.9375$$

$$K_{B2} = (0.5)^4 - 1 = -0.9375$$

$$\sum K = 0.2813 + 0.5625 + 0.9375 - 0.9375 = 0.8438$$

$$C_d = 46.2/(2)^2 = 11.55$$

$$\begin{aligned} F_P &= [1 + (\textstyle\sum K)(C_d)^2/890]^{-1/2} \\ &= [1 + (0.8438)(11.55)^2/890]^{-1/2} = 0.94 \end{aligned}$$

Step 7: Calculate the Reynolds number factor, F_R. For most process applications, this step is not necessary, because in most cases turbulent flow (i.e., $\mathrm{Re}_v > 10{,}000$) conditions exist. The calculation is shown here for illustration purposes. From Equation 6.15(64):

$$\mathrm{Re}_v = \frac{N_4 F_d q}{v F_L^{1/2} C_v^{1/2}}\left(\frac{(F_L C_d)^2}{N_2}+1\right)^{1/4}$$

$$\mathrm{Re}_v = \frac{(17300)(1)(500)}{(0.014)\sqrt{(0.9)(46.2)}}\left\{\frac{[(0.9)(11.55)]^2}{890}+1\right\}1/4$$

$$\mathrm{Re}_v = 98.6\times 10^6$$

Referring to Figure 6.15m, $F_R = 1$.

Step 8: Calculate the final required C_v using Equation 6.15(34) and the values for F_p and F_R that were calculated above:

$$C_v = \frac{q}{F_R F_P}\sqrt{\frac{G_f}{\Delta p_a}} = (500)/[(0.94)(1)](0.94/110)^{1/2} = 49.1$$

Note: It was noted in Step 5 that the maximum C_v for a 2-in. globe valve was found to be $C_{v(\max)} = 51$. The required $C_{v(\mathrm{req})} = 49.1$ is too close to the maximum, because it exceeds 85% of it. Therefore, a 3-in. globe valve should be selected.

Step 9: Calculate the fluid velocity at the 3-in. valve outlet using Equation 6.15(45) with appropriate units conversions.

$$U = q/A_o \qquad \textbf{6.15(45)}$$

where

U = velocity
q = volumetric flow rate
A_o = area of the body outlet port

If q is given in gallons per minute (gpm) and A_o is in square inches, then U can be calculated in feet per second:

$$U_{(\mathrm{fps})} = 0.321\, q_{(\mathrm{gpm})}/A_{o(\mathrm{sq.in.})} \qquad \textbf{6.15(46)}$$

For this example, the outlet velocity is

$U = 0.321(500\text{ gpm}/7.07\text{ sq. in.}) = 22.7\text{ fps}$

Evaluation: The valve sizing and outlet velocity of 22.7 fps is of consequence only under flashing (liquid/vapor) conditions, or where the fluid contains erosive particles. In such cases, the valve manufacturer should also be asked to double-check the sizing for the particular service.

The Cavitation Phenomenon

Cavitation occurs when static pressure anywhere in the valve drops to or below the vapor pressure of the process liquid. Vaporization begins around microscopic gaseous nuclei. The cavitation process includes the vapor cavity formation and sudden condensation (collapse) of the vapor bubble driven by pressure changes. The basic process of cavitation is related to the conservation of energy and Bernoulli's theorem, which describes the pressure profile of a liquid flowing through a restriction or orifice (Figure 6.15b).

In order to accelerate the fluid through the restriction, some of the pressure head is converted into velocity head. This transfer of static energy is needed to maintain the same mass flow through the reduced passage. The fluid accelerates to its maximum velocity, which corresponds to the point of minimum pressure (vena contracta). The fluid velocity gradually slows down as it expands back to the full pipe area. The static pressure also recovers somewhat, but part of it is lost due to turbulence and friction.

If the static pressure at any point drops below the liquid vapor pressure (P_v) corresponding to the process temperature, then vapor bubbles will form. If enough energy is imparted to the growing vapor bubble to overcome surface tension effects, the bubble will reach a critical diameter and expand rapidly. As the static pressure recovers to a point greater than the vapor pressure, the vapor will condense, causing the bubbles to collapse violently back into their liquid phase. The growth and collapse of the bubbles produce high-energy shock waves in the fluid.

The collapse stage of the process (the bubble implosion) produces the more severe shock waves. Shock waves and liquid microjets radiate for short distances from imploding cavities and erode nearby surfaces. Cavitation can cause erosion, noise, and vibration in piping systems and therefore must be avoided. Extensive cavitation also causes choked flow conditions in the valve.

Predicting and Mitigating Cavitation Sizing a valve in liquid service for choked flow allows one to determine its maximum flow capacity, but this is of limited value, because most liquid-service valves should not be operated under choked conditions. Special trim designs with multiple stages or multiple flow paths like those in Figure 6.1y are typically used to prevent severe cavitation and are better able to operate at or near choked conditions without damage.

Metal erosion from cavitation damage has a very distinctive appearance, like that of cinder block or sandblasting. No known material will withstand continuous, severe cavitation without damage and eventual failure. The length of time it will take is a function of the fluid, metal type, and severity of the cavitation. Without special trim geometry, mild or intermittent cavitation can be mitigated in standard valves by the use of extremely hard trim materials or overlays.

Sometimes it is feasible to increase the downstream backpressure, or limit the pressure drop by installing control valves in series to reduce the pressure drop in each valve. Another mitigating effect in some processes is a result of the fluid thermodynamic properties and operating conditions. As liquid operating temperature approaches its critical temperature, the growth and collapse rates of cavities slow down, as heat transfer effects become increasingly significant relative to the dominant inertial effects. This can greatly reduce the energy of cavity collapse and surface damage to the valve parts.

Some cryogenic and hydrocarbon applications are thought to behave this way, which may partly explain why cavitation damage in these cases is minimal or absent even when cavitation is present in the valve. Further information about cavitation and predicting its effects on valve performance can be found in the ISA Recommended Practice RP75.23.01, "Considerations for Evaluating Control Valve Cavitation."

Various methods are in use to establish the pressure drop at which cavitation starts. Two of the common techniques are described here. The first is based on a cavitation index, K_c, determined from flow capacity test data similar to that shown in Figure 6.15d. The second is based on a cavitation index, σ, and vibration test data.

Flow Curve Cavitation Index (K_c) Figure 6.15j illustrates the effect that cavitation has on the linear relationship between flow rate and the square root of pressure drop. The inflection point, the point at which the linear slope of the C_v curve marks the Δp, at which measurable amounts of vaporization exist is measured by a flow test.[10]

The calculation of the index K_c is based on the assumption that a valve may operate cavitation-free at any pressure drop that is less than that associated with K_c, which is defined as[15]

$$K_c = \frac{\Delta P_i}{P_1 - P_v} \qquad \textbf{6.15(47)}$$

where Δp_i is the pressure drop at the inflection in the tested C_v slope. K_c can then be compared to the index describing the actual service conditions of an application in question, K_{sc}:

$$K_{sc} = \frac{\Delta P}{P_1 - P_v} \qquad \textbf{6.15(48)}$$

If K_{sc} for the service is less than the K_c for the valve, the valve is assumed to be adequate for the service. Estimated K_c values for various valve types are shown in Table 6.15c. These values of K_c are only representative and should always be verified with the valve manufacturer. However, care must be exercised with this method, because it has not consistently indicated damaging cavitation for some valve designs.[2,15,18]

Vibration Curve Cavitation Index (σ) Noise and vibration measurements have identified four recurring regimes of cavitation in many valves.[19–22] Figure 6.15k illustrates the relationship between acceleration measurements taken on the downstream pipe and a cavitation index called *sigma* (σ).

There are several forms of sigma, all of which represent a ratio between the forces resisting cavitation and the forces promoting cavitation. The following forms of sigma have been used for valves.

$$\sigma_1 = \frac{P_1 - P_v}{P_1 - P_2} \qquad \textbf{6.15(49)}$$

$$\sigma_2 = \frac{P_2 - P_v}{P_1 - P_2} \qquad \textbf{6.15(50)}$$

Upstream and downstream pressures should be corrected for piping and fitting losses to obtain net values of P_1 and P_2 at the valve for calculating σ when $C_v/d^2 > 20$. The σ indexes

can be related to the *K*-type indexes by using the relationship:

$$\sigma_1 = \sigma_2 + 1 = \frac{1}{K} \qquad \textbf{6.15(51)}$$

Although K_c can be converted to a σ value for subjective comparison, the meaning of the value does not change. There is no proven correlation between specific points on the flow curve Figure 6.15j and the inflection points on the vibration curve in Figure 6.15k. Various cavitation regimes can be identified for many (but not all) valves with the type of plot shown in Figure 6.15k.[22] The ISA Recommended Practice RP75.23.01 uses σ defined by σ_1 in equation 6.15(49), so where σ is used in this section without a subscript, σ_1 is implied.

The various regimes of cavitation identified in Figure 6.15k are determined in a test defined in ISA RP75.23.01, which begins at a maximum attainable pressure drop in the test valve. The pressure drop is then reduced in small steps while maintaining a constant upstream pressure and temperature; vibration, pressures, and flow rates are measured at each step until the noise, vibration, and ΔP indicate that a noncavitating flow regime has been attained. The results are plotted showing vibration as a function of σ.

The *noncavitating regime* in Figure 6.15k is distinguished by turbulent flow noise and mild vibration. The *incipient cavitation regime* begins at a level called incipient cavitation and progresses to another level called *constant*[22] (or *critical*[18]) *cavitation.* Incipient cavitation begins with intermittent cavity formation and collapse. The resulting noise may be scarcely audible above the background noise. Constant cavitation produces a steady process of cavity growth and collapse, so that the sound is no longer intermittent but is constant.

Cavitation in the incipient regime is not generally harmful to valve hardware,[18] and limiting valve operation below a level of constant cavitation is a conservative application approach—although sometimes overly conservative. In the *full cavitation regime*, vibration or sound intensity increases to the maximum vibration level. When damage testing can be done, the onset of cavitation damage, called *incipient damage*, is often found somewhere in this regime.[22]

In many cases, the value of $1/K_c$ plotted on this graph will also appear in this regime. Thus, K_c is sometimes referred to as "incipient choking." Noise and vibration in the *super-cavitation regime*[18] are less than at maximum vibration as a result of the way that large volumes of vapor in the flow affect the fluid density, compressibility, and vibration transmission properties. Super-cavitation may exhibit a vapor pocket extending from the valve downstream into the pipe, where it will collapse back into liquid as the static pressure recovers. This differs from true flashing, in which the downstream pressure remains less than the vapor pressure of the flowing fluid. Damage to downstream piping and fittings is common in this regime.

The cavitation index σ describing the service conditions is useful if it can be compared with a valve cavitation index that represents the resistance of the particular valve to potential cavitation. The coefficient σ_{mr} ("manufacturer's recommended σ") is defined in ISA RP75.23.01 to designate the limit for σ above which the valve may be operated.

If the operating pressures for the valve are very close to the pressures used to test the valve, a direct comparison could be made, such that $\sigma > \sigma_{\mathrm{mr}}$ indicates safe operating conditions. However, research has shown that valve σ coefficients for incipient, constant, and incipient-damage cavitation do not remain constant for all pressures or in different sizes of geometrically similar valves. Scaling equations have been developed that take these effects into consideration, and they have been adopted in the ISA recommended practice.

Pressure Scale Effect (PSE) The scaling factors PSE and size scale effect (SSE) are used to adjust the recommended valve coefficient, σ_{mr}, when the reference size and reference pressure are known for which σ_{mr} was determined. Equation 6.15(52) defines a scaled coefficient for the valve, σ_v.

$$\sigma_v = [\sigma_{\mathrm{mr}}(\mathrm{SSE}) - 1](\mathrm{PSE}) + 1 \qquad \textbf{6.15(52)}$$

σ_v is then compared to the service σ calculated by Equation 6.15(49). The service $\sigma \geq \sigma_v$ means that the valve will operate at a level of cavitation less severe than the level corresponding to the manufacturer's σ_{mr}.

The pressure scale effect, PSE, is

$$\mathrm{PSE} = \left[\frac{P_1 - P_v}{(P_1 - P_v)_R}\right]^a \qquad \textbf{6.15(53)}$$

The subscript *R* refers to reference pressures used in testing the valve. Typically, valves are tested at about $(P_1 - P_v)_R = 100$ psi; this value may be used as an estimate unless otherwise stated by the valve manufacturer. The exponent, *a*, is a constant determined for a specific valve. Table 6.15l shows representative values of *a* for different valve types and different levels of cavitation.[18,22] When the exponent *a* is 0, PSE reduces to a value of 1, indicating that there is no pressure scale effect for those conditions.

Size Scale Effect The size scale effect, SSE, can be estimated from Equation 6.15(54). The exponent *b* was derived from limited testing.[18,20] It should be noted that testing under choked conditions showed no size scale effect; i.e., SSE for choked flow has a value of 1.

$$\mathrm{SSE} = \left(\frac{d}{d_R}\right)^b \qquad \textbf{6.15(54)}$$

$$b = 0.068\left(\frac{C_v}{d^2}\right)^{1/4} \qquad \textbf{6.15(55)}$$

where

d is the inside diameter of the valve port in inches

d_R refers to the reference (tested) valve port diameter in inches

Size scale equations are valid only when the valves are the same style and have approximately the same relative capacity; i.e., C_v/d^2 must be about the same for both valves. There are additional considerations if the valve is larger or smaller than the pipe size with attached fittings (reducers, increasing). RP75.23.01 recommends additional calculations when $C_v/d^2 > 20$. The following example demonstrates how this method can be applied.

Example 2. Rotary Valve Service data:

Fluid: Water
$T = 74°\text{F}$
Line size = 10 in. Sch. 40
$P_1 = 82$ psia
$Q = 3500$ gpm
$G_f = 0.998$
$P_v = 0.41$ psia
$P_2 = 70$ psia

Results of valve sizing: $C_v = 1010$; 8 in., ANSI Class 150 throttling rotary disk valve; body outlet velocity = 22 fps; approximately 75% open with $C_v/d^2 = 1010/(8)^2 = 15.8$, so effects of fittings may be ignored.

Calculate σ using Equation 6.15(49).

$$\sigma = \left(\frac{82 - 0.41}{82 - 70}\right) = 6.8$$

Compare with manufacturer's cavitation data for the butterfly valve, which are given as:

$\sigma_{\text{mr}} = 5.1$
$(P_1 - P_v)_R = 100$ psi, $a = 0.12$
$d_R = 6$ in.

Calculate PSE, b, SSE from Equations 6.15(53–55).

$\text{PSE} = [(82 - 0.41)/100]^{0.12} = 0.976$
$b = 0.068(15.8)^{1/4} = 0.136$
$\text{SSE} = (8/6)^{0.136} = 1.040$

Calculate σ_v from Equation 6.15(52).

$$\sigma_v = [5.1(1.040) - 1](0.976) + 1 = 5.2$$

Evaluation: Since σ is 6.8 and is greater than σ_v of 5.2, the valve can operate without significant cavitation.

Rule of Thumb for Incipient Cavitation One definition of the state of incipient cavitation is when the pressure drop increases to the point where it is first audible that some cavitation bubbles burst. This condition is usually not a cause for concern, although the pressure ratio factor X_{Fzi} is important in noise calculations.[16]

$$X_{\text{Fzi}} = 0.9(P_{1\,\text{ref}}/P_{1\text{actual}})^{0.125}/[1 + 3F_d(C_v/1.17F_L)^{0.5}]^{0.5} \quad \textbf{6.15(56)}$$

In Equation 6.15(38), if $P_{1\text{actual}}$ is in psia, the value of $P_{1\,\text{ref}}$ is 87 psia. If $P_{1\text{actual}}$ is in bars, $P_{1\text{actual}}$ is 6 bars absolute. Using this pressure ration factor X_{Fzi}, the pressure drop causing incipient cavitation can be calculated using Equation 6.15(39):

$$\Delta P_{\text{inc}} = X_{\text{Fzi}}\,(P_1 - P_v) \quad \textbf{6.15(57)}$$

As a rule of thumb that can be used as a guide only in an attempt to avoid damage or noise, one should make sure that the valve's pressure drop does not exceed the following limit:

$$\Delta P_{\text{limit}} = 0.5(X_{\text{Fzi}} + F_L^{0.5})(P_1 - P_v) \quad \textbf{6.15(58)}$$

For more accurate cavitation calculations one should use Equations 6.15(47–55), while for accurate noise calculations, should consult Section 6.14.

Example 3 Assume that a 2 in. globe valve was selected for a particular flow condition where the inlet pressure was 195 psia and the outlet pressure 87 psia. Let us also assume that using Equation 6.15(25), the required C_v was calculated to be 38, and that the supplier's catalog for the particular valve showed an F_L of 0.87 and an F_d of 0.4 at the given valve travel. Finally, assume that the vapor pressure of the flowing fluid is 8.5 psia.

Using Equation 6.15(56), we can calculate the pressure differential ratio for incipient cavitation as

$$X_{\text{Fzi}} = 0.9\ (87/195)^{0.125}/[1 + 3 \times 0.4(38/1.17 \times 0.87)^{0.5}]^{0.5}$$
$$= 0.282$$

Using this X_{Fzi} value, the limiting pressure drop to avoid cavitation damage or noise, using Equation 6.15(58), is

$$\Delta P_{\text{limit}} = 0.5(0.282 + 0.87^2)(195 - 8.5) = 96.8 \text{ psi.}$$

Because the actual pressure drop is only 80 psi, we should not be concerned.

Flashing

Flashing begins in the same manner as cavitation. However, in case of flashing, the pressure downstream of the cavity growth region remains at or below vapor pressure of the process fluid. This causes the vapor to stay in the vapor state as it leaves the valve and enters the downstream piping. The specific volume increases as liquid changes to vapor, which in turn causes an increase in the fluid velocity. If enough vapor is formed, the resulting high valve outlet, or pipe, the resulting velocities can erode metals.

In many cases, flashing is a normal part of the process; it cannot be avoided, and special system and valve designs are required to accommodate it. The heat of vaporization comes from the process liquid, causing its temperature to decrease. The relative masses of liquid and vapor will thereby approach thermodynamic equilibrium. The amount of flashing can be calculated from an energy balance. Even small amounts of flashing (e.g., where the vapor equals 1–3% by weight) can significantly affect a valve's capacity, sizing, and selection; therefore, flashing should be stated in the valve specification data sheets.

Large amounts of flashing (e.g., 10–15% by weight) require special valve designs, such as oversized outlets, and a larger downstream pipe. Note, choking can occur in the downstream pipe due to the large volume. This in turn will increase the back-pressure, P_2, which in turn then causes the valve to undergo cavitation again.

When the valve outlet pressure, P_2, is less than or equal to the vapor pressure of the process liquid, some of the liquid "flashes" into vapor and stays in the vapor phase as it enters the downstream piping. The phase change from liquid to vapor may cause high velocities and erosion of metals at the outlet. Even small amounts of flashing can significantly affect valve sizing and selection. Large amounts of flashing (e.g., where the vapor equals 10–15% by weight) require special valve designs and materials.

In order to select the right valve, it is necessary to know the fraction of the liquid that will flash to vapor and the flowing velocity of the resulting vaporized mixture. If the vapor content and therefore the velocity is high, the resulting back-pressure at the valve outlet can cause "choked flow" in the downstream pipe. This can cause cavitation in the valve and can cause severe erosion of the valve trim.

Calculating the Flash Fraction (X) The method for calculating the vapor fraction is essentially the same for all liquids. Water is the most common liquid that is likely to flash, and data for water are readily available in the steam tables. Data for other fluids may be found in other references.[11]

The vapor fraction by weight can be calculated from Equation 6.15(59).

$$X = (h_{f1} - h_{f2})/h_{fg2} \qquad \textbf{6.15(59)}$$

where h_{f1}, h_{f2}, and h_{fg2} are the enthalpy of saturated liquid upstream, the enthalpy of saturated liquid downstream, and the enthalpy of evaporation at downstream pressure, respectively.

Calculating Velocity Velocity calculations of the liquid-vapor mixture downstream of the valve assume that the mixture is in thermodynamic equilibrium. In most cases, this assumption is a good enough approximation when compared to the accuracy of other valve sizing factors. The velocity, U, for the mixture is

$$U = (w/A)[(1 - X)v_{f2} + Xv_{g2}] \qquad \textbf{6.15(60)}$$

where all units are consistent and v_{f2} and v_{g2} are specific volumes of the saturated liquid and saturated vapor, respectively, at downstream conditions. If mass flow rate, w, is given in lb/hr, area A in in.^{2}, and specific volumes in ft^3/lb, Equation 6.15(60) for the calculation of velocity, U, in fps becomes

$$U = (0.040\ w/A)[(1 - X)v_{f2} + Xv_{g2}] \qquad \textbf{6.15(61)}$$

Similarly, if flow rate is given as q in gpm, then U in fps can be calculated by

$$U = (20.0\ qG_f/A)[(1 - X)v_{f2} + Xv_{g2}] \qquad \textbf{6.15(62)}$$

It has been the experience that velocities exceeding approximately 300–500 ft/s have caused erosion in downstream pipe fittings in flashing water applications. Therefore, flashing water applications often require angle body valves and piping made out of chromium-molybdenum-steel alloys to resist erosion from the flashing water that is moving at high velocities.

Sizing Example 4 A flashing application must always be sized on the basis of choked flow conditions. Piping downstream of a flashing valve should generally be larger than the valve size because it must accommodate the large increase in volume. Therefore, the corresponding combined pressure recovery and piping geometry factor, F_{LP}, must also be applied to the sizing equations. See Equation 6.15(23) and Figure 6.15g.

Using the same configuration and conditions as in Example 1, except that P_2 in this case is 20 psia, determine the valve size and required C_v. (The other conditions in Example 1 were: process fluid was water at 250°F, $P_v = 30$ psia, $G_f = 0.94$, $P_1 = 314.7$ psia, and $q = 500$ gpm.)

Step 1: Calculate actual Δp.

$$\Delta p = 314.7 - 20 = 294.7 \text{ psi}$$

Step 2: Calculate ΔP_{ch} and determine ΔP_a. From Example 1, $F_F = 0.93$. Assuming that an angle valve with a characterized cage and flow over the seat (flow to close) is the preliminary selection for this flashing application, from Table 6.15c one can obtain the values $F_L = 0.80$, $F_d = 1.0$, and $C_v/d^2 = 12$. From Equation 6.15(11)

$$\Delta p_{\text{ch}} = F_L^2 (P_1 - F_F P_v) = 0.8^2 [314.7 - (0.93)(30)] = 183.6 \text{ psi}$$

$$\Delta p_{\text{ch}} < \Delta p, \text{ therefore } \Delta p_a = \Delta p_{\text{ch}} = 183.6 \text{ psi}$$

Step 3: Determine specific gravity of liquid at upstream conditions. This was determined in Example 1; $G_f = 0.94$.

Step 4: Calculate the approximate required C_v assuming F_P and $F_R = 1$. From Equation 6.15(34)

$$C_v = \frac{q}{F_R F_P} \sqrt{\frac{G_f}{\Delta p_a}} = 500(0.94/183.6)^{1/2} = 35.8$$

Step 5: Select the approximate body size. Refer to manufacturers' catalogs or, by using estimates from Table 6.15c, $C_v/d^2 = 12$, in which case the minimum body size is

$$d \approx (35.8/12)^{1/2} \approx 1.73$$

Thus, a 2-in. body size is selected.

Step 6: Determine F_{LP}; $d = 2.0$ in.; $D_1 = D_2 = 4.0$ in.; $d/D_1 = 0.5$.

From Equations 6.15(12–22) and Example 1: $K_1 = 0.2813$; $K_{B1} = 0.9375$; $K_i = 0.2813 + 0.9375 = 1.2188$; $C_d = 35.8/(2)^2 = 8.95$.

Using Equation 6.15(23):

$$F_{LP} = 1/F_L^2 + K_i \, Cd^2/890)^{-1/2}$$

$$= [0.8^{-2} + (1.2188)(89.5)^2/890]^{-1/2} = 0.77$$

Step 7. Calculate the final required C_v from Equation 6.15(30).

$$C_v = (q_{\max}/F_{LP}) \sqrt{G_f/(P_1 - F_F P_v)}$$

$$= 500/0.77 \sqrt{0.94/(314.7 - (0.93)(30))} = 37.2$$

Therefore, the 2-in. valve size is adequate and the capacity required for the application is within the estimated limit.

Example 5 Given the flashing conditions described in Example 4, determine the mass fraction of vapor at the valve outlet.

Step 1: Determine the enthalpies of saturated liquid at upstream conditions and of saturated vapor and liquid at downstream conditions using the steam tables. From saturated steam temperature tables at 250°F for upstream conditions: $h_{f1} = 218.59$ BTU/lbm.

From saturated steam pressure tables at 20 psia for downstream conditions: $h_{f2} = 196.27$ BTU/lbm; $h_{g2} = 1156.3$ BTU/lbm; $h_{hfg2} = 960.1$ BTU/lbm.

Step 2: Using the assumption that the process is adiabatic and therefore the enthalpies immediately upstream and downstream of the valve are equal, Equation 6.15(59) can be used to calculate the vapor fraction, X, or steam "quality" downstream:

$$X = (h_{f1} - h_{f2})/h_{fg2} = (218.59 - 196.27)/960.1 = 0.023$$

Therefore, the amount of fluid mass flashing to steam is 2.3%.

Example 6 Given the flashing case in Examples 4 and 5, estimate the velocity of the two-phase mixture at the valve outlet.

Step1: From the steam tables, find the specific volumes of saturated liquid and vapor at downstream conditions.

$$v_{f12} = 0.016834 \text{ ft}^3\text{/lbm}; \; v_{g2} = 20.087 \text{ ft}^3\text{/lbm}$$

Step 2: Determine vapor fraction or steam quality at downstream conditions. For this example, the vapor fraction, X, was found in Example 5. $X = 0.023$.

Step 3: Find specific gravity (or density) of the mixture and the cross-sectional area at the valve outlet. From Example 4, $G_f = 0.94$. Flow area is the outlet area of a 2-in. ANSI Class 300 valve:

$$A = \pi (2.00)^2/4 = 3.14 \text{ in.}^2$$

Step 4: Calculate velocity using one of Equations 6.15(60–62). Selecting Equation 6.15(62), because the flow rate is in units of gpm and area in square inches,

$$U = [20 \, qG_f/A](1 - X) v_{f2} + X v_{g2}]$$

$$= [(20)(500)(0.94)/3.14][(1 - 0.023)(0.016834)$$

$$+ (0.023)(20.087)] = 1432 \text{ ft/s}$$

Evaluation: This is not a realistic velocity since the actual velocity cannot exceed the speed of sound (about 1300 ft/s). As a result of such high velocity, the pressure at the valve outlet will rise, which in turn will reduce the vapor content until an equilibrium is established at sonic velocity. The result will be choked flow in the pipe.

At that point, the back-pressure in the pipe can cause cavitation in the valve and in the pipe. Wet steam at 1300 ft/s can be erosive. An angle valve with hardened trim exhausting it into either a long, straight run of pipe or directly into a receiver vessel should be used in order to avoid erosion of downstream pipe and fittings.

Another alternative would be to use an expanded outlet with a venturi outlet on the valve to reduce the velocity before it exits into the pipe. A venturi outlet with the same exit area as the 4-in. downstream pipe would reduce velocity to approximately 360 ft/s. These velocities are estimates only because the assumption of thermodynamic equilibrium was used to determine fluid properties. Note: The longer the downstream pipe and the more elbows there are in your piping system, the more the valve's back-pressure will increase, and with it cavitation will also rise.

Laminar or Viscous Flow

The proportionality between flow rate and the square root of pressure drop holds true only for fully turbulent Newtonian fluid behavior. Non-Newtonian fluids include most polymers and many other fluids. If no experimental sizing data exist, one might specify a line size valve and purchase a number of reduced C_v trims for it, so that the final choice of trim would be determined by trial and error.

Laminar or transitional flow regimes may result from very low flows, small valves or passages, low pressure differentials, and high viscosity. The valve Reynolds number, Re_v, is calculated to determine the effect of laminar or transitional flow behavior on the required valve C_v.

Reynolds Number Factor (F_R) In the majority of control valve applications the flow velocities inside the valve are high, which in turn causes the Reynolds number to be high, and therefore turbulent conditions exist. Under turbulent conditions pressure drop relates to the square of flow.

On the other hand, when the viscosity of the process fluid is high or when the size of the valve and the flow velocity through it are low, the Reynolds number will also be low and laminar flow conditions will exist. Under laminar conditions pressure drop linearly relates to flow. Therefore, the same increase in pressure drop results in a larger increase in flow than it would under turbulent conditions.

Here the flow coefficient under laminar or transitional flow becomes

$$C_v = q/F_R\ (\Delta P/G_f)^{0.5} \qquad \textbf{6.15(63)}$$

The valve equivalent Reynolds number, Re_v, is defined as

$$\text{Re}_v = \frac{N_4 F_d q}{\nu F_L^{1/2} C_v^{1/2}} \left(\frac{(F_L C_d)^2}{N_2} + 1 \right)^{1/4} \qquad \textbf{6.15(64)}$$

(See Table 6.15i for the values of constants N_2 and N_4 for various units.)

$$F_R = 0.7 \times 77\ (\text{Re}_v)^{0.5}/F_L\ (C_v/d^2) \qquad \textbf{6.15(65)}$$

When the valve operates in the laminar regime and the diameter (d) is in inches,

$$F_R = 1 + (0.06\ (C_v/d^2)^{0.5} F_L^{0.5}) \log\ (\text{Re}_v/10{,}000) \qquad \textbf{6.15(66)}$$

Note: When operating in the transitional regime, use the smaller of the two F_R values calculated by using Equations 6.15(65) and 6.15(66).

If the diameter (d) is given in millimeters, the F_R numbers are determined by using Equations 6.15(67) and 6.15(68). For the laminar regime use Equation 6.15(67):

$$F_R = 0.0076(\text{Re}_v)^{0.5}/F_L\ (C_v/d^2) \qquad \textbf{6.15(67)}$$

For the transitional regime use Equation 6.15(68):

$$F_R = 1 + (1.53(C_v/d^2)^{0.5}\ F_L^{0.5}) \log\ (\text{Re}_v/10{,}000) \qquad \textbf{6.15(68)}$$

The curves provided in Figure 6.15m relate the valve Reynolds number (Re_v) to the Reynolds number factor (F_R).

Example 7 Assuming that in a particular application $C_v = 10$, $d = 25$ mm, $F_L = 0.9$, $\text{Re}_v = 500$, the F_R in the transitional

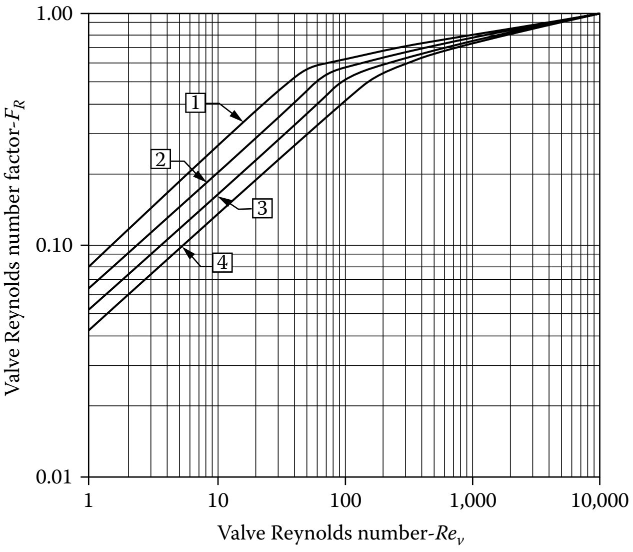

FIG. 6.15m

The valve Reynolds number (Re_v) can be corrected as a function of the Reynolds number factor (F_R) and of the type of valve used (if the diameter d is in inches).[8]

Curve No. 1 applicable for globe style valves $C_d \leq 10$.

Curve No. 2 applicable for globe valves and eccentric rotary plug valves, $C_d = 10$–15.

Curve No. 3 applicable for butterfly valves, $C_d = 15$–25.

Curve No. 4, applicable for ball valves $C_d \geq 25$.

regime is calculated as follows:

$$1 + (1.53(10/625)^{0.5}\ 0.9^{0.5})\ \log\ (500/10{,}000)$$
$$= 1 + 0.193 \times -1.3 = 0.748$$

In Figure 6.15m the straight diagonal lines extending downward from right to left, starting at an F_R value of approximately 0.5, are in the laminar region and operate under the conditions where laminar flow exists. At a valve Reynolds number above 10,000, all three curves in Figure 6.15m reach an F_R value of 1.0. At this number and at all higher values of Re_v, fully turbulent flow conditions exist. Between the laminar region (straight diagonal lines in Figure 6.15m), and the turbulent region (over $\mathrm{Re}_v = 10{,}000$, where $F_R = 1.0$), the flow regime is transitional (i.e., neither laminar nor turbulent).

Equation 6.15(69) can be used for determining the valve Reynolds number Re_v for globe valves and small flow valves. In these cases the Bernoulli correction for reducers (the bracketed term in Equation 6.15[64]) is not required.

$$\mathrm{Re}_v = N_4 F_d\ q/F_L^{0.5} C_v^{0.5} \qquad \mathbf{6.15(69)}$$

The valve-style modifier in Equation 6.15(69) is designated F_d. Baumann[17] defined F_d as the ratio of the equivalent hydraulic diameter(s) of a valve flow orifice to that of a circular one. For representative values please consult Table 6.15c.

Valve Sizing for Viscous (Laminar) Services The following treatment is applicable to valves with or without attached fittings. The F_p factor (Table 6.15c) is assumed to be 1.0, because of the absence of turbulence at the valve outlet. The first step in the valve sizing procedure is to calculate a pseudo valve flow coefficient C_{vt}, assuming turbulent flow and using Equation 6.15(70):

$$C_{vt} = \frac{q}{N_1 \sqrt{\frac{P_1 - P_2}{G_f}}} \qquad \mathbf{6.15(70)}$$

One may calculate the valve's Reynolds number by using either Equation 6.15(64) or 6.15(69) and then determine F_R from Figure 6.15m. The required C_v for the laminar or transitional flow conditions is then found by $C_{vL} = C_{vt}/F_R$.

The problem with this method is that it requires iteration, because one first has to guess the laminar valve C_v in order to calculate the Reynolds number, and later one has to repeat this procedure if the actual C_{vL} is too far off from the estimate.

In the sizing approach below *a simplified method* is presented for two typical valve classes. This approach, while ignoring transitional flow (a minor error), saves the time associated with the above-mentioned iteration.

Globe Valve (Example 8) For the calculations below, the values of $F_L = 0.9$ and $F_d = 0.46$ are assumed. In this simplified approach one would first calculate a pseudo Re_{vi} by modifying Equation 6.15(69) by also using Equation 6.15(70) for C_{vt}, in order to arrive at Equation 6.15(71) below:

$$\mathrm{Re}_{vi} = N4q/0.95 \nu C_{vt}^{0.5} \qquad \mathbf{6.15(71)}$$

Next, the required C_v is calculated under laminar flow conditions:

$$C_{vL} = C_{vt}/0.022\ (\mathrm{Re}_{vi})^{0.666} \qquad \mathbf{6.15(72)}$$

Assuming that $q = 4.13$ gpm, $\nu = 31{,}729$ cSt, $\Delta P = 8.41$ psi, and $G_f = 0.977$, one can, using Equation 6.15(70), calculate the C_{vt} of 1.407. Using that value in Equation 6.15(71), the Reynolds number comes out as 2.

Based on Equation 6.15(72), the C_v under laminar flow conditions is calculated as:

$$C_{vL} = 1.407/0.022\ (2)^{0.666} = 40.3$$

This C_v requirement can be met with a 2-in. globe-style control valve.

Ball or Butterfly Valves (Example 9) For the calculations below, the values of $F_L = 0.6$ and $F_d = 0.5$ are assumed. Here the required C_v under laminar flow conditions is

$$C_{vL} = C_{vt}/0.04\ (\mathrm{Re}_{vi})^{0.666} \qquad \mathbf{6.15(73)}$$

Using the same data as in Example 8 above, but using Equation 6.15(73), we get

$$C_{vL} = 1.407/0.04(2)^{0.666} = 22.$$

For this application, one could select a 1.5-in. ball valve instead of the 2-in. globe valve and thus obtain some cost saving. Note: If Re_v is greater than 10,000, the flow may be taken as turbulent and it can therefore be assumed that $F_R = 1.0$. In this case $C_{vL} = C_{vt}$.

For butterfly valves refer to Section 6.17.

Small Flow Valves (Example 10) The sizing of small flow valves is more complicated, because their F_d factor varies widely depending on the type of their trim. Laminar flow is likely to occur in small valves on liquid service, but at C_v values under 0.1, it is also possible to have laminar or transitional flow with gases.

The F_d values drastically change with valve type. For V-notch-type plugs $F_d = 0.7$, for flat seated trim $F_d = 0.3$, and for tapered needle trim $F_d = 0.09 \times (C_{vL}/d_o)^{0.5}$, where d_o = orifice diameter in inches.

A simplified sizing equation for *liquid* service in small valves is given below:

$$C_{vL} = 0.192(N_{11} G_f \nu q/\Delta P F_d)^{0.666} \qquad \mathbf{6.15(74)}$$

Assuming the following process conditions and the use of a flat seated trim: $q = 0.0035$ gpm, $G_f = 0.87$, $\Delta P = 50$ psi, $\nu = 16$ cSt, $F_d = 0.3$ (flat seat). Having this information, one would first calculate the turbulent C_v using $C_{vT} = q\ (G_f/\Delta P)^{0.5}$, which results in $C_{vT} = 0.00046$.

Next C_{vL} is calculated from 6.15(74) as $C_{vL} = 0.192\ (1 \times 0.87 \times 16 \times 0.0035/50 \times 0.3)^{0.666} = 0.004$.

Note that this C_{vL} value is substantially higher than the turbulent C_v of 0.00046, hence it indicates that laminar flow will occur and that a valve trim with a rated C_v that is above 0.004 has to be selected.

For small flow valves having *tapered needle trims* the sizing is even simpler. Here,

$$C_{vL} = 0.973(N_{12}\ qG_f \nu d_o/\Delta P)^{0.5} \qquad \textbf{6.15(75)}$$

Using the previous example but choosing a needle trim with an orifice diameter of $d_o = 0.055$ in., C_{vL} is calculated to be 0.0071 (a substantial difference from the 0.004 with the flat seat trim).

Sizing for Laminar Gas Flow In case of gases one should use *absolute viscosity* μ, because, in contrast with liquids, the kinematic viscosity varies with the absolute pressure of the gas. Sizing for the most common trim, the tapered needle, can be done as follows:

One should first calculate the turbulent C_v from the appropriate equation from the orientation table, Table 6.15a. Next, the laminar valve coefficient for gas service ($C_{vL\text{gas}}$) is to be determined by using the following equation, where d_o, valve orifice diameter in inches, has to be obtained from the manufacturer:

$$C_{vL\text{gas}} = Cv_T/0.0127(N_g q G_s/\mu d_o)^{0.5} \qquad \textbf{6.15(76)}$$

where

μ = absolute viscosity, centipoises

N_{11} = a constant for liquids = 1 if q = gpm, P = psi for misc. trim 30.7 if q = m^3/h, p = kPa

N_{12} = a constant for liquids = 1 if q = gpm, P = psi, and for tapered trim 1204 if q = m^3/h, P = kPa, and d_o = *m*, d_o = inches

N_g = a constant for gas = 1 if q = gpm, and d_o = inches for tapered trim 0.9 if q = m^3/h, and d_o = *m*

Example 11 Assuming the following process conditions: q = 1.6 scfh and the gas has a specific gravity, G_s, of 1.34. The absolute viscosity μ is 0.0215 cP, P_1 = 190 psia, P_2 = 170 psia. Based on these conditions, the calculated C_{vt} is found to be 0.0005.

If one learns from the manufacturer that the orifice diameter d_o = 0.197 in., one can proceed to Equation 6.15(76) and calculate the required laminar C_{vL} as:

$$\begin{aligned} C_{vL} &= 0.0005/0.0127(1 \times 1.6 \times 1.34/0.0215 \times 0.197)^{0.5} \\ &= 0.0017 \end{aligned}$$

This is 3.5 times the turbulent C_v requirement! Note: One should always calculate C_{vt} and C_{vL} for small valves, especially when C_v is below 0.01. After having made both calculations, one should select the larger of the two values.

GAS AND VAPOR SIZING*

The flow rate of a compressible fluid varies as a function of the ratio of the pressure differential to the absolute inlet pressure ($\Delta p/P_1$), designated by the symbol "x." At values of x near 0, the equations in this section can be traced to the basic Bernoulli equation for Newtonian incompressible fluids. However, increasing values of x result in expansion and compressibility effects that require the use of appropriate correction factors.

Equations for Turbulent Flow

The flow rate of a gas or vapor through a valve or the required C_v may be calculated by using any of the following equivalent forms of the equations, which differ only in the units used. If the flow is in mass units and the density is in specific weight units,

$$\left.\begin{aligned} & w = N_6 F_P C_v Y \sqrt{x P_1 \gamma_1} \\ \text{or} \quad & \\ & C_v = \frac{w}{N_6 F_P Y \sqrt{x P_1 \gamma_1}} \end{aligned}\right\} \qquad \textbf{6.15(77)}$$

For volumetric flow and specific gravity units:

$$\left.\begin{aligned} & Q = N_7 F_P C_v Y \sqrt{\frac{x}{G_g T_1 Z}} \\ \text{or} \quad & \\ & C_v = \frac{Q}{N_7 F_P P_1 Y} \sqrt{\frac{G_g T_1 Z}{x}} \end{aligned}\right\} \qquad \textbf{6.15(78)}$$

For mass flow and molecular weight units:

$$\left.\begin{aligned} & Q = N_8 F_P C_v P_1 Y \sqrt{\frac{xM}{T_1 Z}} \\ \text{or} \quad & \\ & C_v = \frac{w}{N_8 F_P P_1 Y} \sqrt{\frac{T_1 Z}{xM}} \end{aligned}\right\} \qquad \textbf{6.15(79)}$$

For volumetric flow and molecular weight units:

$$\left.\begin{aligned} & Q = N_9 F_P C_v P_1 Y \sqrt{\frac{x}{M T_1 Z}} \\ \text{or} \quad & \\ & C_v = \frac{q}{N_9 F_P P_1 Y} \sqrt{\frac{M T_1 Z}{x}} \end{aligned}\right\} \qquad \textbf{6.15(80)}$$

Note that the numerical value of x used in these equations must not exceed the choking limit ($F_k x_{TP}$), regardless of the actual value of x.

**Q is in cubic feet per hour measured at 14.73 psia and 60°F, or cubic meters per hour measured at 101.3 kPa and 15.6°C.

Constants for Engineering Units

The numerical constants, N, are chosen to suit the engineering units used in the equations. Values for N are listed in Table 6.15n.

Expansion Factor (Y)*

The expansion factor Y accounts for the change in density of a compressible fluid as it passes from the valve inlet to the vena contracta and for the change in area of the vena contracta as the pressure drop is varied (Contraction coefficient). Theoretically, Y is affected by all of the following:

1. Ratio of port area to body inlet area
2. Internal geometry of the valve
3. Pressure drop ratio, $x = \Delta p/P_1$
4. Reynolds number
5. Ratio of specific heats, k

The influence of items 1, 2, and 3 are defined by the factor x_T. Test data indicate that Y may be taken as a linear function of x, as shown in the following equation (and in Figure 6.15n for a valve without attached reducers or fittings):

$$Y = 1 - \frac{x}{3F_k x_T} \quad (\text{limits}: 1.0 \geq Y \geq 0.67) \qquad \textbf{6.15(81)}$$

For a valve with attached fittings, x_{TP} should be substituted for x_T. For the overwhelming majority of applications, Reynolds number effects may be disregarded when the process fluid is compressible except for small flow valves; i.e., if C_v is less than 0.01. The effect of the ratio of specific heats is discussed later.

Choked Flow*

If all inlet conditions are held constant and the differential pressure ratio (x) is increased by lowering the downstream pressure (P_2), the mass flow rate will increase till it reaches a maximum. Flow conditions where the value of x exceeds this limit are described as *choked flow*.

Choking occurs when the jet stream across the cross-sectional area of the vena contracta attains sonic velocity and when the vena contracta ceases to expand. Sonic velocity already occurs when P_1/P_2 exceeds about $0.5 \times F_L^2 \times P_1$, while choked flow occurs at P_1/P_2 ratios, which are higher than the ones causing sonic velocity. Therefore, x_T is always higher than the sonic pressure ratio.

The value of x at the inception of choked flow conditions (x_T) varies with the type of valve (Table 6.15c). It also varies with the piping geometry and with the thermodynamic properties of the flowing fluid. The factors involved are x_T, x_{TP}, and F_k.

Choking affects the use of Equations 6.15(77–81) in the following manner: The value of x used in the equations must not exceed $F_k x_T$ or $F_k x_{TP}$, regardless of the actual value of x. The expansion factor Y at choked flow ($x \geq F_k x_{TP}$) is at its minimum value of $^2/_3$.

---

Critical Pressure Drop Ratio Factor (x_T) For maximum accuracy, the pressure drop ratio factor, x_T, must be established by using the test procedures specified in Reference 10. Representative x_T values for valves are tabulated in Table 6.15c. These representative values are not to be taken as actual. Actual values must be obtained from the given valve manufacturer.

When a valve is installed with reducers or other fittings, the critical pressure drop ratio factor of the assembly (x_{TP}) is different from that of the valve alone (x_T). For maximum accuracy, x_{TP} must be determined by test.[10] When estimated values are permissible, the following equation (or Figure 6.15p) may be used to determine x_{TP}:

$$x_{TP} = \frac{x_T}{F_P^2}\left(\frac{x_T K_i C_v^2}{N_5 d^4} + 1\right)^{-1} \qquad \textbf{6.15(82)}$$

In this equation, x_T is the pressure drop ratio factor for a given valve installed without reducers or other fittings, and K_i is the sum of the inlet velocity head coefficients ($K_1 + K_{B1}$) of the reducer or other fittings attached to the valve inlet.

Ratio of Specific Heats Factor (F_k) The ratio of specific heats of a compressible fluid affects the flow rate through a valve. The factor F_k accounts for this effect. F_k has a value of 1.0 for air at moderate temperatures and pressures, where its specific heat ratio is about 1.40. Both theoretical and experimental evidence indicates that for valve sizing purposes, F_k may be taken as having a linear relationship to k. Therefore,

$$F_k = \frac{k}{1.40} \qquad \textbf{6.15(83)}$$

Compressibility Factor (Z) Equations 6.15(78–80) do not contain a term for the actual specific weight of the fluid at upstream conditions. Instead, this term is inferred from the inlet pressure and temperature based on the laws of ideal gases. Under some conditions, real gas behavior can deviate markedly from the ideal. In these cases, the compressibility factor Z shall be introduced to compensate for the discrepancy.

Z is a function of both reduced pressure and reduced temperature. In this section, reduced pressure P_r is defined as the ratio of the actual inlet absolute pressure to the absolute thermodynamic critical pressure for the fluid in question:

$$P_r = P_1 / P_c \qquad \textbf{6.15(84)}$$

The reduced temperature is defined similarly. That is,

$$T_r = T_1 / T_c \qquad \textbf{6.15(85)}$$

Absolute thermodynamic critical pressures and temperatures for most fluids and curves from which the compressibility factor, Z may be determined can be found in many reference handbooks of physical data.[11]

Velocity of Compressible Fluids

The velocity of sound in a compressible fluid is an important parameter. Pressure changes travel through an ideal gas at the velocity of sound. Most valve and piping systems are restricted to fluid velocities less than the speed of sound, due to the nature of the geometric discontinuities (supersonic wind tunnels being a notable exception). In valves, the throttling element and seat produce the vena contracta.

As flow rate and fluid velocity increase, the effects of compressibility cause the relationship of mass flow $(x)^1/_2$ to depart from a straight line. Once sonic velocity is attained in the vena contracta and the pressure ratio of x_T is reached, choking occurs. Reducing the downstream pressure will not increase the flow rate or the velocity at the vena contracta.

However, if local downstream geometry permits (e.g., similar to diverging nozzles), it is possible for velocity to increase downstream of the vena contracta to supersonic levels. Shock waves from supersonic velocities can produce undesirable and even dangerous vibration in process systems; use of supersonic velocities in system or valve applications should be avoided. The ratio of the actual fluid velocity, U, to the sonic velocity, c, is the Mach number, M_N. For valves with standard trim M_N should not exceed 0.3 at the outlet of the valve body. In order to avoid excessive noise. (See Section 6.14 for details.)

$$M_N = U / c \qquad \textbf{6.15(86)}$$

The sonic velocity can be determined from the first law of thermodynamics and the ideal gas law. Gas constants and ratios of specific heat are required in the calculation.

$$c = \sqrt{\frac{g_c k R T_1}{M}} \qquad \textbf{6.15(87)}$$

Flow rate for gases is usually given in terms of mass flow rate, w, or volumetric flow rate, Q. The velocity is

$$U = wv / A = Q / A \qquad \textbf{6.15(88)}$$

From these equations and from appropriate units conversions, the Mach number can be derived as follows:

For gases (using molecular weight, M):

$$M_N = \frac{Q}{5574\,A\sqrt{\frac{kT_a}{M}}} \qquad \textbf{6.15(89)}$$

For gases (using specific gravity, G_g):

$$M_N = \frac{Q}{1035\,A\sqrt{\frac{kT_a}{G_g}}} \qquad \textbf{6.15(90)}$$

For air:

$$M_N = \frac{Q}{1225\,A\sqrt{T_a}} \qquad \textbf{6.15(91)}$$

For steam:

$$M_N = \frac{wv}{1515\,A\sqrt{T_a}} \qquad \mathbf{6.15(92)}$$

where

Q = actual volumetric flow, ft^3/hr (not scfh)
A = flow area of the valve outlet, in.^{2}
T_a = absolute temperature, °R (°F + 460)
w = mass flow rate, lbm/hr
v = specific volume, ft^3/lbm
G_g = specific gravity of the fluid at standard conditions relative to air at standard conditions
M = molecular weight
k = ratio of specific heats

The calculated exit velocity or Mach number should be compared to the limits set by the process or the valve manufacturer for the specific valve and application. Mach numbers exceeding 0.3 can cause significant noise problems.

Sizing for Compressible Fluids (Example 12)

The above working equations can be used in a logical sequence to determine the required valve capacity for a given application. The following example illustrates the basic steps. However, there are other considerations when selecting a valve, such as noise, erosion, corrosion, and actuator sizing, that are discussed in other sections of this chapter and in the references.

For the example below, assume that the process conditions are the following:

Fluid: Steam
Temperature: 450°F
Upstream pressure (P_1): 150 psia
Downstream pressure (P_2): 65 psia
Specific volume downstream (v): 7.98 ft^3/lb
Flow rate (w): 15,000 lb/hr
Flow characteristic: Equal percentage
Line size: 3 in., Class 600

Step 1: Select the appropriate equation based on the available process information and its units. As the information is given in mass flow units, Equation 6.15(79) can be used and N_8 can be selected from Table 6.15n as 19.3. Thus, the working equation becomes

$$C_v = \frac{w}{19.3\,F_P P_1 Y}\sqrt{\frac{T_1 Z}{xM}} \qquad \mathbf{6.15(93)}$$

In order to be able to use this equation, one must obtain other physical data for critical pressure and temperature, for molecular weight, and for the ratio of specific heats. Table 6.15q lists such data for a variety of gases and vapors.

For steam:

Critical pressure (P_c): 3208.2 psia
Critical temperature (T_c): 1165.5°R
Molecular weight (M): 18.02
Ratio of specific heats (k): 1.33

Step 2: Check for choked flow. Determine the critical pressure drop ratio, x_T, from manufacturer's data or from the estimates in Table 6.16c. In order to do that, a preliminary valve-type selection is required. Assuming the use of a single-seated globe valve with contoured plug for this type of application and referring to Table 6.15c, $x_T = 0.72$. The ratio of specific heats factor, F_k, must be calculated from Equation 6.15(83):

$$F_k = k/1.40 = 1.33/1.40 = 0.95$$

Calculate the actual pressure drop ratio, $x = \Delta p/P_1$: $x = (150 - 65)/150 = 0.57$.

Choked flow occurs when x equals or exceeds the value of $F_k x_T$ or $F_k x_{TP}$ (when the valve is installed with reducers or other fittings). The flow is not choked when x is less than $F_k x_T$ or $F_k x_{TP}$,

$$F_k x_T = (0.95)(0.72) = 0.684$$

Note: If the value of x had been greater than $F_k x_T$, then the value of $F_k x_T$ would replace the value of x in the calculation of Y and C_v below.

Step 3: Calculate the expansion factor, Y, from Equation 6.15(81) or obtain it from Figure 6.15o.

$$Y = 1 - x/(3F_k x_T) = 1 - 57/[(3)(0.684)] = 0.72$$

Step 4: Determine the reduced pressure, P_r, and the reduced temperature, T_r using Equations 6.15(84–85). The compressibility factor, Z, is found from generalized compressibility charts available in reference books such as Perry and Chilton's *Chemical Engineer's Handbook.*[11]

$$P_r = P_1/P_c = 150/3208.2 = 0.04$$

$$T_r = T_1/T_c = 910/1165.5 = 0.78$$

$$Z = 1.0$$

Step 5: Calculate a preliminary C_v using the equation identified in Step 1 and assuming a line size valve with $F_P = 1$.

$$C_v = \frac{15{,}000}{19.3(1)(150)(0.72)}\sqrt{\frac{(910)(1)}{(0.57)(18.02)}} = 67.7$$

Step 6: Select the approximate body size based on the calculated preliminary C_v. Manufacturers' tables are the best source for C_v values, but estimates can be made based on C_d($C_d = C_v/d^2$) values from Table 6.15c. Observing that

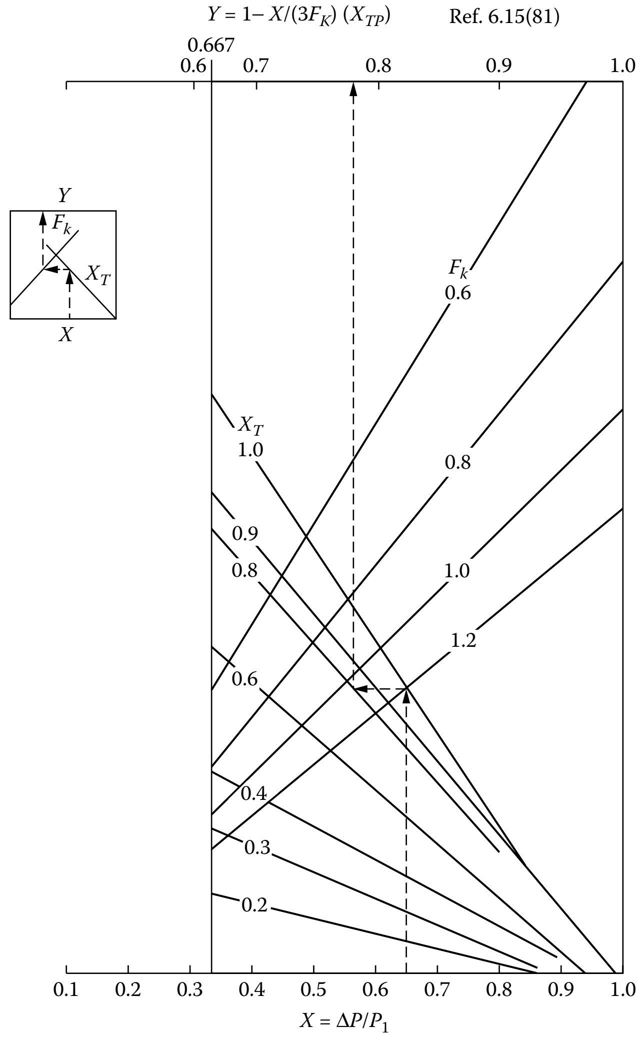

FIG. 6.15o
Graph for determining the expansion factor Y.

a single-ported, plug-type globe valve has a C_d = 11, d = (67.7/11) = 2.48. Thus, a 3-in. valve is selected for further evaluation.

Step 7: Determine the effect of piping geometry. If the valve had been smaller than line size and installed with reducers, F_p and x_{TP} would need to be known or estimated. Where appropriate, F_p can be estimated using Equations 6.15(12–22) or Figure 6.15f. The factor, x_{TP}, can be estimated from Equation 6.15(82) or Figure 6.15p. Y and C_v values may require recalculation using the value of $F_k x_{TP}$, if this product is less than x, to replace x in calculating Y and C_v. In this case, the line size and the valve size are 3 in. NPS, so this step is not required.

Step 8: Calculate the final required C_v using the actual or estimated F_P. In this example, $F_P = 1$, so the required C_v remains 67.7. The body size must be verified if the C_v changes at this step.

Note: The Reynolds number factor, F_R, is generally not considered when sizing for gases and vapors. However, in case of very small valves, with $C_v < 0.01$, F_R should be applied (when it becomes significant) in the same manner as for liquids.

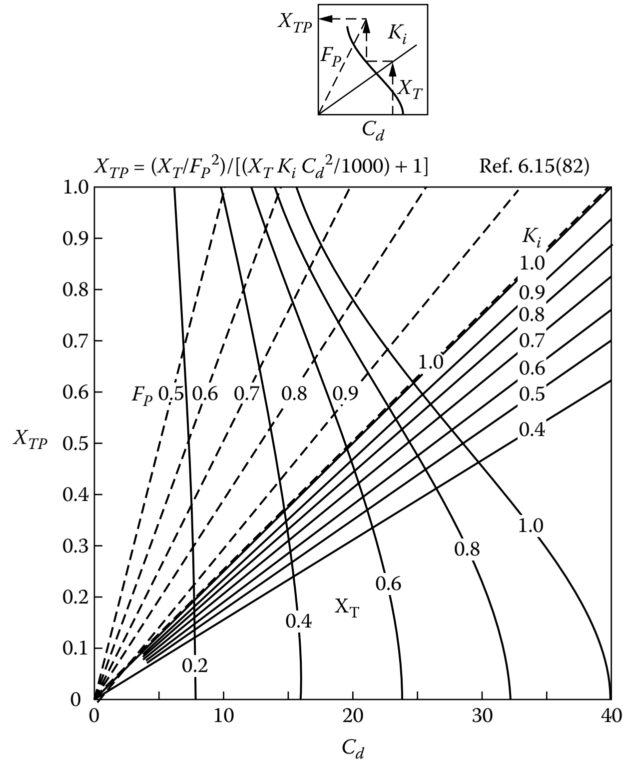

FIG. 6.15p
Graph for determining the critical pressure drop ratio factor for the combined assembly of valve and fittings (x_{TP}).

Step 9: Calculate valve exit velocity to evaluate the likelihood of velocity-related problems in the valve or in the downstream piping. Excessive velocity can result in noise, structural vibration, erosion, equipment damage, and personal injuries. Using Equation 6.15(92), with a flow area A = 7.07 in.^{2}

$$M_N = (15000)(7.98)/[(1515)(910)^{1/2}(7.07)] = 0.37$$

This is a high Mach number for the application; its acceptability should be verified with the manufacturer and with the process system engineer. Valve noise should be predicted and appropriate noise reduction measures taken to safeguard against hazards of excessive noise, as discussed in Section 6.14.

TWO-PHASE FLOW

Valve sizing for two-phase flow is approximate at best, because the effects of thermal, mass, and energy transfer between phases of the mixture are not easily quantified. The methods commonly used by the control valve industry[12,13,14] will be explained here. More elaborate experimental and numerical methods may produce more accurate results for specific cases.

Flow through a control valve is considered isenthalpic (adiabatic) overall and isentropic between the valve inlet and

TABLE 6.15q
Physical Data for a Number of Common Gases and Vapors

Gas	Critical Pressure, P_c (psia)	Critical Temperature, T_c (°R)	Molecular Weight, M	Ratio of Specific Heats, k
Air	492.4	227.1	28.97	1.40
Ammonia	1636.1	729.8	17.0	1.31
Argon	707.0	271.4	39.9	1.67
Butane	551.0	765.2	58.1	1.09
Carbon dioxide	1070.2	547.5	44.0	1.29
Carbon monoxide	507.1	239.2	28.01	1.40
Chlorine	1120.0	751.0	70.91	1.34
Ethane	708.5	549.7	30.0	1.18
Ethylene	730.5	508.3	28.05	1.21
Helium	33.2	9.45	4.00	1.67
Hydrogen	188.1	59.9	2.02	1.40
Methane	673.0	343.9	16.04	1.32
Natural gas	673.0	343.9	16.04	1.32
Nitrogen	492.4	227.1	28.02	1.40
Oxygen	736.0	278.6	32.0	1.40
Propane	615.9	665.9	44.1	1.12
Steam	3208.2	1165.5	18.02	1.33

the vena contracta. It is also assumed for this analysis that the velocities of the liquid and gas or vapor are essentially equal at the throttling point or at the vena contracta. This discussion considers two cases of mixed-phase flow: (1) a liquid and a gas of different chemical species, and (2) a liquid and vapor of the same chemical species.

Liquid-Gas Mixtures

The procedure for sizing valves for liquid-gas mixtures applies to a homogeneous mixture of a nonvaporizing liquid and a noncondensible gas. As the mixture passes through the valve, the specific volume of the liquid remains essentially constant, but the volume of the gas expands, thereby increasing the effective specific volume, v_e, of the mixture.

$$v_e = f_g v_g / Y^2 + f_f v_f \qquad \textbf{6.15(94)}$$

where f_g and f_f are the weight or mass fractions of gas and liquid, respectively, and Y is the expansion factor from Equation 6.15(81). Equation 6.15(94) expresses v_e as the specific volume of an equivalent incompressible fluid, allowing use of v_e in equations for incompressible fluids.

The required valve capacity, $F_P C_v$, assuming $F_R = 1$, can be obtained from rearranging Equation 6.15(36):

$$F_P C_v = \frac{w}{N_6 \sqrt{(P_1 - P_2)\gamma_1}} \qquad \textbf{6.15(95)}$$

By substituting $1/v_e$ for γ_1 and generalizing the equation for both choked and non-choked flow using Δp_a as the smaller of $P_1 - P_2$ and Δp_{ch} (see Equation 6.15[11]), the valve capacity is

$$F_p C_v = \frac{w}{N_6}\sqrt{\frac{v_e}{\Delta p_a}} \qquad \textbf{6.15(96)}$$

These equations have provided the required C_v values within an error of about ±10% based on limited testing on air and water mixtures in small globe valves in horizontal pipe.[15]

Example 13 The goal in this example is to find the required valve capacity ($F_p C_v$) for the conditions listed below:

Air flow rate: 600 lb/hr
Water flow rate: 26,000 lb/hr
Upstream pressure, P_1: 150 psia
Pressure drop, Δp: 50 psi
Temperature: 90°F (550°R)
Line size: 3 in. schedule 40

Step 1: Make a preliminary selection of valve type and determine the critical pressure drop ratio factor (x_T) for the valve. Assume a single-seated globe valve with a contoured plug with flow under the plug (to open). Using Table 6.15b, obtain an estimate of $x_T = 0.72$. (Manufacturers' catalogs may also be used.)

Step 2: Determine the relative mass fractions of gas and liquid, f_g and f_f. The total mass flow rate is $w = 600 + 26{,}000 = 26{,}600$ lb/hr.

$$f_g = 600/26{,}600 = 0.0226$$

$$f_f = 26{,}000/26{,}600 = 0.9774$$

Step 3: Calculate the pressure drop ratio, (x), the ratio of specific heat factor (F_K), and the expansion factor $(Y) \cdot x = \Delta p/P_1 = 50/150 = 0.333$. Because $x < x_T$, and the gas flow is not choked, $\Delta p_a = \Delta p = 50$ psi.

From Equation 6.15(83), using $k = 1.40$ for air, $F_k = 1.40/1.40 = 1.0$. Using Equation 6.15(81):

$$Y = 1 - \frac{x}{3F_k x_T} = 1 - 0.333/[(3)(1)(0.72)] = 0.846$$

Step 4: Determine the effective specific volume of the mixture at upstream conditions using Equation 6.15(94). The specific volume of the air can be calculated from the gas law equation of state:

$$v_g = \frac{RT_1}{MP_1} \qquad \textbf{6.15(97)}$$

$$v_g = \frac{\left(1545\,\frac{\text{ft}\cdot\text{lbf}}{\text{lb}\cdot\text{mol}\cdot{}^\circ\text{R}}\right)(550^\circ\text{R})}{\left(29\,\frac{\text{lbm}}{\text{lb}\cdot\text{mol}}\right)\left(150\,\frac{\text{lbf}}{\text{in.}^2}\right)\left(144\,\frac{\text{in.}^2}{\text{ft}^2}\right)} = 1.357\,\frac{\text{ft}^3}{\text{lbm}}$$

From saturated steam temperature tables at 90°F, the saturated liquid specific volume is $v_f = 0.016099$ ft^3/lbm. The mixture effective specific volume from Equation 6.15(94) is $v_e = (0.0226)(1.357)/(0.846)^2 + (0.9774)(0.016099) = 0.0586$ ft^3/lbm.

Step 5: Calculate valve capacity from Equation 6.15(96).

$$F_P C_v = \frac{w}{63.3}\sqrt{\frac{v_e}{\Delta p_a}} = \frac{26{,}600}{63.3}\sqrt{\frac{0.0586}{50}} = 14.4$$

Liquid-Vapor Mixtures

Liquid-vapor mixtures are a more difficult, if not impossible, problem owing to the difficulty in determining the inlet vapor fraction and because of the nonequilibrium conditions prevailing as the fluid passes through the valve.

Tests have shown that the flow rate of low-quality (vapor fraction $X < 0.03$) steam-water mixtures can be as much as ten times the amount predicted using calculations based on thermodynamic equilibrium, and about twice the flow predicted assuming no change of state between valve inlet and vena contracta.[15]

Calculations produced better predictions for very high-quality (vapor fraction $X > 0.9$) steam-water mixtures. For high vapor fraction mixtures, the same procedure is used as in Equations 6.15(94–96). For low vapor mixtures, while recognizing the possibility of large errors, use the effective specific volume at inlet conditions, v_e, and Equation 6.15(98).

$$C_v = \frac{w}{N_6 F_{LP}}\sqrt{\frac{v_e}{P_1(1 - F_F)}} \qquad \textbf{6.15(98)}$$

F_{LP} is the combined piping and pressure recovery factor from Equation 6.15(23).

Example 14 Let us assume that the following conditions are given for a liquid-vapor mixture in near-equilibrium conditions. Find the required valve capacity, $F_{LP}C_v$.

Fluid: Ammonia
Vapor flow rate: 200 lb/hr
Liquid flow rate: 9000 lb/hr
Upstream pressure, P_1: 110 psia
Pressure drop, Δp: 5 psi
Temperature: 60°F
Line size: 2 in. schedule 40

Step 1: Make a preliminary selection of valve type, and determine the valve x_T. Assume a throttling (segmented) ball valve. Using Table 6.15c for an estimate, $x_T = 0.25$.

Step 2: Determine the relative mass fraction of gas and liquid. The total mass flow rate is $w = 200 + 9000 = 9200$ lb/hr.

$$f_g = 200/900 = 0.0217$$

$$f_f = 9000/9200 = 0.9783$$

Step 3: Calculate pressure drop ratio (x), ratio of specific heat factor (F_K), and expansion factor $(Y) \cdot x = \Delta p/P_1 = 5/110 = 0.0455$. Since $x < x_T$, the vapor flow is not choked. From Equation 6.15(83) and Table 4.17q, using $k = 1.40$ for air and 1.31 for ammonia, $F_k = 1.31/1.40 = 0.936$. Using Equation 6.15(81):

$$Y = 1 - \frac{x}{3F_k x_T} = 1 - 0.0455/[(3)(0.936)(0.25)] = 0.935$$

Step 4: Calculate F_F from Equation 6.15(10). The critical pressure of ammonia from Table 6.15q is $P_c = 1636.1$ psia. The vapor pressure from ammonia tables[11] at 60°F is $P_v = 107.6$ psia.

$$\begin{aligned} F_F &= 0.96 - 0.28(P_v/P_c)^{1/2} \\ &= 0.96 - 0.28(107.6/1636.1)^{1/2} = 0.89 \end{aligned}$$

Step 5: Determine the effective upstream specific volume at upstream conditions using Equation 6.15(94). The specific volume of the ammonia vapor taken from thermodynamic tables[11] is only approximate, because the vapor is not in true thermodynamic equilibrium. However, using the values for saturated ammonia provides sufficient accuracy due to the relative uncertainty of the capacity estimate. From saturated ammonia tables,[11] $v_g = 2.751$ ft^3/lb and $v_f = 0.02597$ ft^3/lb. Therefore, one can calculate v_e from Equation 6.15(94).

$$v_e = (0.0217)(2.751)/(0.935)^2 + (0.9783)(0.02597) = 0.0937 \text{ ft}^3/\text{lb}$$

Step 6: Calculate valve capacity from Equation 6.15(98).

$$F_{LP}C_v = \frac{w}{63.3}\sqrt{\frac{v_e}{P_1(1-F_F)}} = \frac{9200}{63.3}\sqrt{\frac{0.0937}{110(1-0.89)}} = 12.8$$

CONCLUSIONS

Due to the uncertainties in correctly determining the process conditions, there is a tendency to be overcautious; i.e., to overestimate pressure losses in pipes and to increase the normal flow rates by safety factors. This tends to oversize the control valves. This in turn affects the installed gain of the valve and greatly reduces the turn-down, or rangeability of the valve.

It is recommended that the pump heads be selected on the basis that the control valve will add no more than 10% to the pressure drop in the piping system at maximum flow. This will not only reduce the size of the pump, but will also save on the required operating energy. If this approach is taken to determine the required pump head, the maximum differential pressure across the control valve will be the pump head at maximum flow minus the sum of the pressure drop across the piping system and any altitude changes, plus 10% of the pipe friction losses.

There are instances when the flow conditions are not accurately known. This might be the case if an old valve is to be replaced in a piping system and its serial number or source is not known. In such cases, the "best guess" approach would be to select the same type of valve having the same pressure rating as the surrounding pipe and having a flow coefficient (C_v) one size smaller than that listed for a full size orifice of a line size valve.

Another important rule is to make sure that the maximum required flow capacity for the valve does not exceed 85% of the valve's maximum rated capacity. This is because there is a typical tolerance of ±10% between what is advertised as the maximum C_v number and what actually is the C_v of the particular valve.

Similar rules apply to the minimum required flow coefficient, which is obtained by considering a process condition when the flow is the minimum and the valve pressure drop is the maximum. Once this $C_{v(\min)}$ is determined, one has to make sure that the valve travel at the required minimum flow coefficient is not less than 10% of the rated travel (or twice the expected dead band of the valve, whatever is higher) away from touching the valve seat. This safety margin is necessary to make sure that the plug does not touch the seat during any excursion caused by a disturbance in the control loop.

If the minimum flow capacity of the larger valve is insufficient to provide the required rangeability for the loop, use two valves in parallel by split-ranging the control signal among them, as shown in Figure 6.1i.

NOMENCLATURE

A	Area
A_1	Cross-sectional area of pipe, in.^{2}
A_2	Area of valve opening, in.^{2}
a	Pressure scale exponent
A_v	Metric capacity coefficient, m^2
b	Size scale exponent
C_d	Relative valve capacity or valve discharge coefficients, $C_d = C_v/d^2$ (Table 6.15c)
C_v	Valve capacity coefficient. Its value is 1.0 when the valve passes 1 gpm of cold water, having a specific gravity of 1.0, at a pressure drop of 1 psid.
C_{vt}	Pseudo valve coefficient
d	Valve body port diameter, inches
d/D	Valve to pipe diameter ratio
D_1	Upstream pipe inside diameter, inches
D_2	Downstream pipe inside diameter, inches
F_d	Valve-style modifier
F_F	Liquid critical pressure ratio factor
F_f	Mass fraction of liquid in a liquid-gas mixture
F_g	Mass fraction of gas in a liquid-gas mixture
F_k	Ratio of specific heats factor; k/1.4
F_L	Liquid pressure recovery factor of a valve without attached fittings
F_{LP}	Combined liquid pressure recovery factor and piping geometry factor of a valve with attached fittings
F_P	Piping geometry factor of a valve with attached fittings
F_R	Reynolds number factor
F_s	Laminar (streamline) flow factor
g	Gravitational acceleration, 32.174 ft/s^2
g_c	Units conversion constant, 32.174 (lbm-ft)(lbf-s^2) or 1.0 (kg-m)/(N-s^2)
G_f	Specific gravity relative to water at 60°F
G_g	Specific gravity relative to air 1 atm. and 60°F
H	Enthalpy
K	Ratio of specific heats for gases; 1.4 for air
K_{B1}	Inlet fitting Bernoulli coefficient (static pressure to velocity exchange)
K_{B2}	Outlet fitting Bernoulli coefficient

K_c	Valve cavitation coefficient
K_I	Inlet fitting combined loss coefficient
K_{sc}	Cavitation index of service conditions
K_v	Metric valve sizing coefficient, $(m^3/h)/(bar)^{1/2}$
K_1	Inlet fitting friction loss coefficient
K_2	Outlet fitting friction loss coefficient
m	Mass, lbm
M	Molecular weight
M_N	Mach number
N_1 to N_9	Numerical constants
P	Pressure, psia
P_1	Valve inlet pressure, psia
P_2	Valve outlet pressure, psia
P_c	Critical pressure, psia
PSE	Pressure scale effect for cavitation
P_{vc}	Pressure at the vena contracta, psia
P_v or P_{vp}	Vapor pressure at flowing conditions, psia
P_r	Reduced pressure (used with compressibility curves); defined as P_1/P_c
q	Volumetric flow rate, gpm
Q	Volumetric flow rate, ft^3/hr
R	Universal gas constant, 1545 (ft-lbf)/(lb-mol-°R) or 1.987 cal/(gm-mol-°K)
Re	Pipeline Reynolds number
Re_v	Valve Reynolds number
SSE	Size scale effect for cavitation
T	Temperature, °F or °C
T_a	Absolute temperature, °R
T_c	Critical temperature, °R or °K
T_r	Reduced temperature; defined as T_1/T_c
T_1	Absolute temperature at valve inlet, °R or °K
U	Velocity, ft/s
v	Specific volume, ft^3/lbm
V	Volume, ft^3
v_e	Effective specific volume of a liquid-gas mixture, ft^3/lbm
v_f	Specific volume of saturated liquid, ft^3/lbm
v_g	Specific volume of gas or saturated vapor, ft^3/lbm
W	Mass flow, rate, lbm/hr
X	Vapor portion of a liquid-vapor mixture, related to steam quality
X_Fzi	Differential pressure ratio for incipient cavitation at actual inlet pressure.
X_T	Critical pressure drop ratio factor (inception of choked flows)
X_{TP}	Critical pressure drop ratio factor for a valve and fitting assembly
Y	Expansion factor for gases
Z	Compressibility factor

ΔH	Head loss, ft.
Δp	Pressure difference (drop), psi
Δp_a	Allowable sizing pressure drop (the smaller of $P_1 - P_2$ and Δp_{ch}), psi
Δp_{ch}	Pressure drop at onset of choked flow defined in terms of F_L, psi
Δp_I	Pressure drop at flow curve inflection point where C_v begins to decrease due to cavitation
γ (gamma)	Weight density, lbm/ft^3
γ_1	Specific weight at upstream conditions, lbm/ft^3
μ (mu)	Absolute viscosity, centipoise = 10^{-3} N·sec/m^2
ν (nu)	Kinematic viscosity, centistokes = 10^{-6} m^2/sec
σ (sigma)	Cavitation index at flowing conditions
σ_c	Valve coefficient for constant cavitation
σ_I	Valve coefficient for incipient cavitation
σ_{id}	Valve coefficient for incipient damage cavitation
σ_{mv}	Valve coefficient at maximum vibration cavitation
σ_R	Recommended operating cavitation coefficient for a valve at a reference pressure
σ_v	Valve cavitation coefficient adjusted for pressure and size scale effects

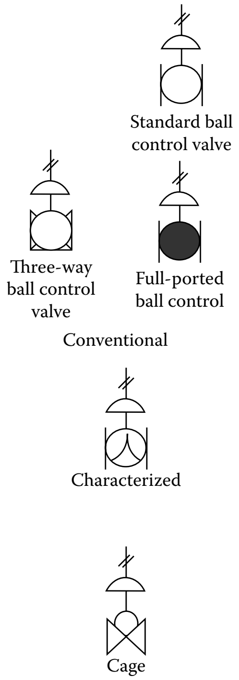
6.16 Valve Types: Ball Valves

C. E. GAYLER F. D. MARTON (1970, 1985) **B. G. LIPTÁK** (1995)
H. L. MILLER (2005)



Flow sheet symbols

Types of Ball Valves:	A. Conventional B. Characterized C. Cage
Size and Design Pressure:	A. ½ to 42 in. (12 to 1180 mm) in ANSI Class 150; to 12 in. (300 mm) in ANSI Class 2500 B. Segmented ball—1 to 24 in. (25 to 600 mm) in ANSI Class 150; to 16 in. (400 mm) in ANSI Class 300; to 12 in. (300 mm) in ANSI Class 600 C. ¼ to 14 in. (6 to 350 mm) C. Up to ANSI Class 2500
Design Temperature:	A. Varies with size and material, typically from −250 to 600°F (−155 to 315°C), with special designs available from −300 to 1800°F (−185 to 1020°C) B. From −50 to 300°F (−45 to 150°C); special units available from cryogenic to 1000°F (540°C) C. From −425°F to 1800°F (−255°C to 980°C)
Rangeability:	Refer to Section 6.7; generally claimed to be about 50:1
Characteristics:	See Figure 6.16a
Capacity:	A and B. Standard ball: $C_v = 30\ d^2$ to $C_v = 45\ d^2$; segmented ball: $C_v = 24\ d^2$ to $C_v = 30\ d^2$; full bore ball: $C_v = 35\ d^2$ to $C_v = 100\ d^2$; see Table 4.3c for details C. $C_v = 20\ d^2$ (noncritical flow)
Materials of Construction:	A. *Body:* Cast or bar stock brass or bronze, carbon steel, stainless steel, ductile iron, aluminum, Monel, titanium, Hastelloy C, plastics, glass; also hafnium-free zirconium (for nuclear applications) and ceramic for abrasives. *Ball:* Forged naval bronze, carbon steel (also plated), stainless steel, plastics, glass, ceramics, Alloy 20, Monel, Hastelloy C, aluminum, titanium. *Seats:* Teflon, Kel-F (both tetrafluoroethylene), Delrin, buna-N, neoprene, Perbunan, Hypalon, natural rubber, graphite.

	B. Body, ball, seal ring, and shaft are available in 316 stainless steel. Chrome and tungsten carbide plating available for ball and carbon steel for valve bodies. All-ceramic valves are also available. C. Stainless steel, other materials available.
Leakage:	A. ANSI V (see Section 6.1). B. Metal seats, ANSI IV to VI; composition seats, ANSI V or better.
Costs:	A. Low-cost ½ to 1 in. PVC valves with on/off actuators can be obtained for $300 or with positioned throttling actuator for about $1200. For process control-quality valve costs, see Figure 6.16b below. Cost data are based upon ANSI Class 150 flanged bodies with single-acting, spring-return actuator for on/off service. Other operators can be furnished and positioners added for throttling service. Ball and stem materials are 316 SST for both carbon and stainless steel bodies with TFE seat seals. Other alloys are available at higher cost. B and C. See Figure 6.16b for on/off; modulating with metal seats for high temperature will be three to four times higher.
Special Features:	A. Full-ported, three-way, split body, two-directional. B. Depending on "contour edge" of ball the flow characteristics vary slightly between suppliers. Slurry design provides for continuous purging of low-activity zone of valve to prevent build-up of solids, dewatering, or entrapment. C. Good resistance to cavitation and vibration.

INTRODUCTION

The rotary ball, butterfly, and plug valves, which in the past were considered only as on/off shut-off valves, are extensively used today as control valves. Relative to the traditional globe valve, their advantages include their lower cost and weight and higher flow capacity (two to three times that of the globe valve, as listed in Table 6.16c). Other features, such as tight shutoff, fire-safe designs, and low stem leakage, make it easier to meet governmental regulatory requirements from OSHA and EPA in the United States and the Pressure Equipment Directive (PED) in the EEC. Some ball valve designs, such as the characterized ball valve, also provide a near-equal-percentage characteristic. For a comparison of ball and globe valves in terms of their features and performance, see Reference 1.

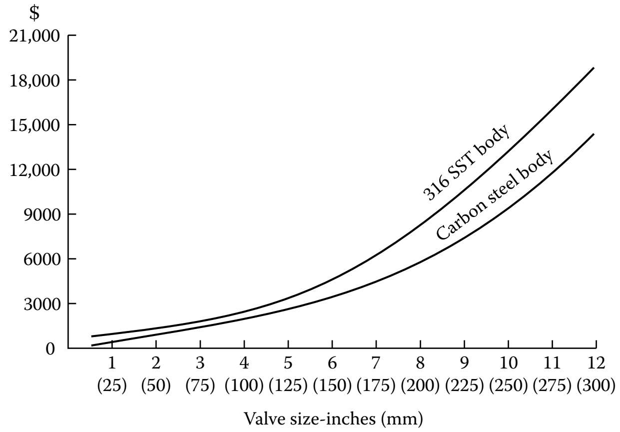

FIG. 6.16b
The costs of conventional ball valves with on/off actuators are provided above. For characterized ball valves add 10%, and for cage-type ball valves add 20% to these costs.

Throttling Ball Valves

When used for throttling service, some of their disadvantages are a direct consequence of the above-listed advantages. Their high capacity results in either using oversized valves or installing small valves in large pipes. This means a substantial waste of pumping energy caused by the reducer pressure drops. Also, the characteristic of a high-pressure recovery results in low vena contracta pressures. This in turn increases the probability of cavitation and noise.

Reduction of these problems has been achieved by adding perforated parallel plates in the ball valve openings (see Figure 6.16o) or by adding other tortuous path features (see Figure 6.16p) to the initially fully open flow path. These design improvement have added measurably to the range of trouble-free applications.

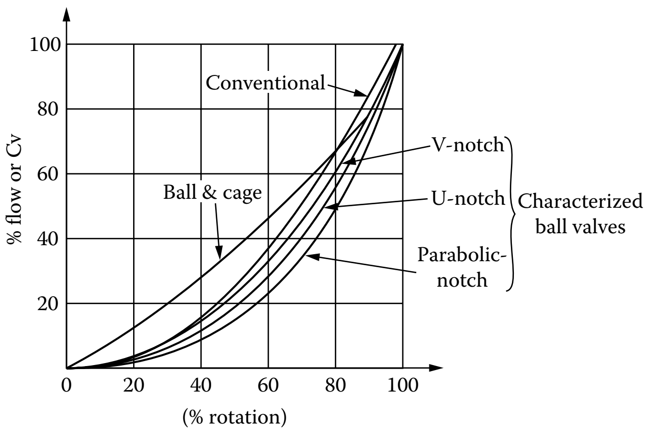

FIG. 6.16a
The characterized ball valve with a parabolic notch is near-equal-percentage, while the ball-and-cage valve characteristics are closer to linear, when used on water service. On gas service at critical velocities, the characterized ball valve's performance lines move closer to linear.

In a ball valve, critical flow occurs when the pressure drop through the valve rises to about 15% of the inlet pressure to the valve. In operating rotary valves, the linear movement of cylinder- or spring/diaphragm-type actuators must be converted by linkages, which introduces hysteresis and dead play. In addition, a nonlinear relationship exists between actuator movement and the resulting rotation. These considerations make the use of positioners essential, which on fast processes can lower the quality of control.

The torque characteristics of these valves are also highly nonlinear (Figure 6.4v), and because of the high “break-torque” requirement, the actuator is usually oversized for the operation in the throttling range. Some pneumatic piston actuators have a torque characteristic that has a high torque delivery at the closed position, therefore allowing a better matching of the torque needs (see Figure 6.4w).

The ball valve contains a spherical plug that controls the flow of fluid through the valve body. The three basic types of ball valves that are manufactured are (1) the conventional or quarter-turn pierced ball type, (2) the characterized type, and (3) the cage type.

CONVENTIONAL BALL VALVES

The quarter-turn (90°) required to fully uncover or fully cover an opening in the valve body can be imparted to the ball either

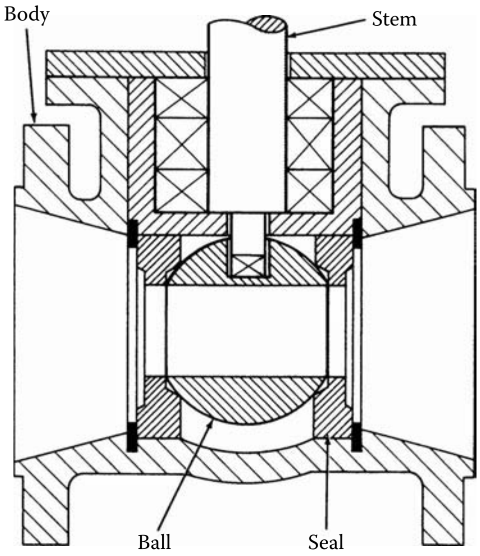

FIG. 6.16d
Top-entry pierced ball valve.

manually by turning a handle, or mechanically by an automatic valve actuator. Actuators used for ball valves may be the same as those used to control other valve types. As was discussed in Sections 6.3 and 6.4, they can be pneumatic, electric (including electronic or digital), hydraulic, or a combination.

The latter types include electropneumatic, electrohydraulic, electromechanical, and pneumohydraulic actuations. Most of the ball valves on the market are available with built-in, or integral, valve actuators. The valves are designed so that they can be used with or without an actuator, and they can be fitted with other manufacturers' actuators.

The spherical plug lends itself not only to precise control of the flow through the valve body but also to tight shut-off. Thus the ball valve may assume the double role of control and block valve (Figure 6.16d). Special materials used for valve seats help achieve these functions.

Ball valves are available with the features listed in the front of this section. Their tight shut-off characteristics correspond to ANSI Class IV and VI. The valve body can be configured as two-way, three-way, or split-body. Figure 6.16e illustrates some of the available multiport configurations.

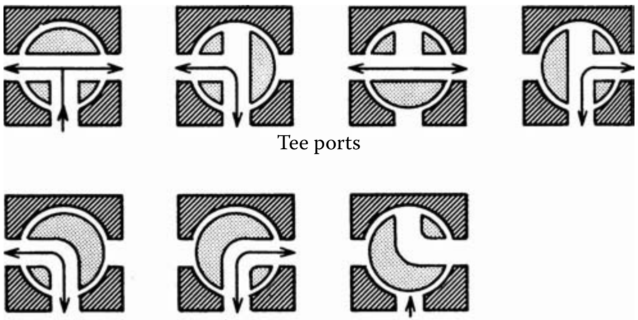

FIG. 6.16e
Porting arrangements of various multiport ball valve designs.

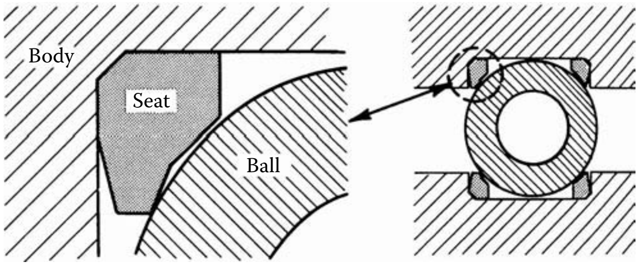

FIG. 6.16f
The design of ball valve seats.

The Valve Trim

The ball in a ball valve is cradled by seats on the inlet and the outlet side. The seats are usually made of plastic and are identical on both sides, especially in double-acting valves. Tetrafluoroethylene materials are preferred for seat materials, because of their good resilience and low-friction properties (Figure 6.16f).

In some valve designs the plastic seats are backed up by metallic seats in order to ensure tightness in the event that the soft seat gets damaged by high temperature, such as in a fire (Figure 6.16g). Such precautions are imperative on shipboard, for nuclear installations, and in cryogenic applications.

The fire-safe design of ball valves can be certified to API-607, which specifies the types of secondary seats that are acceptable to control the leaking of flammable fluids, when the primary seat (usually PTFE) sublimes during fire. The secondary metal seats of the fire-safe designs are also useful on erosive or abrasive services and on saturated steam service.

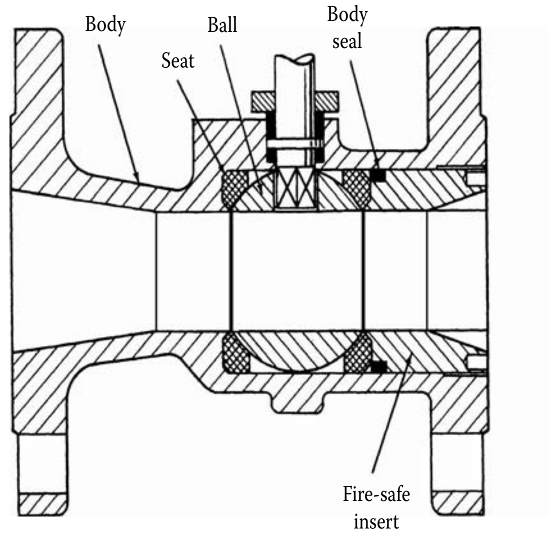

FIG. 6.16g
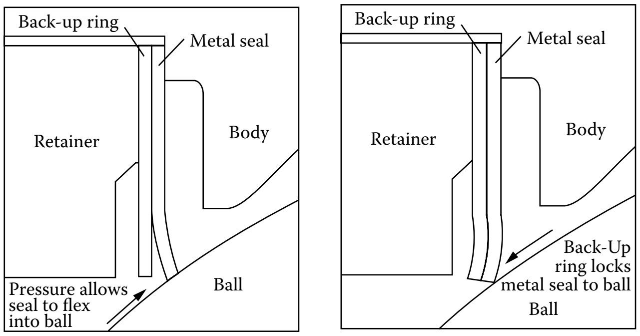
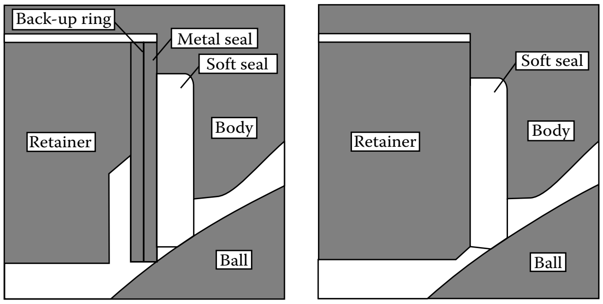
Fire-safe ball valve design.



Bi-directional flex-loc seal



Soft seals

FIG. 6.16h
Ball valves can be sealed by using either flexible metal seals or soft seals. (Courtesy of Valtek Inc.)

Some seat designs are such that the seat is always under compression, which allows the use of such nonresilient seat materials as carbon graphite.

Seats and Their Maintenance Other seat designs utilize the flexing of metal seals or soft PTFE seats, usually backed up by stainless steel or Inconel metal seals (Figure 6.16h). Where fluids of high temperature are handled, graphite seats are recommended. They hold tight up to 1000°F (540°C).

There have been significant advancements in the manufacturing processes that allow the use of primary metal seats in direct contact with the ball (see Figure 6.16i). Such designs can deliver better than ANSI Class V performance in terms of their seat leakage.[1]

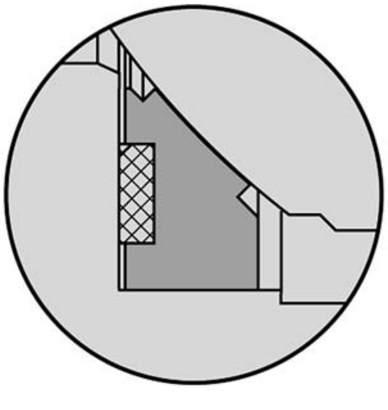


FIG. 6.16i
Contoured metal ball seal. (Courtesy of Metso Automation.)

The ball valves are designed so that lubrication is unnecessary and the torque required to turn the ball is negligible. Both upstream and downstream seats of the pierced ball can sometimes be freely rotated in order to reduce wear. In some designs the seats are forcibly rotated a fraction of a turn with each quarter turn of the ball. Thus seat wear, which is concentrated at the points where the flow begins or ends on opening or closing of the valve, is distributed over the periphery of the seat.

To facilitate cleaning or replacing worn seats in some designs the whole seating assembly is made in the form of a tapered cartridge. If the valve has top-entry design, the cartridge can be removed without disturbing the valve arrangement. O-rings usually close off stem and seats, and thrust washers made of tetrafluoroethylene compensate for axial stem thrust due to line pressure and reduce stem friction to a minimum.

Some seats are preloaded by springs or are made tapered for wear compensation and leak-tight closure.

Ball and stem are often machined from one piece. Other designs use square ends on the stem to engage in square recesses of the ball. In this case, the ball is made floating in fixed seats, while other designs provide a fixed location of ball and stem through the application of top and bottom guiding and ball bearings.

Balls are subject to wear by friction. Where long life and dead-tight closures are of paramount importance, the design is recommended that provides for lifting the ball off its seat before it is turned. This measure also prevents freezing or galling. Lift-off is achieved by mechanical means such as an eccentric cam. Valves of this design facilitate the handling of slurries and abrasive fluids, and they can be used for high pressures.

The proper materials for body and trim depend on the application. For handling chemicals or corrosive fluids, all wetted parts will possibly require stainless steel, plastics, or glass (borosilicate glass is preferred for impact strength).

Ball valves are made with the same connections as used in all other valve types. Where screwed connections must be used, valves with ends that take the place of unions are preferred.

Flow Characteristics

The flow characteristics of a ball valve approximate those of an equal-percentage plug (Figure 6.16a). These characteristic curves compare favorably with those of other rotary-stem valves. The flow path through a ball valve includes two orifice restriction locations (Figure 6.16j). Balls characterized either by a notch or by a noncircular bore give somewhat better characteristics (Figure 6.16a). Critical flow in ball valves is encountered at $\Delta P = 0.15P_1$, far below the usual figure of 50% of absolute inlet pressure.

Sizing of ball valves proceeds along the lines described in Section 6.15, with the possible exception that due to the

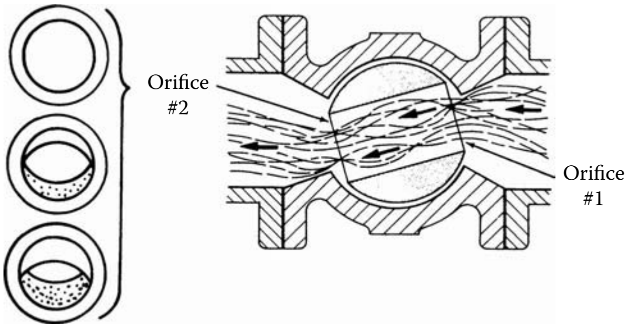

FIG. 6.16j
Two restricted orifice locations are formed when a ball valve is used for throttling the flow.

essentially straight-through flow feature, a ball valve can be chosen whose size is equal to the nominal pipe size, which usually is an advantage on slurry service. This can only be done if an oversized valve can be tolerated, which also implies the acceptance of reduced sensitivity and increased cost. The low-pressure loss and high-pressure recovery of a ball valve must also be considered in the calculations.

The application of ball valves for control requires some caution. Where a lot of noise is encountered some have found it necessary to bury the valve. Such may be the case with natural gas flowing at high speed. Valves handling liquids could cavitate and erode the pressure boundary as well as produce substantial noise.

On the other hand, the use of ball valves to control liquid oxygen in the experimental X-15 air-space vehicle as early as 1961, and later in the Atlas rocket, attests to the precise controllability with ball valves. A special valve with a dual-ball design for mixing liquid oxygen with liquid ammonia in precise proportions has also been used in the Atlas rocket system.

CHARACTERIZED BALL VALVES

The characterized ball valves can be V-notched, U-notched, parabolic, and anticavitation-antinoise designs. The notched trim valves and the partial-ball trim valves were introduced partially in an effort to solve the problem of valve clogging and dewatering in paper stock applications. Since then these valves have come into more widespread use as a result of increased valve rangeability and the shearing action at the sharp edges of the valve as it closes.

In essentially all characterized ball valves, the “ball” has been modified so that only a portion of it is used (Figure 6.16k). The edge of the partial ball can be contoured or shaped to obtain the desired valve characteristics. The V-notching of the ball in Figure 6.16k serves this purpose as well as the purpose of shearing the process stream.

This shape or contour of the valve’s leading edge is the main difference between the various manufacturers’ products. The ball is usually closed as it is rotated from top to bottom, although this action can be reversed.

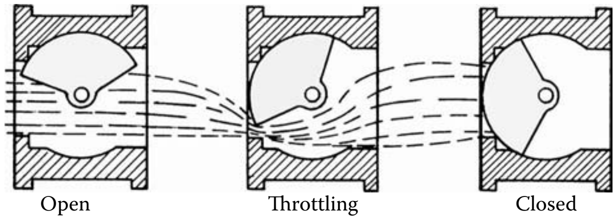

FIG. 6.16k
The open, throttling, and closed positions of the characterized ball valve.

Construction

Mechanically, the characterized ball valves are very similar to their ancestor, the conventional full ball designs. However, because of the asymmetrical design, the characterized ball valve has some design problems that are not significant with the conventional ball valves. A typical characterized ball valve is shown in Figure 6.16l, in its end and side views. The main parts of a characterized ball valve are described below.

The controlling edge of the ball can be notched or contoured to produce the desired flow characteristics. Characterized ball valves are available as U-notched, as V-notched, and as a parabolic curved designs. Mechanically, this part can create problems by bending under pressure and thus introducing movement into the shaft seals. Also, the stub shafts can be distorted by the bending of the partial ball under operating loads.

Early bodies were not designed for high-pressure services or for installations other than insertion between flanges. Today they are available with up to 12 in. (300 mm) flanges with up to ANSI Class 600 ratings.

The seal ring and seal-retaining ring are usually held in place by companion flanges. Damage due to overtightening of flange bolts sometimes occurs. Figure 6.16m illustrates a special sealing arrangement useful in slurry applications, due to the purging effect created by the flow into the otherwise low-activity zone, through the indent in the ball plug.

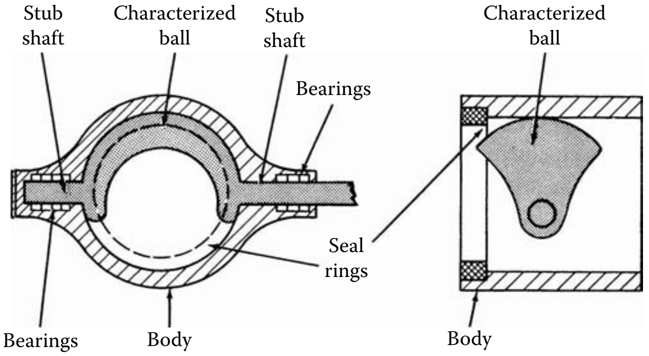

FIG. 6.16l
The component parts of a characterized ball valve.

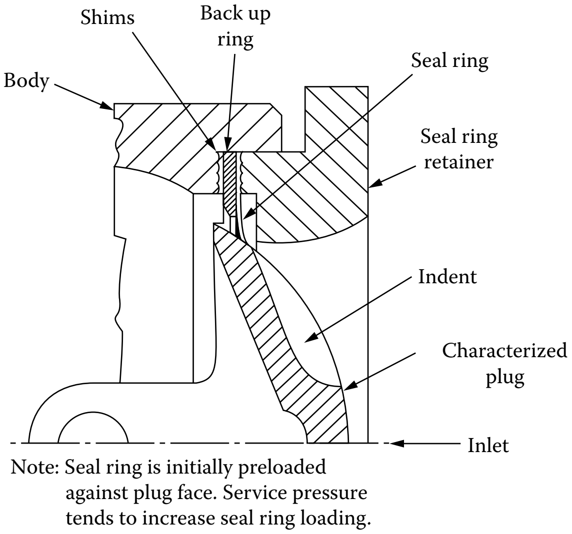

FIG. 6.16m
Special seal ring arrangement, where service pressure increases seal ring loading.

Characteristics

The flow characteristics are dependent upon the shape of the edge of the partial ball and on the installed flow direction. The shape of the V-notch at the edge of the valve varies from concave for small openings to convex for large openings. Figure 6.16n illustrates this characteristic together with the corresponding shapes for the parabolic ball valves.

The flow characteristics for parabolic, U-notched, and V-notched valves are given in Figure 6.16a. These curves are based on water flow and are also applicable to compressible fluid flow at less than critical (choking) velocities. If the characteristics were evaluated using compressible fluids at critical velocities, these curves would be flatter, closer to linear.

The characteristics of the conventional ball valves are also modified by the anticavitation and antinoise designs. One such design approach is illustrated in Figure 6.16o. Here the attenuator is placed inside the ball, so that when the valve is throttling, the fluid has to pass the attenuators, creating a number of pressure drop stages. The size, location, and distribution of perforations on the attenuator plates can be modified to obtain changes in the valve characteristics. These valves can also handle impurities in the process fluid.

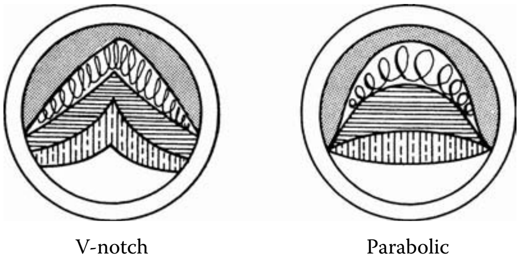

FIG. 6.16n
Shapes of throttling areas of the V-notched and U-notched characterized ball valves.

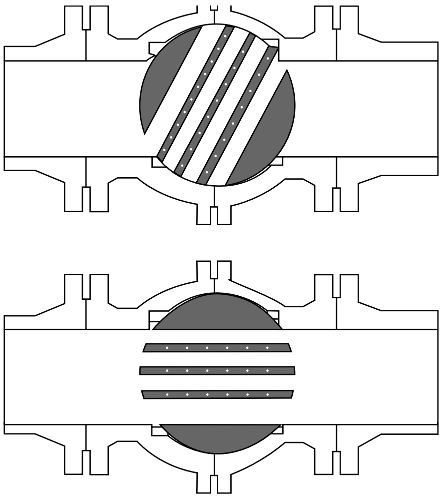

FIG. 6.16o
Internal attenuation plates reduce noise/cavitation and can also modify the throttling characteristics of ball valves.[1]

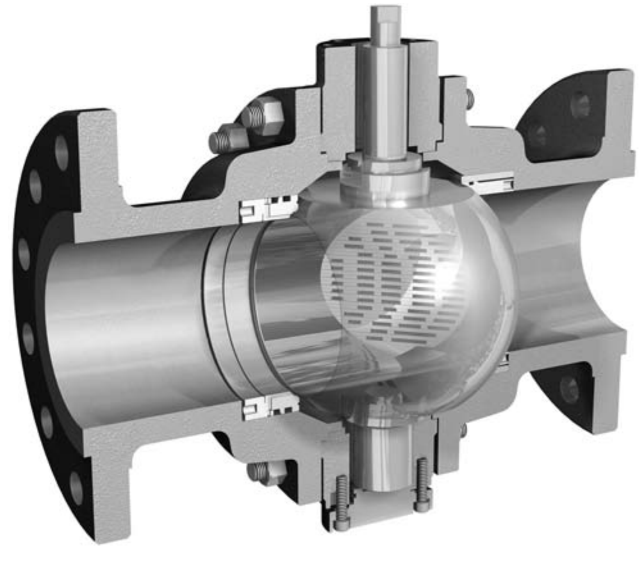
Another approach to the anticavitation, antinoise designs is to add a multistep tortuous trim feature in the ball so that, because of the small openings, the fluid velocity is maintained below damaging levels. Such a design having 16 discrete stages of pressure drop is shown in Figure 6.16p. This design provides a rangeability of up to 300:1 and operating noise levels of less than 75 dBA. The flow passages are designed to continually expand so that any solids that enter the trim will pass through and solids that are blocked will be swept through the valve at larger openings.

The anticavitation and antinoise designs are particularly useful in eliminating the need for low-flow bypass systems, which have been used in the start-up and shut-down of many gas pressure regulation applications.

BALL AND CAGE VALVES

Positioning of a ball by a cage, in relation to a seat ring and discharge port, is also used for control (Figure 6.16q). This valve design consists of a venturi-ported body, two seat rings, a ball that causes closure, a cage that positions the ball, and a stem that positions the cage. Seat rings are installed in both inlet and discharge, but only the discharge ring is active. The body can be reversed for utilization of the spare ring.

The cage rolls the ball out of the seat as it is lifted by the stem, positions it firmly during throttling, and lifts it out of the flow stream for full opening (Figure 6.16r). The cage is contoured for unobstructed flow in the open position. Cage design includes four inclined control surfaces. The two surfaces next to the downstream seat lift the ball out of the seat and roll it over the top edge of the seat ring as the valve is opened.



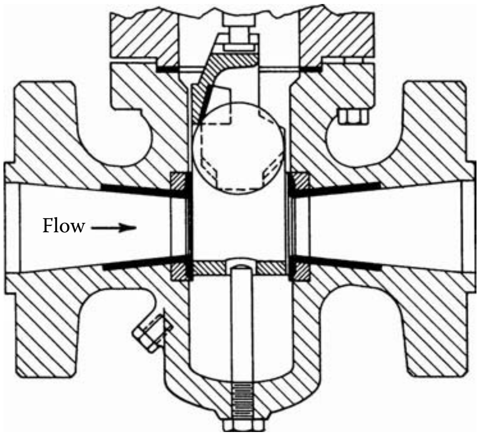


FIG. 6.16q
The ball is positioned by a cage in this valve design.

FIG. 6.16p
Multistage low-flow control valve design with anticavitation and antinoise capability. (Courtesy of Control Components Inc.)

As the valve opens farther, the ball rolls down the first two inclined surfaces to the center of the cage to rest on all four inclined surfaces. The Bernoulli effect of the flowing stream holds the ball cradled in this position throughout the rest of the stroke. A nonrotating slip stem is guided by a bushing at the bottom and by a gland at the top of the bonnet. A machined bevel near the base of the stem acts as a travel limit and allows for back-seating.

Sizes and Other Features

Ball and cage valves are furnished in sizes from 1/4–14 in. (6–350 mm), with ratings from 150–2500 PSIG (1–17 MPa). Reported flow coefficients (C_v) are consistently high. The flow characteristic reflects the increasing enlargement of the crescent between the surface of the ball and the discharge port (Figure 6.16a). With a flow characteristic starting at zero flow, the rangeability is very high, over 50:1, depending only upon the ability of the actuator to position the cage.

Tight shut-off occurs over a long operating life due to the continual rotation of the ball at each operation, which offers a new seating surface each time it is closed. Closure is positive due to the wedging of the cage in addition to line pressure. Although tightly closed, the stem force for opening is approximately 25% of a single-seated globe valve due to the manner in which the inclined surfaces of the cage roll the ball away from the seat.

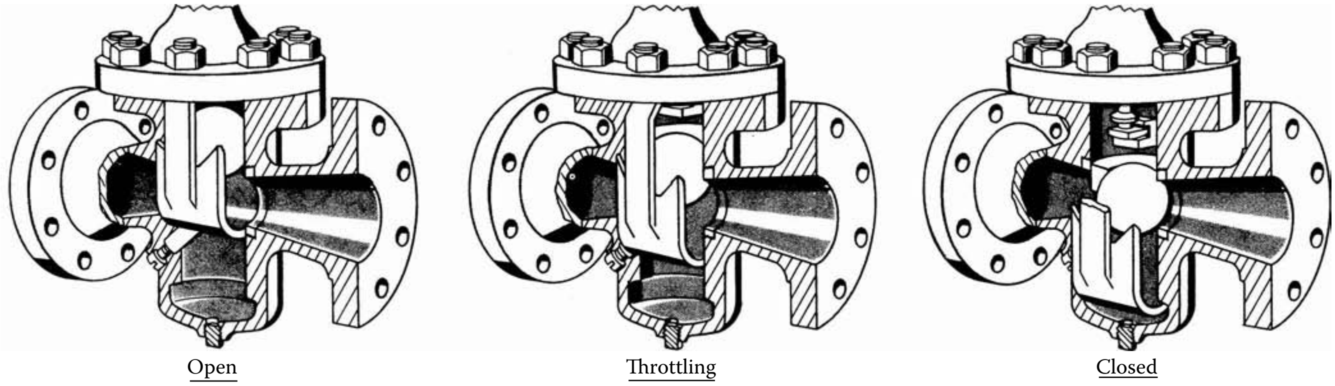

FIG. 6.16r
The open, throttling, and closed positions of a cage-positioned ball valve.

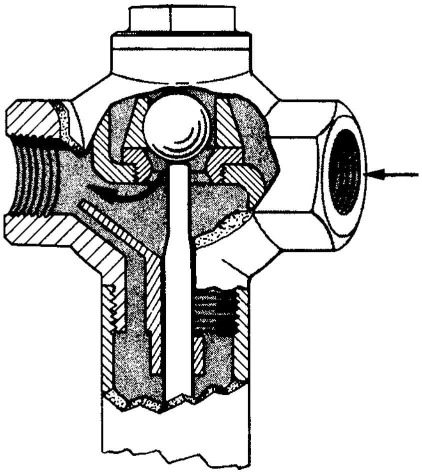

FIG. 6.16s
Valve design in which the ball is unseated by the valve stem. (Courtesy of Powers Process Control.)

Opening and closing force factors have been determined for all sizes of the valve. The low opening force requirement (9520 lb for a 4 in. valve at 2000 PSIG, or 42,400 N for a 100 mm valve at 13.8 MPa) is beneficial in being able to use a relatively small actuator. The design is conducive to minimizing cavitation effects because flow tends to follow the curve of the ball, thus reducing turbulence. Cavitation tends to occur in the venturi passage, not at the seat, allowing use of hardened or replaceable throats. The expanding venturi discharge assists in handling flashing liquids.

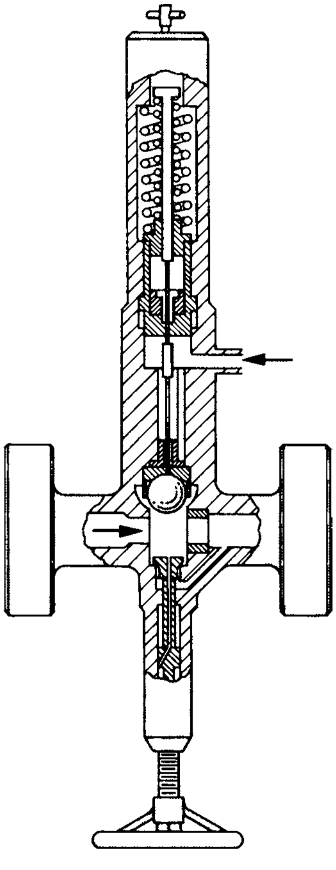

FIG. 6.16t
Ball-and-cage valve design, which is used to provide emergency closure.

The bonnet design lends itself to the adaptation of a variety of linear or rotary actuators. Because the ball must be moved completely out of the flow stream, stem travels are at least as much as the diameter of the valve throat.

Ball Unseated by Stem

The ball cage has also been used for regulators. The ball is cradled in the cage with the valve installed in the vertical position (Figure 6.16s). The stem of the regulator, coming from below the ball, forces the ball away from the seat. Flow is around the ball through the annular space, similar to the flow in a single-seated valve.

Ball Gripped by Cage

A variation of the ball-and-cage design is used for emergency closure (Figure 6.16t). Separate springs and ejection pistons allow high and low limit settings. Pressure above the high setting pushes the piston down to eject the ball from the holder into the seat. Low pressure allows the low-pressure spring to push the piston down. The ball is held firmly on the seat by the differential pressure. An internal bypass is opened to equalize the system pressures. Rotation of the bypass handwheel moves the ball back into the holder, the reset rod is retracted, and the bypass valve closed for normal operation.

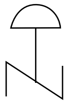
6.17 Valve Types: Butterfly Valves

C. E. GAYLER (1970) **B. G. LIPTÁK** (1985) **J. B. ARANT** (1995, 2005)



Flow sheet symbol

Types of Designs:	A. General-purpose, aligned shaft B. High-performance, offset (eccentric) shaft
Sizes:	A. 2 to 48 in. (51 mm to 1.22 m) are typical, but units have been made in sizes from 0.75 to 200 in. (19 mm to 5 m) B. 4 to 16 in. (0.1 to 0.4 m) are common, but units are available from 2 to 80 in. (50 mm to 2 m)
Design Pressures:	A. Most are available through ANSI Class 300 ratings and for up to 200 psid (1.4 MPa) pressure drop. Special units have been designed for up to 6000 PSIG design pressure B. For installation purposes most are available through ANSI 600 ratings and for up to 720 psid (5 MPa) pressure drop
Design Temperature:	A. –450 to 1000°F (–268 to 538°C). Special refractory lined units have been made for up to 2200°F (1204°C) B. –320 to 450°F (–196 to 232°C) for Teflon-seated valves; 1200°F (649°C) for metal-seated ones. Special units are available up to 1700°F (927°C)
Body/Disc Materials:	A. Iron, ductile iron, carbon or alloy steels, stainless steel (302–316), aluminum bronze, Alloy 20, Monel, Hastelloy C, titanium, chrome plating, nickel plating, Kynar, Nordel, Viton, EPDM, Buna-N, neoprene elastomer lining, TFE encapsulation B. Steel, 316 stainless steel, alloy steel, Durimet 20, aluminum bronze, Alloy 20, Monel, Hastelloy C, titanium, tungsten titanium carbide (TTC) coating
Seal Materials:	A and B. TFE, Kel-F, EPT, polyethylene, PTFE with titanium, Inconel, or 316 stainless steel or other metals
Characteristics:	See Figure 6.17a
Rangeability:	Generally claimed as 50:1
Leakage:	A. Unlined, 2 to 5%; lined, ANSI V (see Table 6.1gg) B. Metal seat, ANSI IV; soft (toggle) seat, ANSI VI
Capacity:	A. With 60° rotation, $C_v = (17 \text{ to } 20)d^2$. Typical for throttling with 75° rotation, $C_v = (25 \text{ to } 30)d^2$; with 90° rotation, $C_v = (35 \text{ to } 40)d^2$ B. $C_v = (20 \text{ to } 25)d^2$; see Figure 6.17c
Special Features:	Reduced torque disc designs, fire-tested seals, reduced noise disc, special disc seal designs
Cost:	See Figure 6.17b

INTRODUCTION

The orientation table (Table 6.1a) compares the main features of butterfly valves to other control valve designs. The rotary valves such as butterfly, ball, and plug valves were once considered to be only on/off valves. In recent decades the rotary valves in general and the butterfly design in particular have been used more and more as throttling control valves.

Relative to the traditional globe control valve, the butterfly valves have the advantages of lower cost and weight, two to three times the flow capacity of globe valves (as shown in Figure 6.17c), fire-safe designs, and low stem leakage, which enables them to more easily meet the Federal Clean Act. Their leakage is high, unless special soft-seated configurations or high-performance designs are used. Some of them can also be provided with near-equal-percentage characteristics and tight shut-off.

When used for throttling service, some of their disadvantages are a direct consequence of the above advantages. Their high-capacity design results in either using oversized valves or having small valves mounted in large pipes. If small valves are used, this means substantial waste of pumping energy caused by the reducer pressure drops. Also, their high-pressure recovery nature results in low vena contract pressures, which in turn increase the probability of cavitation and noise.

Reduction of these problems has been attempted by adding flutes to the butterfly disc, but the problems have not been fully resolved. In operating rotary valves, the linear movement of cylinder or spring/diaphragm actuators must be converted by linkages, which introduces hysteresis and dead

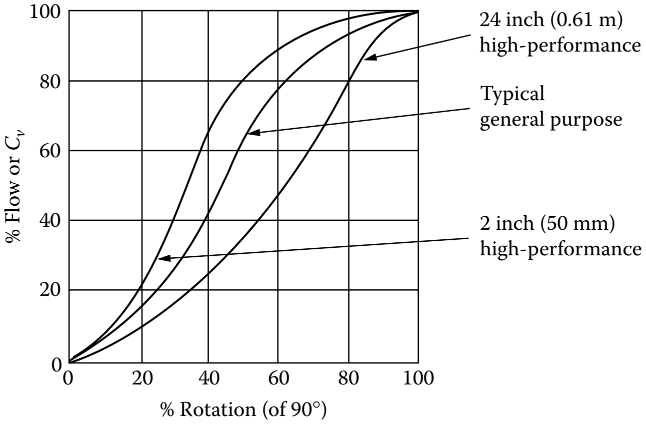

FIG. 6.17a
The flow characteristics of butterfly valves are affected by the location of the shaft (aligned or eccentric) and by the relative size of the shaft compared to the valve. The characteristics of high-performance designs are also slightly affected if the shaft is moved from the upstream to the downstream side of the disc. For throttling purposes the rotation of the valve is usually limited to move between the 0° and 60° positions.

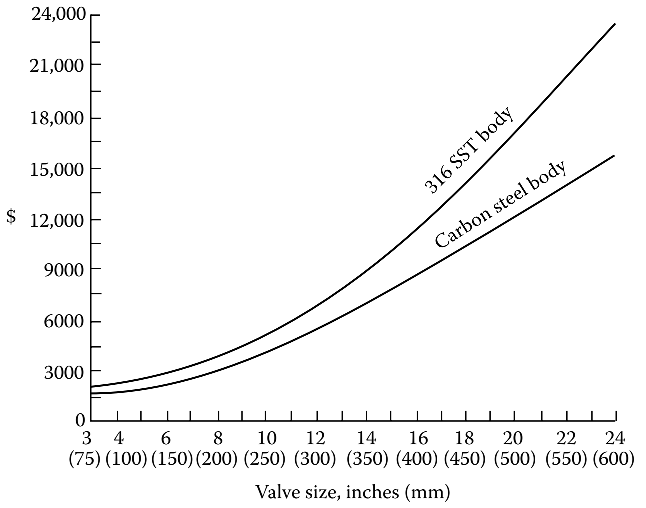

FIG. 6.17b
Approximate costs of high-performance butterfly valves provided with throttling actuators and positioners. Cost data are based upon standard high-performance, eccentric disc, soft-seat valves with double-acting piston operator and positioner. Carbon steel bodies up through 8 in. (200 mm) size have 316 SST disc and 17-4PH shaft. Above 8 in. size, discs are chrome-plated carbon steel. Stainless steel bodies have 316 SST disc with 17-4PH shaft in all sizes. Other operators can be furnished. Other alloys are available at higher cost.

play. In addition, a nonlinear relationship exists between actuator movement and the resulting rotation. These considerations make the use of positioners essential, which on fast processes can lower the quality of control.

The torque characteristics of these valves are also highly nonlinear (Figure 6.4v), and because of the high "break-torque" requirement, the actuator is oversized when operated in the throttling range. The characteristics of butterfly valves (Figure 6.17a) are somewhere between linear and quick-opening.

CONVENTIONAL BUTTERFLY VALVES

The butterfly valve is one of the oldest types of valves still in use. The dictionary defines the butterfly valve as a "damper or throttle valve in a pipe consisting of a disc turning on a diametral axis" (Figure 6.17d). Butterfly valves are not only used in industry, but variations are found in consumer products such as furnace dampers, automobile carburetors, and shower heads.

FIG. 6.17d

The vane positions of butterfly valve when closed, throttling, or open.

Wide use of butterfly valves dates back only to the 1920s, when improved designs resulted in their acceptance for public waterworks applications. The valve was particularly applicable to the low-pressure on/off service usually encountered in waterworks applications. Today's modern butterfly valve designs are suitable for a wider variety of fluid applications, including those with higher pressure drops, tight shut-off, and corrosive characteristics.

The straight-through design has a high capacity and has advantages when erosion is a consideration. Especially since the development of the eccentric shaft and disc designs known as the high-performance butterfly valve (HPBV), it is one of the fastest-growing segments of the valve industry.

Operation

Butterfly valve operation is basically simple, because it involves only rotating the vane, disc, louver, or flapper by means of the shaft to which it is fastened. This may be done manually by a lever handle on smaller valves or by a handwheel and rotary gear box on larger sizes. Automatic operation may be accomplished by pneumatic, hydraulic, or electrical motor drives attached to the shaft by various methods.

Unfortunately, some of these methods of attachment do not provide good valve control, and the design of the operator-to-shaft connections must be closely examined. For the connection, some manufacturers just use the same square shaft end and clamp with set-screw that is used on manual valves. This type of connection is very prone to "wear play," which is not acceptable for automatic control, where dynamically responsive valve operation is needed.

The proper way to make a suitable connection is by using a valve shaft with a spline end and a corresponding mating connection at the operator shaft. Linkages should be the "self aligning" ball end type for an overall "best" connection.

As the disc moves through a 90° rotation, the valve moves from fully closed to fully open (Figure 6.17d). The area open to flow increases as the disc rotates from closed to open, and this variation is used for throttling. The characteristic curve, which is a plot of the free area vs. percentage vane rotation, is shown in Figure 6.17a for a general-purpose butterfly valve and for some high performance designs.

However, modern valve operator positioners are available either with cams or signal conversion units that can be programmed to give almost any valve characteristic that is desired. For a detailed discussion of intelligent positioners, refer to Section 6.12.

Construction

Mechanically, butterfly valves vary widely in their construction features. However, common to all are the valve body, the disc and shaft, shaft support bushings or bearings, shaft packing, and a means of attaching an operator to the shaft. Butterfly valves also fall into two basic categories, swing-through and shut-off designs.

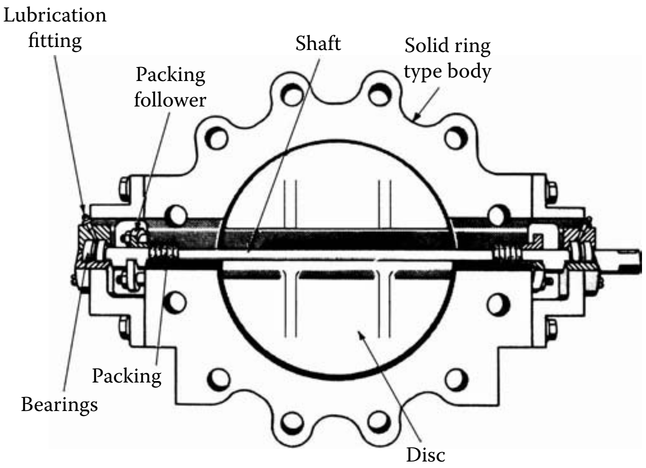

FIG. 6.17e
The design of a swing-through butterfly valve. (Courtesy of Emerson Process Management, Fisher Controls Company.)

Most swing-through designs (Figure 6.17e) have a symmetrical disc and shaft design with a certain clearance required between disc and body. The body is usually the solid ring type, which is mounted between pipe flanges. It can be either the wafer type or the single flange lug pattern, where the flange bolting also goes through the valve body.

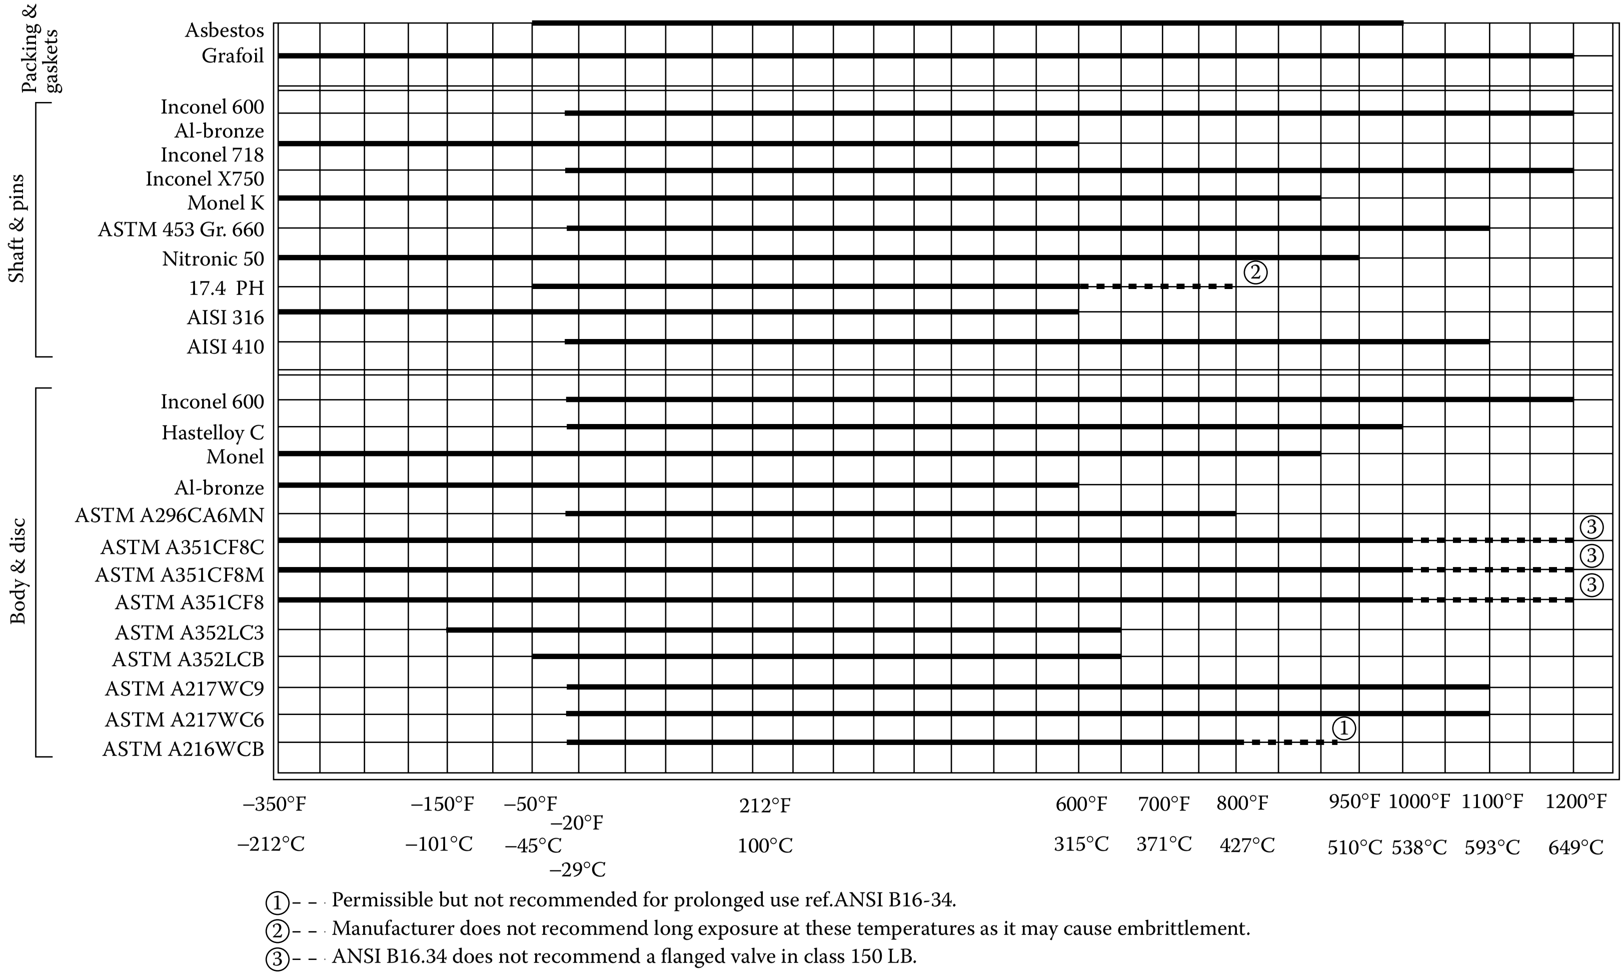
Discs are cast in one piece. The thickness of the disc and hub along with the diameter of the shaft is a function of the maximum pressure drop and torque required. Careful alignment of the body, bushings, shaft, and disc eliminates binding. Hard facing materials can be applied to the disc edge and body bore where erosive fluids such as steam are involved. Refractory-type linings are also available for the body. The operating temperature ranges of the various materials used in the construction of butterfly valves are given in Figure 6.17f.

The swing-through butterfly valve designs are available with a variety of disc shapes that serve to reduce the required torque and to increase throttling angle range (Figure 6.17g).

Swing-through butterfly valves are normally limited to a maximum throttling of angle about 70° open for the standard patterns and 60° open for the heavy patterns, due to their larger diameter shafts (Figure 6.17h). This is because the disc profile projection tends to "disappear" into the shaft area as the valve opens.

HIGH-PERFORMANCE BUTTERFLY VALVES

The most significant design advance in butterfly valves was the development of the high-performance butterfly valve. This design concept combined the tight shut-off of the lined valves, the reduced operating torque and excellent throttling capabilities of the swing-through disc shapes, and the ability to operate with relatively high pressure drops.



①- - Permissible but not recommended for prolonged use ref.ANSI B16-34.
②- - Manufacturer does not recommend long exposure at these temperatures as it may cause embrittlement.
③- - ANSI B16.34 does not recommend a flanged valve in class 150 LB.

FIG. 6.17f

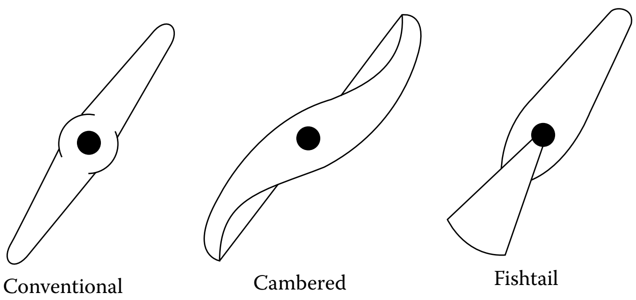

FIG. 6.17g
Cambered and fishtail disc shapes are used to reduce the required torque and to increase the throttling angle range.

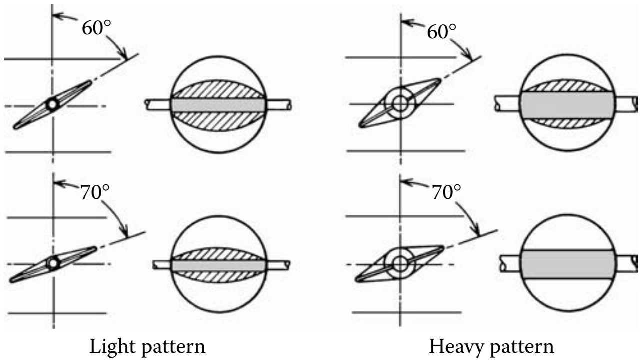

FIG. 6.17h
Effect of design pattern and shaft diameter on the flow area of butterfly valves.

The compact size, reduced weight, and lower cost have made the HPBV a formidable competitor to other control valve designs in sizes 3 in. (75 mm) and larger. There are many designs available, which usually all have the characteristics of 1) a separable seat ring contained in the body and 2) an eccentric cammed disc (Figure 6.17i). This camming action enables the disc to back out of and into the seat before and after the disc rotation when throttling. This is accomplished by having the shaft offset from both the centerlines of the disc and the valve body.

Tight Shut-off Designs

Special shut-off seals, such as piston rings for high temperatures to 1500°F (816°C) and T-ring seals for tight shut-off, are available (Figure 6.17j). These seals are not as popular as they used to be before the development of the HPBV valves and other designs with improved high-temperature seals.

Butterfly valves designed for tight shut-off fall into two categories. One is the valve that is provided with an elastomer or plastic liner. In this configuration, the disc is also encapsulated in some cases (Figure 6.17k).

The other tight shut-off design is the HPBV with the cammed disc and a separate seal ring clamped into the body (Figure 6.17l).

In addition, there are some special designs with laminated seal rings located on the disc edge that wedge into a conical seat in the valve body (Figure 6.17m). These laminated seal designs are especially suitable for high pressure and temperature shut-off.

Some time back, the lined butterfly valves were the only butterfly valves designed for tight shut-off. For their lining,

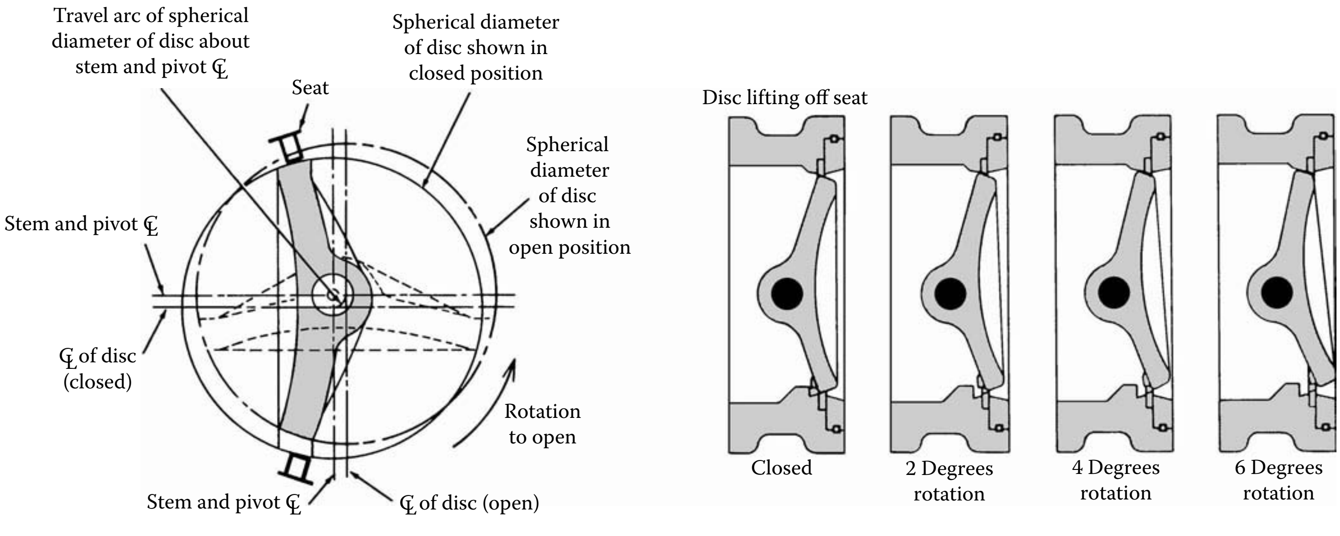

FIG. 6.17i
The high-performance butterfly valve with eccentric shaft and cam action disc operation is shown on the left. On the right it is illustrated how the disc is lifting off the seat as the valve begins to open. (Courtesy of Flowserve-Valtek, Inc.)

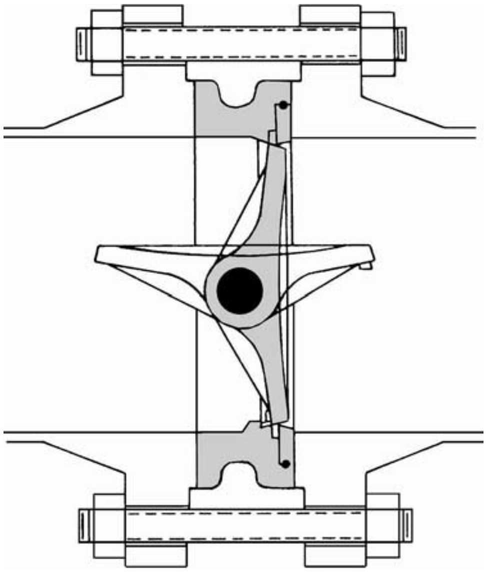

FIG. 6.17l
High-performance butterfly valve design provided with cammed disc. (Courtesy of Flowserve-Valtek, Inc.)

various elastomer materials were used, with a more rigid backup ring, which completely lined the bore of the valve and the valve gasket face area. Some liners can be bonded to the body and others are removable. Plastic liners, such as Teflon, are suitable for corrosive applications. In some cases the disc is also encapsulated in the elastomer or Teflon.

Sealing in these valves is usually accomplished by a wedging action of the disc edge into the elastomeric or plastic seat. The discs may be symmetrical on the shaft (similar to swing-through), offset from the shaft, or canted on the shaft. The objective of the latter two designs is to give a 360° seal contact on the disc edge.

Caution must be exercised in the selection of elastomers because they may be subject to attack by the process fluid. This attack may result in softening, swelling, cracking, or other effects. Plastic liners are not immune to these problems if the process fluid seeps past liner shaft seals and attacks the backing material or the body metal. By their very nature, these materials are also temperature limiting and can seldom exceed 350°F (177°C).

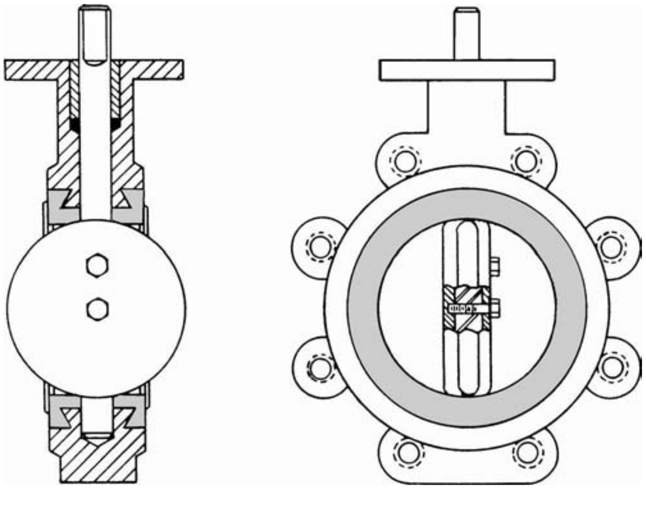

FIG. 6.17k
Lined butterfly valve design. (Courtesy of Keystone International, Inc.)

Leakage Ratings

The seat retainer rings are fastened to the body by various means. The most common method is by countersunk screws or bolts. Usually these fasteners are within the gasket area, and it is advisable to evaluate this interference in the gasket area for the intended service. Normally, this does not pose a problem, but it may require special gaskets or a change in gasket type to effect a proper seal. Other methods, such as a snap ring, friction fit, or retaining pins, do not intrude into the gasket area and may offer a better choice in some applications.

Seats are commonly made of plastic materials such as Teflon or various elastomers. Each manufacturer has a specific idea of how this seat seal should be designed and configured. These designs range from very simple to very complex shapes, and in some cases may incorporate elastomers behind the Teflon to effect a pressure-energized seal.

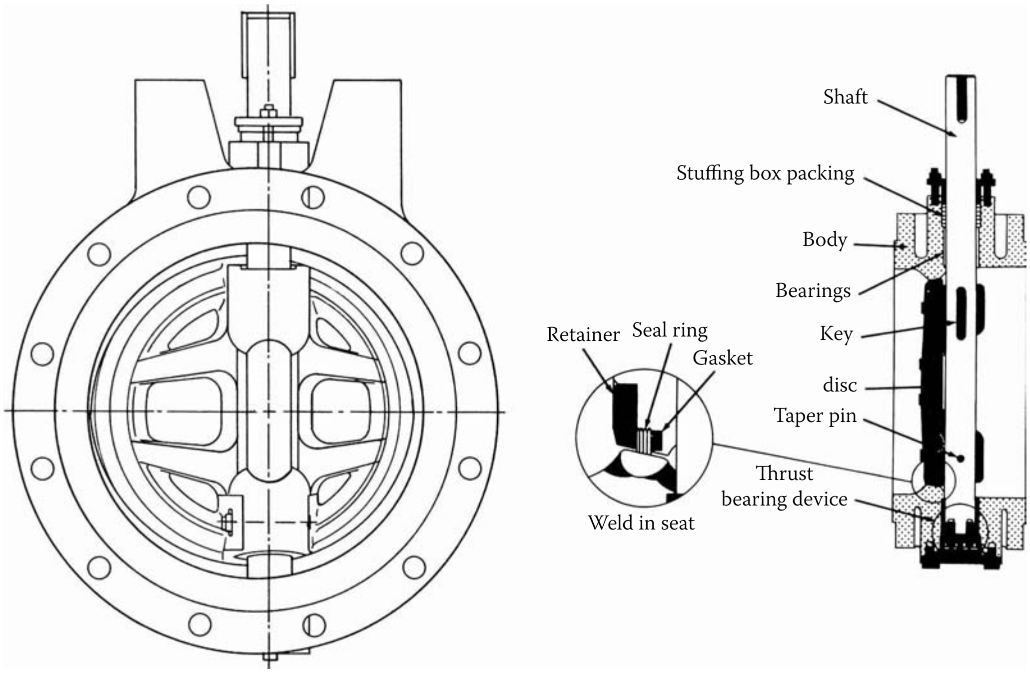

FIG. 6.17m
Eccentric disc butterfly with laminated disc seal ring. (Courtesy of Tyco-Vanessa, Inc.)

Basically, these various seat designs are all classified as ANSI Class VI, which is commonly construed to be "bubble-tight." Where temperatures are too high for the soft seat materials, metal seats are available that can also provide excellent shut-off equivalent to ANSI Class IV. Some metal seat designs can even approach ANSI Class V. Table 6.17n gives the seat leakage options for a particular HPBV design.

Fire-Safe Designs

A special design variation known as a "fire-safe" seat is also available from many manufacturers. This combines the soft seat discussed above with a backup metal seat. If the fire destroys the soft seat, the metal seat will serve to minimize leakage (Figure 6.17o). These designs also incorporate special fire-resistant gaskets and stem packing to minimize external leakage during and after a fire.

TORQUE CHARACTERISTICS

Operating torque requirements of butterfly valves require more careful consideration than do any other types of control valves (Figure 6.4v). The disc acts much like an airfoil or the wing of an aircraft. However, the special disc shapes and the HPBV designs already discussed have much lower torque requirements due to the shape effects, much like "spoilers" on an airfoil.

The conventional symmetrical disc behavior as an airfoil results in different pressure distributions around the face of the disc, producing a torque that tends to close the valve. Only at 0 and 90° are the pressures equal on both sides of the disc. Between 0 and 90° the thrust load of the disc wing turned toward the upstream side is larger than that on the downstream side. This is called the unbalanced, or hydraulic, torque, and its magnitude is a function of the pressure drop and disc diameter.

The valve operator must have enough power to overcome the unbalanced torque and, in addition, overcome the friction of the bearings and packing on the valve shaft. The total is known as combined torque. The combined torque required to open the valve is larger than that required to close the valve because the unbalanced torque helps to close the valve. This difference is known as torque hysteresis.

In fact, when the symmetrical disc closes, the torque may become negative somewhere around 30–35° from the closed position, and the valve will tend to close itself. The torque characteristics also indicate that at about a 75–80° opening, the torques for both opening and closing maximize. Above this rotation angle, the torque falls quickly to zero. Thus, the

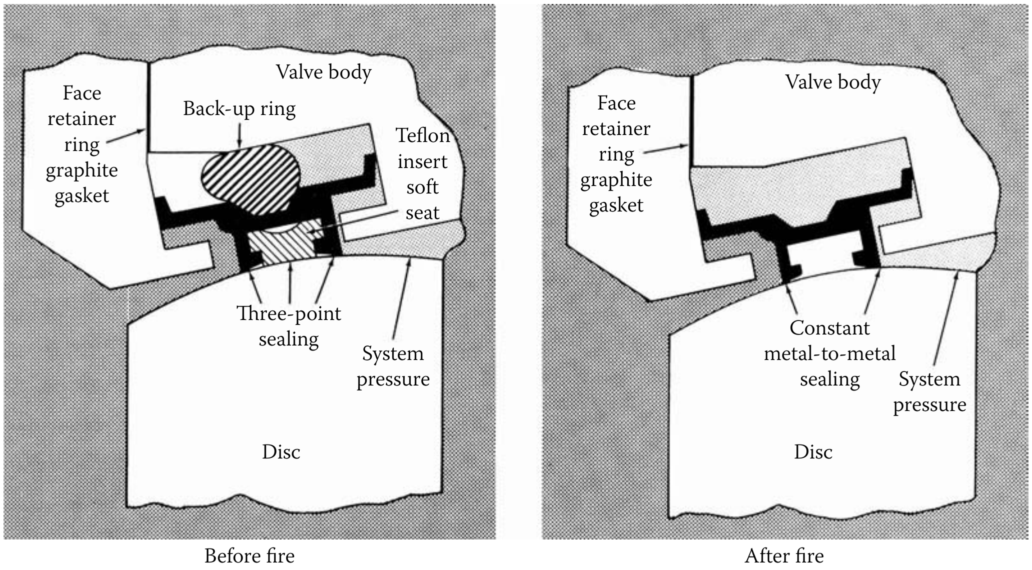

FIG. 6.17o

FIG. 6.17p
Combined torque requirements (sum of shaft friction and unbalanced torque) of a number of butterfly disc shapes at various degrees of rotation. (Courtesy of H. D. Baumann Co.)

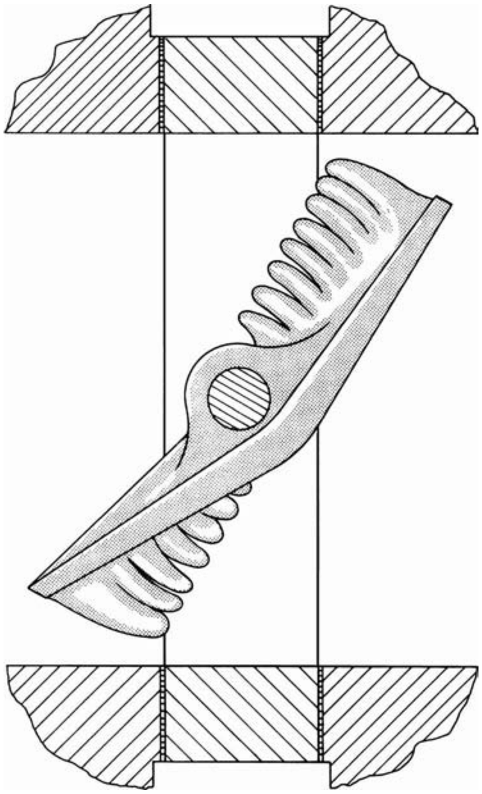

FIG. 6.17q
Substantial noise reduction can be obtained by the fluted butterfly disc design.

torque characteristics are highly nonlinear. They pose a considerable burden on the valve automatic operator, because it must cope with sharp increases and decreases in torque as well as positive and negative forces.

Typical torque curves for conventional symmetrical, special shape, and fluted discs are shown in Figure 6.17p. It should be noted that while HPBV disc designs can be considered a reduced torque disc, the amount of torque and its characteristic behavior curve is a function of whether the valve is installed with the shaft upstream or downstream. Flow tends to open the valve with the shaft downstream and tends to close the valve with the shaft upstream. However, with the shaft downstream, dynamic torques with the disc open are much lower. On gas service, the shaft can be in either location, but on liquid service the shaft should be downstream only because of the effects of liquid inertial forces.

Lined butterfly valves are not only subject to the above torque considerations but also encounter the additional torque required to seat and unseat the disc into the liner. The manufacturers usually rate the torque requirements of the various butterfly valve designs, because they are subject to so many variables. The manufacturer's recommendations should be followed for selecting the appropriate operator size required to operate the particular valve. It is best to be conservative when sizing butterfly valve operators, because operating and seating torques can often be greater than predicted.

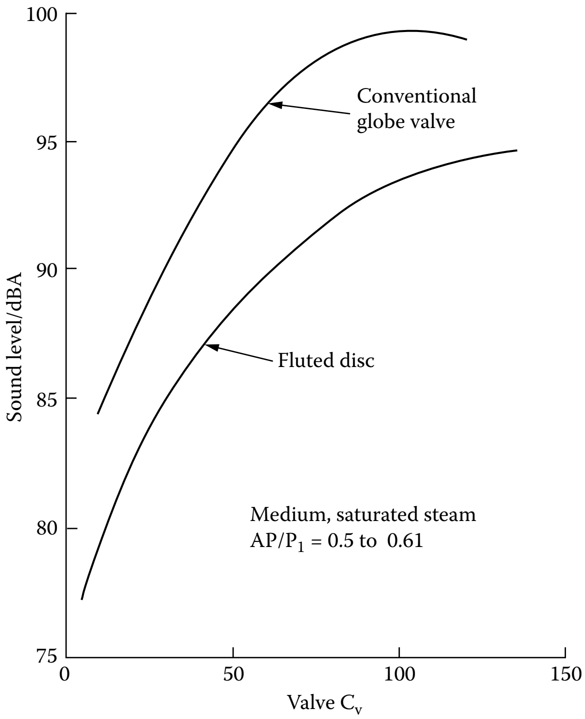

FIG. 6.17r
Noise reduction produced by a fluted disc in comparison to the noise level produced by a conventional globe valve.

NOISE SUPPRESSION

Butterfly valves will generate noise, as will any other valve when throttled at high flow rate and pressure drop, as is discussed in full detail in Section 6.14. The noise characteristics of some special disc designs, such as the cambered and the fishtail designs shown in Figure 6.17g, are improved in comparison to the conventional swing-through disc shape designs. However, with higher mass flows and pressure drops the generated noise can still be substantial.

A newer design development for the butterfly is the fluted disc shown in Figure 6.17q.

For compressible fluid applications, the fluted disc design is capable of delivering noise reductions of up to 10 dBs on the A-weighted scale (dBA), as shown in Figure 6.17r. In addition, the airfoil "spoiler" effect of the flutes enables this disc to have the lowest operating torque requirements of any disc design. It can be provided for valve sizes 2 in. (25 mm) through 16 in. (400 mm).

The fluted disc design is more expensive than others but is a very useful alternate where needed. The cost of manufacturing the noise-reduction spoilers has been somewhat reduced by relocating the flutes, as shown in Figure 6.17s.

The addition of swing-through vanes to the butterfly disc not only reduce noise emissions and cavitation, but it also increases valve rangeability and improves valve characteristics (Figure 6.17t). The valve characteristics can be changed by varying the area, spacing, and number of the flow orifices. It is possible to provide such spacing of the flow orifices that the two semispherical contours will generate near-equal-percentage characteristics. The addition of a diffuser pack (shown in Figure 6.17t) brings the characteristics closer to linear.

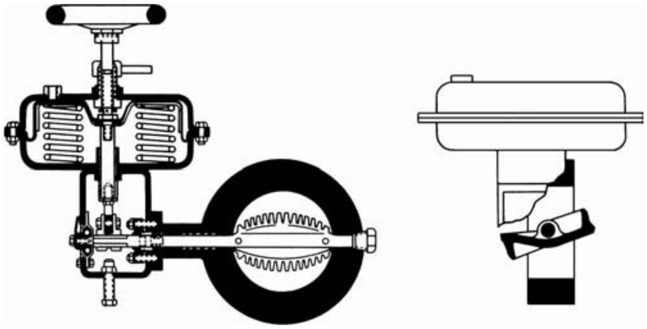

FIG. 6.17s
Flutes can be added to the butterfly disc to act as noise-reduction spoilers. (Courtesy of Flowserve-Valtek, Inc.)

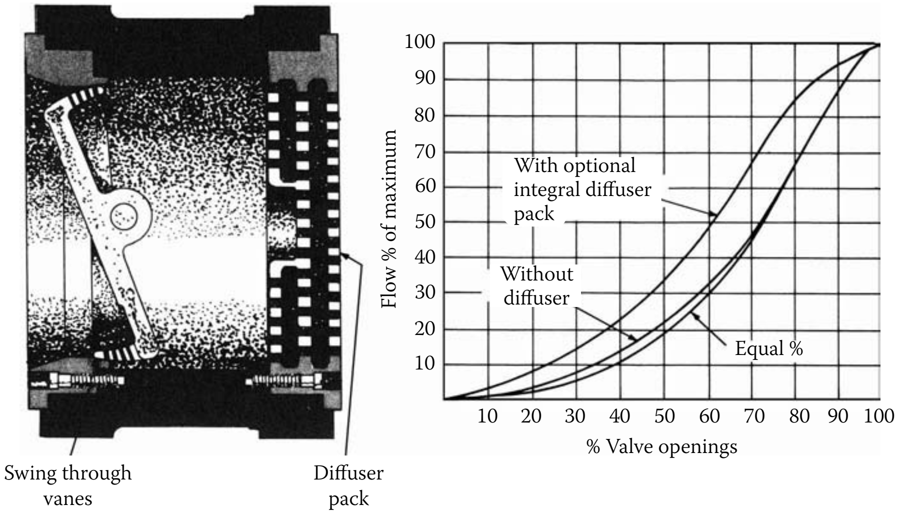

FIG. 6.17t

The addition of perforated swing-through vanes not only reduces noise and cavitation but also improves valve characteristics. (Courtesy of ABB Kent.)

Body—Aluminum, carbon steel, stainless steel, titanium
Seals—Buna, rubber, Viton, TFE, Kel-F, Derlin, Hypalon, and graphite

Cost: Typical prices for ANSI Class 600 carbon steel body, 12-bit valves are \$5000 for $^3/_4$ in. (20 mm), \$5000 to \$10,000 for 1, $1^1/_2$, and 2 in. (25, 32, 40, and 50 mm), \$12,500 for 3 in. (75 mm), \$15,000 for 4 in. (100 mm), \$20,000 for 6 in. (150 mm), and \$30,000 for 8 in. (200 mm). For 316 SST bodies, add \$1000 for $^3/_4$ in., \$2000 for 1, $1^1/_2$, and 2 in., \$3000 for 3 in., \$5000 for 4 in., \$7000 for 6 in., and \$14,000 for 8 in.

INTRODUCTION

These days, when one refers to digital control valves, people think of intelligent control valves that are provided with fieldbus interaction capability (Figure 6.18a). Fieldbus interaction is not the topic of this section; it is covered in Section 6.11. The digital control valves discussed in this section (while they can also be operated by digital networks) are multiported valves, with the number of ports ranging from 8 to 16.

A digital valve contains a group of valve elements assembled into a common manifold. The elements have a binary relationship to each other; i.e., starting with the smallest, each

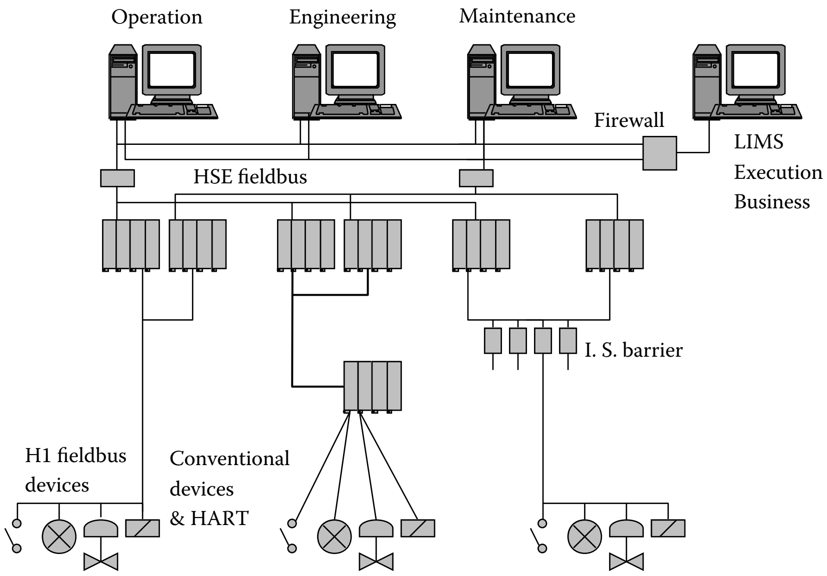

FIG. 6.18a
Networked system architecture.

increasing size element is twice as large as its next smallest neighbor (Figure 6.18b). Each element is controlled by an individual electric or electronic signal. Thus, an 8-bit digital valve requires 8 parallel, on/off electric (or electronic) signals, a 12-bit digital valve will require 12 parallel signals, and a 16-bit digital valve will require 16 parallel signals.

The main advantages of digital control valves are their speed, high precision, and practically unlimited rangeability. Their main disadvantages are their high cost and their suitability for only clean services, because the smaller ports plug very easily.

HISTORY

In the early digital control valves, the ports were distributed circumferentially, as shown in Figure 6.18c. These designs were difficult to manufacture. In the later designs the circumferential distribution of ports was replaced by top-entry, vertical ports.

Balanced Piston Digital Control

Balanced piston type designs (Figure 6.18d) are also called digital control valves, because their piston-operated main inner valve is positioned by the opening or closing of two solenoid pilots. Their advantages include their positive shutoff and fail-safe nature, as they close on loss of electrical failure. These valves provide precise flow rate and batch controls, including preprogrammed low flow start-up, high-rate delivery, and low-flow shutdown.

Top-Entry Design

An 8-bit digital valve throttles the flow by controlling the openings of eight flow elements in the valve body (Figure 8.18e) and provides a flow rangeability of 255:1. This body, an in-line, top-entry design, includes an air reservoir to ensure the fail-safe operation of the cylinder actuators. The design includes adequate manifold area to ensure consistent performance of the individual elements. The manifolds are large enough to minimize the possibility of cavitation and resulting erosion.

Each element in the array is on/off. Flow throttling is accomplished by opening enough ports to provide the exact flow area required by the controller output signal. There is a 1:1 relationship between the binary weighted signal and the binary weighted flow area. Figure 6.18b illustrates schematically the size relationship between binary elements in a digital valve.

Applications The main applications of digital valves are ones where speed, rangeability, and precision are critical. Such applications include the accurate blending and batching of both gases and liquids. The high-speed operation of compressor surge controls and all flow control applications, where the process fluid is clean and the rangeability of the

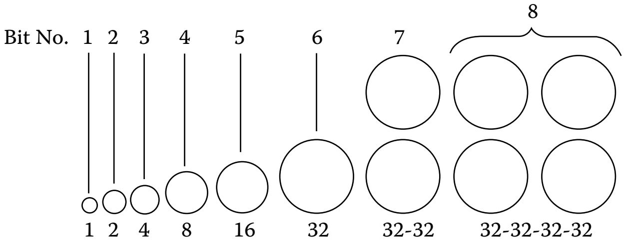

FIG. 6.18b
An 8-bit digital valve is provided with a balanced distribution of ports and guarantees a resolution of 255:1, which corresponds to a flow control accuracy within 0.39% of the total valve C_v. (Courtesy of Emco-Digital Valve.)

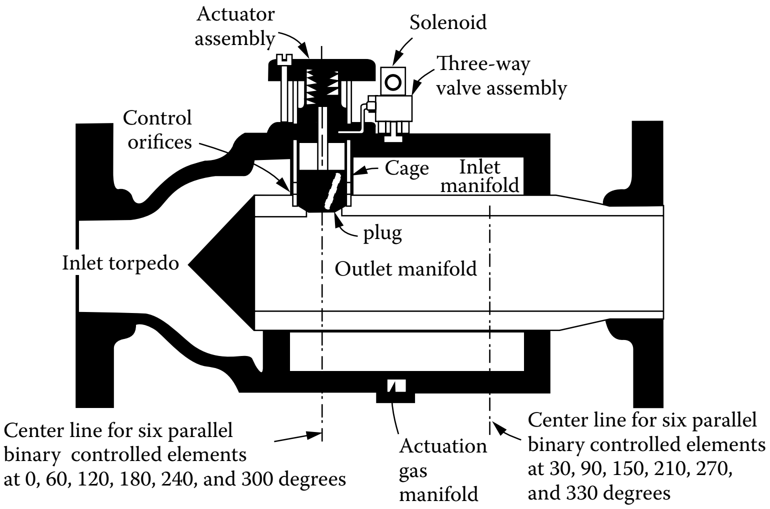

FIG. 6.18c

flow exceeds the capabilities of conventional valves. Such applications include but are not limited to environmental chamber controls, aircraft pressure cycling, and the operation of both liquid and gas provers.

Resolution and Throttling Because a binary array of 12 bits will provide resolution of 1 in more than 4000 (the area of the smallest flow element in a 12-bit digital valve is less than 0.025% of the total flow area), it is essential that the digital valve be leak-tight (Figure 6.18f). Leakage rates that are acceptable in standard globe valves would make the above-mentioned resolution impossible to achieve. It is for these reasons that digital valves are commonly manufactured to extremely high leak-tight standards.

In order to smoothly change the valve opening, say between 49% and 50%, it is usual to use two 25% elements instead of one 50% element for the largest bit. Thus, an 8-bit digital valve would have nine elements—three 25%, one 12.5%, one 6.25%, one 3.125%, one 1.56%, one 0.78%, and one 0.39% element, as was shown in Figure 6.18b.

FIG. 6.18d

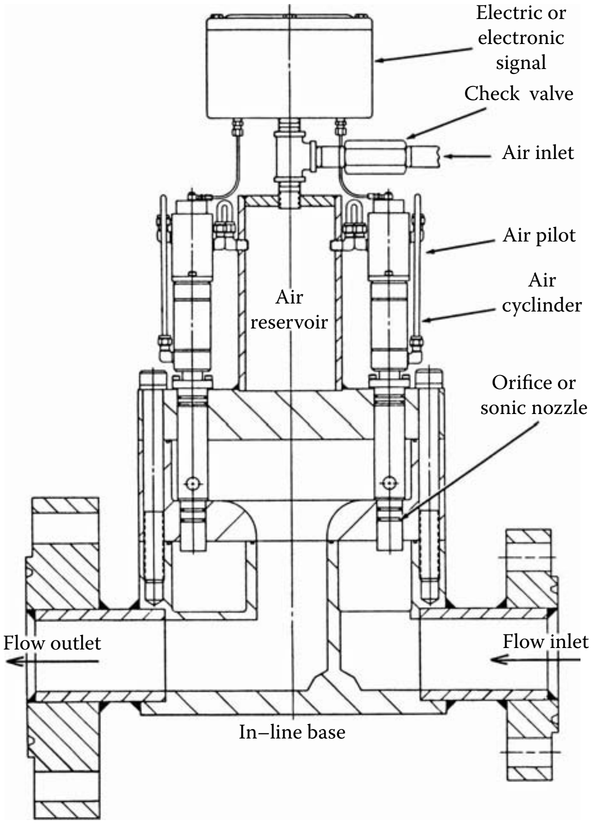

FIG. 6.18e
An 8-bit, 3 inch, carbon steel digital control valve designed for high pressure service (3000 ANSI).

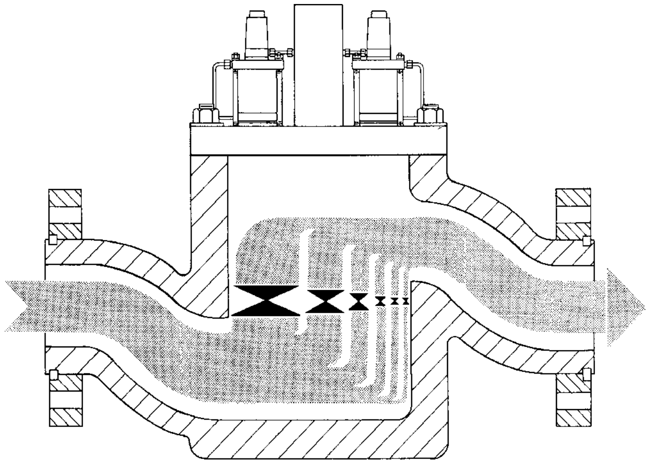

FIG. 6.18f

In a digital valve, the area of each valve port is half that of the previous port.

In higher-resolution digital valves, multiple elements are common; i.e., a 12-bit digital valve could have 16 elements, and a 14-bit digital valve could have 18 elements. The largest element then would be 12.5%. Each such valve would have seven 12.5% elements.

The 6 in. (150 mm) cast steel body digital valve (Figure 6.18g) uses 12 elements to provide 8-bit performance. The binary series of control element capacities is 1, 2, 4, 8, 16, 32-32, 32–32, 32–32. In this way no individual element handles more than 12.5% of the total flow. The largest bit (50%) is handled by four elements spread out around the body.

This arrangement improves redundancy in operation and uniformity in individual element sizing. Noise generation is reduced by breaking the flow up into many flow paths. The 8-bit computer word remains the same but operates 12 control elements.

This method of breaking the flow into many streams has a number of advantages. Each element actuator (electric, hydraulic, or pneumatic) is small and very quick. The multiple element arrangement provides redundancy, usually permitting operations to continue even if one or more elements are disabled. Flow calibration requirements are affected, because the calibration unit need be only $^1/_8$ as large to qualify 100% capacity.

Leakage, Ratings, and Speed Flow difference between individual elements is determined by the control orifice or the nozzle size. Each element consists of a plunger and a seat. The plunger is operated by a solenoid or solenoid-piloted

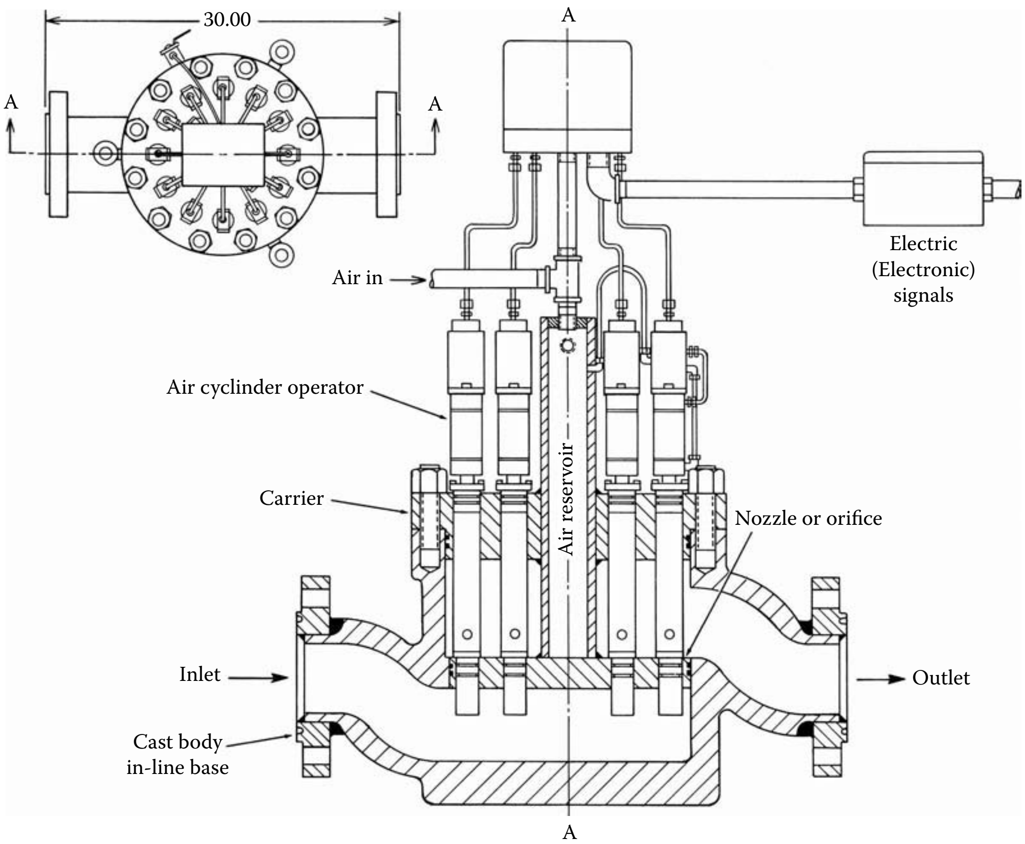

FIG. 6.18g

A 6 inch, 8-bit, explosion-proof cast steel (900 ANSI) digital valve with 12 elements. (Courtesy of Emco-Digital Valve.)

cylinder (pneumatic or hydraulic). Elements are usually dynamically balanced for low actuating force and are designed to assure tight shut-off.

Because of the necessary leak-tight construction, digital valves of very small capacity coefficients (C_v) are practical. Standard digital valve body sizes range from $^3/_4$ in. NPT (19 mm) through 10 in. (254 mm) pipe size. Pressure ratings up to 10,000 PSIG (68, 788 kPa) have been supplied.

Digital valves have been used effectively in cryogenic service, and special high-temperature models are under development (to 1250°F, or 677°C). Fluid temperatures above 450–500°F (232–260°C) require special seals and seal design.

Digital valves provide exactly repeatable performance, because each digital command causes the opening of a precisely defined port area. Nominal transfer time from any one position to any other position is usually under 100 ms, and the transfer time is uniform from one position to another.

The binary relationship between elements provides a linear increase of port area with a linearly increasing digital signal command. Any desired valve characteristic can be obtained by the correct programming of the digital control command.

FLOW METERING

A valve-flowmeter is a version of the digital valve that is equipped with flow sensing nozzles or orifices in each element (flow port).

Gas Flow

When gas is flowing through a "sonic venturi" and the inlet pressure is high enough to induce sonic flow at the vena contracta (throat) of the venturi, that condition is called "choked flow." Under such conditions, the rate of gas flow will only be dependent on the inlet conditions (i.e., absolute temperature and absolute pressure) of the flowing gas. When a "sonic venturi" is installed in each of the ports of a digital valve (Figure 6.18h), the "choked flow" at each port is independent of the downstream pressure.

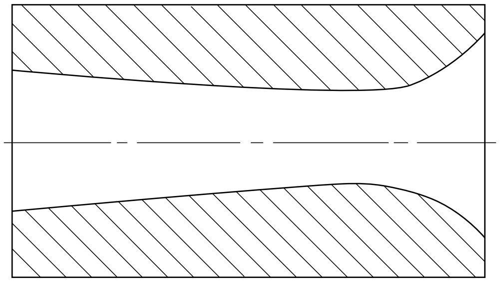

FIG. 6.18h
The sonic venturi element.

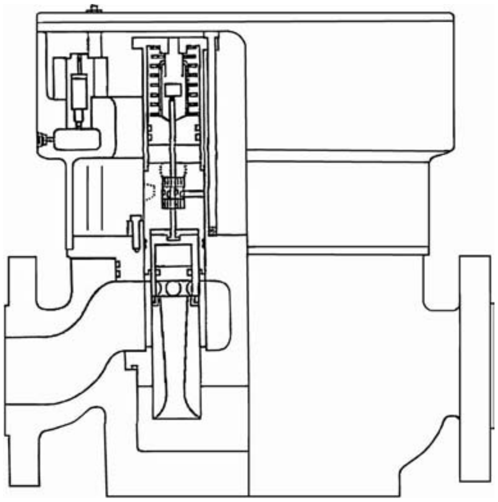

FIG. 6.18i
Extremely wide rangeability can be provided by using sonic venturi-type digital flowmeters.

As long as the downstream pressure is less than the critical pressure at the vena contracta, choked flow can usually be maintained with a pressure drop across the venturi of 15% of the inlet absolute pressure. The divergent portion of the sonic venturi recovers part of the velocity head. Thus, variations in the downstream pressure do not affect the flow rate.

The flow measurement is so accurate under these conditions that a digital valve-based flowmeter can be used as a transfer standard for calibrating other flow meters. An example of such installations is an 8 in. (200 mm) digital valve-flowmeter equipped with sonic venturis that has been installed in a power plant fuel line to act as a combination pressure regulator and fuel flowmeter (Figure 6.18i).

Liquid Flow

An orifice can be installed in each element, and the differential pressure across the digital valve can be used as a measure of the fluid flow through the open port area. Digital valves can be used as wide-range flowmeters by controlling the valve opening to maintain a constant pressure drop across the valve. Thus, a low-pressure drop-based measurement can provide a very wide flow range (up to 16,000:1 or more).

CONCLUSIONS

In summation, digital valves can provide high resolution, very fast response, exact repeatability, and very wide range. They can also be equipped with flow elements to provide both measurement and control of flow. Recommended applications are flow blending, compressor surge control, gas meter-regulators, transfer-standard flow provers, and precise liquid flow rate measurement and control. In fact they are appropriate any place where speed, accuracy, and high resolution are needed and the process fluid is clean.

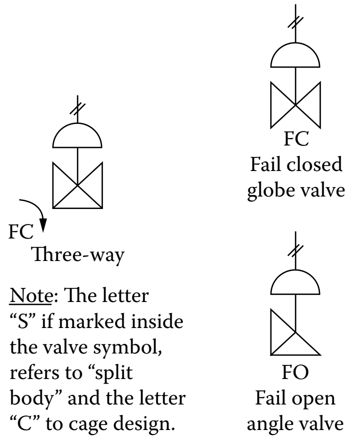
6.19 Valve Types: Globe Valves

H. D. BAUMANN (1970) **J. B. ARANT** (1985)
B. G. LIPTÁK (1995) **F. M. CAIN** (2005)



Note: The letter "S" if marked inside the valve symbol, refers to "split body" and the letter "C" to cage design.

Flow sheet symbols

Types:	A. Single-ported with characterized plug B. Single-ported, cage-guided C. Single-ported, split body D. Double-ported, top-bottom-guided or skirt-guided plug E. Angle F. Y-type G. Three-way H. Eccentric plug, rotary globe
Sizes:	A. Typically NPS 1/2 to 16 in. (DN 15 to DN 400); available up to NPS 48 in. (DN 1200) B. Typically NPS 1/2 to 16 in. (DN 15 to DN 400); available up to NPS 48 in. (DN 1200) C. NPS 1/2 to 10 in. (DN 15 to 250) D. NPS 1/2 to 16 in. (DN 15 to DN 400) E. Typically NPS 1/2 to 16 in. (DN 15 to DN 400); available up to NPS 48 in. (DN 1200) F. NPS 1 to 16-in. (DN 25 to DN 400) G. Typically NPS 1/2 to 6 in. (DN 15 to DN 150); available up to NPS 24 in. (DN 600) H. NPS 1 to 12 in. (DN 25 to DN 300)
Design Pressure Ratings:	DN = diameter, nominal—mm assumed. Typically all ratings are available from ANSI Class 150 (PN 20) to Class 2500 (PN 420) with special designs up to Class 4500; types C and H are limited to ANSI Class 600 (PN 100) PN = Pressure, nominal—bar assumed.
Maximum Pressure Drop:	Up to maximum allowed by body pressure rating depending on limitations of actuator size and trim design and materials
Design Temperature:	Depends on material properties. Generally from –20 to 1200°F (–29 to 538°C). Cryogenic designs for temperatures down to –423°F (–253°C). Special valves have been designed for operation up to 1600°F (871°C).
Materials of Construction:	*Body and bonnet materials:* Most cast and forged grades of carbon steel, low-alloy steel, stainless steel, Alloy 20, duplex stainless steel, nickel and nickel alloys, bronze, titanium, and zirconium. See Table 6.19ww. Fluoropolymer lining also available for corrosion protection. *Trim materials:* Generally available in stainless steel, nickel, nickel alloys, bronze, titanium, and zirconium. Hard facing is available for erosive applications. See Table 6.19j. *Seal and soft seat materials:* FEP, PFA, PTFE, PCTFE, ETFE, EPT/EPDM, Fluoroelastomers, Nitrile, polyethylene, polyurethane, UHMWPE, compressed graphite, and soft metals.

Leakage:	(See Table 6.1gg for FCI leakage classes.) Metal seats in double-ported designs are Class II, while in single-seated designs they can meet Class IV or Class V. Soft seats in double-ported designs can meet ANSI Class IV or V, while in single-seated globe valves they can give Class VI performance.
Characteristics:	Refer to Section 6.7 for details; see Figure 6.19a.
Rangeability:	Based on Instrumentation, Systems, and Automation Society-75.11 or IEC 60534-2-4, it seldom exceeds 30:1. Special designs can achieve 50:1 or higher by increasing precision of control at small valve openings. See the discussion under Rangeability below and Section 6.7 for details.
Capacity:	C_v/d^2 = 10 to 15 with single-ported designs closer to the bottom of the range and with double-ported and eccentric disc designs closer to the top of the range (see Table 6.19c).
Cost:	See Figure 6.19b.

VALVE TRENDS

When this handbook was first published some 35 years ago, the overwhelming majority of throttling control valves were the globe types, characterized by linear plug movements and actuated by spring-and-diaphragm operators. At that time, the rotary valves were considered to be on/off shut-off devices. Globe valves are still widely used, but their dominance in throttling control applications has been diminished by the less expensive rotary (ball, butterfly, and plug) valves as a result of improvements in rotary valve and actuator designs.

Generally, globe valves use a linear-motion stem connected to a plug head that controls the flow area through a stationary seat ring. One exception to this is the rotary globe valve, which rotates an eccentric spherical plug into the seat ring; this type of rotary stem valve will be discussed later. Unless otherwise noted, the discussion of globe valve characteristics will apply to the linear-stem globe valve.

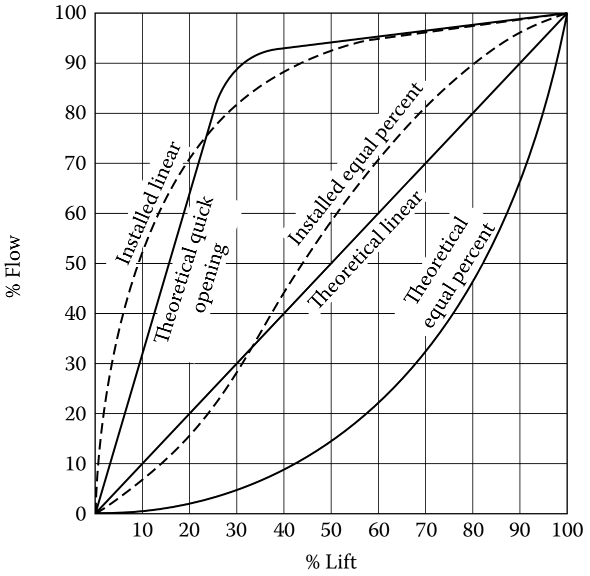

FIG. 6.19a
The theoretical valve characteristics shift as a function of installation. The dotted lines reflect such a shift in a mostly friction process where at 100% flow, 20% of the pressure drop was assigned to the control valve.

The main advantages of the traditional globe design include

1. The simplicity of the pneumatic actuator designs
2. The availability of a wide range of valve characteristics
3. The relatively low likelihood of cavitation and noise
4. The availability of a wide variety of specialized designs for corrosive, abrasive, and high-temperature or high- pressure applications
5. Relatively small amounts of dead band and hysteresis

The main reason for the increasing popularity of rotary valves is their lower manufacturing cost and higher capacity ($C_v/d^2 = 20–40$ for rotary vs. $C_v/d^2 = 10–15$ for globe). They generally weigh less, some designs can act as both control and shut-off valves, and they can be easier to seal at the stem to meet clean air requirements.

The limitations of globe valves, in addition to their higher cost per unit C_v, include their greater weight and dimensional envelope relative to their flow capacity. For the valve coefficients of globe valves, refer to Table 6.19c.

One major disadvantage of rotary valves is their higher tendency to cavitate and produce excessive amounts of noise (Section 6.14). They are also more likely, due to their smaller size per unit C_v, to have larger pipe reducers with the associated waste of pressure drop and distortion of characteristics. Their control quality can suffer from the linkages, which can introduce substantial hysteresis and dead band.

As a result of advances in distributed control system (DCS) technologies, both rotary valves and globe-style (linear) valves generally benefit from the use of positioners with either single-acting or double-acting pneumatic actuators (diaphragm or piston types). Previous problems with positioners in fast processes are largely relics of old-fashioned control systems, but much misinformation has perpetuated an aversion to positioner use on fast processes, even though DCS technology overcame these issues decades ago.

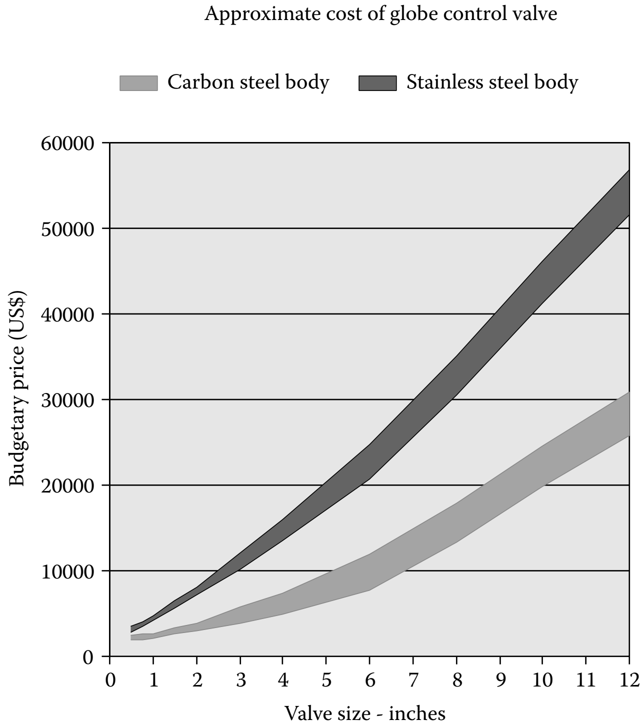

FIG. 6.19b
Approximate cost data are based upon typical globe control valves with Class 300 flanged bodies, double-acting piston actuator, and positioner with I/P transducer. As an example, Figure 6.19b would estimate the average cost of a 4 in. globe valve with a steel body and cage-type trim to be about $6000. Other actuators such as single-acting piston, spring-and-diaphragm, and electric motor drive are available. Bodies and trim are available in numerous metal alloys but usually at higher prices.

For more information about control theory in general and controller tuning in particular, consult Chapter 2, and about DCS systems refer to Chapter 4. For conventional and for intelligent positioners, refer to Sections 6.2 and 6.12 respectively, in this chapter.

TRIM DESIGNS

The valve trim consists of the internal parts contained within the body and wetted by the process fluid. The main components are the plug and stem and the seat ring(s). Some globe valve body designs also incorporate other parts such as cages or seat retainers, spacers, guide bushings, and special elements. The trim parts create the flow restriction or throttling action responsible for most of the pressure loss dissipated in the valve. The trim design also serves to determine the inherent flow characteristics of the valve. The various aspects of trim design, construction, and selection will be discussed.

Typical components that make up a globe valve are shown in Figure 6.19d. Globe valve trims are available in many design variations, depending upon manufacturer and the intended application of a particular valve. A complete discussion of every trim design variation is impossible, but those with the most general application use will be covered, including special trims for severe services such as noise, cavitation, and erosion. See Sections 6.1 and 6.14 for discussions of low-noise control valves.

Trim Flow Characteristics

All control valves are pressure-reducing devices; in other words, they have to throttle the flowing fluid in order to achieve control. The most widely used form of throttling is with a single-stage orifice and plug assembly. Multiple-stage orifice elements are usually found in trim designs for combating noise, erosion, and cavitation (Figure 6.19g). In all cases, the valve trim is the heart of the valve and operates to give a specific relationship between flow capacity and valve plug lift. This relationship is known as the valve flow characteristic and is achieved by different cage orifice patterns (Figure 6.19e) or valve plug contours (Figure 6.19f).

The term “flow characteristic” usually refers to the “inherent” characteristic, which is a function of a number of valve design and manufacturing parameters. The inherent characteristic is determined by testing the valve flow vs. valve lift using a constant differential pressure across the valve throughout the test. These types of tests are standardized by ANSI/ISA-75.02-1996 and IEC 60534-3-2: 1997.

Therefore, the manufacturers’ trim characteristic curves or tables should not be confused with the installed flow characteristic in the actual process fluid flow loop. In actual service, the differential pressure across the valve varies throughout the valve lift and flow range as a function of the system characteristics. This variation is due to such factors as pump head changes with flow, piping friction losses, and the hydrostatic resistance of pipe fittings, block valves, flow measurement devices, heat exchanges, and other system elements.

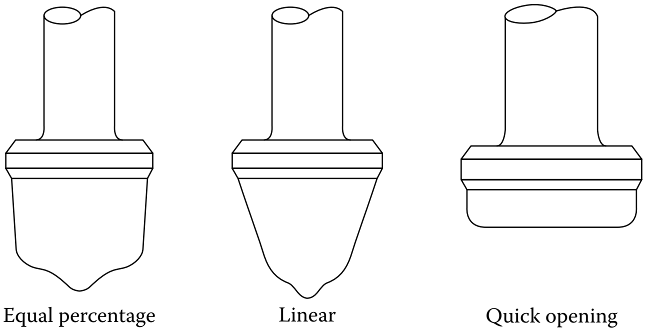

FIG. 6.19f
Valve plug shapes to produce the three common flow characteristics: equal percentage, linear, and quick opening.

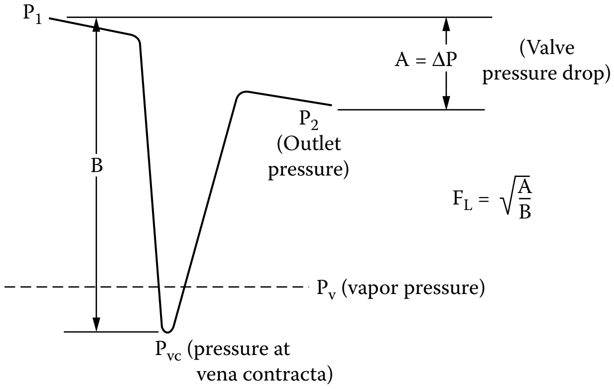

FIG. 6.19g
Pressure profile of a single-seat valve that is experiencing cavitation.

Control valve inherent characteristic data are expressed in graphs or tables, such as shown in Table 6.19c, where a flow coefficient ($C_v = K_v/1.17$) is expressed as function of the percentage of valve opening. It is important to understand the meaning of these flow coefficients. A detailed discussion of control valve sizing is provided in Section 6.15, which discusses control valve sizing. In its simplest form, the valve capacity coefficient, C_v (or K_v), for liquids can be expressed as

$$C_v(\text{or } K_v) = Q\sqrt{\frac{G_f}{\Delta p}} \qquad \mathbf{6.19(1)}$$

where Q is volumetric flow rate in gpm (or m^3/h for K_v), G_f is specific gravity relative to water, and Δp is the pressure differential (the lesser of the actual Δp or the choked Δp) across the valve in lb/in.^{2} (or bar for K_v). Important observations should be made from this simplified expression.

1. C_v and K_v are not dimensionless coefficients. They have units of (volume/time) × (area/force)$^{1/2}$ = (length)^4/[(time)(force)$^{1/2}$].
2. Valve manufacturers publish valve inherent characteristic in terms of C_v (or K_v) vs. lift (or percentage open).
3. Valve users need to know flow rate vs. lift for the installed characteristic. They must determine the system pressure differential allocated to the valve for the full range of flow rates in order to calculate the flow rate vs. lift.

Control valve manufacturers commonly furnish three types of inherent characteristic valve trims along with some minor variations (Figure 6.19a). These are idealized curves and do not accurately reflect the actual characteristic as determined by test. Examination of actual test data will show deviations in lift vs. flow of 10% or more, slope variations, and other distortions from the ideal curve.

This is due to a number of factors; in order of their significance, they include a) the trim type and design, b) valve body geometry effects, c) test variations and repeatability, and d) manufacturing variations. For practical purposes, these distortions, if kept within reasonable limits, do not materially affect the valve in actual service. Allowable limits on variations in flow characteristic are established in industry standards ANSI/ISA-75.11 and IEC 60534-2-4.

The typical inherent characteristic (i.e., C_v or K_v vs. lift) test data and pressure loss vs. flow rate data for the static elements of the process system can be used to approximate the valve characteristic behavior in the installed system. This can be used to select the best valve trim for the controlled process, which will keep the control loop gain constant or optimized for process control (see Figure 6.7a in Section 6.7).

A traditional rule of thumb is to use a linear trim if the control valve pressure drop is relatively constant (such as in pure pressure reducing). Where there is significant system and valve pressure drop variation as flow changes, the equal-percentage trim is recommended.

Rangeability

Rangeability can be expressed in different ways with different meanings. *Inherent rangeability* is the ratio of the largest controllable flow coefficient (C_v or K_v) to the smallest controllable flow coefficient within specific deviation allowances.[1]

Valve *flow rangeability*, referred to as *turndown*, is the ratio between the valve's maximum and minimum controllable flow rate at stated operating pressures. Generally, the minimum controllable flow is considered to be about twice the minimum clearance flow as the plug lifts off the seat. For single-seated contoured plug control valves, manufacturers often state inherent rangeability from 30:1 to 50:1 based on C_v vs. lift tests.

In practice, these numbers are merely benchmarks. When applied to processes with high system pressure losses, the installed flow rangeability of the control valve is more likely to be in the order of 7:1 to 15:1. This is usually enough because most processes do not operate much over 5:1 turndown. Some processes can require flow rangeability beyond the capability of one valve and will require parallel valves with split-ranging. For more details, see Figures 6.1i and 6.1j.

While linear and equal-percentage trims are designed to throttle essentially over the full valve travel, the quick-opening characteristic is designed to act more like a "bath stopper" plug. The flow characteristic develops approximately 80% of its C_v capacity in a nearly linear manner over the initial 20–30% of valve lift. The remaining capacity is added over the balance of the lift. This plug can be used for on/off service, for short-stroke valves such as self-contained pressure regulators, or in some process applications where a decreasing valve gain is required as the load increases.

---

[1] See ANSI/ISA-75.11-1985 and IEC 60534-2-4: 1989.

Standard Trim Configurations

The valve plug configurations used on modern control valves include the contoured plug, ported plug, or piston plug (see Figure 6.19e). The turned or contoured plug is probably the most common, followed by the piston and ported plugs. The contoured plug is simple to machine out of bar stock from stainless steels and special alloys and can be hard-faced easily for erosive services. The contoured plug is usually used with single-seat valves, but it is also available in double-seat designs.

The ported plugs usually have cast or forged stainless steel or special alloy heads mechanically attached to a similar stem material. They are more difficult to hard-face than designs with uninterrupted control surfaces. This plug is most common in double-seat valves, but it is also available in single-seat designs. Both the contoured and ported plugs are shaped to obtain the desired flow characteristic as they move in and out of the seat ring.

The piston plug is relatively easy to fabricate and is usually made from a hardenable type of stainless steel such as 410, 440, or 17-4PH™. Other materials such as nickel alloy 718, alloy K-500, and austenitic stainless steel with hard-facing are also available. Plug heads are usually a hardened material, or hard-facing must be done, because these plugs are normally guided in a cage assembly. The flow characteristic for this trim design is incorporated into the cage.

Special Trim Configurations

There are severe applications that may require special trim configurations. These applications usually involve noise, cavitation, erosion, or combinations of these problems. The special trim designs for all of these are often similar in concept although they will differ in design detail. Because noise is an especially difficult and complex problem to deal with, it is covered in depth in Section 6.14. The following discussion will touch upon the noise reduction trims, but will primarily concentrate on cavitation and erosion services.

Cavitation Liquid cavitation is a complex fluid dynamic reaction to pressure change, which is also discussed in Sections 6.1, 6.14, and 6.15. It has many aspects that have not been successfully explained, but the fundamentals are relatively simple. The basic process of cavitation is related to the conservation of energy and Bernoulli's theorem, which describe the pressure profile of a liquid flowing through a restriction or orifice (Figure 6.19g).

In order to accelerate the fluid through the restriction, some of the pressure head is converted into velocity head. This transfer of static energy is needed to push the same mass flow through the smaller passage. The fluid accelerates to its maximum velocity, which is also the point of minimum pressure (vena contracta). The fluid velocity gradually slows down as it again expands back to the full pipe area. The static pressure also recovers, but part of it is lost due to turbulence and friction.

If the static pressure at any point drops below the liquid vapor pressure (P_v) for that temperature, then vapor bubbles will form. As the static pressure recovers to a point greater than the vapor pressure, the vapor bubbles collapse back into their liquid phase. The cavitation process includes the vapor cavity formation and sudden condensation (collapse) driven by pressure changes. The growth and collapse of the bubbles produce high-energy shock waves in the fluid. The collapse stage of the process (the bubble implosion) produces more severe shock waves.

These implosions generate noise, fluid shock cells, and possible microjets that impinge upon the trim parts. This generates highly concentrated impact forces that cause surface fatigue and localized fractures that destroy the metal. This erosion process gives cavitation damage a very distinctive appearance, like that of cinder block or sandblasting.

No known material will withstand continuous, severe cavitation without damage and eventual failure. The length of time it will take is a function of the fluid, metal type, and severity of the cavitation. Without special trim geometry, some of the possible mitigating actions include the use of extremely hard trim materials or overlays, increasing the downstream back-pressure, or limiting the pressure drop by installing control valves in series to reduce the pressure drop in each valve.

Another mitigating effect in some processes is a result of the fluid thermodynamic properties and operating conditions. As liquid operating temperature approaches its critical temperature, heat transfer effects become increasingly significant relative to the dominant inertial effects, which causes the growth and collapse rates of cavities to slow down. This can greatly reduce impingement stresses on the valve parts. Some cryogenic and hydrocarbon applications are thought to behave this way, which may partly explain why cavitation damage in these cases is minimal or absent even when cavitation is present in the valve. Further information about cavitation and predicting its effects on valve performance can be found in Section 6.15 of this text and in the Instrumentation, Systems, and Automation Society (ISA) Recommended Practice RP75.23.01, "Considerations for Evaluating Control Valve Cavitation."

Some of the special trim designs for combating cavitation are the Drag®, Cavitrol®, Turbo-Cascade®, VRT®, Hush®, ChannelStream®, and various other staged or step-type plugs and orifices, which are shown in Figures 6.1y, 6.1z, and 6.1aa. The multihole Cavitrol-style trims are designed to break the flow into multiple fluid jets and force the jets to impinge upon themselves with extreme turbulence. This turbulence converts part of the upstream energy (static pressure) into heat energy. Bubbles from the many small fluid jets are small and tend to implode within the turbulent fluid core away from the internal surfaces, which greatly reduces trim damage. However, these trims are suitable for only moderate cavitation and moderate pressure drops.

The balance of the trims listed can be considered variations of staged trims. These trims reduce the total valve pressure drop in multiple steps such that the vapor pressure of the fluid is not reached in any stage. In some cases, the fluid is also forced to undergo multiple changes in direction to promote gradual head loss and energy conversion.

It should be pointed out that virtually all anticavitation trims are designed on the basis of data from tests with water. Therefore, actual performance with different fluids cannot be absolutely extrapolated. However, because water is one of the most destructive fluids under high pressure drop conditions, it is likely that a particular valve trim that is tested with water will be reasonably effective with most other fluids. In most applications, actual field experience is necessary to demonstrate the adequacy of a particular trim design.

Erosion Erosion of the valve trim can also be caused by high-velocity liquid impingement, abrasive particles, and erosive-corrosive combination action. Erosion damage is roughly proportional to some power (e.g., $1.4 \le n \le 6$) of velocity, which depends on the erosive environment and the boundary material. As in cavitation, one major key to the solution is to reduce the velocity through the trim. It is no surprise that the valve and trim designs discussed above are also useful on most erosion problems, although there may be some variations of design and materials of construction needed to better cope with a particular problem.

A properly chosen and specified control valve and trim type can be one of the most reliable pieces of equipment in process service. Indeed, many companies no longer use control valve bypasses, except in some unique situations. However, it is a requirement that there be close consultation with the control valve manufacturer in specification of special trims. High-velocity liquid impingement erosion is usually associated with high pressure drop coupled with undesirable valve geometry. High-velocity fluid jets developed through the seat area will often result in erratic flow patterns that allow the liquid to impinge directly on the valve trim and body. Such damage is often confined to specific areas in the valve. Liquid droplets in a vapor stream can also cause impingement erosion, but it is generally spread over a greater area. Impingement damage is characterized by relatively smooth grooves and pockets worn into the metal.

Abrasive erosion occurs when the fluid stream contains solid particles that are harder than the trim surface and are traveling at sufficient velocity. This erosion can be likened to a type of scouring action that wears away metal, similar to a file or grinder. Solutions to the problem involve the use of harder trim materials, streamlining the flow pattern, and reducing velocity. However, abrasive erosion can only be reduced in magnitude and not entirely eliminated.

Good valve and trim service life can be obtained in some cases, but in severe problems other alternatives should be considered. If the fluid and operating conditions are compatible with elastomers, it might be better to consider pinch valves (see Section 6.20). With high velocities or corrosive fluids, ceramic-lined valves or chokes can be used.

Erosion-Corrosion Metals in most ambient and process environments resist corrosion by means of a protective metal-oxide film. Rust is a form of protective film on iron and steel, even though it has some undesirable characteristics. If the protective film is damaged, worn, or dissolved, the base metal is exposed to further corrosive action and a new oxide film is formed at the expense of the base metal. Protective films can be damaged by particle abrasion, mechanical wear, cavitation, chemical attack, and fluid velocity or turbulence.

Common rust is a relatively weak film that is easily disturbed chemically or mechanically. Small additions of alloys, such as copper, to the steel can increase the stability of the iron oxide against atmospheric corrosion, such as in "weathering" steel. Substantial additions of chromium to steel create a "stainless" steel that forms a relatively strong protective chromium oxide film instead of iron oxide, which protects against further attack in a wide range of chemical environments and is referred to as the *passive* layer or film.

The flow of fluid through a piping system and especially through valves and fittings can have both electrochemical and mechanical effects on protective films. Velocity, turbulence, and impingement can increase the polarization rates of the oxidation and reduction reactions at the metal-electrolyte interface, which can weaken or dissolve metal-oxide films.

The mechanical effects of fluid velocity can more easily remove a weakened or thinned protective film, leaving the base material exposed to further corrosion. When these effects are combined in a way that accelerates the rate of corrosion from a static state, it is called *erosion-corrosion* or *flow-accelerated corrosion*. This is a complex phenomenon, and actual service experience may be needed to determine which alloys and trim configuration will give the best service.

Depending on the actual metal, chemical, and velocity characteristics of a specific application, erosion-corrosion may appear in different ways. In some cases, the eroded surface may appear like a sandy beach with wave-like ripples or ridges. When there is more direct impingement or severe turbulence, the surface might have deep gouges, undercuts, or gullies. Some cases exhibit a pattern of elongated pits. Erosion-corrosion has been observed in the following applications.

- Deoxygenated water (condensate and boiler feedwater) or wet steam in the temperature range of 212–480°F (100–250°C) in carbon steel valves and fittings of fossil-fueled and nuclear power plants
- Polluted or silty, salt or brackish waters with dissolved or entrained gases with low levels of sulfur compounds in copper, bronze, or brass systems of oilfields and wastewater applications
- Slurry flow or cavitation in stainless steel systems

Users should consult experienced corrosion specialists or metallurgists regarding alloy selection, system design, and process chemistry (or water treatment) to prevent or correct these situations.

Trim Materials

The most popular general service trim material is austenitic type 316 stainless steel, which is commonly used with and without hard-facing up to about 800°F (427°C) and in special cases up to 1200°F (649°C). Other harder materials are frequently required in special trims, higher temperatures, and trim parts that might gall because of close tolerance metal-to-metal sliding action (cage guiding and guide bushings). Among these materials are 17-4PH, 410, 416, and 440C stainless steels; hardenable Ni-Cr-Fe-Mo alloys (e.g., Inconel® 718); cobalt-chromium alloys (e.g., Stellite®); nickel-boron alloys (e.g., Colmonoy® and Deloro® hard-facing); tungsten carbide; and ceramics.

For very corrosive services, more noble or high alloy metals are used to advantage. Among these are Alloy 20 stainless steel, nickel, titanium, tantalum, zirconium, 70Ni-30Cu alloys (e.g., Monel® 400, Monel K-500), Ni-Cr-Fe-Mo alloys (e.g., Inconel), Ni-Cr-Fe alloys (e.g., Incoloy®), Ni-Mo alloys (e.g., Hastelloy®-B/B2), and Ni-Cr-Mo alloys (e.g., Hastelloy-C/C276, -C22). It is difficult to generalize on recommended materials or material combinations for valve trims because of the wide range of valve designs and process application requirements.

The specifying engineer should utilize not only his or her own knowledge, but also enlist the experience and expertise of the manufacturer and material specialists and metallurgists when needed. Fortunately, many applications are reasonably straightforward, and standard trim material combinations set forth by the manufacturer can be used.

Some general guidelines can be given for specifying trim. When specifying hard-faced plugs and seats, the plug can be supplied with hard-facing alloy on the seat surface only (Figure 6.19h). This may be sufficient if the valve is subject to high pressure drop primarily during shut-off. However, for continuous high pressure drop throttling, the full face or contour of the plug should be completely overlaid with hard-facing alloy, unless the base material is already hardened.

If the plug is stem-guided or post-guided, the lower guide area should also be hard-faced for high pressure drop throttling or if the fluid temperature is above 750°F (400°C). As with the plug, the seat ring can be hard-faced only on the seating surface or over the entire bore surfaces, depending on the severity of the pressure drop and temperature. A variety of cobalt-chromium and nickel-chromium-boron alloys are available for hard-facing. In some cases, coating techniques such as flame or plasma spraying will be used. The valve manufacturer's recommendations are valuable guidance.

Commonly used hardenable alloys for trim materials include

- 410 and 416 stainless steels hardened up to about 38 Rockwell C (HRC)
- 440C stainless steel with hardness up to 60 HRC
- 17-4PH stainless steel, a precipitation-hardened material combining good corrosion resistance with a range of tensile properties and hardness between 28 and 42 HRC depending on heat treatment

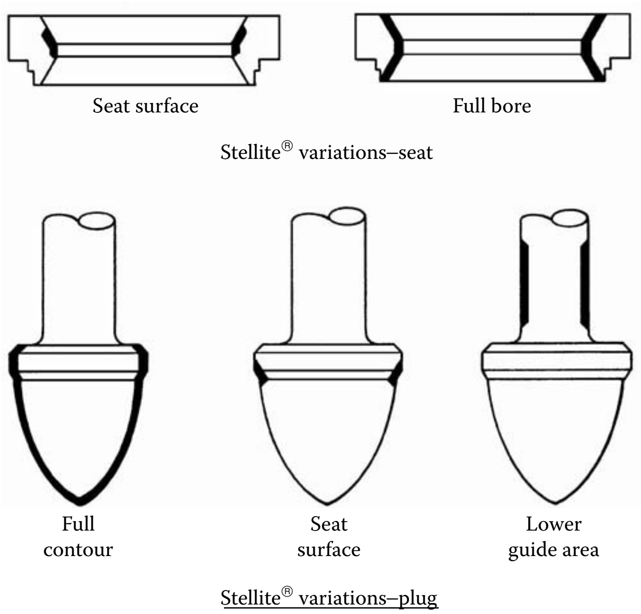

FIG. 6.19h
Hard-facing of plug and seat rings typically used in erosive services. (Courtesy of Flowserve Corporation.)

The 400-series (martensitic) stainless steels have limited corrosion resistance suitable for most water and steam service up to about 700°F (371°C). They are generally used for trim parts that can be made from bar stock or forgings, but some types are available as castings. Stainless steel 17-4PH is available in cast and wrought forms and is a usable general-purpose alloy up to 750°F (400°C). It is not as corrosion resistant as austenitic 316 stainless steel, but it is significantly better than most common 400-series types. Where 316 or other soft alloys are indicated as the proper alloy for a cage-guided trim, hard-facing will be required to minimize metal-to-metal galling problems.

Leakage

Control valves have varying degrees of shut-off capability, depending upon the valve and internal trim design, material, and manufacturing methods. Tight shut-off is not always a requirement, especially for throttling control valves. However, as reliability of control valves has increased, more applications are requiring tight shut-off for control valves in order to minimize the number of isolation valves and bypass loops. Another consideration should be the cost of lost or contaminated product and wasted energy resulting from leakage through valves. Users should consider all of these factors along with the cost and operating requirements of the valve before specifying the shut-off requirements.

Shut-off requirements are usually specified as an allowable volumetric leakage rate measured in a standardized test.

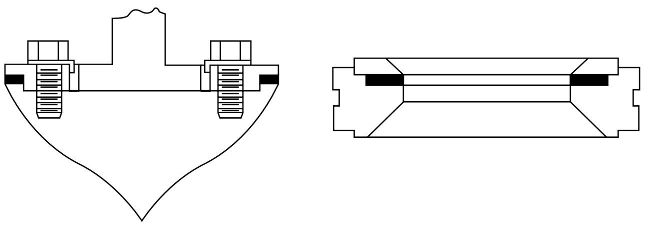

FIG. 6.19i
Typical soft-seat insert designs. (Courtesy of Dresser Flow Solutions.)

While it is permissible for a user to specify any value for the allowable leakage at a specified pressure drop, it is more common to specify one of the standard *leakage classes* defined by industry standards. The two most commonly applied standards, FCI 70-2 (formerly ASME B16.105) and IEC 60534-4, define several classes, with Classes II, III, IV, V, and VI being most commonly used for globe valves. Class V and Class VI represent the smallest allowable leakage depending on the pressure drop and test method specified. Refer to Section 6.1 for information about determining allowable leakage in each class.

Good single-seated valve trims can give Class IV or V shut-off in nonbalanced plug designs. Leakage Classes III or IV are typical for balanced plugs, but elastomer seals and special pilot-operated balanced trims have been used to achieve Class V shut-off. Figure 6.1gg gives the seat leakage class tabulation. Typically, Class VI shut-off is specified for soft seat inserts such as polytetrafluoroethylene (PTFE) or Teflon®, ETFE (Tefzel®), or other plastics.

Figure 6.19i shows two typical configurations where the soft insert can be located in either the plug or the seat ring. Class VI leakage is also achievable with special lapped-in or precision-fit metal plugs and seats.

Note that operating service temperatures, high or low, will limit the use of soft seat materials. The pressure drop across the valve is another limiting factor, although some "protected insert" designs (Figure 6.19j) will operate at very high pressure drops.

Seat leakage tests and classes are defined only for new valves, and it should not be assumed that the same level of tightness can be maintained in service. When a valve is placed in service, the seating surfaces can be worn or damaged by high velocity, pipe scale, process solids, corrosion, or vibration, which cause leakage to increase over time. Wear-resistant materials and careful installation and start-up practices can minimize wear and damage to seating surfaces.

Plug Stems

The valve stem connects the plug head to the actuator stem or coupling. It has several requirements as part of a carefully balanced mechanical system consisting of the plug head and stem, seat ring, cage, bonnet, stem bushings, stem packing, and actuator. It must be strong enough to transfer the load from the actuator to plug and bear the seat loading forces without cyclic fatigue. It must be stiff enough under maximum actuator loading to prevent buckling or significant deflections that promote packing wear and leakage. Yet it cannot be so big as to generate excessive packing friction or unnecessary static pressure forces that make actuation and control difficult.

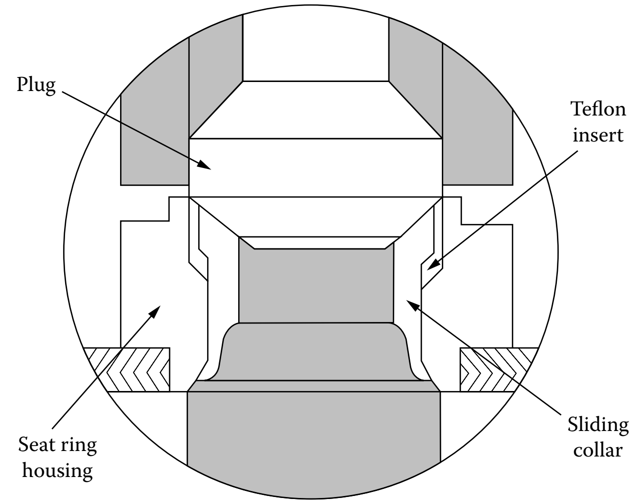

FIG. 6.19j
Protected soft seat insert for high pressure drop and tight shut-off. (Courtesy of Dresser Flow Solutions.)

The proper function of the valve also requires precise alignment of the plug and stem with the seat, bonnet, and actuator in order to prevent excessive friction and binding and to ensure minimal leakage at the seat or through the packing. Materials, design, and surface finish of the stem and bushings must prevent galling and minimize friction and packing wear. Material selection of the stem includes consideration of the process environment inside the valve, the range of environmental conditions outside the valve, and a mixture of those environments in the packing interface. In some unusual corrosive services, moisture or chemicals in the atmosphere can react with process chemicals to create a more corrosive mixture in the stem-packing interface. This situation may require a stem material with more corrosion resistance than the plug head that is exposed only to the process fluid.

Valve stems are normally the same material as the plug head, but they can be different based on the design criteria discussed above. Depending upon the type of valve design, the valve stem may be integral (one piece) with the plug, or it can be threaded into the plug and then pinned to prevent unscrewing. Because the manufacturer does a number of things to insure proper alignment and a solid, vibration-resistant threaded connection, good maintenance practice may dictate replacement as a unit rather than separate pieces.

Stem guides in one form or another are an integral part of the trim assembly. Metal stem guide or bushing material is selected to minimize metal-to-metal wear and galling

TABLE 6.19k
Common Trim Material Characteristics

Trim Material	*Hardness Rockwell C*	*Impact Strength*	*Corrosion Resistance*	*Recommended Max. Temperature*	*Erosion Resistance*
316 stainless steel (without hard-facing)	80–90 Rockwell B	Excellent	Excellent	600°F 316°C	Fair
316 stainless steel (with hard-facing)	Varies with hardfacing	Excellent	Excellent	1200°F 649°C	Excellent
410/416 stainless steel	35–42	Good	Fair	700°F 371°C	Good
420 stainless steel	50	Good	Fair	800°F 427°C	Excellent
17-4PH H1025	38	Good	Good to excellent	800°F 427°C	Good
440C stainless steel	55–60	Fair	Fair	800°F 427°C	Excellent
Ni-Cu Alloy K-500	32	Good	Good to excellent	600°F 316°C	Fair to good
Tungsten carbide	~72	Fair to good	Good (with nickel alloy binders)	1200°F 649°C	Excellent
Co-Cr-W Alloy 6 (hard-facing, cast, or wrought)	42	Fair	Good	1500°F 816°C	Good
Ni-Cr-B No. 5 (hard-facing)	45–50	Fair	Good	1200°F 649°C	Good

against the stem. For lower temperatures and light duty, nonmetallic guide bushing materials, such as reinforced PTFE fluoroplastic or compressed graphite, are common choices. Metal guides may be of such materials as 17-4PH, 440-C, Stellite, or hard-chrome plated or nitrided stainless steel, bronze, and aluminum-bronze. For the main characteristics of the common trim materials refer to Table 6.19k.

BONNET DESIGNS

The valve bonnet is the top closure assembly for the globe valve, as well as for several other valve body design types. In addition to closing the valve body, the bonnet also provides the means for mounting the actuator assembly to the valve body and sealing the valve stem against process fluid leakage. The various bonnet designs will be discussed along with the subject of stem sealing utilizing packing materials, lubricants, and special seal designs.

In addition to considerations of pressure containment, manufacturers design bonnets to provide features that predominate in their particular philosophy of valve design. The depth of the stuffing box and surface finish, provision of guides, method of operator attachment, packing design flexibility, and packing follower design are all details that vary from manufacturer to manufacturer or even among various body designs offered by one manufacturer.

Some low-pressure valves, especially in sizes below 2 in. (DN 50), can be provided with a threaded bonnet. This reduces the weight and is more economical in first cost than the flanged and bolted design. Depending on the materials of construction, it can be difficult to remove a threaded bonnet after extended service in high temperature or corrosive service, making this type more costly to maintain in these types of applications. Economic justification for using a valve with a threaded bonnet is sometimes based on a life-cost model of “discard and replace,” whereas larger valves, bolted bonnet valves, and control valves typically require a “maintain and repair” cost analysis. In special cases the bonnet-to-body joint can be seal welded to prevent leakage of highly reactive, lethal, or radioactive fluids.

Bolted Bonnets

The most common valve bonnet design is the bolted bonnet, like the one shown in Figure 6.19l. It is usually fastened to the valve body by high-strength stud bolts and heavy nuts. Removal of the bonnet gives complete access to the valve trim for maintenance purposes. Because the bonnet is a pressure-retaining part of the overall fluid containment system,

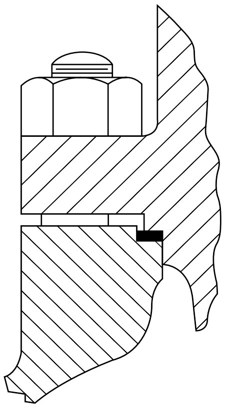

FIG. 6.19l
Bolted bonnet joint showing retained gasket design.

the design and materials are determined in accordance with an applicable pressure vessel standard. For example, the ASME Pressure Vessel Codes, ASME B16.34, API 6D, AD Merkblätter, European norms, ISO standards, and numerous individual nations' pressure vessel standards give material requirements and design criteria for flanges, wall thickness, and flange bolting.

Bonnet Gaskets The seal between the valve bonnet and body can take several forms depending upon the valve design and application range, including containment pressure and fluid temperature. Fluid corrosion is also a factor that must be considered. The most common seal is a contained gasket, either a flat or spiral-wound composite design (Figure 6.19l).

Other designs that may be found are the API ring joint (oval or octagonal cross-section), lens type, delta gasket, and Bridgeman gasket (Figure 6.19m). These latter designs are metal gaskets. The flat gasket is usually either graphite-based or a reinforced PTFE. The spiral-wound gasket usually consists of graphite ribbon or PTFE wound between thin metal strips. The metal windings of a spiral-wound gasket are usually stainless steel, but they are available in a variety of corrosion resistant and high-temperature alloys.

Asbestos fillers were commonly used in gaskets until the late 1970s, largely due to the lack of effective substitutes for many high-temperature or corrosive sealing applications. Since then, sealing materials and technologies have improved to the point where there should be no further requirement for using this potentially hazardous material in gaskets. Proper handling and disposal are required if very old valves are encountered in order to reduce the risks of asbestos exposure.

Pressure Seal Bonnets

Another typical bonnet seal is called the *pressure seal,* and it is used in high-pressure valves Class 900 (PN 150) and higher to minimize size and weight of the bonnet-to-body connection. The pressure-sealed bonnet does not rely on heavy bolting and a thick flange to retain pressure, like the bolted bonnet. Instead, a wedge-shaped graphite-composite gasket is installed on top of a bonnet sealing lip and is compressed between the bonnet and a set of antiextrusion or spacer rings and heavy retaining ring segments that are indexed into the body. During assembly, the bonnet is pulled up tightly against the seal, spacer ring, and gasket retainer segments by the pull-up bolting and bonnet retainer to create a radial seal between the body neck and bonnet, as shown in Figure 6.19n.

When the valve is pressurized in service, the upward force from pressure under the bonnet further energizes the radial sealing. The design and materials of pressure-sealed

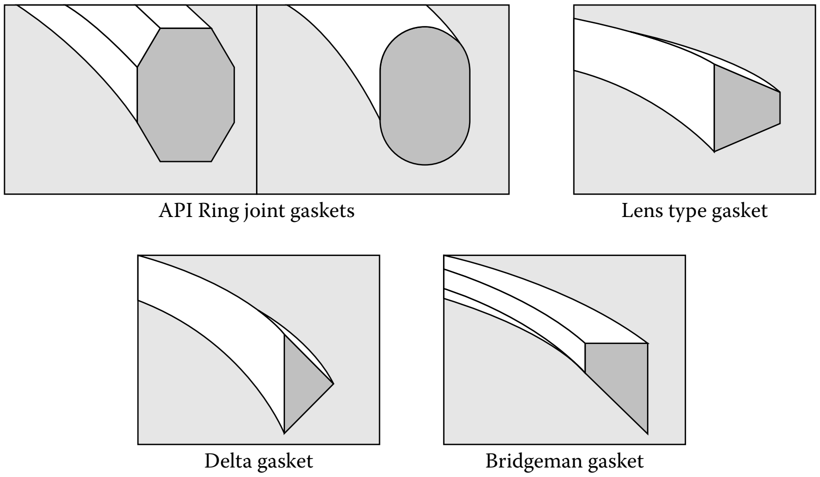

FIG. 6.19m
Special bonnet gaskets for high pressure and temperature.

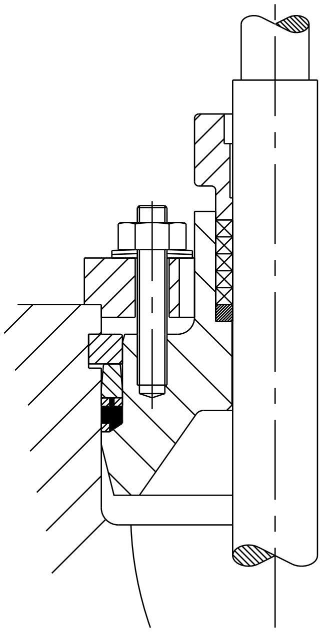

FIG. 6.19n
Pressure seal bonnet configuration showing composite wedge gasket. (Courtesy of Flowserve Corporation.)

gasket joints are especially important. If the gasket material bonds so tightly in service to the inside bore of the body that it becomes difficult to remove for maintenance, it may be time-consuming or impossible to free the bonnet without damage to the body. Fortunately, recent design and material improvements have minimized these types of maintenance problems. Pressure-sealed bonnet joints have advantages in high-pressure, high-temperature applications, because they permit more uniform body wall thickness at the body neck opening, which minimizes thermal stresses in the body during temperature transients. The valves are frequently lighter in weight than comparable bolted bonnet valves, and they are relatively easy to assemble.

Bonnet Classification

Bonnets fall into basically three classifications. These are standard, extended for hot or cold service, and special designs such as cryogenic extensions and bellows seals. These classifications along with the stem seal systems, guides, and bushings will be discussed in more detail later in this section.

Standard Bonnet The standard or plain bonnet (Figure 6.19d) is the normal bonnet design furnished on most valves. It covers the range of pressures and temperatures compatible with standard seal gaskets and stem packing materials. Generally, this includes valves designed for ANSI Pressure Classes 150 (PN 20) through 2500 (PN 420) and temperatures from −20 to 600°F (−30 to 315°C). Above 450°F (230°C) graphite-based packing or extended bonnets are recommended. The reason for setting a temperature limit for standard-length bonnets is to limit the temperatures to which the packing and actuator are exposed. Over 90% of all control valve applications can be handled by the plain bonnet design. It may or may not incorporate stem guides or bushings and may have very broad or very limited packing configurations available, depending upon the specific manufacturer and valve design.

Extended Bonnet The extended bonnet (Figure 6.19o) is usually required when the fluid temperature is outside the plain limitations of the standard bonnet temperature. Even when normal process temperatures are within the plain bonnet limits, it may be necessary to use the extended bonnet to protect the packing and actuator against temperature excursions during occasional process upsets.

Originally, the extended bonnet used different designs for hot and cold service. The hot service extended bonnet was provided with “cooling fins,” while the cold service extended bonnet was a plain casting without fins. Over many years it was demonstrated that fins on the bonnet added only marginal capability to heat dissipation in the packing area. It made a costly and complex casting and has been largely abandoned in favor of the plain extension.

In most modern control valve designs, the bonnet extension is similar for hot or cold service, except where deep cryogenic temperatures under −150°F (−100°C) are encountered. Some manufacturers offer two standard bonnet extension

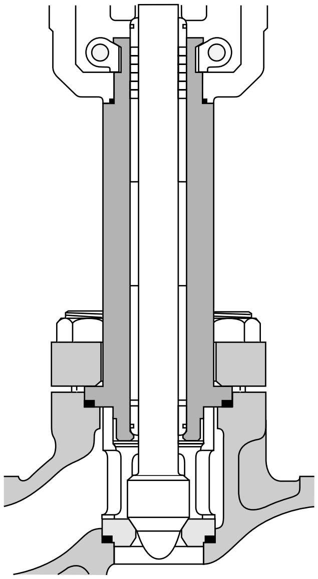

FIG. 6.19o

lengths (other than cryogenic) depending upon the operating temperature. In general, the standard extension bonnet is suitable from −20 to 800°F (−30 to 425°C) in carbon steel construction and from −150 to 1500°F (−100 to 815°C) in austenitic stainless steel construction.

Cryogenic Bonnet The cryogenic bonnet or cold-box bonnet (Figure 6.19p) is a special design adaptation of the extended bonnet. Depending upon a manufacturer's valve design, this style bonnet may be required with operating temperatures ranging from −150 to −300°F (−100 to −185°C) down to −425°F (−255°C) using a bolted bonnet. The main purpose for extending the bonnet for cold service is to keep the packing and upper plug stem warm enough to prevent icing or frost around the packing area and stem. Ice crystals on the stem can be pulled into the packing, damage the seal, and create a leak path.

The bonnet length is selected for the application based on valve body size, piping requirements, and operating temperature needs; it will generally range from 12 in. (300 mm) to 36 in. (900 mm). The standard cryogenic bonnets are distinctly different from cold-box designs or extended-neck designs (Figure 6.19q). The standard design is usually similar to the standard extension bonnet, except much longer. It can be cast or fabricated from multiple pieces by welding.

For extreme temperatures near −454°F (−270°C), the body neck is often extended to remove the bonnet gasket away from the extremely low temperature and to make the bonnet joint accessible outside of the cold-box. The extended neck of the cold-box body is usually fabricated from thin-walled stainless steel tubing (to reduce cool-down weight and heat leakage into the cryogenic process). The extension is welded directly to the body casting or forging (Figure 6.19q). At the top of the extension is the flange for connecting with the bonnet. In general, these applications are limited to ANSI Pressure Class 600 or below.

Special designs are also available for high-pressure service up to ANSI Class 4500 and above. Because the extreme cold requires good impact resistance, materials of construction are limited to the austenitic stainless steels (Types 304L or 316L) and bronze. These valves incorporate a stem seal system at the plug end of the bonnet to keep the cryogenic liquid out of the bonnet and packing area. This seal may be vented or nonvented, but it must allow a pocket of vapor to exist below the bonnet as insulation against severe convective heat loss from the warmer bonnet area if exposed to cryogenic liquid.

The seal design must also allow any build-up of gas pressure in the warmer bonnet area to relieve back into the valve body. Vented designs are typically used if the valve is installed with the neck and stem oriented vertically up to within 30° of horizontal to prevent liquid from getting to the packing area. Nonvented designs incorporate a unidirectional seal and are used when the valve neck is installed at or near horizontal. In some cases, where additional insulation is needed to reduce outside heat flow, the bonnet can be fitted with a vacuum jacket.

Bellows Seal Bonnet When no stem leakage can be permitted, many globe valve manufacturers provide extended bonnet designs that incorporate a bellows seal around the stem (Figure 6.19r). Bellows seals are justified in applications involving toxic or radioactive fluids, where leakage to the

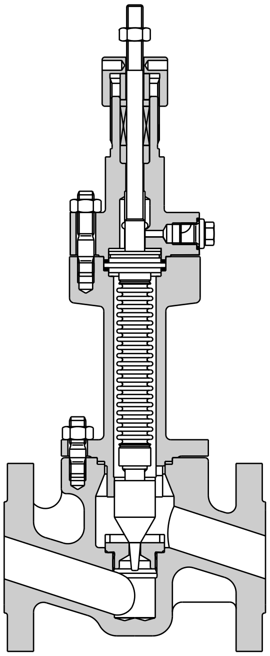

FIG. 6.19r
Typical bellows seal bonnet with formed bellows. (Courtesy of Flowserve Corporation.)

outside would pose personnel safety hazards. The bellows is usually made of stainless steel or other corrosion-resistant nickel alloys such as Hastelloy C-276 and Inconel 625. They can be hydraulically or mechanically formed (as shown in Figure 6.19r), or they can be made by stacking many individual leaf segments that are welded together at their outer edges and are known as welded or nested bellows.

The bellows is attached to one end of the stem by welding; the other end is welding to a clamped-in fitting with an antirotation device. The antirotation device prevents the bellows from being twisted during assembly and disassembly or by vibration of the plug in service.

Bellows seals are usually leak-tested from atmospheric pressure to vacuum using a mass spectrometer to detect helium leakage rates below 1×10^{-6} cc/sec. The service life of a metal bellows depends on the design, material, manufacturing processes, service pressure and temperature, corrosion effects, and stem cycle history. Failures of metal bellows usually occur by cyclic fatigue.

Bellows manufacturers that have tightly controlled production processes have cycle-tested their designs and are able to make reasonable predictions of expected cycle life. Bellows-sealed bonnets are backed up with a standard stem packing set and a leakage monitoring port between the bellows and the packing in order to prevent catastrophic release of hazardous fluid in the event of a bellows leak.

Metal bellows seals have pressure and temperature limitations. Ratings of about 150 PSIG (1030 kPa) at 100°F (40°C) or 90 PSIG (620 kPa) at 600°F (315°C) are typical. The average full stroke cycle life can vary from 50,000 cycles for size 1 in. (DN 25) and smaller valves to 8000 cycles for sizes 3–6 in. (DN 75–DN 150). In some cases, cycle life can be improved by reducing operating pressures or by using special short stroke valve plugs.

Operating pressures can be increased to as much as 2900 PSIG (20,000 kPa) and temperatures up to 1100°F (590°C) by multiple or heavy-wall bellows and selection of a high-strength metal alloy. However, this reduces cycle life considerably. As a result of these various factors, metal bellows bonnet seals are selected for relatively few applications. Improved environmental packing systems are specified for a majority of hazardous fluids, except for dangerous applications where the risks justify the additional costs of purchase and maintenance for metal bellows seals.

Bonnet Packing

In order to seal the valve stem against leakage of process fluid to the atmosphere, the upper part of the bonnet contains a section called the stuffing or packing box. This assembly consists of a gland flange, packing follower, packing spacer or lantern ring, lower packing retainer, and a number of packing rings. The surface finish of the stem should be very fine, on the order of 8 Ra (micro-inch roughness average), and the internal finish of the bonnet stuffing box should be 16 Ra or better. Various valve packing materials are available, but for control valves use three general groups of materials: fluoroplastics (PTFE, FEP, PCTFE), carbon graphite (compressed rings and braided yarn), and synthetic polymer fibers (PBI® and aramid).

Control valve packing must be compatible with the process fluid, seal the stem and bonnet, produce minimum starting and sliding friction, and give long service life in modulating service. The most popular material that meets all of these conditions over the broadest range of fluid applications is PTFE, used as V-rings or braided filament. As a result, the majority of control valve manufacturers provide a variety of packing configurations with this material.

Fluoroplastic Packing Polytetrafluoroethylene (or Teflon) is the most common packing material in the family of fluoroplastics. It is normally formed or machined as chevron or V-rings from virgin (not reprocessed) material. For special needs, a shape variation known as "cup-and-cone" is available. Note that in V-ring and cup-and-cone configurations, the top and bottom rings are adapter rings with one flat surface. Braided packing is also formed from PTFE filament. For higher temperature or pressure applications, PTFE can be reinforced or filled with up to about 25% by volume of glass fibers, silica, carbon, or graphite and other fillers to add strength and stiffness and to improve its resistance to cold-flow or creep. PTFE braided packing can be reinforced by using PBI or aramid fiber in the corner braids. As noted earlier, PTFE is limited to a maximum exposure temperature

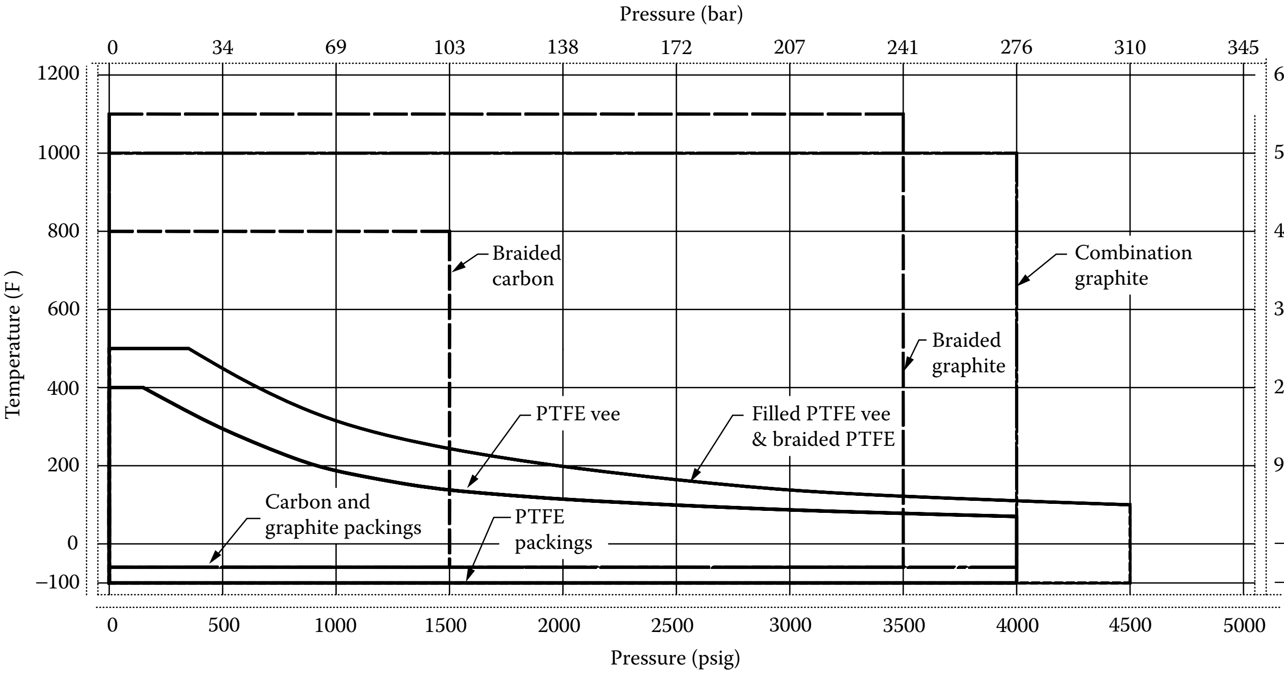

FIG. 6.19s
Recommended temperature-pressure limits for some common packing materials. (Courtesy of Flowserve Corporation)

of about 450°F (230°C) in a plain bonnet, depending on the service pressure.

When used in extended bonnets, some users have successfully used reinforced PTFE packing with process temperatures up to about 850°F (455°C), providing the packing box temperature remains below 450°F (230°C). Although PTFE packing has useable properties down to –320°F (–195°C), its practical lower limit for packing in a standard length bonnet ranges from –50°F (–46°C) to –100°F (–73°C), depending on bonnet design. See Figure 6.19s for pressure-temperature limits for PTFE and other packing in standard bonnets. In order to prevent ice damage to packing at lower temperatures, extended bonnets or cold-box-style bodies are used (Figures 6.19p and 6.19q).

Contrary to some claims, PTFE packing does not require *live-loading* springs to be effective as a stem seal. Normal packing follower loading and adjustment is all that is required, especially with the V-ring or chevron shape (Figure 6.19t). The cup-and-cone style requires a higher loading to effectively energize the seal. Live-loading springs are beneficial in special applications, such as in temperature cycling duty and for some types of environmental seals to reduce volatile organic chemicals (VOCs) and toxic emissions.

The packing rings and stuffing box dimensions should be very accurate for proper contact with the sealing lips of the V-rings. Dimensional tolerances are even more critical for the PTFE cup-and-cone rings because of the high degree of stiffness and packing loading required. PTFE packing has extremely low friction characteristics and does not require supplemental lubrication. However, excessive overtightening of the gland bolting can transform the V-ring structure into a solid compression packing capable of transferring high radial forces and excessive friction to the stem.

Asbestos Packing Asbestos is one of the oldest packing materials and was in wide use until the late 1970s, even though the health hazards of airborne fibers were known before then. Health risks were generally insignificant when handling new packing with binders to keep the fibers from fraying. However, in high-temperature service, the binders disappear, and removal of old packing from stuffing boxes

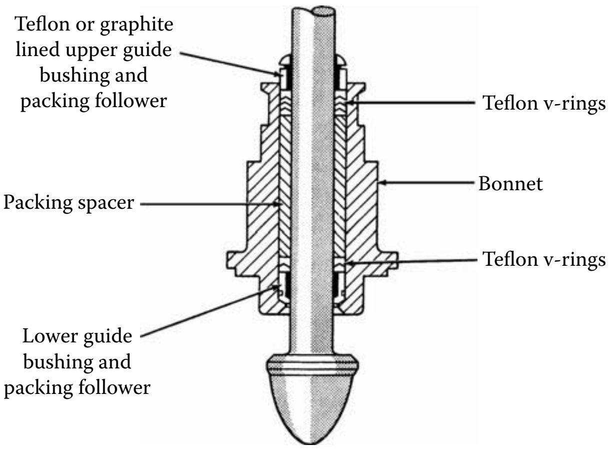

FIG. 6.19t
Typical Teflon V-ring arrangement.

had the potential of creating airborne fibers unless special dust mitigation procedures were employed. The lack of effective asbestos substitutes for many high-temperature or corrosive sealing applications made it difficult to abandon its use. Since then, sealing materials and packing technologies have virtually eliminated further need for using this potentially hazardous material. In order to reduce the risks of asbestos exposure, proper handling and disposal are required if very old valves are encountered.

Graphite Packing The improvement and optimization of graphite foil and yarn for use as valve packing came about largely out of the need to find substitutes for asbestos packing. Flexible graphite packing is available in formed rings of laminated graphite foil. Rings are formed in square, wedged, and cup-and-cone cross-sections.

A wide variety of braided constructions are available. Braided graphite can include dry lubricants to reduce friction. Braided graphite can be reinforced for high-pressure service using synthetic fibers like PBI or aramid. Reinforcing of the graphite braid with an Inconel wire core or fine wire-encapsulated yarn is common for high-temperature, high-pressure service. Several typical graphite packing configurations consist of a combination of formed laminated rings with braided rings above and below the laminated set to act as wiper rings.

Flexible graphite packing can be used in many fluids including reducing and mildly oxidizing acids (not strong oxidizers), caustics, hydrocarbons, solvents, water, steam, and gases. It has high-temperature capability up to 1200°F (649°C) in steam; and in inert, nonoxidizing media (i.e., oxygen-free environments like nitrogen or carbon dioxide) pure graphite it is useable up to 4500°F (2500°C). In atmosphere and oxidizing media, the high-temperature limit can vary between 650°F (343°C) and 850°F (454°C) depending on the specific materials; consult with packing manufacturer for specific applications. If an extended bonnet is used, the upper temperature can be extended to 1200°F (650°C) on both oxidizing and nonoxidizing service. The low temperature limit for pure graphite braided packing can be as low as –400°F (–240°C).

Packing and valve manufacturers have undertaken considerable developmental work in an attempt to overcome or mitigate past problems with graphite. Among these shortcomings are the following:

- Relatively high stem friction
- Difficulty in "energizing" the packing to give an effective stem seal
- Low cycle life without leakage
- Electrolytic pitting of stainless steel stems in conductive or high-temperature services
- Shortened packing life due to graphite plateout on the stem

There are several methods that can be used to extend the life and improve the performance of graphite packing. The packing or valve manufacturer should be consulted for proper methods for their specific sealing system. Some general things that have helped to improve graphite packing performance include the following:

1. Use combination packing assemblies consisting of laminated graphite and braided graphite fiber rings. The braided graphite rings help as antiextrusion or wiping rings and prevent graphite plateout on the stem.
2. Use sacrificial zinc washers where possible or hard chrome plating or stem materials resistant to pitting attack. Some packing include a zinc powder as anodic protection for the stem.
3. Carefully torque the packing flange nuts to the minimum torque recommended by the valve manufacturer. Overtorque will result in excessive valve stem friction and may even lock the stem.
4. Remove the packing while the valve is in storage or out of service for extended time periods.
5. Clean graphite plating from the stem before installing new packing.
6. Avoid trapping air between the rings during installation. Leave the ring level with the chamfer of the stuffing box cavity and install the next ring on top.
7. "Breaking in" new packing by tightening the gland in gradual steps while cycling the valve at least 10 times may help. A break-in lubricant applied to the packing rings and stem (e.g., nickel antiseize or silicone grease) is also recommended.

One of the oldest methods for reducing stem friction with graphite or any braided packing (such as asbestos) involved a lubricator fitting that was added to the bonnet. In this design, a compatible grease compound is injected into the *lantern ring* area by a packing lubricator assembly (Figure 6.19u). A loading

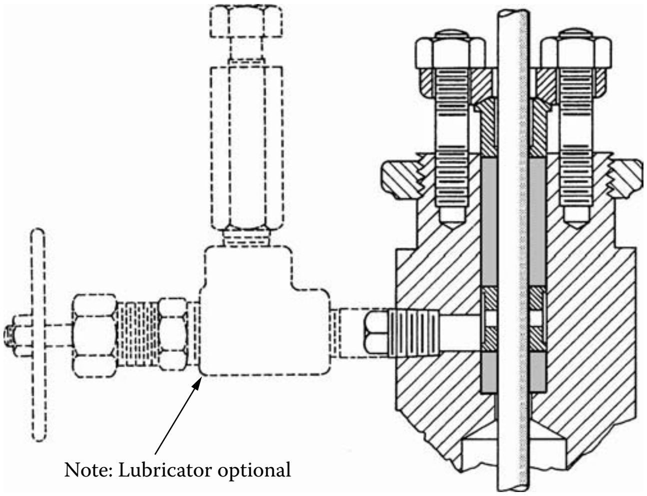

FIG. 6.19u
Stuffing box assembly with external lubricator.

bolt is turned to force the grease sticks into the packing. An isolating valve should be used for safety. External lubrication works reasonably well, although it is cumbersome and requires constant maintenance for checking and reloading of the lubricator. Also, it is sometimes difficult to find lubricants compatible with the process fluid.

Packing Arrangements There are a number of packing arrangement systems in use to suit various types of packing and fluid containment problems (Figures 6.19v). In general, the arrangements are equivalent for either Teflon V-rings or square rings (braided and laminated), although the number of rings will vary for each packing type and manufacturer's sealing system. In a standard packing arrangement, a lower set of rings serves to minimize ingress of solids from the process into the stuffing box and acts as a stem wiper. The upper set provides the primary seal and consists of several rings.

For harder-to-hold fluids or when a leak detection port, bonnet purge port, or lubricator is used, a packing arrangement known as the twin-seal is often used (Figures 6.19w). A variation of the twin seal arrangement is also recommended for vacuum service. In the twin seal, there are two full sets of packing installed. This system requires a bonnet with deeper stuffing box, because space is needed for spacers or lantern rings and a lower guide bushing as well as the packprimary stem seal. However, in vacuum service, the upper set is inverted with the V-opening toward the atmospheric side as the primary seal, because positive pressure is from atmosphere to the negative pressure inside of the valve.

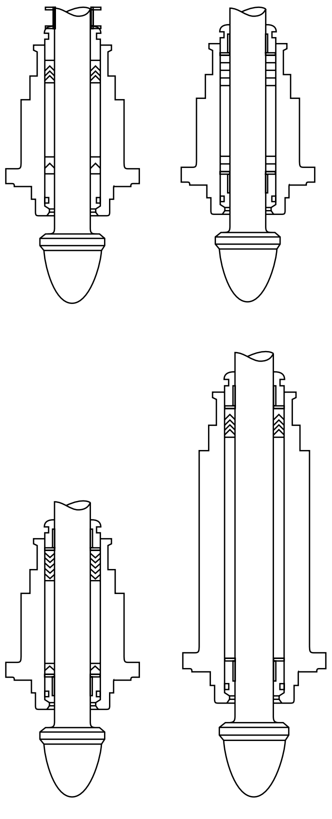

FIG. 6.19v
Typical standard packing arrangements. (Courtesy of Flowserve Corporation.)

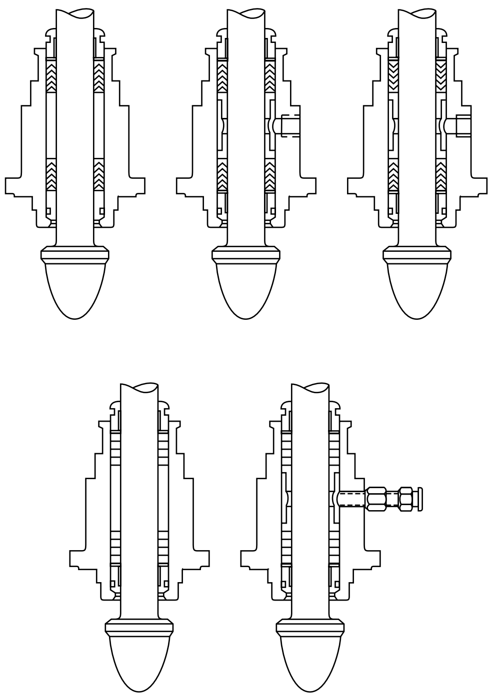

FIG. 6.19w
Typical twin- or double-packing arrangements. (Courtesy of Flowserve Corporation.)

For toxic or radioactive fluid services, the bonnet can be tapped at the lantern ring area, and this connection can be used in three different ways, depending upon specific design requirements. 1) The tap can be used for a leakage monitor connection using a pressure gauge or switch. 2) It can be used for sampling the process. 3) More commonly, the tap is used as a leak-off connection, whereby any process leakage is piped to a disposal header or nonpressurized waste container.

In cases where the fluid is a slurry or tends to solidify, the tap can be used as a purge connection to keep process media out of the bonnet. Here, an inert gas or liquid (depending upon the process) is introduced at a pressure well above the highest expected process pressure. This purge material provides an additional pressure seal, and any packing leakage will be in the direction of purge into the process or from the purge to atmosphere.

Environmental Packing The need for more aggressive protection of the environment against volatile organic chemicals and clean air regulations in Europe (e.g., TA-Luft standards), United States (e.g., EPA standards), and most other countries have motivated the development of special packing configurations and

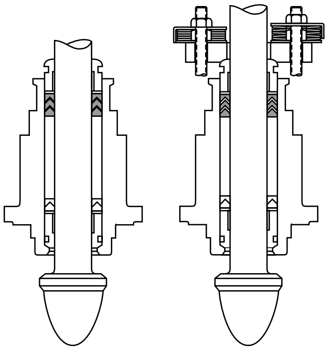

FIG. 6.19x
Typical configurations of environmental (fugitive emissions) packing. (Courtesy of Flowserve Corporation.)

materials. These regulations generally establish compliance below benchmark levels varying from 500–100 parts per million (ppm) of VOC. Figure 6.19x shows only two of many different environmental packing system designs.

Environmental packing systems often consist of a combination of ring designs and different materials. For low to moderate temperatures, a common packing set can have unfilled PTFE or chemically inert elastomer V-rings stacked between stiffer thermoplastic or reinforced PTFE chevrons for a tighter and more durable seal. For higher temperatures, various combinations of graphite braided rings with laminated graphite rings (square, wedged, or cup-and-cone) are used. Any of these configurations can include live-loading spring arrangements to help maintain constant packing loads and make up for consolidation or cold-flow of the packing over time. Antiextrusion rings are also used in some systems to promote longer packing life. Most valve manufacturers offer a variety of environmental packing styles to suit a wide range of applications.

Other Packing Materials Elastomeric O-rings are used for stem sealing in some globe valve designs, usually for less low-pressure, low-temperature utility services such as water. O-ring stem packing tends to be more common for rotary valves than for sliding stem valves. Proper selection of an elastomer that is compatible with the process fluid chemistry and temperature can also be a problem. In gas service or with liquids containing gases, many elastomers will absorb some gas. Depressurizing the valve will result in sudden expansion of this gas. If the gas cannot diffuse rapidly out of the elastomer, the resulting internal pressure can rupture or split the O-ring. This effect is called explosive decompression (ED). Most O-ring manufacturers now offer special grades of some elastomers that are resistant to ED failures.

The O-ring gland design requires a fully retained groove and probably backup rings to minimize extrusion or blowout. Installation of O-rings requires great care to avoid cutting, twisting, or other damage. Lubrication may be needed to overcome sliding friction, and gradual loss of this lubrication in service can cause excessive O-ring wear or sticking in dry service. A standard stem seal packing ring system is usually preferred in sliding stem valves.

Packing Temperature The relationship between the process and the packing temperature is a function not only of the type of bonnet used but also of the valve metallurgy and the valve and bonnet physical relationship. Heat is transmitted to the packing area by conduction through the metal, by convection via the process fluid, and by the relative heat radiation balance with the ambient environment. Stainless steel, for example, has a much lower heat conductivity coefficient than carbon steel and thus is about 20–30% less "efficient" in conducting heat into the packing area. This does not mean that the packing temperature rating can be increased, but it may serve to reduce some heat load and increase packing life. (See Figure 6.1o in Section 6.1 for further discussion and illustration of packing temperature determination.)

In some cases, the valve can be installed upside down so that the bonnet is below the valve body. In liquid service, this reduces convection, and heat is transferred to the bonnet mainly by conduction. In vapor service (with or without superheat), it may be possible in the stem-down orientation to condense sufficient vapor in the bonnet to create a condensate seal and lower the packing temperature to a suitable level. The potential corrosive effects of alternate wetting and drying must be considered with this approach. However, this approach to controlling packing temperature has serious disadvantages where maintenance is concerned, and the benefits generally do not justify the potential maintenance difficulties except in unusual cases.

BODY FORMS

The actual pressure containment and fluid conduit portion of a control valve is called the valve body assembly. This assembly consists of the body, a bonnet or top closure, sometimes a bottom flange closure, and the internal elements known as the trim. The body can have flanged, threaded, or welded end (butt weld or socket weld) connections for installation into the piping. The trim consists of such elements as the plug and stem, guide bushings, seat rings, cages or seat retainers, and stuffing box lantern ring.

The body configuration can be in-line, angle, offset in-line, Y-type, and three-way. Some of these will be discussed in more detail.

The shape and style of the valve body assembly is usually determined by the type of trim elements it contains, piping requirements, and the function of the valve in the process system. There are a large number of body designs on the market, including a number of special-purpose designs. The end result is a device that can be fitted with an actuator and used to modulate the flow of process fluid to regulate such things as pressure, flow, temperature, liquid level, or any other variable in a process system. Examples of some of the more widely used body configurations are shown in Figure 6.19y.

Double-Ported Valves

The double-ported (double-seated) balanced valve (Figure 6.19z) was one of the first globe valves developed during the early 20th century. It is still available today, but has been replaced in most applications by single-seated globe valves. Size for size, it is much larger and heavier than its single-seated counterpart. Shut-off is poor because it is not practical to have both plugs in tight contact with the seats at the same time, but the valve was intended for throttling control rather than for tight shut-off. Some special seat designs have been developed to help overcome this, but application is limited.

The double-ported valve is considered semibalanced; i.e., the hydrostatic forces acting on the upper plug partially cancel out the forces acting on the lower plug. The result is less actuator force requirement, and a smaller actuator can be used. However, there is always an unbalanced force due to the difference between the upper and lower plug diameters required for assembly. In addition, unbalance forces are generated by the effect of dynamic fluid forces acting on the respective throttling areas of each plug. Such forces can be quite high, particularly with the smooth contoured plugs; these can reach as much as 40% of the forces of an equivalent unbalanced single-seated valve plug. Double-ported valves have been built in sizes up to 24 in. (DN 600), although most manufacturers now limit them to 12 in. (DN 300) as a maximum.

Figure 6.19z shows that the valve can be converted from the push-down-to-close configuration shown to a push-down-to-open design. This is done by removing the bottom closure flange, bonnet, and stem, and by inverting the entire assembly and reinstalling the stem, flange, and bonnet. This, coupled with the use of direct-acting (air pushes the stem down) and reverse-acting (air pushes the stem up) actuators, gives full flexibility to provide the required valve failure mode.

Single-Seated Valves

Single-seated valves are the most widely used of the globe body patterns. There are good reasons for this. They are available in a wide variety of configurations, including special-purpose trims. They have good seating shut-off capability, are less subject to vibration due to reduced plug mass, and are generally easy to maintain. There are three general types of seat construction.

1) The *floating seat ring* sits in machined bore in the body with a gasket to seal the joint between the body and seat ring. It must be retained in the body by a cage or seat retainer to maintain gasket tightness and concentricity with the plug. 2) The *screwed-in seat ring* is threaded into matching body threads with a special tool; a gasket may or may not be required. A separate seat retainer is not required, but some designs use a cage for guiding the plug or characterizing the flow. 3) The seating surface can be machined directly into the body; this is called an *integral seat*. The floating and screwed-in seat rings can be replaced after they wear out, but the integral seat requires resurfacing or machining of the body to repair wear or damage.

Single-seated valve plugs are guided in one of four ways: post-guided (Figure 6.19aa), top-and-bottom-guided (Figure 6.19bb), stem-guided (Figure 6.19cc), and cage-guided (Figure 6.19dd). The most popular globe valves are stem-, cage-, or post-guided types, which require only one body opening for the bonnet and have one less closure gasket subject to leakage than the top-and-bottom-guided configuration.

The stem-guided and post-guided designs provide more streamlined flow and are less subject to fouling in dirty service. The stem-guided valve minimizes stagnant fluid cavities and may be a better selection than the post-guided and cage-guided valves when dealing with fluids containing solids, sticky or viscous fluids, or highly corrosive fluids. The top-and-bottom single-seated valve (Figure 6.19bb), like its double-seated counterpart (Figure 6.19z), has similar limitations, but some users still prefer this design where the plug is held by two, widely spaced bushings. The top-entry single-seat globe valve is most commonly used in sizes from 1 in. (DN 25) through 12 in. (DN 300) from most manufacturers.

Some top-entry designs are manufactured with bodies suitable for slip-on flanges (Figure 6.19y) rather than with integral cast flanges. This type of flange construction is discussed in more detail below, under Split-Body Valves and Valve Connections.

Cage Valves The cage valve is a variant of the single-seated valve and is the most popular design used in the process industries. The top-entry bonnet and trim design makes it extremely easy to change the trim or to do maintenance work. Cages are used with floating seat rings and with screwed-in seat rings. The design is very flexible in that it allows a variety of trim types to be installed in the body. This includes such variations as reduced trim, anticavitation, and low-noise trims (Sections 6.1 and 6.14).

The overall design is very rugged, and with proper specification of trim type and materials, cage valves provide relatively trouble-free service for extended time periods. These valves may eliminate the need for block and bypass valves in some cases, because their service life can be as good as or better than most other components in the process that require periodic maintenance.

There are two basic design configurations available for cage valves. One type uses the cage solely as a seat retainer to clamp a floating seat ring into the valve body (Figure 6.19cc). This design is usually stem-guided or post-guided, and the valve plug is characterized and does not guide or control flow through the cage.

The other type uses the cage to guide the plug head, and the cage openings are shaped to provide the desired flow characteristic as the valve plug exposes the ports (Figure 6.19dd), and it is called a *cage-guided valve*. In the cage-guided valve,

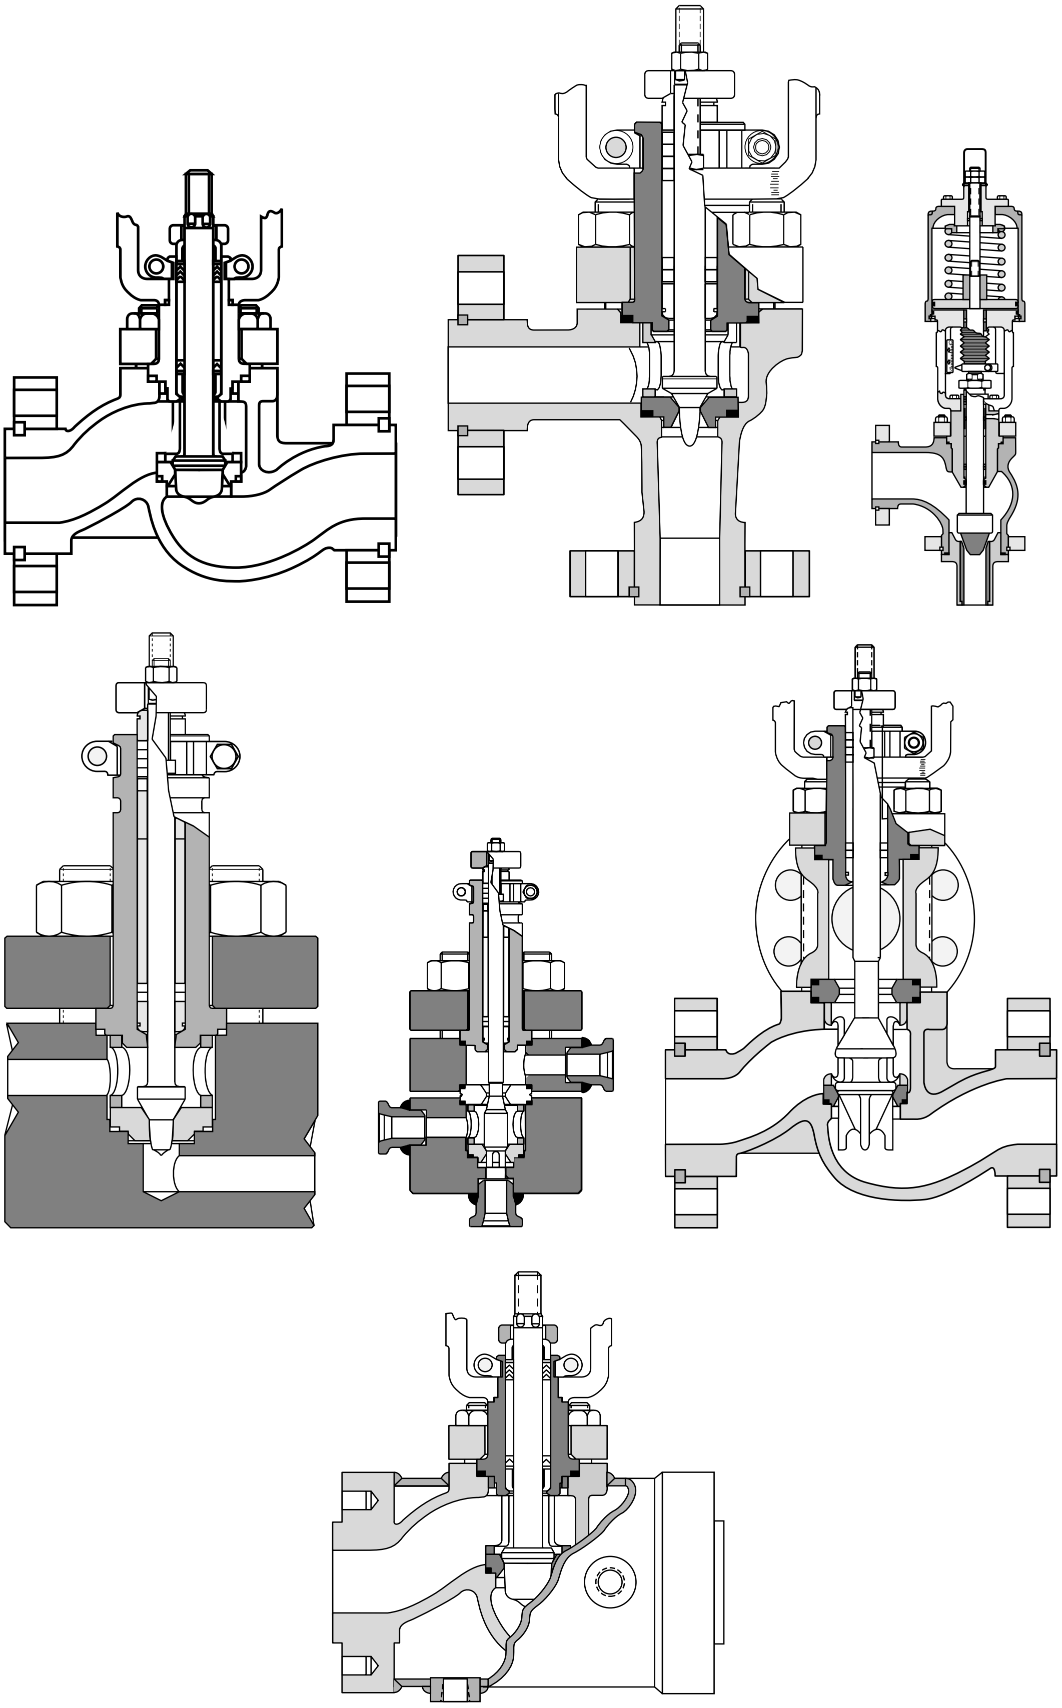

FIG. 6.19y

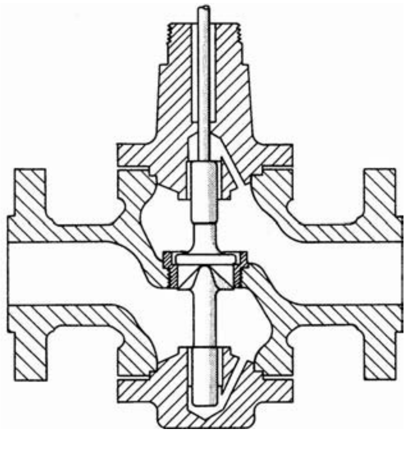

FIG. 6.19bb
Top- and bottom-guided invertible single-seated globe valve.

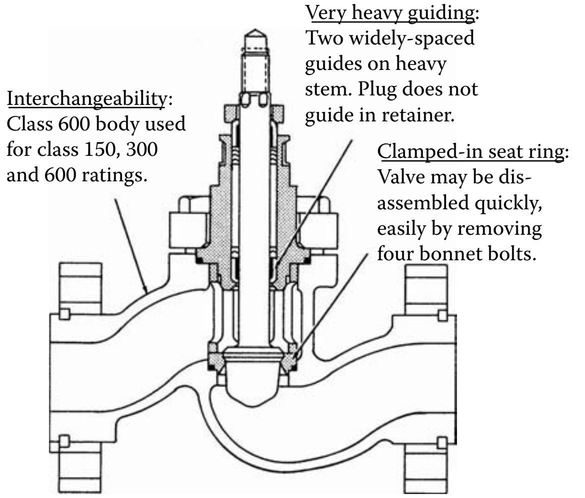

FIG. 6.19cc
Cage valve with clamped-in seat ring and characterized plug. (Courtesy of Flowserve Corporation.)

the cage may be used to clamp a floating seat ring, or it may be used with a screwed-in seat where the cage is part of the bonnet assembly. Both of the above cage designs are usually provided in smaller valve sizes with unbalanced plugs for best shut-off.

The stem-guided design (Figure 6.19cc) has advantages when handling fluids with solids, sticky fluids, fluids that coat or plate out onto the trim, and corrosive fluids. This is because the large plug-to-cage clearances in the stem-guided design are not sensitive to debris or build-up, and corrosion-resistant trim materials (316 stainless steel and nickel alloys) are more practical to use without special treatments to prevent metal-to-metal galling.

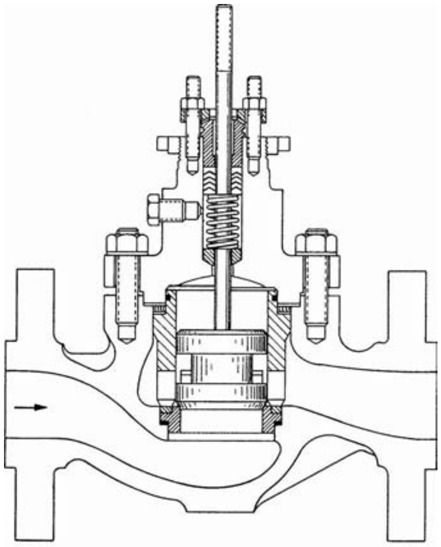

FIG. 6.19dd

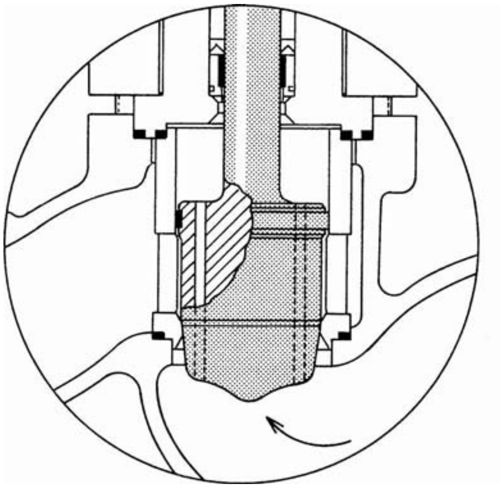

FIG. 6.19ee
Cage valve with balanced and characterized plug. (Courtesy of Flowserve Corporation.)

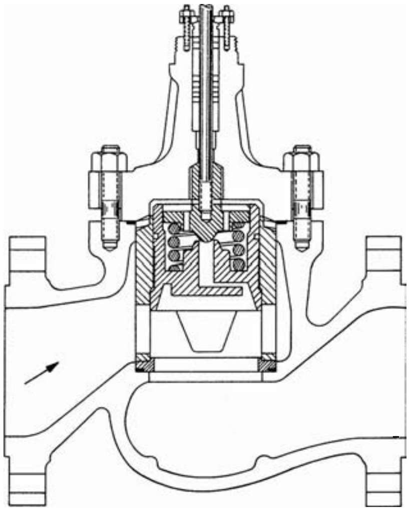

FIG. 6.19gg
Cage valve with pilot-balanced construction and characterized cage ports. (Courtesy of Dresser Flow Solutions.)

Tight clearances are required in the cage-guided version, which requires that metal surfaces must be hardened by heat treatment, hard-faced with Co-Cr or Ni-Cr-B alloys, plated with hard chrome or electroless nickel, or surface treated (e.g., nitriding) to eliminate metal-to-metal galling.

Pressure-Balanced Valves Pressure-balanced trims are also available in stem-guided (Figure 6.19ee) and cage-guided (Figure 6.19ff) versions.

Pressure-balanced designs help provide better control of high-pressure drops, reduce the magnitude of unbalanced plug forces, and help to reduce actuator size. The balanced plug designs can be provided with a variety of balance seal styles and materials to meet service conditions. These may be plastics such as PTFE, elastomeric O-rings, and metal piston rings. Generally, the use of balanced plugs will degrade the valve shut-off capability to some degree. For example, an unbalanced valve rated for Class V shut-off may drop to Class IV with balanced trim. This is due to leakage past the balance seal. (Refer to the discussions on leakage in this section and in Section 6.1.)

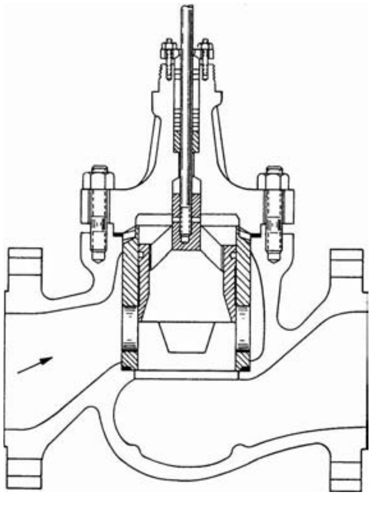

FIG. 6.19ff
Cage valve with balanced plug and cage port characterization. (Courtesy of Dresser Flow Solutions.)

One variation of the pressure-balanced plug that has improved shut-off capability is shown in Figure 6.19gg. This is called the *pilot-balanced* plug. This design is particularly helpful when dealing with high-temperature, high-pressure drop situations when tight shut-off is difficult to achieve without the use of elastomeric seals. When the valve is shut off, the actuator has compressed the pilot spring and closed the pilot.

There is provision for a pressure path from the upstream pressure side of the plug to the area above the pilot plug, allowing upstream pressure on the upper plug area to assist the actuator in achieving a tight shut-off. In the shut-off position, there is no pressure drop across the conventional balance seals. When the actuator begins to open the valve, the stem first lifts the small pilot plug off its seat. This allows the pressure above the plug to vent to the downstream side, and the valve operates as a conventional pressure-balanced valve. The spring shown in this particular design holds the pilot valve off the pilot seat during normal operation. When the valve begins to close for shut-off, the plug first seats off on the valve seat, and a small amount of additional stem travel compresses the spring and seats the pilot valve.

Special Designs Many customized, special-purpose designs are possible to meet unique service and operating requirements. The example in Figure 6.19hh shows a cage and seat that are installed from the bottom of the valve and supported by a bottom flange. This design was intended as a "flangeless"

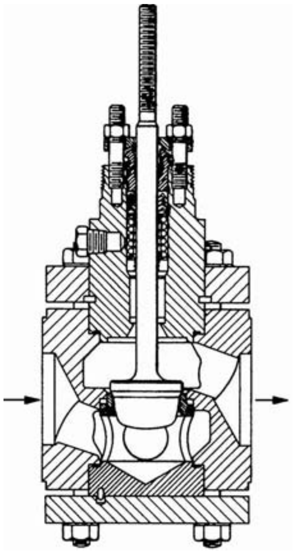

FIG. 6.19hh
Quick-change trim valve designed for bottom trim removal. (Courtesy of Emerson Process Management.)

valve for small sizes of forged or bar stock corrosion-resistant alloys such as Alloy 20, nickel, and Hastelloy C-276 for corrosive service. It allows for a bottom drain and quick inspection of the valve trim without removal of the actuator and bonnet. Similar bodies can be machined in custom configurations and may be more economical in small sizes for special alloys than other globe designs.

Split-Body Valves Another type of single-seated globe body is the split-body valve (Figure 6.19ii). This design was the original stem-guided chemical service valve intended for hard-to-handle services involving slurries, sticky fluids, and corrosive services. The seat ring is clamped between the body halves, and the body is easily disassembled for replacement of the seat and plug.

Another feature is the adaptability for building the body to use slip-on flanges. This results in cost savings when corrosion-resistant alloy castings or forgings are required for the wetted body. Because the flanges are not normally subject to wetting by the process fluid, they can be of carbon steel or lower alloys than the body. In small sizes, it is economical to cast or forge the body for a standard ANSI Class 600 rating and install Class 150, 300, or 600 slip-on flanges as needed. It is also possible to rotate the lower body 90 degrees to the line axis and eliminate a pipe elbow, although this is rarely done. The design of the split body makes it possible to be molded in structural plastics for low-pressure corrosive applications. Refer to the discussion on lined and thermoplastic valves below.

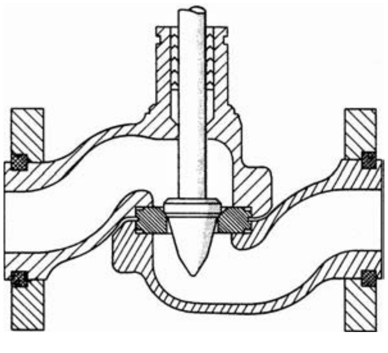

FIG. 6.19ii
Split-body valve with separable end flanges. (Courtesy of Dresser Flow Solutions.)

While still popular for some applications, split-body valves have limitations on installing special trim options. The bolted body joint may leak if exposed to large piping stresses from severe thermal cycling, and it should not be welded into the piping because maintenance requires body separation.

Split body valves are available with flanged ends up to size 10 in. (DN 250), but separable (slip-on) flanges are only available up to size 4 in. (DN 100), and threaded ends are available up to size 2 in. (DN 50). Availability is generally limited to small sizes in high-pressure classes. ANSI Class 900, 1500, and 2500 ratings (PN 150, PN 250, and PN 420) are in sizes 2 in. (DN 50) and smaller.

Angle Valves Angle valves (Figure 6.19y) are often used in a flow-to-close direction for high-pressure drop service. This is favorable to the valve body and trim but requires careful design of the downstream piping to avoid erosion problems in high-velocity liquid or two-phase flow. Depending on actual downstream velocities, these applications can require a larger pipe size than the valve and up to 20 diameters of straight pipe before the first elbow.

Angle valves are also used to accommodate special piping arrangements to aid drainage, on erosive services to minimize solids impingement problems, and on other special applications such as coking hydrocarbons. Figure 6.19jj shows a coking valve design with a streamlined, sweep-angle flow path and a replaceable venturi outlet sleeve. This body flow path is designed to reduce flow velocity in the body to minimize erosion.

Trim materials such as tungsten carbide and ceramics can be selected to resist erosion due to the higher trim velocities. The venturi-style outlet has high-pressure recovery and low vena contracta pressures, which makes the trim and downstream pipe highly susceptible to cavitation on liquid service, even with moderate pressure drops. In order to avoid damage to piping, these valves can be installed directly on vessel inlets or with a larger downstream pipe to mitigate the effects of cavitation or flashing.

Y-Type Valves The Y-type valve has application in several special areas. Among these applications are those where good drainage of the body passages or high flow capacity is required, such as in controlling molten metals or polymers, cryogenic fluids, and liquid slurries. Cast or forged Y-type valves are available up to size 16 in. (DN 400) and with pressure ratings up to Class 4500 (PN 760). The valve can be installed in

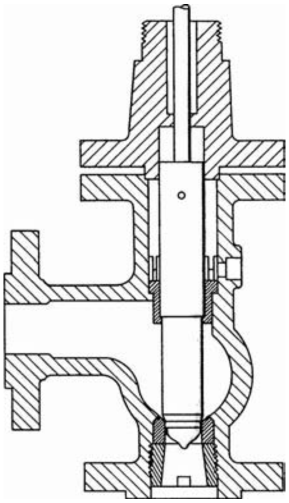

FIG. 6.19jj
Streamlined (sweep) angle valve with lined venturi outlet.

horizontal, vertical, or angled piping to suit the application requirements. Because of the simple body shape and bonnet design, they are easy to fit with thermal or vacuum jackets.

Figure 6.19kk shows a Y-type valve with a vacuum jacket that has been specially designed for low-pressure cryogenic liquid service. The vacuum jacket provides maximum thermal insulation for such applications as liquid hydrogen. This body is designed for minimum and uniform wall thickness, which enables rapid cool-down rates. The single-seated design allows good shut-off and can be provided with soft inserts for exceptionally tight shut-off. Note that the vacuum jacket is designed with a metal bellows to allow for mechanical tolerances or dimensional changes during temperature transients and has a provision for welding to a matching jacket around the adjacent piping.

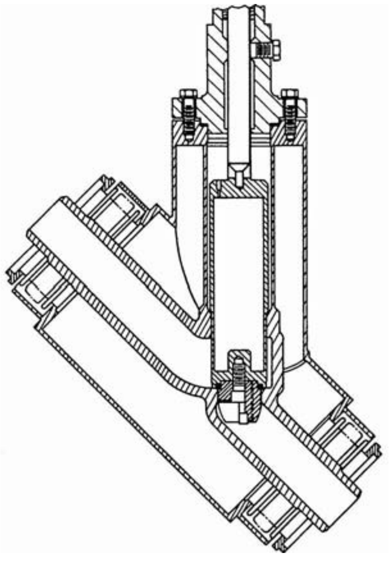

FIG. 6.19kk
Y-pattern valve fitted with vacuum jacket for cryogenic service.

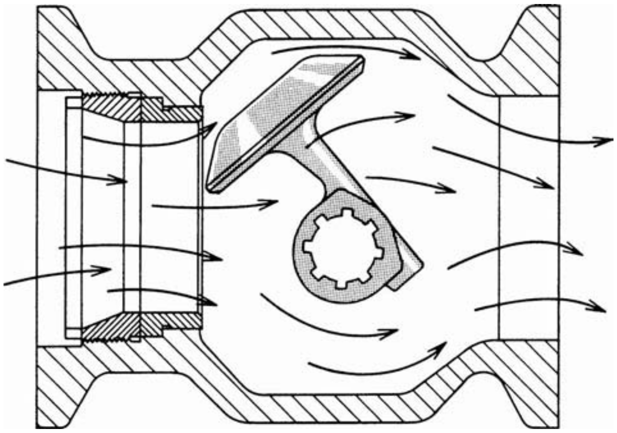

FIG. 6.19ll
Rotary globe with eccentric spherical segment plug. (Courtesy of Dresser Flow Solutions.)

Eccentric Plug Rotary Globe Type The rotary globe valve (Figure 6.19ll) is mentioned here, because its design and performance combine features of conventional rotary valves with conventional globe valves. Compared to most rotary valves, the eccentric spherical segment plug valve has the advantage of lower torque requirements. The seating surface of the plug has the form of a spherical segment. The plug design makes exaggerated use of the offset center to obtain contact at closure without rubbing on the seat, like ball valves. It is capable of substantial seat contact loading for tight shut-off approaching that of conventional globe valves.

The flow characteristic approaches linear (Figure 6.19a). Changes in control characteristic can be accomplished with a cam in the positioner or by modifying the controller output signal. Capacity (C_v) is between that of a double-ported globe and a high-performance, double-offset butterfly valve. High-flow capacity is achieved with only moderate pressure recovery in the body, so the critical flow coefficient (F_L) is higher than that of a butterfly valve throughout its throttling range and therefore less likely to cavitate.

The valve is made in sizes from 1–16 in. (DN 25–400) in pressure Classes 150, 300, and 600 (PN 20, PN 50, PN 100). Flanged and flangeless versions are available in most sizes. Allowable operating pressure drops depend on the manufacturers' designs, materials, and actuators. In most cases, the valves are rated for operating pressure differentials significantly less than the body's maximum pressure rating, so it is necessary to consult the manufacturer's data for specific limitations.

C_v rangeability data are stated in ranges from 100:1 up to 160:1. However, these ratios are achievable in service only if the actuator and control system can control in the range of 1–5% open, which is possible but often not practical. From a practical control standpoint, assuming a control range from 5–95% open, the C_v rangeability for eccentric rotary plugs is about 35:1 or lower, which is comparable with conventional globe valves.

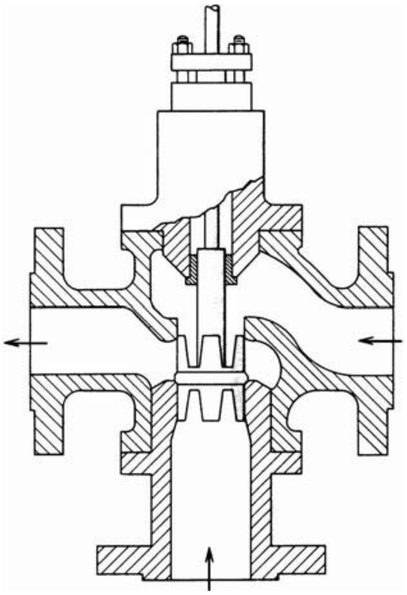

FIG. 6.19mm
Three-way valve for mixing service.

Three-Way Valves

Three-way valves are a specialized double-seated globe valve configuration. There are two basic types. One is for mixing service, i.e., the combination of two fluid streams passing to a common outlet port (Figure 6.19mm).

The other is for diverting service, i.e., taking a common stream and splitting it into two outlet ports (Figure 6.19nn). The three-way design shown in Figure 6.19y uses an adapter to convert a conventional single-seated globe into mixing or diverting configurations.

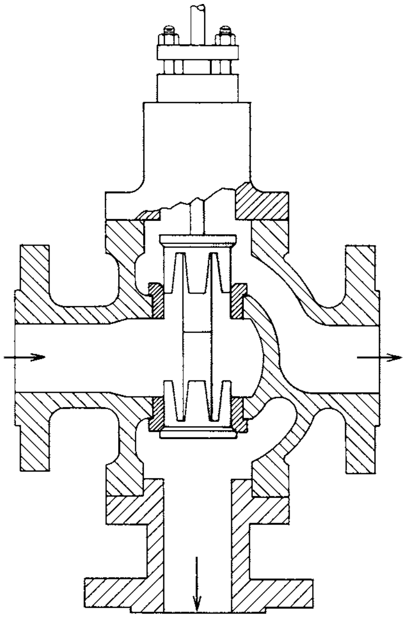

FIG. 6.19nn
Three-way valve for diverting service.

A typical mixing valve application would be the blending of two different fluids to produce a specific outlet end product. A diverting valve might be used for switching a stream from one vessel to another vessel or for temperature control on a heat exchanger. In the latter, the valve would direct one portion of the flow through the exchanger, and the balance of the flow would bypass the exchanger. The relative split would provide the heat balance needed for temperature control.

The forces acting on the double-seated, three-way plug do not balance in the same way that a double-seated, two-way plug is balanced. This is because different pressure levels exist in each of the three flow channels. Also, there are different dynamic forces acting on each plug head. Therefore, these valves are not normally used in high-pressure drop service. The valve plugs are usually seat-guided and post- or stem-guided to maintain stability under fluctuating dynamic forces. Due to the larger size and piping complications, some users prefer to use two opposite-acting, two-way globe valves operating from one controller to do the same job as a three-way valve.

Lined and Thermoplastic Valves

For extremely corrosive services, high alloy metals such as Alloy 20, nickel, nickel alloys, titanium, and zirconium are often required where austenitic stainless steels are inadequate. However, special alloy valves are very expensive and the service life may still be limited by corrosion.

An alternative to special alloys could be the lined globe valve (Figure 6.19oo). The lined valve uses a carbon steel or stainless steel shell for retaining pressure, but the inside surfaces of the body and bonnet are bonded with a chemically inert or corrosion-resistant fluoroplastic, such as PFA or PTFE. These valves are commonly for 1 in. (DN 25) through 2 in. (DN 50) sizes with capacity from $C_v = 0.33$ to 45.

For very low C_v flow capacities, the design shown in Figure 6.19pp is available in 1 in. size (25 mm) with trim selections covering a C_v range from 0.001 to 1.0. These valve designs are limited to operating temperatures below 300–400°F (149–204°C) and pressure drops less than 125–250 PSI (8.5–17 bar). Lined valves are also available in various rotary valve types and pinch valves (see Section 6.20).

Conventional globe patterns and split-body designs can be molded entirely from structural thermoplastics for corrosive applications with low to moderate pressures and temperatures. Bodies can be molded in polyvinylidene fluoride (PVDF), polyvinyl chloride (PVC), polypropylene (PP), and other plastics. Allowable pressures and temperatures vary with material and body design.

Typically, PVDF is limited to 300 PSIG (21 bar) at 73°F (23°C) and 150 PSIG (10.3 bar) at 225°F (106°C). PVC has a limit of 300 PSIG (21 bar) at 73°F (23°C) and 150 PSIG (10.3 bar) at 140°F (60°C). Polypropylene can operate up to 300 PSIG (21 bar) at 73°F (23°C) and 150 PSIG (10.3 bar) at 175°F (79.4°C). End connections are available in Class 150 flanged,

flangeless (for clamping between pipe flanges with through-bolting), or threaded ends. Packing and gaskets are generally made of PTFE or perfluoroelastomer (e.g., Kalrez®) materials.

VALVE CONNECTIONS

Valve connections to adjacent piping can be categorized into four general types: 1) flanged, 2) welded, 3) threaded, and 4) clamped. Each style incorporates elements that contain pressure, bear piping loads, and seal the joint between the valve and piping.

As a general rule, valves smaller than 2 in. (DN 50) can use threaded connections, while sizes 2 in. (DN 50) and larger use flanged connections. In a few process systems where fugitive emissions or process leakage is not a problem (such as water systems), threaded connections up to size 4 in. (DN 100) have been used. Most applications require both ends of the valve to have identical connections, but on some vent and drain valves, the upstream port and the downstream port may require different sizes or types of connections. Typical end connections are discussed below.

Flanged Ends

Flanges are the most common valve connection to piping. Most countries and piping codes accept the flange design and ratings from the standard ASME B16.5, Pipe Flanges and Flanged Fittings commonly referred to as “ANSI” flanges (because the earlier standards were published by the American National Standards Insitutue). Some countries and applications use other flange standards, such as American Petroleum Institute (API) standard for oil production equipment and the International Standards Organization (ISO) ISO-7005 flanges (adopted from the German DIN standards).

These rating systems are different and are not interchangeable; they use different rating systems, bolting, gaskets, and flange dimensions. The ASME (or ANSI) flanges use a Pressure Class rating system (e.g., steel flanges are Class 150, Class 300, Class 400, Class 600, Class 900, Class 1500, and Class 2500). API flanges are designated by a nominal pressure system (e.g., 2,000 PSI, 3,000 PSI, 5,000 PSI, 10,000 PSI, 15,000 PSI, and 20,000 PSI). The ISO (and DIN) standards also use a nominal pressure or PN numbering with typical ratings PN 10, PN 16, PN 20, PN 40, PN 64, PN 100, PN 160, PN 250, PN 320, and PN 400, which indicate maximum nominal pressure in bar (1 bar = 14.504 PSI = 100 kPa).

Flanges may be flat face, raised face, ring-type joint (RTJ), tongue and groove, male and female, or other configuration to suit the application. Cast iron, ductile iron, and bronze are usually flat face; carbon steel and alloys are usually raised face; and above ANSI 600, the RTJ is fairly common.

Figure 6.19qq shows three common configurations of flanges: separable flange-raised face, integral flange-raised face, and integral flange-RTJ. Raised face and flat face flanges use gaskets from sheet stock, such as graphite or PTFE composites, or a spiral wound thin metal strip with graphite, PTFE, or other mineral filler between each metal winding. RTJ gaskets are oval or octagonal in cross-section made of any suitable metal softer than the flange.

Valves with separable (slip-on) flanges retain the flange on the valve body ends with two circular half-rings held in the body grooves. Separable flanges are used mainly on small sizes from NPS $^1/_2$ in. up to 4 in. With separable end flanges, the body can be designed for an ANSI Class 600 rating and then adapted as needed with ANSI Class 150, 300, or 600 flanges.

Separable flanges are not wetted by the process, which permits less expensive carbon steel or stainless steel flanges to be used on high alloy valves. Separable flanged valves are easy to install with the mating piping, because the flanges can be rotated to fit mismatched line flange hole patterns. However, care must be taken during installation to prevent the valve from rotating in the line until the flange bolts are properly tightened.

Flangeless bodies (clamped between pipe flanges) are sometimes used in the small bar-stock bodies. While they permit lower cost where expensive alloys are involved, they require care with bolting, gasket, and piping alignment. The tie-rod bolting should be high tensile strength material, and the valve must be carefully centered to permit proper gasket sealing and loading. The longer the bolt studs are, the more they are affected by longitudinal thermal expansion differences with the valve body and piping, which can lead to gasket leakage in thermal shock or severe temperature cycling.

Welded Ends

Welded ends are not common in the chemical process industries, but they are generally recommended in power generation and other applications where high piping stresses or thermal shock conditions exist. They are also used in hazardous services when no leakage is allowed from gasketed joints. Socket-weld ends (Figure 6.19rr) are easy to align and may be used in small sizes of 2 in. (25 mm) or under.

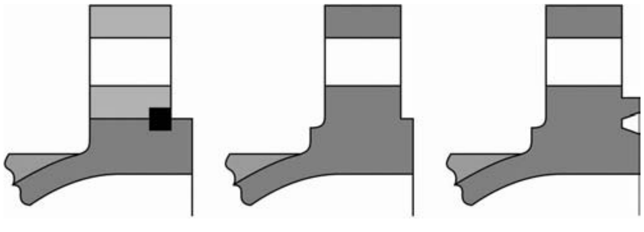

FIG. 6.19qq
Flange configurations: separable raised-face, integral raised-face, ring-type joint (RTJ) integral flange. (Courtesy of Flowserve Corporation.)

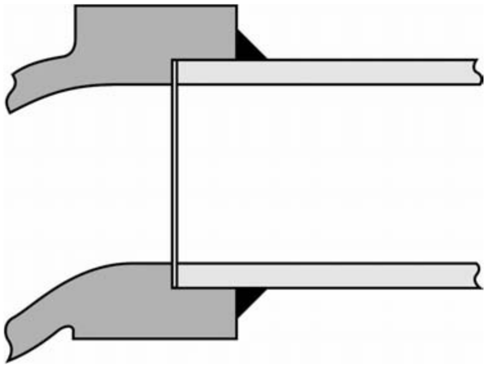

FIG. 6.19rr
Socket-weld end valve and pipe joint with fillet weld. (Courtesy of Flowserve Corporation.)

However, most valves are installed with butt-weld ends where maximum joint strength is achieved by full penetration of the weld (Figure 6.19ss). Butt-weld joints are commonly checked by radiographic inspection (X-ray) to confirm full penetration and lack of defects such as cracks, voids, and slag.

The valve body material should be selected so that it is suitable for welding to the adjoining piping. In many cases the valve and adjacent pipe require a post-weld, stress-relieving heat treatment. The mating ends of the body and pipe are usually machined at an angle to form a V-joint for ease of welding. The design of joint (end-preparation) depends on the thickness of the mating parts. ASME B16.25 is the most common standard for design of the butt-weld end preparation, but some users and engineering contractors choose their own dimensions for the end preparation to suit their particular fabrication practices.

Threaded Ends

Threaded connections with NPT (tapered pipe threads per ASME B1.20.1) threads are common on valve sizes 1 in. (DN 25) and smaller and are sometimes used on valves up to 2 in. (DN 50). Threaded connections are usually used in pressure ratings up to ANSI Class 600 (PN 100). The threaded connection normally consists of the valve body with female NPT threads; then the pipe with male NPT threads is screwed into the body end. Materials commonly used in

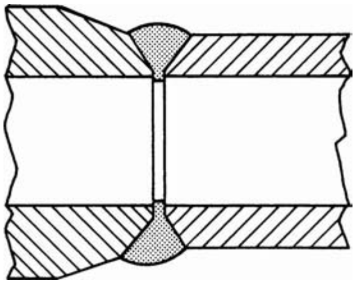

FIG. 6.19ss
Butt weld end valve and pipe joint showing full penetration weld.

threaded end valves are brass, bronze, and carbon steel. Stainless steel bodies usually do not have NPT threads, because they gall easily with stainless steel pipe. An antigalling thread sealant compound should be applied to the threads during installation to prevent leakage and seizing and to allow for future disassembly.

Threaded connections are not normally used with process valves because they can leak more easily, they are more difficult to make up in the piping, and they may corrode or gall together, making disassembly difficult. Threaded connections do not work well on corrosive fluids, because the corrosion attack is generally more severe in the threaded crevice, causing the threads to corrode together and making it difficult to disassemble. Accelerated corrosion in the threads also promotes leakage. Threaded joints also tend to loosen in services where the temperature fluctuates.

Threaded ends are not recommended for services with severe thermal shock or thermal cycling that occurs above 500°F (260°C) or below −50°F (−46°C). However, some small valves under size 2 in. (DN 50) are furnished with threaded end connections for utility services such as low-pressure steam, water, and gas. Where it is necessary, threaded end valves can be converted to flanges by welding a flange to a pipe nipple, threading it into the valve, and seal-welding the nipple to the body.

Special End Fittings

In very high pressures, usually above 5000 PSIG (345 MPa), some operating companies use proprietary fitting and flange designs. One widely used high-pressure connection design is the lens-ring-type fitting shown in Figure 6.19tt. This is a self-energizing type of seal; i.e., the lens-ring deforms to give a tighter seal with increase in-line pressure. (Further details are given in Section 6.1.)

In other high-pressure applications, special clamped fittings are very effective. One proprietary clamped fitting called the Grayloc® fitting (developed by the Gray Tool Company) greatly reduces the bulk of the valve end as compared to the large high-pressure, bolted flanges. The Grayloc fitting utilizes a lens-ring-type seal, similar to one shown in Figure 6.19tt, but the special hub design is fastened together with a bolted clamp-type fitting instead of flanges. See Figure 6.19uu.

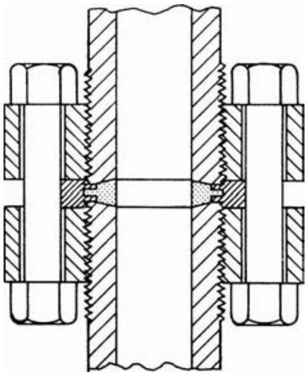

FIG. 6.19tt
High-pressure lens-ring-type joint.

These fittings are also available in 10,000 and 15,000 PSIG (69 and 104 MPa) designs. The ASME Boiler and Pressure Vessel code permits the use of clamped connections and includes design rules in Section VIII, Division 1, Appendix 24.

For standards on globe valve end connections, see Table 6.19vv.

MATERIALS OF CONSTRUCTION

A valve body assembly is a pressure containment vessel. As such, design and material selection must follow guidelines of a pressure vessel code that is recognized by the country or state in which it will be operated. Some of the

* Always use the current edition of any standard, unless governmental or construction specifications require otherwise.

prominent standards include the ASME Unfired Pressure Vessel Code (Section VIII and Section III), ASME B31.1, "Power Piping," and ASME B31.3, "Process Piping." Most other countries have similar standards, and the European Community has moved to harmonize and unify some of these standards under a European Pressure Equipment Directive (PED) 97/23/EC. Most of these codes recognize ASME B16.34, "Valves—Flanged, Threaded, and Welding End," as an accepted standard for design, materials, and testing of valves.

The selection of proper materials for valves requires consideration of all factors related to the process fluid and operating conditions. This can include forces applied from actuators and piping, (wind and seismic loads, hoists and rigging, accidental loads), changes in process and ambient temperatures, and the erosive and corrosive potential of both the process fluid and the outside environment. The complex scope of material selection is outside the purpose of this text, but a few of the common globe valve materials are listed in Table 6.19ww with typical ASTM specifications and process applications.

TABLE 6.19ww
Common Valve Body Materials, Specifications, and Applications

Common Material Designation	Body Material Specification (Castings)	Body Material Specification (Forgings)	Max. ANSI Pressure Class Rating (ASME B16.34a-1998)	Temperature Limit °F (°C)*		Typical Service/Applications
				Min.	Max.

Flow sheet symbols

Applications:	Abrasives, minerals in suspensions, hydraulically transported solids, slurries, viscous, or food industry products
Sizes:	Generally 1 to 24 in. (25 mm to 0.61 m); special units from 0.1 to 72 in. (2.5 mm to 1.8 m)
Design Pressures:	Generally up to ANSI Class 150, with special units available with up to ANSI Class 300 ratings. See Figure 6.20a
Maximum Pressure Drop:	Generally about 10 to 200 psid (69 to 138 kPa)
Design Temperatures:	–20° to 350°F (–29° to 204°C)
Materials of Construction:	*Sleeve materials:* Buna-N, Chlorobutyl, EPDM, Hypalon, Neoprene, PGR, Polyurethane, Teflon, Viton *Bodies:* Aluminum, cast grey iron, cast ductile iron, cast steel, stainless steel, Polyamide blend plastic
Characteristics:	For the characteristics of reduced port and Clarkson pinch valves, refer to Figures 6.20v and 6.20w; for others, refer to Figure 6.20b
Costs:	See Figure 6.20c
Capacity:	$C_v = 60\ d^2$ for full-ported pinch valves and $C_v = 20\ d^2$ for reduced-ported pinch valves; see Tables 6.20e and 6.20f
Rangeability:	From 5:1 to 10:1
Leakage:	Generally ANSI Class IV or Class V (see Table 6.1gg in Section 6.1for definitions)
Partial List of Suppliers:	Clarkson Co. (www.tycovalves.com) Elasto-Valve Rubber Products Inc. (www.evrproducts.com) Ever-Flex (www.ever-flax.net) Larox (Finland–USA) (www.larox.fi) Onyx Valve Co. (www.onyxvalve.com) Red Valve Co. (www.redvalve.com) Richway Industries (www.richwayind.com)

INTRODUCTION

These valves are called either pinch or clamp valves, depending upon the configuration of the flexible tube and on the means used to compress the tube. The compression can be done by mechanical clamping mechanisms or by external pneumatic or hydraulic power within a metal jacket enclosure. Pinch valves have been improved due to introduction of plastic tubes, elastomers, and reinforcing fabrics.

Tubes can be fabricated from pure gum rubber or from a variety of rubber-like elastomers such as Buna-N, butyl, neoprene, Nordel, hypalon, Viton, silicone, polyurethane, polypropylene, white butyl, and odorless and tasteless white neoprene. The latter two materials are often used in the food and allied industries. Reinforcing fabrics may include some of the materials used in automobile tire fabrication, such as cotton duck, rayon, nylon, fiberglass, and Kevlar®, which is a new arimid polymer material that is as strong as steel at

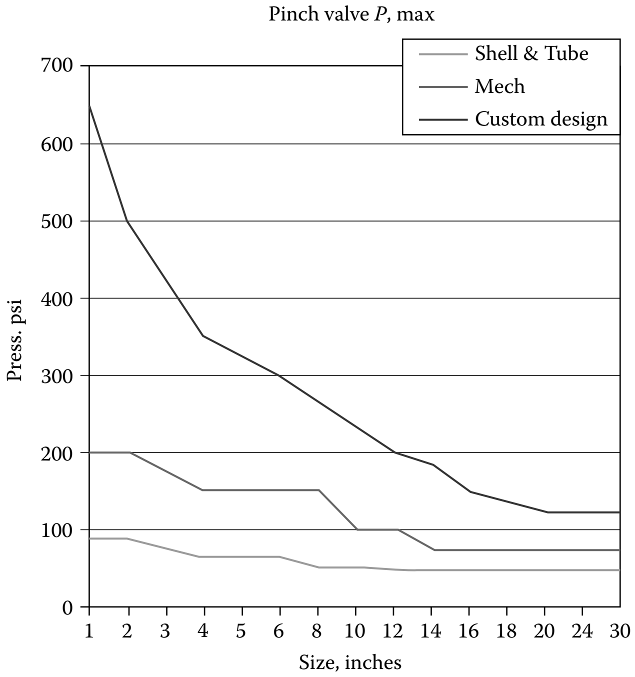

FIG. 6.20a
Pinch valve pressure rating drops as size increases. The bottom curve gives the rating of shell and tube, the center of mechanical and the top of custom designs.

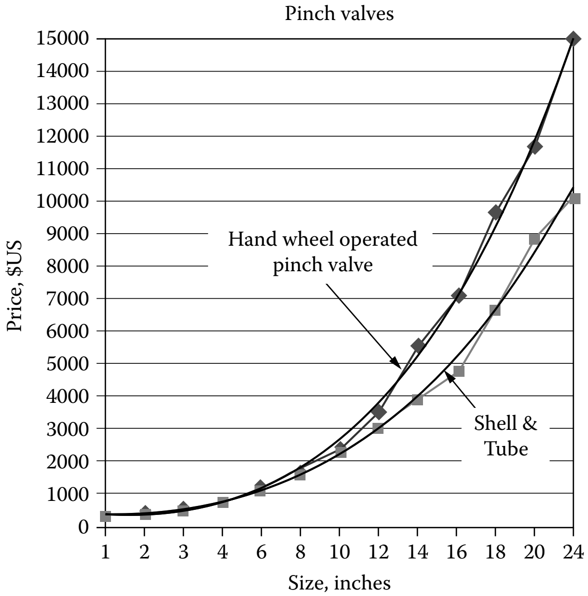

FIG. 6.20c
The shell and tube-type pinch valves are less expensive than cylinder or electric-operated valves and generally cost less than hand-operated valves. Cost data are based upon standard flanged cast iron housing, pure gum rubber sleeve, and on/off operation. Numerous other elastomers are available for the sleeve, a range of material for the body, and a variety of actuators and drives.

one sixth the weight. Teflon plastic tubes are uniquely capable of handling highly corrosive or sticky fluids.

As was shown in Figure 6.20b, pinching a standard full round sleeve from 100% to 50% of travel has little effect on the flow through the valve. The advantage of the prepinched tube design is that this "dead" part of the valve control is nearly eliminated. As can be seen from Table 6.20e and Table 6.20f, fluid capacity is sacrificed, because the shape of a full open

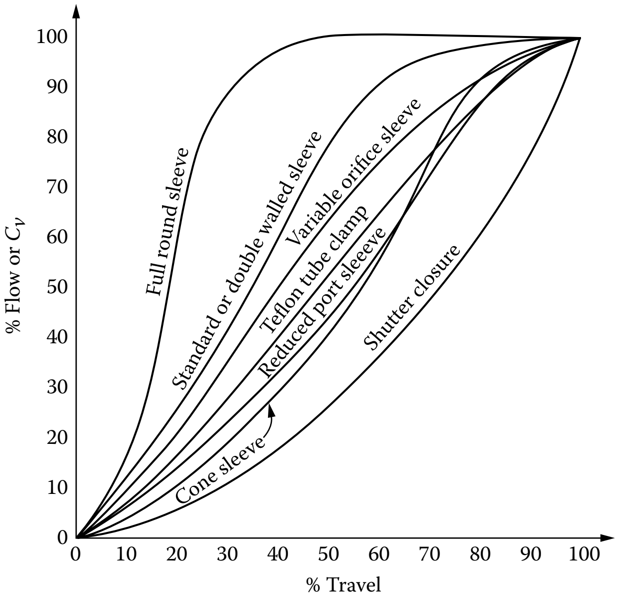

FIG. 6.20b
The characteristics of a full round sleeve is nearly quick opening. Double-walled or cone-shaped sleeve cross-sections bring the characteristics closer to linear.

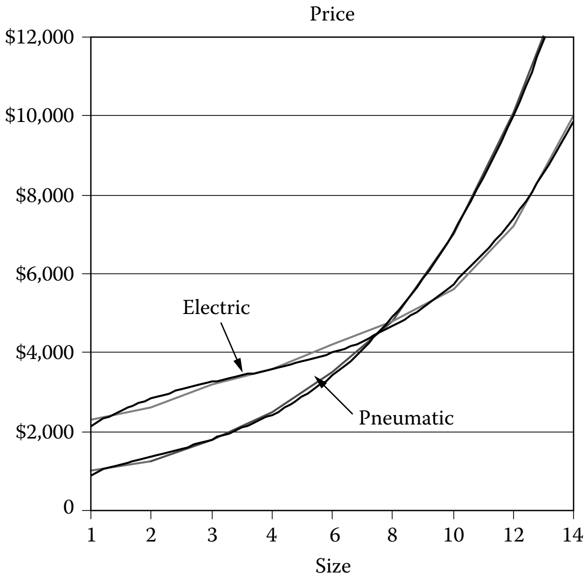

FIG. 6.20d
Price comparison pinch valves provided with electric or pneumatic actuators.

prepinched tube has approximately 80% of the area of a full open standard round tube.

Pinch valves can be mechanically pinched or be of the shell and tube type. The mechanically pinched design can have a frame that is open or enclosed and can be provided with handwheel, pneumatic, or electric operators. If a pneumatic actuator is selected for a mechanically pinched valve, that design is available with either an open or a closed failure position. The shell and tube designs can be pinched pneumatically or hydraulically and can only fail open. A summary of pinch valve features is given in Figure 6.20g.

THE SLEEVE

A pinch valve consists of a short section of flexible hose combined with a mechanism for throttling or completely closing the hose. The hose is made of a composite matrix of elastomer and a fabric carcass. The fabrication and materials of construction are similar to automobile tire manufacturing, but inside out, in the sense that the tire has the wear surface on the outside, a pinch valve has the wear surface on the inside of the tube.

Much of the art of making pinch valves lies in the design and manufacture of the elastomer sleeve. By balancing the number of fabric layers, the type and orientation of the fabric, and the ratio of rubber to fabric, the sleeves can be made soft and pliable for low-pressure or tough and rigid for high-pressure applications. Table 6.20h lists the properties of a variety of elastomers used as pinch valve sleeves.

The tensile strength of the sleeve is of particular importance because it limits the ability to resist tearing and delamination of the rubber and fabric. As can be seen from Table 6.20h, natural gum rubber is superior to all the synthetic compounds for abrasion resistance, tensile strength, and elongation. It is also the least expensive. This makes it the material of choice for most pinch valve sleeves.

In addition to the elastomers listed in Table 6.20h, most manufacturers offer rubber compounds in FDA White Odorless and Tasteless versions for food and cosmetic applications. The white pigments in these compounds compromise temperature resistance and tensile strength. Pinch valves are available with conductive gum rubber sleeves that safely dissipate static electricity. These are routinely used in the manufacture of nitro-glycerin, gunpowder, and ordinance materials.

Some manufacturers offer proprietary extreme abrasion resistant compounds such as Linatex Red Crepe© and Onyx Blue©. Urethane compounds are available on special order; they offer good abrasion resistance but are plagued by delamination and splitting at the pinch points. Kalrez© has been debated for years as a pinch valve material but its extreme cost has made it prohibitive even for small pinch valves.

Reinforcing fabrics for pinch valves borrow heavily from the tire industry and include polyester, nylon, cotton, rayon,

Kevlar®, and occasionally fiberglass. They can be built up in either a bias-ply or radial pattern, or a hybrid combination where different layers in the same sleeve have different orientation.

The rubber sleeve is the most critical component of the pinch valve and it determines the maximum time between service intervals. Sleeve quality varies considerably between manufacturers, and price tends to reflect quality.

There are two methods for making pinch valve sleeves. One is the vulcanization process, where they are held together with heat tape, or they can be compression molded.

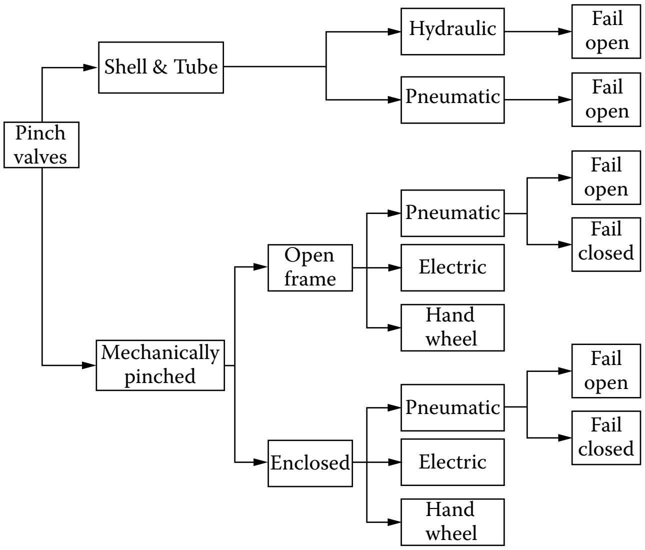

FIG. 6.20g
Pinch valves design variations and feature options.

An important feature of the sleeve design is the positive opening feature (POF), which is illustrated in Figure 6.20i. This feature is provided by a pair of rubber and fabric tabs, which are molded into the trunk of the pinch valve sleeve. These tabs are clamped to the pinch bars. They force the sleeve to open properly when there is no process pressure on the inside to open it, which is of value if the sleeve has been closed for an extended period of time.

PINCH VALVE TYPES

Pressure Limitations

As was shown in Figure 6.20a, shell and tube-type pinch valves have the lowest pressure rating. Their main limitation is the available pressure of the compressed air used to close the valve.

Standard mechanically pinched valves can operate against line pressure in the range of 75 to 200 PSIG, depending on size. The limitation is the strength of the fabric reinforcement in the rubber sleeve. Special-order pinch valves can be fabricated for high-pressure service. Manufacturers use exotic fabrics including Kevlar and the latest engineering software to create hybrid sleeves built up with a mix of bias ply and radial layers to increase working pressure.

Shell and Tube Design

The simplest pinch valve is the *shell and tube* type, which is also referred to as a *direct operated* or as a jacketed pinch valve. This design consists of a cast iron, aluminum, or plastic shell with a rubber sleeve inside. For a cost comparison between shell and tube-type and handwheel-operated pinch valves, refer to Figure 6.20c.

As shown in Figure 6.20j, injecting compressed air into the housing causes the rubber sleeve to collapse, thereby blocking flow of the process fluid through the valve. The valve housing is usually configured to coax the sleeve into a straight-line closure to operate with the lowest possible differential pressure.

Flanged bodies are available in 1 through 72 in. sizes. Body material for flanged valves is cast iron, ductile iron,

cast aluminum, and fabricated carbon steel. Small valves in the range of 1/8 through 3 in. are available with screw-on pipe connections with steel, stainless steel, and plastic bodies. Valves in the 1/2 through 4 in. size are available with slip-on connections, where the mating pipe is simply inserted into the valve body and is retained solely by friction with no threads or grooves required. These are generally made in cast aluminum.

Advantages

1. Simple operation, sleeve is the only moving part
2. Light weight
3. Compact
4. Inexpensive
5. Closes around suspended particles, rags, powder, pellets, and other debris without jamming or leaking

Caveats

1. Limited line pressure capability. This is because a higher pressure is needed on the outer surface of the sleeve to force it closed. Typically a 35 to 40 psi differential between internal and external pressure is required to close the sleeve. In a compressed air system operating at 100 psi, this limits the process pressure to 60 psi.
2. The valve must fail open (FO). There is no practical way to put a spring or other energy storage device inside the valve so it is not available in a true fail-closed version. Auxiliary devices can be added to the valve; for example, a solenoid valve can be configured for fail closed on loss of *electric* power. Likewise, designers add air reserve tanks and other peripheral devices to close the valve on compressed air failure. None of these devices are functional when the sleeve wears through; at that point there is no way to sustain air pressure in the valve housing and the valve opens.
3. Low-pressure and vacuum systems can inhibit full opening or cause valve to “flutter,” thereby compromising flow capacity. There are ways to force the valve open using vacuum jet pumps but they add complexity.
4. Disappointing performance in throttling applications. Because these valves have no valve stem, there is no place to attach a positioner feedback lever. The alternative is to use the valve in concert with an I/P transducer coupled to a pneumatic amplifier. This converts a

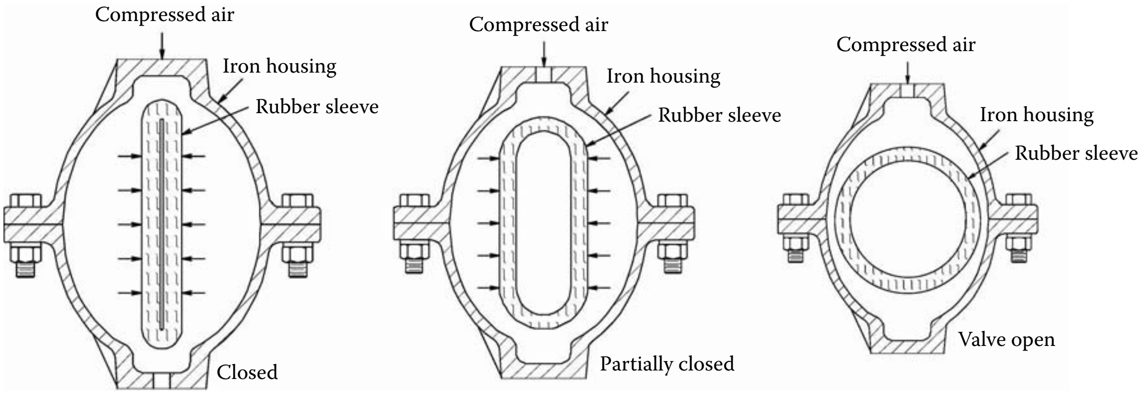

FIG. 6.20j

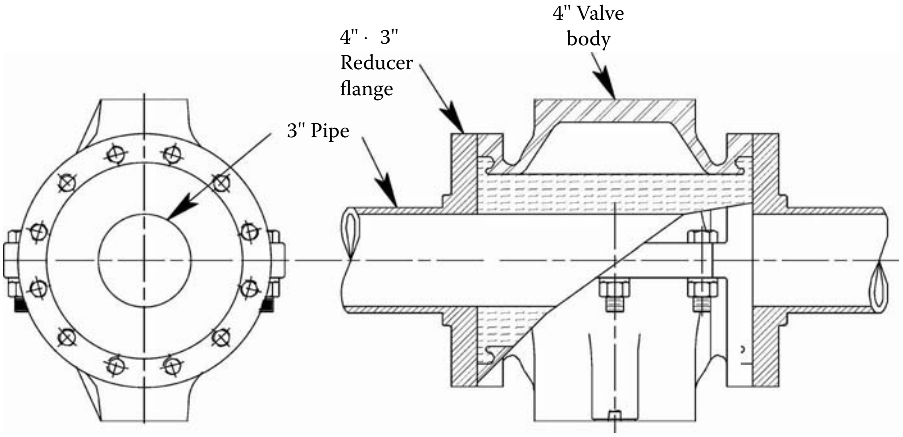

FIG. 6.20k
The design of a double walled, 3 in. size, shell and tube pinch valve.

4–20 mADC electronic signal to a pneumatic 0–100 PSIG signal that is introduced into the valve shell. This varies the opening of the rubber sleeve, but without any feedback in the valve. The only means of closing the loop is through the measuring element and controller. This makes for sluggish response, erratic stability, and shallow turndown. Modulating shell and tube valves are generally limited to slow, linear applications like level control on large vessels. Exception to the rule: For pH control, use a shell and tube pinch valve with a solenoid valve instead of an I/P transducer. Configure the controller for pulse width modulation (PWM) with a *s-l-o-w* time base around 10 sec. This introduces a response time lag but cranks the turndown up to 100:1 or better with zero sleeve abrasion. Want well all-around modulating control? Read on and see how well *mechanically* pinched valves work in throttling applications.

5. Limited sleeve life. In mechanically operated pinch valves, designers add extra fabric for ample reserve strength. Designing a shell and tube valve does not offer this luxury. Additional fabric adds stiffness and increases the differential pressure needed to close the valve. This drives the sleeve design to the minimum number of fabric layers. The result is that the fabric operates right up to its yield point. After a certain number of open-close cycles the fabric fails through fatigue and the sleeve delaminates. Sleeve life in a shell and tube pinch valve operating at its maximum rated pressure is usually around a mean of 75,000 cycles with a variation of ±25,000.

In comparison, mechanical pinch valves operate through practically an unlimited number of cycles because the fabric is operating at reduced stress. Mechanical pinch valves operating for millions of cycles over a period of 20 years are not uncommon.

One method to increase the sleeve life is to regulate the compressed air pressure to precisely 40 psi over process pressure. For example, a 4 in. valve might be rated for 65 psi max process pressure with 105 psi max compressed air pressure. However, if the actual process pressure is 25 PSIG, reducing the air pressure from 105 down to 65 PSIG greatly reduces stress in the reinforcing fabric. This increases sleeve life by about 50%. The additional cost of an air pressure regulator pays for itself in improved sleeve life.

Another method of improving sleeve life is to double the sleeve's wall thickness. As illustrated in Figure 6.20k, this can be done by increasing the valve size, underboring the hole through the sleeve, and doubling the thickness of the rubber sleeve. This requires the use of reducer flanges to make the connection between the pipe and valve.

The Clarkson-C Valve The Clarkson division of Tyco makes a unique variation of the shell and tube valve (Figures 6.20l)

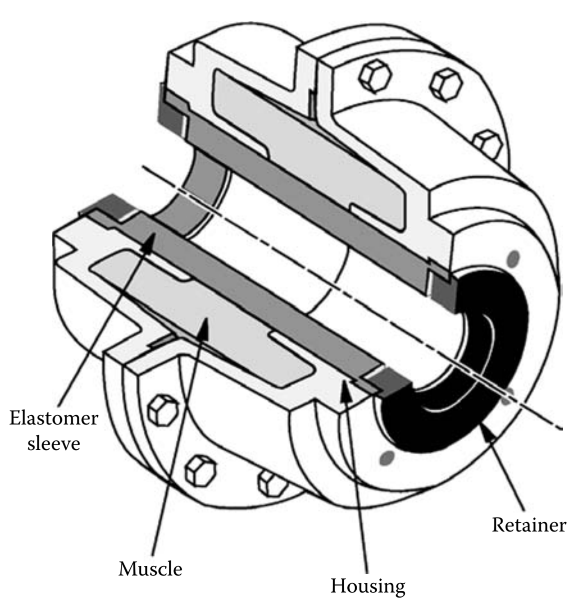

FIG. 6.20l
The Clarkson-C valve.

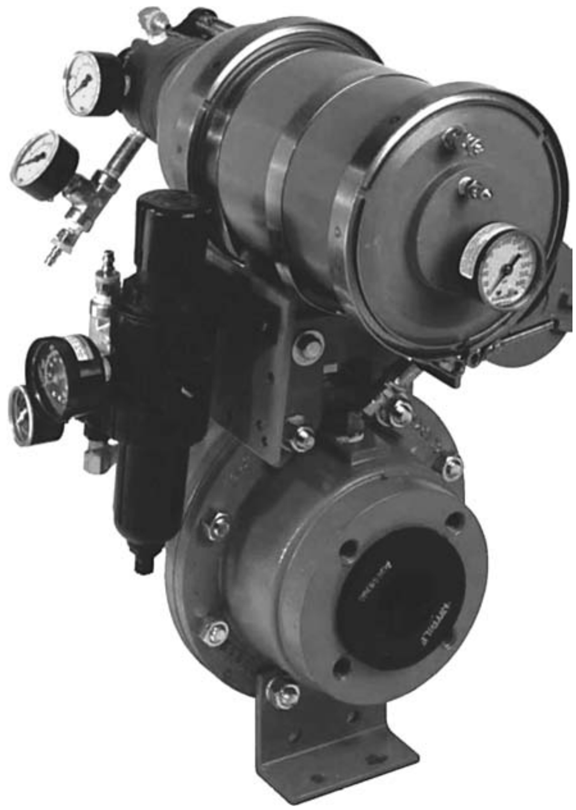

FIG. 6.20m
The Clarkson "C-Valve" showing the air-powered hydraulic pump, amplifier, tank, positioner, check valve, pressure regulator, and gauges.

and 6.20m. It is called the "Clarkson-C" or "shutter valve." This rather unusual valve has been around since the late 1960s. Instead of compressed air, this valve uses hydraulic fluid, which is pressurized to several hundred PSIG, in order to be able to collapse the rubber sleeve. The assembly includes an air-powered hydraulic pump, valves, positioner, air filter-regulator, and gauges piggybacked onto the valve.

The hydraulic fluid is separated from the sleeve by a thick-walled rubber cylinder called the "muscle." To throttle the slurry, the muscle is compressed inward by hydraulic pressure, reducing the orifice size of the sleeve in a 360° squeeze. As it constricts, a round concentric aperture is maintained throughout the usable throttling range. Compared to conventional shell and tube pinch valves, this valve can handle higher pressure and more abrasive fluids, and it offers more precise throttling.

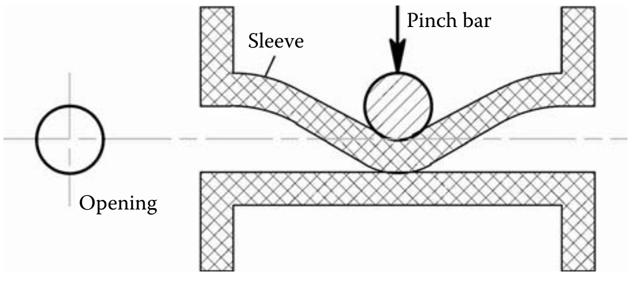

FIG. 6.20n
Full ported and fully round single pinch design.

Naturally, the use of hydraulics adds another level of complexity and, therefore, both maintenance and first-investment costs.

Mechanically Pinched Valves The alternative to the shell and tube-type pinch valve described above is the mechanically pinched valve. In this design, steel pinch bars clamp the rubber sleeve closed. A handwheel, lever, electric actuator, or pneumatic cylinder actuates the pinch bars. The mechanically pinched valve has ample energy available to effect closure so the rubber sleeve can incorporate more reinforcing fabric. This enables the valve to handle higher process pressure and extends potential sleeve life to millions of cycles.

A pneumatic actuator can be a double-acting cylinder, which, if you combine it with a two-coil solenoid valve, is inherently a fail-in-last position device. Pneumatic actuators are available for fail-open and fail-closed operation, using mechanical springs or air reservoirs to store the energy required to operate in the absence of compressed air pressure.

As a general rule, pneumatic actuators are the least-expensive for pinch valves up to 6 in. size, electric actuators have the advantage for valves over 10 in., and in between it is roughly a draw.

The majority of mechanically pinched valves use flanged connections, although there are some designs that use a slip-on connection with a hose clamp. 125/150 lb flanges are the most common, with 250/300 lb flanges also available.

A word of explanation on the difference between 125 and 150 lb flanges: The bolt circles are identical between 125 and 150 lb flanges. The difference is the housing material: If the valve housing is cast grey iron or aluminum, ANSI 125 lb specifications apply; if the housing is steel, ductile iron, or stainless steel, then ANSI 150 lb specifications apply. The same relationship holds for 250 and 300 lb flanges.

Single Pinch Design As illustrated in Figure 6.20n, the simplest mechanical pinch valve design consists of a rubber tube and a single steel bar that pinches the tube from above.

When the valve is open, the inside is a round circle with its diameter of opening equal to the diameter of the adjacent pipe. Therefore, a full open 2 in. valve can pass a 2-in.-diameter sphere. This design offers good abrasion resistance, allows the pipe to drain completely, and can be cleaned with a pipe pig. This design is also a simple and economical mechanism.

The main limitation of this design is valve size: It works for pinch valve sizes up to and including 3 in. Another problem is due to the fact that as the steel bar pinches the tube closed, the rubber and reinforcing fabric have to stretch. On small valves, this is not a problem. But on larger valves, the change in length exceeds the allowable elongation of the rubber and fabric matrix.

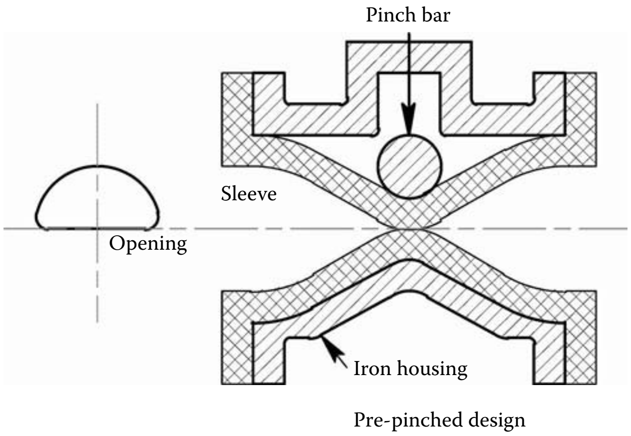

FIG. 6.20o
Prepinched design.

There are three possible solutions to this dilemma:

1. Make the valve longer. This reduces the elongation on the sleeve. This solution is controversial, because longer valves take up more space, and in today's competitive environment, plant space is a valuable commodity.
2. Prepinch the valve.
3. Use two moving pinch bars.

Prepinched Design The valve in Figure 6.20o is a prepinched design. The term "pre-pinched" refers to the iron housing. The valve itself is "full ported," because the sleeve has a full round shape before insertion into the housing. The iron housing has a weir cast into it that pinches the valve to centerline, resulting in a "D" shaped opening. This valve can pass a sphere equal to half nominal line size. If you want to pass a 4-in.diameter grapefruit through a 4 in. valve, you have to cut it in half and push the pieces though flat side down.

Advantages

- Simple operation.
- Reduced cost (compared to dual pinch valves).
- Shorter actuator stroke, reducing the cost of the associated actuator.
- Good throttling characteristic.

Disadvantages:

- Largest particle that the valve can pass is half nominal valve size.
- Reduces valve capacity by 20%.
- With valve full open, adjacent pipe will not drain below centerline.
- You cannot pig out the line.
- Accelerated sleeve wear in high-velocity, high-abrasion applications

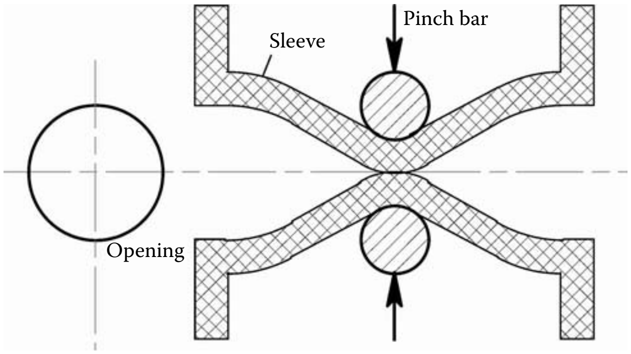

FIG. 6.20p
Fully round and full ported dual pinch mechanism.

Dual-Pinch Mechanism As shown in Figure 6.20p, an alternate design is the dual-pinch mechanism, where two separate pinch bars squeeze the rubber tube closed. Here, there are two moving pinch bars that meet at the centerline of the valve to pinch off the rubber sleeve. "Full round" refers to the mechanical parts of the valve; "full port" refers to the sleeve design.

Advantages

- Excellent abrasion resistance.
- Minimal friction.
- Valve can pass particles equal to line size.
- Adjacent pipe can drain completely.
- Valve can pass a cleaning pig.

Disadvantages

- Mechanism is more complex.
- More expensive than prepinched.
- Actuator moves when stroking valve.
- Requires longer stroke actuator compared to prepinched design.

Open and Enclosed Designs Most mechanical pinch valves have a housing that surrounds the rubber sleeve. As shown in Figure 6.20q, this housing connects the flanges, supports the handwheel or actuator, and protects the rubber sleeve from the environment. This housing also serves to contain the process fluid when the rubber sleeve wears out.

An alternative is the open frame design. This pinch valve consists of a rubber sleeve, a clamping mechanism, and little else. Its light weight makes it popular for use in nonmetallic piping systems. It is also popular in mining operations as a "throw-away" valve.

Advantages

- Easy visual inspection of the rubber sleeve
- Economy
- Lightweight

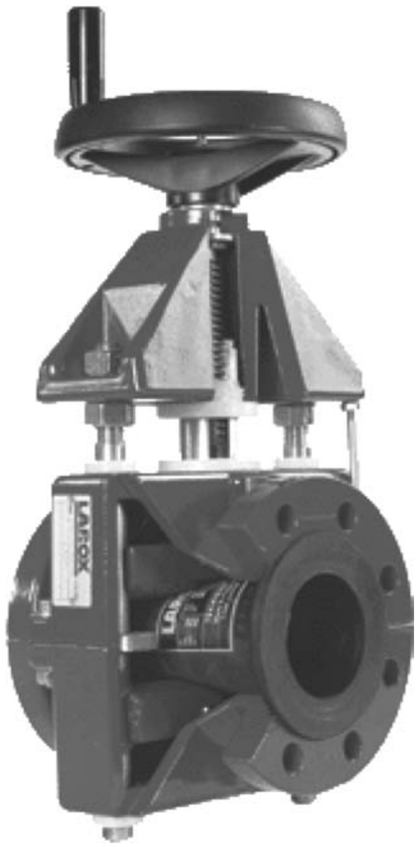

FIG. 6.20q

Caveats The rubber sleeve is a sacrificial part. When the sleeve wears out, whatever is being pumped just sprays all over the place. These valves are well suited for sand mining and stormwater applications, because if one inadvertently dumps a ton or two of sand on the ground, one just sends a crew to clean it up, but no serious harm is done.

On the other hand, always use a *fully enclosed* pinch valve when the process fluid is scalding hot, acidic, caustic, toxic, or flammable. Always consider the consequences of leakage, and never compromise safety.

Actuators Mechanical pinch valves can be actuated by:

- Handwheel
- Handwheel and gearbox
- Pneumatic actuators
- Electric actuators

Handwheel When a pinch valve is to be buried or installed in a pit, it can be equipped with a torque tube extension and a handwheel operator. From an esthetic point of view, the occasional handwheels protruding from the ground are acceptable, but the cost can be substantial when one has to dig up the valve for servicing.

Gearbox and Handwheel Pinch valves require extraordinary amounts of thrust to operate. The pinch valve requires brute force and lots of it to close the sleeve against the pressurized process fluid, which is a similar task as trying to crush a pressurized truck tire. For example, a 10 in. hand-operated pinch valve closing against, say, 75 PSIG process pressure requires about 5 tons of force at the seat. Using a normal acme-threaded stem, this works out to 150 ft lb_f of torque.

If one uses an unassisted handwheel, one will require a 6-foot diameter handwheel to reduce the rim pull down to 50 ft lb_f. Therefore, once the valve size exceeds 6 or 8 in. and depending on the process pressure, consider the use of a gear assist for manual valve operation.

This is particularly true in case of chain wheel operators. Cutting corners by eliminating the gearbox or using a small-diameter chain wheel can cause serious problems, because once one exceeds the requirement of 150 ft lb_f rim pull, the plant operator might not be able to provide it.

Pneumatic Actuators Pneumatic actuators work particularly well with pinch valves. They are simple, economical, and dependable. One should use pressure regulator controls so that the closing thrust can be set precisely. This is necessary, on the one hand, to provide sufficient thrust to close the valve drop tight, and on the other hand, to avoid overpinching to the point where one might damage the rubber sleeve. Also, as the sleeve wears from erosion, a pneumatic actuator has reserve travel to compensate for the lost material.

The most common pneumatic actuator used on pinch valves is the conventional double-acting air cylinder. When the air supply fails, a double-acting air cylinder fails in its last position.

Using an Air Cushion The pneumatic cylinder can be supplied with a spring or air cushion on either top or bottom for fail-closed or fail-open operation. Air cushions are cheaper than springs but are less reliable, because a minor leak can void the actuator's ability to execute the proper fail action.

The operation of the air cushion is shown in Figure 6.20r, where compressed air is supplied through tube a to pressure regulator b, which reduces the pressure to 45 PSIG. Air flows through check valve c and into cylinder head d and is trapped in the cylinder head by check valve c at a pressure of 45 PSIG. If the air supply fails and, therefore, the pressure below the piston drops, this drives the piston cylinder rod e down, closing the valve.

To retract the cylinder rod, one needs both the air supply to be on and the three-way solenoid (f) to be energized. When this is the case, 90 PSIG air is injected underneath the piston, which lifts it up, compressing the air in the cylinder head (d) to about 80 PSIG.

If the solenoid valve is de-energized or the compressed air supply fails, the 80 PSIG air that is trapped air above the piston will drive the piston down, thereby closing the valve. As the air cushion expands, its 80 PSIG pressure falls back

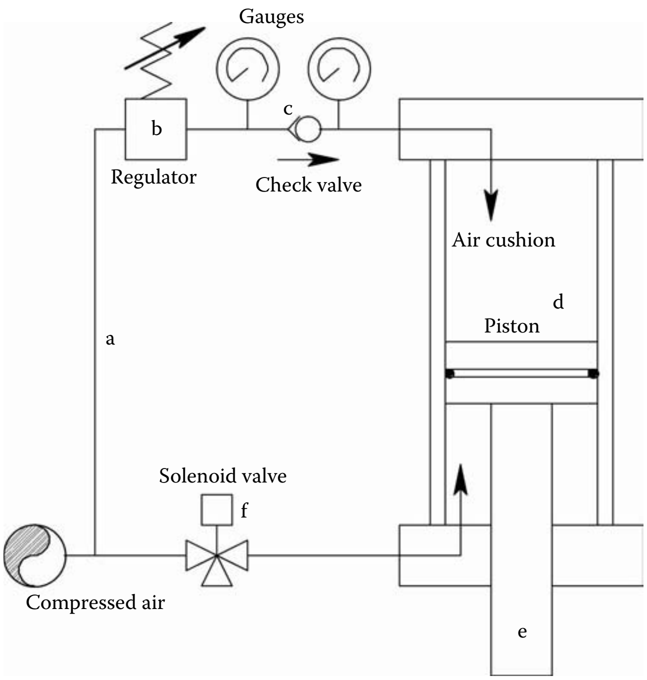

FIG. 6.20r
Double-acting cylinder can be configured to fail closed on air failure, when it is provided with an air cushion.

to 45 PSIG. Therefore, the cylinder has to be sized to operate at this reduced pressure.

Suspension Bag One pinch valve manufacturer has devised a particularly clever pneumatic actuator, where instead of a conventional air cylinder, a rubber pneumatic suspension bag is used as the actuator (Figure 6.20s). One advantage of this actuator on modulating applications is that it has a nonlinear thrust output. The reason for this is that as the suspension bag expands vertically, it "necks in" around its circumference. This eliminates breakaway friction and overtravel, enabling them to position a valve with 1/1,000th in. precision.

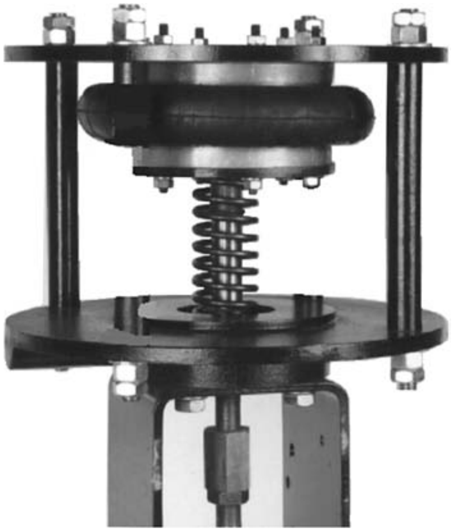

FIG. 6.20s
Suspension bag actuator with its cover removed to clearly show its components. (Courtesy Onyx Valve Company.)

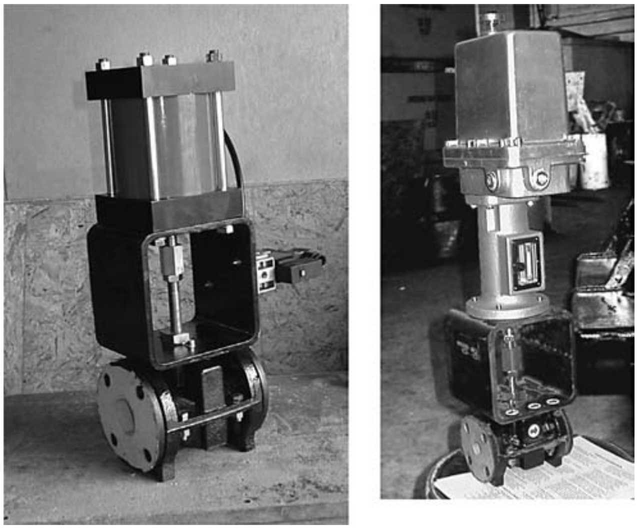

FIG. 6.20t
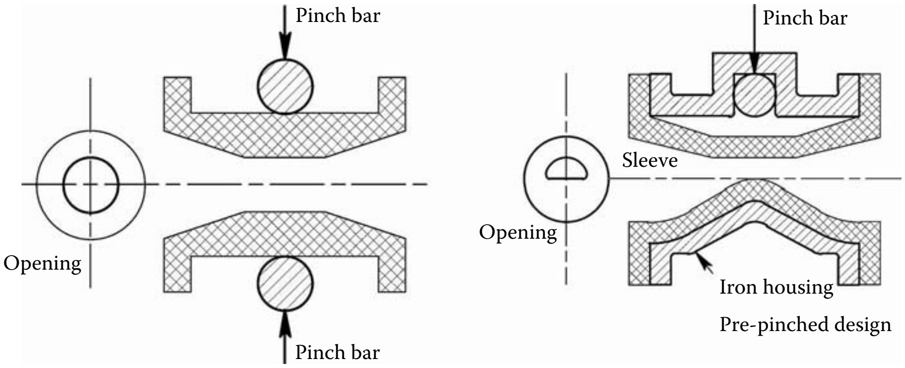
1 in. mechanically operated pinch valves, with pneumatic actuator on the left and electric on the right. As can be seen in Figure 6.20d, the cost of the electric valve in this size range is higher. For its cost, the user can purchase the pneumatic valve, plus a 2 hp compressor, and have $700 left over.

Pneumatic suspension bags are normally used in trucks and buses as shock absorbers. They are visible on tractor-trailers between the frame and axel assembly. Air bags have a decades-long track record of reliable operation in temperature extremes, rain, snow, sleet, dust, oil, vibration, and shock. They tolerate contamination of the compressed air system without adverse effects. They require no lubrication and operate virtually friction free.

Electric Electric actuators also work well with pinch valves (Figure 6.20t). They avoid problems associated with compressed air including, compressor maintenance, condensation freezing, and the need to run airlines throughout the plant. In smaller valves, pneumatic actuators are more economical. As it was shown in Figure 6.20d, at around 6 or 8 in., the balance of economy tips towards electric actuators.

Throttling Characteristics

The performance of the first throttling pinch valves was very poor, because they were grossly oversized. Until 1985, when David Gardellin ran the first capacity tests on pinch valves, nobody had a clue as to what their C_v and F_L values were. As it turns out, pinch valves offer higher C_v values per valve size than any other valve style (see Tables 6.20e and 6.20f). This is not unexpected, because they have a smooth streamlined internal configuration with no disk, seals, gate tracks, packing cavity, or other sources of friction or turbulence.



Full round reduced port

Pre-pinched reduced port

FIG. 6.20u
Pinch valves can be provided with reduced-port sleeves in two ways. The full round reduced port version is shown on the left and the prepinched reduced port version is shown on the right.

The reason for the poor performance of the full-ported modulating pinch valves is their excess capacity. The consequence of it being oversized is that the automatic controller tends to operate it nearly fully closed, down near the seat. This precipitates two problems:

One is accelerated sleeve erosion caused by the high velocity flow. Pumping abrasive slurry through a pinch valve running just off the seat is like firing a shotgun through a mail slot. The sleeve doesn't last very long.

The other problem is poor control quality. This was because if a 6 in. valve is used, but it needs to open only 1/4 in. to pass the required maximum flow, throttling over such narrow range is next to impossible, and no positioner can correct that.

Reduced Port and Clarkson Sleeve One way to improve the control performance of pinch valves is to use reduced port sleeves. As shown in Figure 6.20u, the reduced port can be provided either in a "full round" form or in a "prepinched" form.

On the left of Figure 6.20v, the inherent throttling characteristics of a full round reduced port valve is described. It is not exactly linear, but using a characterizing positioner with the X^2 function gets it close enough to provide a nearly linear and stable control in most situations.

On the right of Figure 6.20v, the inherent throttling characteristics of a prepinched reduced port pinch valve is shown. It is "prepinched" by the weir in the cast iron housing. Because the sleeve is prepinched, the opening is "D" shaped. It is "reduced port" because of the taper molded into the rubber sleeve.

The prepinched design offers considerable cost savings and a more linear inherent throttling characteristic (on the left of Figure 6.20v) than a full round valve.

Figure 6.20w illustrates the throttling characteristics of the Clarkson C-1 pinch valve, which is between linear and equal percentage.

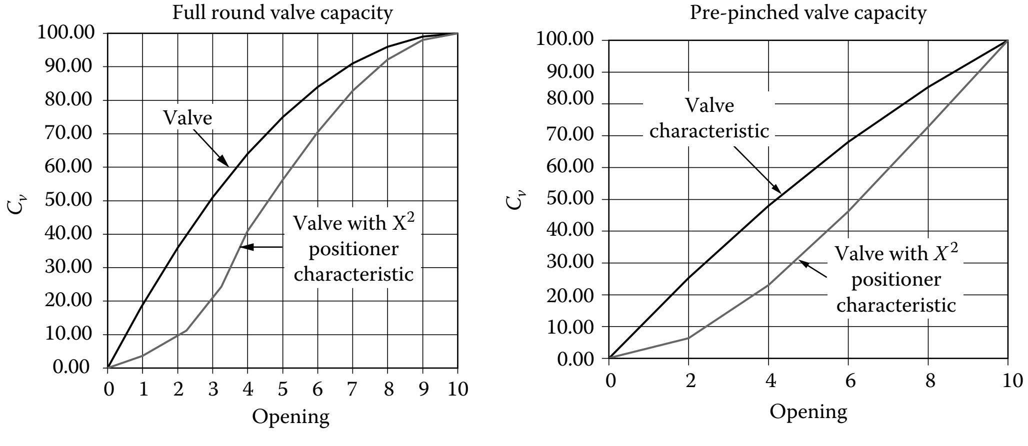


FIG. 6.20v
Characteristics of reduced port pinch valves: On the left the characteristics of the full round, on the right the prepinched design is shown.

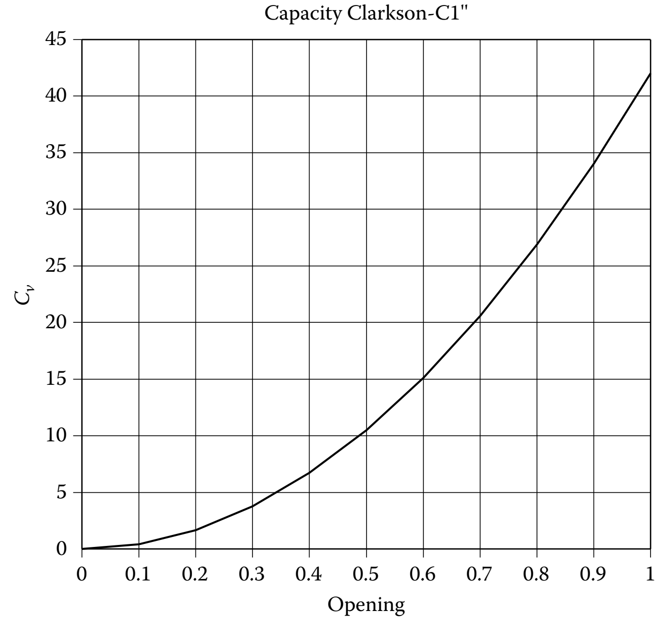

FIG. 6.20w
Characteristic curve of a 1 in. Clarkson "C" valve.

Example When compared to ball, butterfly, or plug valves, the reduced port and Clarkson pinch valves have higher valve coefficients (C_v and F_L) and better throttling characteristics. In many installations, they are also more cost effective.

As an example, let us assume that we have an application that requires a maximum C_v of 336, and the pipe size is 6 in. From both Tables 6.20e and 6.20f, we find that the C_v of a full ported 3 in. valve is the most suitable (C_v = 570). This application, therefore, works out to require a 6 in. × 3 in. pinch valve. There are three ways to design this system:

Option 1 Buy a 6 in. × 3 in. reduced port pinch valve that (according to Table 6.20f) has a C_v measured from 6 in. flange to 6 in. flange of 336. This option (shown on the left of Figure 6.20x) is the most expensive solution, but it also offers the most flexibility, because if the plant capacity increases, one can just change the rubber sleeve to a 6 in. × 4 in. to double the C_v to 680. If more capacity is required, a 6 in. × 5 in. sleeve will give a C_v = 1723 and a full 6-in. sleeve will provide a C_v = 2200, which is a sixfold increase in capacity without changing the valve or the fittings.

Option 2 The second option (shown on the right side of Figure 6.20x) is to purchase a 3 in. full ported valve and install it within 6 in. × 3 in. reducer fittings. This installation will also provide a C_v (measured from 6 in. flange to 6 in. flange) of 336. This second option is the least expensive, but it also offers the least flexibility in terms of accommodating future increases in plant capacity.

Option 3 One can compromise between the above options by installing a 4 in. × 3 in. pinch valve inside two 6 in. × 4 in. pipe reducers. This solution might be the best of both worlds. It offers better economy than buying a 6 in. reduced ported pinch valve, but it does have flexibility for increased capacity by changing out the 4 in. × 3 in. reduced port rubber sleeve to a 4 in. full ported one.

This change would increase the C_v from 336 to 680: double the original capacity without having to change the valve, actuator, or adjacent fittings. Such options do not exist with ball, butterfly, or plug valves.

APPLICATIONS

Pinch valves are used in a surprising range of industries and applications. Their primary application is in controlling the flow of abrasive slurry streams, but they are also used elsewhere. Some examples will be listed below.

Wastewater

Pinch valves can control sewerage and stormwater streams, which might contain oil, paper, rags, sticks, disposable razors, garbage, grit, and other contaminates.

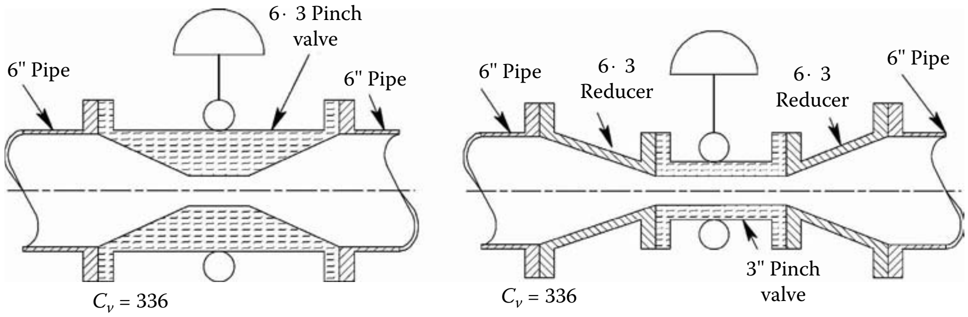

FIG. 6.20x
The same valve coefficient (C_v = 336) can be obtained by installing a 6 in. × 3 in. reduced ported pinch valve (left) or by using a 3 in. full ported pinch valve inside 6 in. × 3 in. reducers (right).

Flue-Gas Desulfurization

Pinch valves are suited for lime slurry service because they offer a straight-through design without any crevices or cavities for material to accumulate. Closing a pinch valve causes the rubber sleeve to stretch. As the rubber sleeve stretches, any scale that has built up on the surface will flake off. The fluid acceleration that occurs as the valve is closing helps to wash these flakes off the rubber surface, so the interior of the valve is self-cleaning. Unlike ball and plug valves, there is no dead space in the valve where a plug of slurry can solidify and block the line.

Mine Slurries

Pinch valves have numerous applications in mining applications, including:

Sand mining	Coal and water slurry	Diatomaceous earth
Copper tailings	Coal and oil fuel	Tar sands
Gold slime	Borax	Mercury
Taconite slurry	Phosphate slurry	Molybdenum
		Kaolin and other clays

Paper and Tile Manufacturing

Pinch valves can handle countless fluids in paper manufacturing, including bleaching and coating applications. As shown in Figure 6.20y, pinch valves can control the levels in head boxes in ceiling tile manufacturing applications, where the thickness of the finished tiles is within 1/16th in. of the specifications.

Toxic Gas Applications

Pinch valves are frequently used to handle carbon monoxide, methane gas from sewerage and landfill applications, and so on. Abrasion is not an issue; the pinch valve is preferred because there is NO PACKING BOX that could leak toxic or flammable gasses into the atmosphere. Consequently, fugitive emissions are not a problem with pinch valves.

Pigments, Paint, and Ink

Pinch valves routinely handle thick viscous fluids that would cement out in other valves after prolonged closure. Pinch valves never jam or clog.

Glue

Pinch valves are used to modulate the pressure in a closed-loop system that sprays the glue onto plywood layers prior to lamination. A pinch valve can provide both throttling control and reliable drop-tight closure even on wood glue.

FIG. 6.20y
A 10 in. modulating pinch valve used for throttling pulp stock and chopped glass fibers to make acoustic ceiling tiles. (Courtesy Onyx Valve Co.)

Food

Pinch valves are used to convey tomatoes, chili peppers, live shrimp, chicken feet (for export to China), mustard, chicken bones and entrails (pet food stock), pig and cattle hooves (for glue), and grains.

Powders and Grinding Compounds

Pinch valves are routinely used to control air-conveyed cement, dry lime, dust, detergent powder (they fill containers very precisely), and fertilizer. They are also used to transport grinding compounds including diatomaceous earth, aluminum oxide, and garnet slurry used to polish teeth, TV screens, auto bodies, and the kitchen sink.

Chemicals

Pinch valves can handle a variety of chemicals without corrosion and with zero leakage because there is no packing box in their design.

CAVITATION

The phenomenon of cavitation has been discussed under the subjects of control valve applications (Section 6.1), control valve noise (Section 6.14), and control valve sizing

(Section 6.15). For that reason, its discussion here will be brief, and the reader is referred to the noted sections for a detailed treatment.

The Phenomenon

The pressure recovery factor (F_L) relates to the ratio between the pressure drop across the valve and the pressure difference between the inlet pressure and the vena contracta pressure (P_{vc}).

$$F_L = [(P_1 - P_2)/(P_1 - P_{vc})]^{1/2} \qquad \mathbf{6.20(1)}$$

The higher the pressure recovery factor (F_L), the better the cavitation resistance of a particular valve design (see Figure 6.1v for a range of valve designs). The cavitation coefficient (K_c) is the ratio of the difference between the in- and outlet pressures and the difference between the inlet and the vapor pressure of the flowing fluid (P_v).

$$K_c = (P_1 - P_2)/(P_1 - P_v) \qquad \mathbf{6.20(2)}$$

If the pressure at the vena contracta falls below the vapor pressure of the liquid, gas pockets form in the flowing liquid. The process reverses itself when the liquid emerges from the restriction, because as the fluid decelerates its pressure recovers. Pressure does not recover to its original magnitude, but if it recovers beyond the vapor pressure, the cavities collapse and the vapors reliquefy. This is cavitation.

Figure 6.1w illustrates a pressure profile where cavitation takes place as vapor bubbles form at the vena contracta and then implode as the pressure recovers and exceeds the vapor pressure. The microjets generated by these implosions cause the damage to metallic surfaces in the area. The resulting micro shockwaves generate localized impact pressures over 200,000 PSIG, which no material can withstand. The location where the cavitation damage occurs is where the bubbles start to collapse, which is downstream of the vena contracta.

Figure 6.15d shows that the formation of these bubbles reduces the process flow until it reaches the "choked flow" condition, when an increase in inlet pressure to the valve will not increase the flow through it. The pressure drop, which will cause choking (Δp_{choked}), can be approximately calculated as

$$\Delta p_{\text{choked}} = F_L^2 (P_1 - 0.93P_v) \qquad \mathbf{6.20(3)}$$

The Pinch Valves

Pinch valves are one of the "high recovery" valve designs with a pressure recovery factor around $F_L = 0.68$. Reduced port valves have higher F_L coefficients, and the more severe reduction in port size, the higher it will be. Figure 6.20z shows the F_L coefficient of a reduced port pinch valve as a function of its percentage opening.

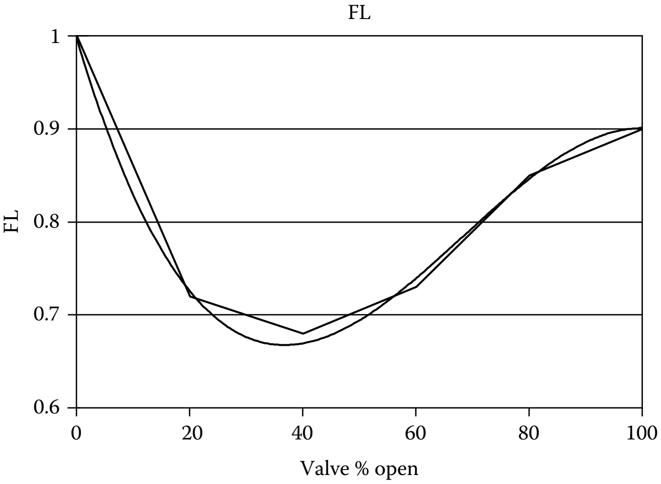

FIG. 6.20z
The recovery coefficient F_L as a function of the opening of a reduced ported pinch valve.

Some manufacturers suggest that one way to avoid cavitation is to size the control valve, not for the available total pressure drop ($P_1 - P_2$), but the pressure drop that would cause choking, or some fraction of that ($0.9\ \Delta p_{\text{choked}}$). This approach will redistribute the total system drop and eliminate cavitation in the valve (see C in Figure 6.2aa), but it does it by oversizing the valve, which will also deteriorate the quality of control.

Metal valves and rubber-lined valves respond differently to cavitation. Metal valves begin to deteriorate at a point between incipient cavitation and choked flow. Ironically, rubber fares better than metal under cavitation conditions. Rubber absorbs much of the shock of the imploding bubbles, so pinch valves can wade far into the chocked flow zone without any adverse effects.

Limiting or Eliminating the Damage

Figure 6.20aa illustrates five ways how cavitation can be eliminated by making changes in the installation or in the valve design.

One pinch valve manufacturer provides a calculated approximation based on the available total pressure drop ($P_1 - P_2$) and the pressure drop that would just begin to cause choking (Δp_{choked}). They argue that the difference between these two pressure drops is the energy source that drives cavitation (the formation and collapsing of bubbles), and therefore a cavitation damage factor (G) can be calculated by using this difference:

$$G = [(P_1 - P_2) - (\Delta p_{\text{choked}})](Q/17.44\text{d}) \qquad \mathbf{6.20(4)}$$

It is claimed that if G is calculated by using Q in gpm units of ambient water and d as the diameter of a rubber pinch valve, Table 6.20bb will give acceptable selection guidance for cavitation.

Using a Choke Fitting Cavitation does not start at the throat of the valve, but develops past the throat where pressure

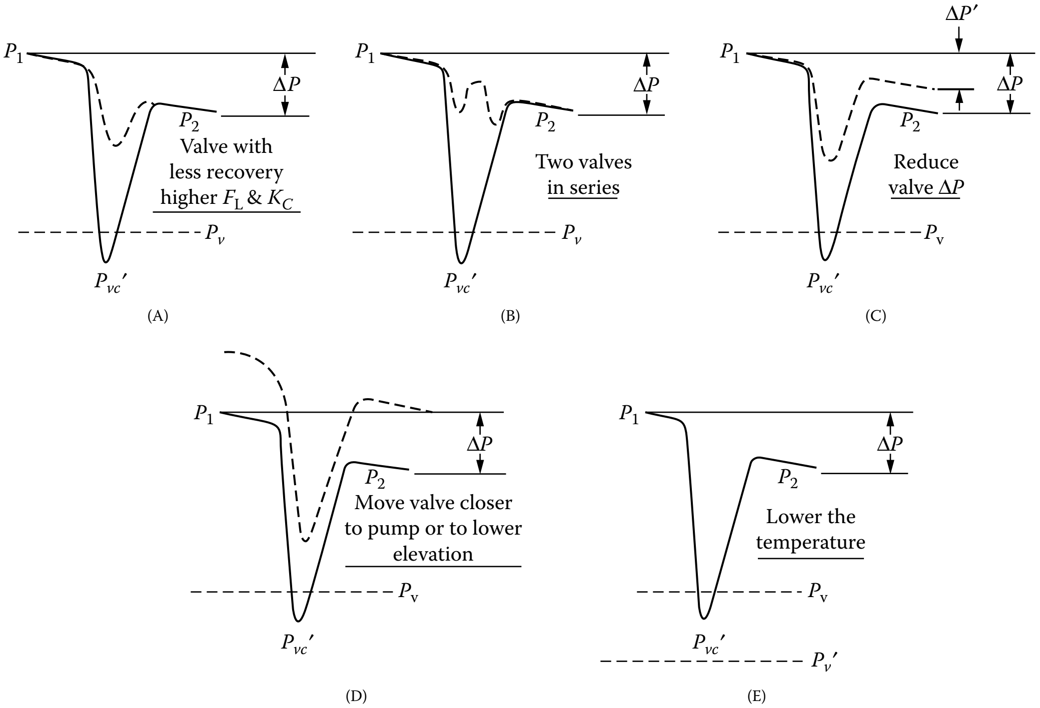

FIG. 6.20aa
Ways to eliminate cavitation: A) use valve with higher Kc and F_L, B) use two valves, C) reduce valve pressure drop, increase valve size, D) move valve to lower elevation or closer to pump, and E) reduce the temperature of the flowing process fluid.

begins to recover. As a result, cavitation damage occurs downstream of the valve throat and destroys the pinch valve's sleeve between the pinch point and the valve exit. Modulating pinch valves are usually supplied with a reduced port sleeve. The sleeve is molded with a venturi shape that tapers down to a small diameter in the center of the valve. The sleeve is normally symmetrical, tapered on both inlet and outlet so the valve can be installed for either flow direction. This design is vulnerable to cavitation damage.

Revising the sleeve design to an asymmetrical shape will enable the valve to withstand high levels of cavitation (Figure 6.20cc). This design is called a "trumpet mouth" or "cone sleeve." The thicker rubber at the valve outlet can absorb more cavitation damage. There are several ways to exploit this feature to tolerate even higher levels of cavitation with minimum sleeve damage.

One method is to install the valve at the end of the piping run, allowing the pressure to recover as the fluid emerges from the piping system. Here the cavities form after they have emerged from the choke fitting, where they cascade harmlessly into the open tank.

If it is not practical to install the valve at the end of the pipe run, some pinch valve manufacturers recommend the use of a trumpet mouth-type valve, followed by a short spool piece of pipe having a diameter that equals the valve's port size. The minimum spool piece length is typically 10 times the nominal diameter of the valve. The spool is connected to

TABLE 6.20bb
The Predicted Degree of Cavitation Damage Based on the Size of the "G Factor"

Cavitation Damage Factor (G)	*Predicted Degree of Cavitation Damage*
$0 \le G \le 100$	Cavitation damage will be undetectable.
$100 \le G \le 300$	Some damage will be observable after 1 year of operation.
$300 \le G \le 500$	Sleeve damage will be observable in 6 months.
$500 \le G \le 750$	Frequent maintenance and sleeve replacement is likely.
$750 \le G$	Consult factory.

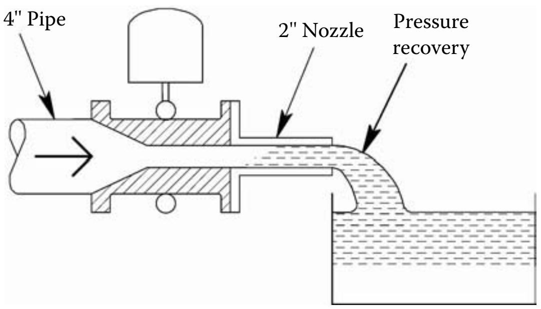

FIG. 6.20cc
If the valve can be located at the end of a pipeline, the addition of a choke fitting at the end of an asymmetric sleeve can move the zone of pressure recovery (cavitation) away from the valve.

the downstream full-size piping by a reducer flange, which creates a sharp, sudden expansion.

This design is not desirable because it does not eliminate the cavitation, but only moves its location downstream of the valve. Yet, some manufacturers argue that if the expansion downstream the spool is made with a rubber hose-type pipe joint, it can absorb a fair amount of wear and can be replaced once or twice a year at relatively low costs.

CONCLUSIONS

The phenomenon of cavitation is discussed in more detail in connection with control valve applications (Section 6.1), control valve noise (Section 6.14), and control valve sizing (Section 6.15). In general, one should note that the difference between the total available pressure drop ($P_1 - P_2$) and the pressure drop that would cause choking (Δp_{choked}) is the energy that drives cavitation (the formation and collapsing of bubbles). Therefore, instead of trying to find ways of harmlessly wasting this excess and unnecessary energy, one should concentrate on finding ways to NOT introduce it in the first place.

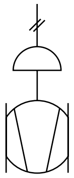
6.21 Valve Types: Plug Valves

C. S. BEARD (1970) **R. D. BUCHANAN** (1985) **B. G. LIPÁTK** (1995, 2005)



Flow sheet symbol

Sizes:	1/2 to 36 in. (12.5 mm to 0.96 m)
Types:	V-ported, three-way, four-way, five-way, fire-sealed
Design Pressure:	Typically from ANSI Class 125 to ANSI Class 300 ratings and up to 720 PSIG (5 MPa) pressure, with special units available for ANSI Class 2500. The retractable seat design is suited for 10,000 PSIG (69 MPa) service.
Design Temperature:	Typically from −100 to 400°F (−73 to 204°C), with special units available from −250 to 600°F (−157 to 315°C)
Rangeability:	Refer to Section 6.7; generally 20:1
Characteristics:	See Figure 6.21a
Capacity:	$C_v = (25 \text{ to } 35)d^2$; see Tables 6.1a and 6.21b
Leakage:	Metal seats ANSI Class IV, composition seats ANSI Class V; see Table 6.1gg for definitions
Materials of Construction:	Iron, forged and alloy steel, chrome plating, 302 through 316 stainless steel, Alloy 20, Ni-resist, Monel, nickel, Hastelloy B and C, and zirconium, plus rubber or plastic, including PTFE linings
Costs:	Costs vary drastically with design and accessories. In general, the cost of conventional plug-type control valves is about half that of globe valves, while the cost of eccentric rotating plug valves is about the same as that of globe valves of the same size and materials. (For the costs of carbon steel and stainless steel globe valves, refer to Figure 6.19b.)

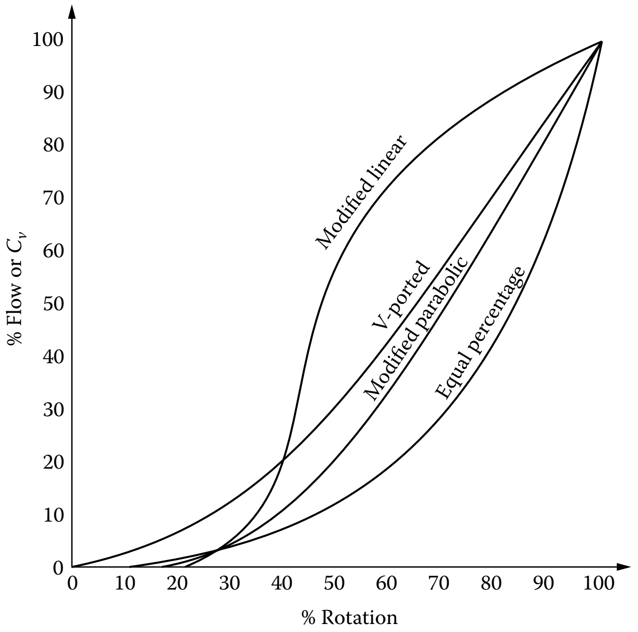

FIG. 6.21a
Plug valve characteristics are a function of the type of the particular V-port or of the shape of the throttling plate used.

GENERAL CHARACTERISICS

The rotary plug valves (similar to ball and butterfly valves) used to be considered only as on/off shutoff valves, but today they are also used as control valves. Table 6.1a shows how they compare in their characteristics and applications to some of the other control valve designs. Plug valves are well suited for corrosive, viscous, dirty, fibrous, or slurry services, while they are generally not recommended for applications where cavitation or flashing is expected.

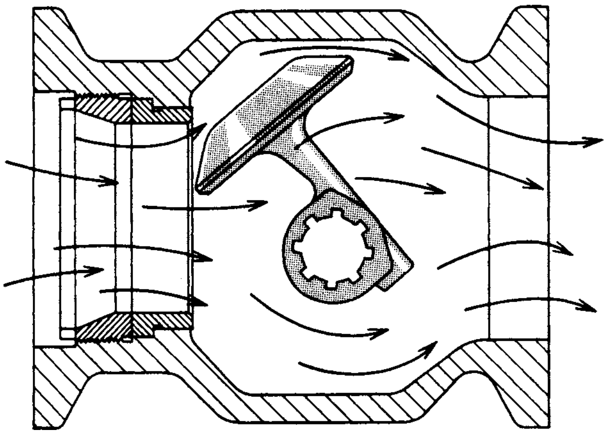

FIG. 6.21c
The self-cleaning nature of the eccentric rotating plug valve makes it a good option for slurry service applications.

Relative to the traditional globe valve, the advantages of conventional plug valves include their lower cost and weight, higher flow capacity, which can be two to three times that of the globe valve, if the plug is not characterized. In addition, they provide tight shutoff, fire-safe designs, and low stem leakage, which meets OSHA and EPA requirements.

The designs using characterized or eccentric rotating plugs provide good control performance and a self-cleaning flow pattern, which also reduces noise and cavitation. Actually, the performance of the rotating spherical segment-type valve is just as good as that of a globe valve, and for that reason some refer to it as a globe valve (Figure 6.21c).

In addition to their superior stem-sealing capability, plug valves are also suited for such corrosive applications as chlorine, phosgene, hydrofluoric acid, and hydrochloric acid. Plug valves are widely used on lethal and toxic services and can be made fire-safe by the use of Grafoil packing and can meet the external leakage requirement limits of API 607.

Plug Valve Features

The plug valve is a type of quarter-turn valve that is among the oldest designs known in engineering. Wooden plug valves were used in the water distribution systems of ancient Rome and probably predate the butterfly valve. Although no longer as popular as ball or butterfly valves, they lend themselves to special designs that work very well in specific control applications.

Conventional plug valves are usually lower cost and lighter weight than comparable gate or globe valves. Plug valves afford quick opening or closing with tight, leakproof closures under conditions ranging from vacuum to pressures as high as 10,000 PSIG (69 MPa). Some, including the various characterized and Y-ported or diamond design, can be used for throttling, while others, like the multiport, are used for diverting and bypass applications.

Plug valves are used on gas, liquid, and nonabrasive slurry services. Lubricated plug valves can also be used for abrasive slurries, and eccentric plugs are also used on applications involving sticky fluids. Plug valves are also used for applications requiring the contamination-free handling of foods and pharmaceuticals. In general, plug valves can handle applications with the following requirements:

- High flows at low pressure drops
- Low flow control
- Flow diversion
- High- or low-temperature applications
- Vibration-free operation
- Throttling control, only with eccentric and V-ported characterized designs.

The conventional plug valves are generally undesirable for the following types of applications:

- Flow modulation or continuous, exact flow throttling
- Maintenance-free operation (occasional lubrication is usually required and plugs may wear)

Throttling and Actuator Considerations

When used for throttling service some of the above-mentioned advantages of rotary valves, such as their high-capacity, can become disadvantages. Their high flow capacity can result in installations where small valves are mounted in large pipes. This results in a substantial waste of pumping energy, as the pump has to overcome the reducer pressure drops.

Also, the high-pressure recovery provided by most plug valve designs results in low vena contracta pressures, which in turn increase the probability of cavitation and noise. These problems, which are even more pronounced with pinch, butterfly, and ball valves, have been reduced by various means. In case of ball valves, perforated parallel plates have been inserted into the ball valve openings (Figure 6.16o) or flutes have been added to the butterfly disc (Figure 6.17s); however, the cavitation problems associated with high recovery valve designs have not been fully resolved.

In operating rotary valves, the linear movement of cylinder or spring-and-diaphragm actuators must be converted by linkages, which introduces hysteresis and dead play. In addition, a nonlinear relationship exists between actuator movement and the resulting rotation. These considerations make the use of positioners essential, which on fast processes can lower the quality of control. The torque characteristics of these valves are nonlinear (Figure 6.4v), and because of the high "break-torque" requirements, the actuators can be oversized relative to the torque requirements in the throttling range.

DESIGN VARIATIONS

The first plug valves consisted of a tapered or straight vertical cylinder containing a horizontal opening or flow-way inserted into the cavity of the valve body (Figure 6.21d). They have developed through time into numerous shapes and patterns, depending on the application, but almost all are adaptations of the cylindrical or tapered plug. Within that plug, however, the ports may be round, oval, rectangular, V-, or diamond-shaped, and can be the flow-through type two-way valves or multiport. These make up the special designs described in subsequent paragraphs.

Plug valve designs can be categorized as lubricated or nonlubricated. In the lubricated type, the thin film of lubricant serves not only to reduce friction between the plug and the body, but also to form an incompressible seal to prevent gas or liquid leakage. Because the seating surfaces are not exposed in the open position, gritty slurries may be handled. The lubricant hydraulically lifts the plug against the resilient packing to prevent sticking. A special lubricant must be injected periodically while the valve is either fully open or fully closed.

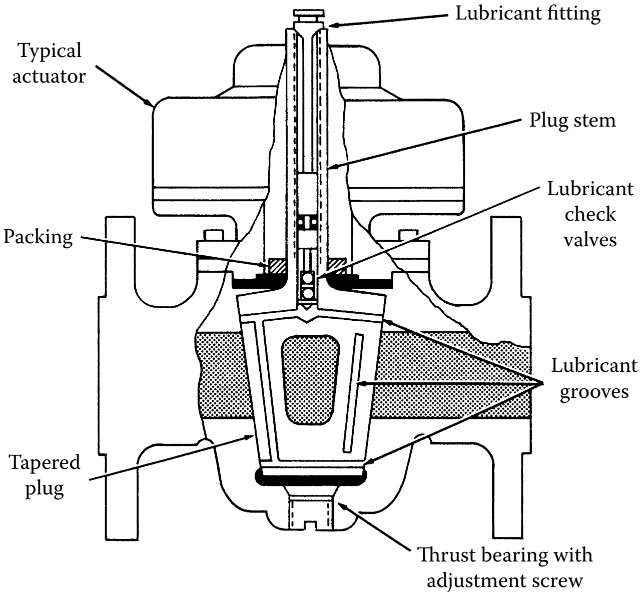

FIG. 6.21d
Conventional, lubricated plug valve with tapered plug.

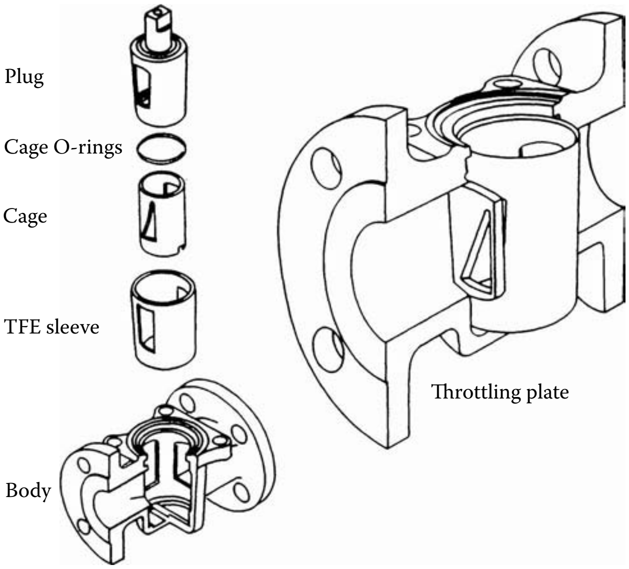

FIG. 6.21e
Throttling plates and characterizing cages can both be used to modify the inherent characteristics of plug valves. (Courtesy of Xomox/Tufline.)

The plugs of nonlubricated plug valves are treated with coatings such as Teflon or are specially heat-hardened and polished to prevent sticking. Often they are constructed so the tapered plug may be lifted mechanically from the seat for easier operation.

Characterized Plug Valves

Plug valves can be characterized by the use of characterizing cage or plate inserts (Figure 6.21e). The resulting characteristics are a function of the shape of the opening on the cage or plate.

Some examples of available plug valve characteristics are illustrated in Figure 6.21f. Rotation of the plug is inside a TFE sleeve, which is locked into the body in such a way that recessed areas minimized. Although a rangeability of 20:1 is claimed, this is made possible only if the valve can be fully open in order to provide full flow. The valve is available in 1/2–12 in. (12.5–300 mm) sizes and up to 600 PSIG ANSI (4.1 MPa) rating for use up to 400°F (204°C).

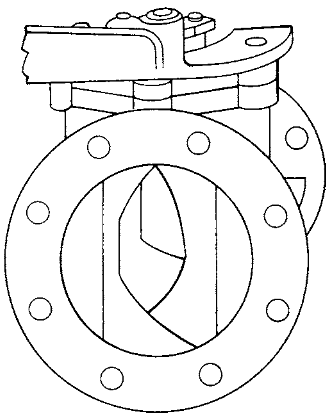

FIG. 6.21g
The design of a V-ported plug valve.

V-Ported Design

The V-ported plug valve (Figure 6.21g) is used for both on/off and throttling control of slurries and fluids containing solid concentrations in suspensions greater than 2%. These applications occur principally in the chemical and pulp and paper industries. A diamond-shaped opening is created by matching a V-shaped plug with a V-notched body.

Straight-through flow occurs on 90° rotation, when the plug is swung out of the flow stream. Shearing action and a pocketless body make the valve applicable for use on fibrous or viscous materials. The opening develops a modified linear flow characteristic with C_v capacities approximating 17d^2. Valves are flanged from 3–16 in. (75–400 mm) in bronze, corrosion-resistant bronze, or stainless steel. The body may be rubber-lined with a rubber-coated plug. A cylinder actuator and valve positioner are used for throttling control.

A variation is the true V-port opening (Figure 6.21h). It is obtained by a rotating segment that is closing against a

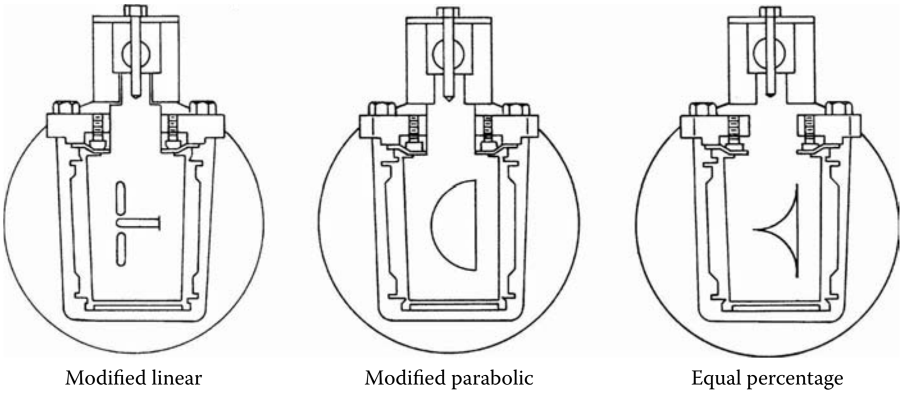

FIG. 6.21f
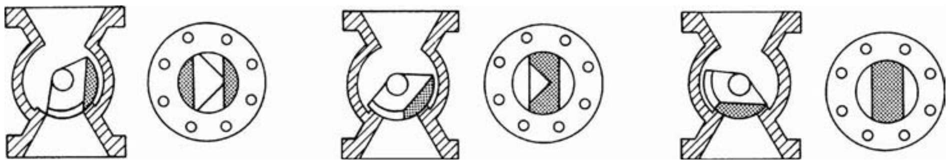
Plug valve characteristics can be modified to linear, parabolic, equal-percentage, and so on.



Open

There are no sharp corners or narrow openings to pack with stock. Large port area and clean interior design assure high flow capacity.

Throttling

Close plug-to-seat clearance remains constant. The V-orifice retains its shape throughout the cycle.

Closed

Flow continues until the V-orifice in the leading edge of the plug rotates past the seat, throttling is smooth down to the shutoff position.

FIG. 6.21h
Illustration of how throttling is provided by a V-ported plug valve.

straight edge. The valve can be smoothly throttled on thick stock flows without the stock packing or interfering. The valve is available in sizes from 4–20 in. (100–500 mm) and with C_v stated as more than $20d^2$. The valve is available in many body and trim materials for use in the chemical or pulp and paper industries. A cylinder-operated rack and pinion is used for on/off service with the addition of a valve positioner for throttling services.

Adjustable Cylinder Type

In another form of quarter-turn valve, flow is varied by rotating the core and by raising or lowering a “curtain” with an adjusting knob (Figure 6.21i). Proportional opening at any curtain position is made with the control handle, which may be attached to an actuator for automatic control. Various openings are obtained by these manipulations.

The valve is used for combustion control and for mixing applications, in which case valves are “stacked” on a common shaft or operated by linkages from the same actuator. To obtain linear flow with constant pressure drop, a port adjustment technique is used. After installation, the curtain is closed until the pressure drop across the valve is one sixth of the total pressure drop of the system using the control handle in wide open position. This provides a flow characteristic approximating linear without decreasing sensitivity by limiting valve stroke. The percentage of flow is equalized by manipulation of the linkage to the actuator.

Semispherical Plugs for Tight Closure

Various designs have been developed to obtain tight closure while eliminating the continuous friction of the seals during rotation, as with most ball valves. The valve design illustrated in Figure 6.21j uses an eccentric ball. In the closed position, the rectangular end of the stem protrudes into the ball and the closure face is wedged toward the seating surface. As the stem is rotated to open the valve, the closure surfaces separate and the pin moves into a vertical slot so that rotation occurs. A nonlubricated seal can be provided with a primary Teflon seal enclosed in a body seat retainer ring. The valve is adapted for automatic operation by connecting the stem to a diaphragm actuator.

Expanding Seat Plate Design

As shown in Figure 6.21k, metal-to-metal or resilient seats can be provided in two seating segments. These segments are

carried on a rail that is tapered so that downward stem movement forces the plates against the inlet and outlet ports. When the valve is being opened, the first few turns of the actuator cause the retraction of the plates and then plug rotation proceeds. These plates can be removed by merely removing the bottom plate of the valve V-body.

Retractable Seat Type

Positioning a movable seal after a spherical plug is in the closed position creates tight closure with sliding friction. In the retractable seat plug valve, a trunion-mounted partial sphere is operated by spur or worm gears (Figures 6.21l). The gear system rotates the plug until it is in a closed position, at which point additional rotation of the drive creates a camming action to compress the packing ring.

When the valve is being opened, the packing ring is released before the rotation of the plug occurs. Although also applicable to low-pressure service, this valve is particularly useful up to API 5000 PSIG (34.5 MPa) rating for 10,000 PSIG (69 MPa) service. It is used mostly in oil fields.

Overtravel Seating Design

By fabricating a cylindrical flow passage within a tapered cylindrical plug, a plug valve can be built at least up to the 60 in. size, without undue weight and attendant inertia to rotation. In the overtravel seating design shown in Figure 6.21m, the rotation of the inner valve is caused by a rod operated by a piston pushing down on a rotator. Continuous movement of the rod closes the plug, but leaves a small crescent, because the plug is slightly raised from seating. For tight closure, the rod contacts a seating adjustment to force the plug into a tapered seating surface.

In this design, the restriction of the flow area is rapid; 30% rod travel causes about 65% closure. Complete rotation of the plug occurs at about 65% stroke, with the additional stroke being utilized for seating. If rapid closure to about 20% opening does not create serious surge pressures, this valve can be used for emergency closure without much consideration of the piston speed. The rangeability of the valve exceeds 50:1 for proportional control. Free rotation and relatively low plug weight contributes to lower power requirements.

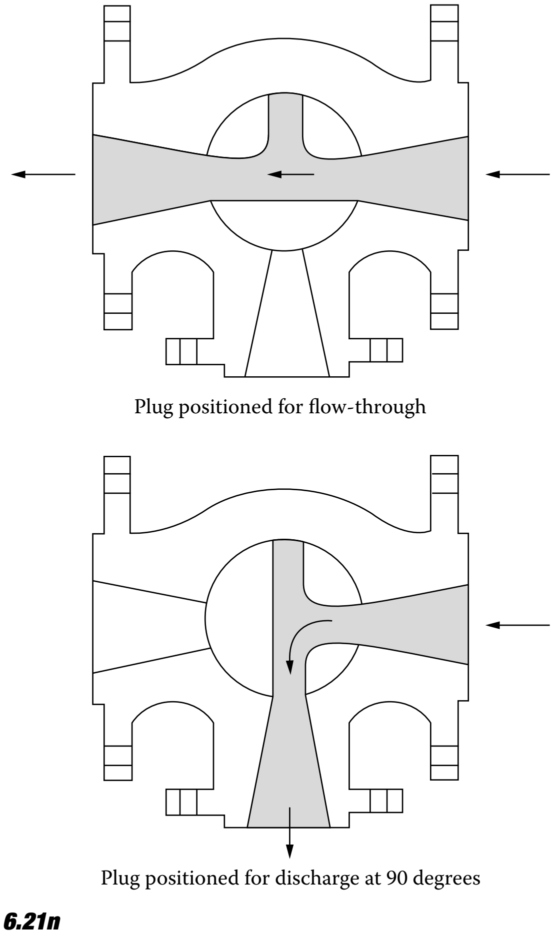
Two views of a plug valve of the overtravel seating design, shown in a throttling position.



Plug positioned for flow-through

Plug positioned for discharge at 90 degrees

FIG. 6.21n
The design of a three-way plug valve.

Multiport Design

As shown in Figure 6.21n, a three-way plug valve is obtained by providing the plug with an extra port at 90° from the inlet, so that flow can be directed in either of two destinations. A multitude of directions can be achieved by nesting combinations of the simple multiport valves or by using more complex designs. These include a multistoried arrangement with the plug extending upward to connect to a series of tiered outlets. In such multistoried configurations, the plug has a long, vertical passageway connecting the horizontal ports.

Another method of increasing the number of flow-directions is to design the plug with a diameter that is sufficiently larger than the ports so that intermediate ports can be placed at 45° or even 30 and 60°. In that case, the actuators can be programmed to serve a variety of process applications.

INTRODUCTION

The advantages of Saunders valves include their relatively low costs, tight shut-off, and suitability for corrosive, dirty, viscous, or slurry services (Table 6.1a). Their limitations include their poor control characteristics, although the use of the dual-range design improves it. They are also limited in their temperature (high and low) and pressure (high) ratings and are not suited for cavitating or flashing services.

The valve coefficients for a number of Saunders valve sizes with a variety of connection types and lining options are tabulated in Table 6.22c.

SAUNDERS VALVE CONSTRUCTION

The Saunders valve is also referred to as a diaphragm valve or less often as a weir valve. Conventional Saunders valves utilize both the diaphragm and the weir for controlling the

The characteristics of conventional Saunders valves are nearly quick opening, while the characteristics of dual-range Saunders valve designs are closer to linear.

flow of the process fluid (Figure 6.22d), while straight-through and dual-range ones do not necessarily use a weir.

The conventional Saunders valve is opened and closed by moving a flexible or elastic diaphragm toward or away from a weir. The elastic diaphragm is moved toward the weir by the pressure applied by a compressor element on the

diaphragm. The compressor is connected to the valve stem, which is moved by the actuator. The diaphragm, which at its center is attached to the compressor, is pulled away from the weir when the compressor is lifted.

For high-vacuum service it is often desirable to evacuate the bonnet of the Saunders valve in order to reduce the force that is pulling the diaphragm away from the compressor. This is especially desirable for large valves, where the vacuum might be sufficient to tear the diaphragm from the compressor.

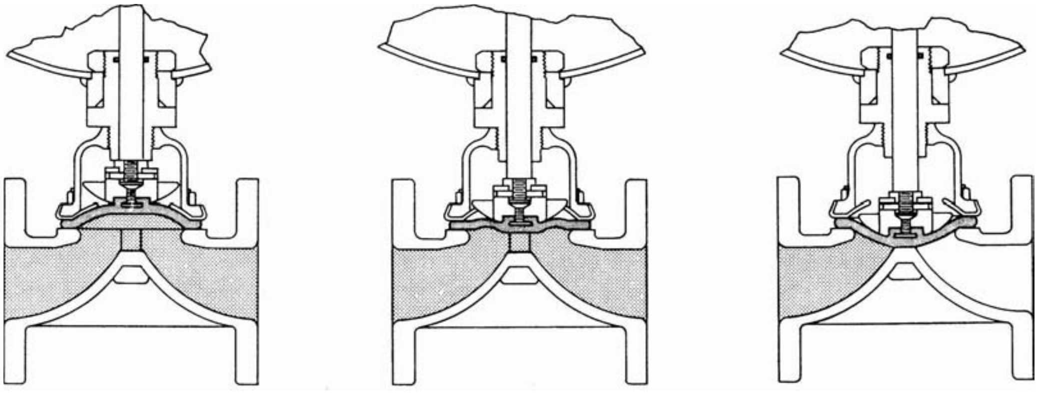
The compressor is designed to clear the finger plate, or diaphragm support plate, and to contour the diaphragm so that it matches the weir (Figure 6.22d). The purpose of the finger plate is to support the diaphragm when the compressor has been withdrawn. The finger plate is utilized for valve sizes 1 in. (25 mm) and larger. For valves larger than 2 in. (50 mm), the finger plate is built as part of the bonnet.

A Saunders valve can be considered as a half pinch valve (Section 6.20). The pinch valve operates as if two diaphragms were moved toward or away from each other, whereas the Saunders valve has only one diaphragm and a fixed weir. Because of their design similarity, their flow characteristics (see Figures 6.20v and 6.20w for pinch valves) are also similar, as it was shown above in Figure 6.22b.

Figure 6.22e shows the three basic positions of a conventional Saunders valve.

Materials of Construction

The body of a conventional Saunders valve (Figure 6.22d), because of its simple and smooth interior, lends itself well to lining with plastics, glass, titanium, zirconium, tantalum, and other corrosion-resistant materials (Figure 6.22f). Valve bodies



Streamline flow in open position
Flow control in throttling position
Leak-tightness in closed position

FIG. 6.22e
The open, throttling, and closed positions of a conventional Saunders valve.

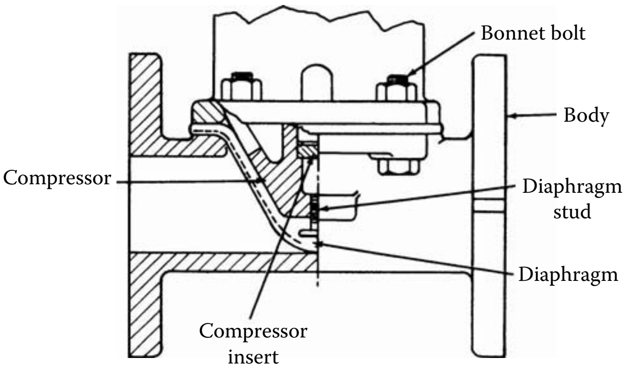


FIG. 6.22g
The design of a straight-through Saunders valve.

are available in iron, stainless and cast steels, alloys, and plastics. Iron bodies are lined with plastic, glass, special metals, and ceramics. As it was shown in Table 6.22c, lining lowers the valve capacity of smaller Saunders valves (under 2 in., or 50 mm) by about 25% below that of the unlined ones (Table 6.22c).

The diaphragm for the conventional Saunders valve is available in a wide range of materials. These include polyethylene, Tygon, white nail rubber, gum rubber, hycar, natural rubber, neoprene, hypalon, black butyl, KEL-F, and Teflon, with various backings, including silicone. Some of these diaphragms also contain reinforcement fibers.

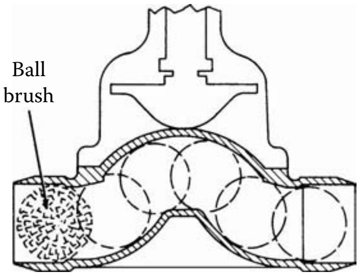

FIG. 6.22h
Full-bore Saunders valve.

Maintenance requirements of Saunders valves are mainly determined by the diaphragm life, which is a function of the diaphragm's resistance to the controlled process fluid (which may be corrosive or erosive) and also of the operating pressure and temperature (Figure 6.22a).

Straight-Through Design

The valve seat of the straight-through diaphragm valve is not the conventional weir. Here the compressor is contoured to meet the walls of the body itself (Figure 6.22g). The longer stem stroke of the straight-through valve necessitates a very flexible diaphragm. The increased flexure requirement tends to shorten the life of the diaphragm, but the valve's smooth, self-draining, straight-through flow pattern makes it applicable for hard-to-handle materials, such as slurry.

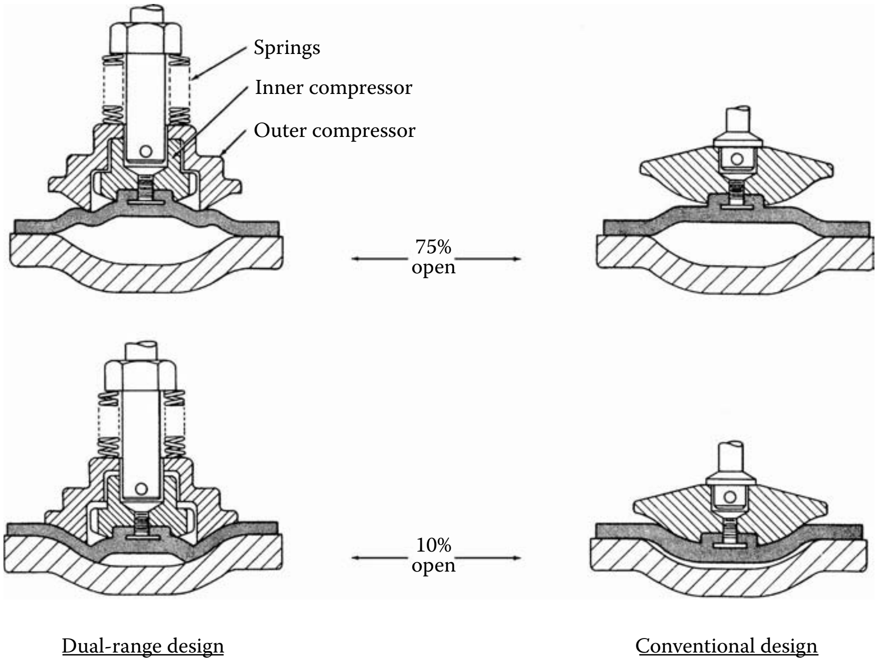

FIG. 6.22i
The shape of the openings of a 10 and 75% open Saunders valves are compared in the dual-range (left) and single-range (right) designs.

The flow characteristic of the straight-through design is more nearly linear than those of the conventional Saunders valves.

Full Bore Valve

The body of a full-bore Saunders valve is modified to provide a special shape to the weir. As a result, the opening of the internal flow path is fully rounded at all points, permitting ball brush cleaning (Figure 6.22h). This is an important feature in the food industry, where a smooth, easy-to-clean interior surface is required.

Dual-Range Design

The rangeability and flow characteristics of a conventional Saunders valve are rather poor, and so it is not suitable if high precision control is required. The flow characteristics of the dual-range design is an improvement, in comparison to the characteristics of the conventional Saunders.

The dual-range valve contains two compressors, which provide independent control over two areas of the diaphragm (Figure 6.22i). The first increments of stem travel raise only the inner compressor from the weir. This allows flow through a contoured opening in the center of the valve. This is superior to the operation of the single-range design, where the corresponding flow is the result of a slit across the entire weir.

This improvement in the shape of the value opening helps prevent clogging and the dewatering of stock and it also keeps abrasion at a minimum. In this dual-range design, while springs hold the outer compressor firmly seated, the inner compressor may be positioned independently to provide accurate control over small amounts of flow.

When the inner compressor is opened to its limit, the outer compressor begins to open. From this point on, both compressors move as a unit. When wide open, this valve provides the same flow capacity as its conventional counterpart.

6.23 Valve Types: Sliding Gate Valves

C. S. BEARD (1970, 1985) **B. G. LIPTÁK** (1995, 2005)

Flow sheet symbol

Types:	A. Knife gate B. V-insert C. Plate and disc (multi-orifice) D. Positioned disc
Sizes:	A. On/off; 2 to 120 in. (50 mm to 3 m) B. Throttling: $^1/_2$ to 24 in. (12 to 600 mm) C. Throttling: $^1/_2$ to 6 in. (12 to 150 mm) D. Throttling: 1 to 2 in. (25 and 50 mm)
Design Pressures:	A and B. Up to ANSI Class 150; higher with "wedge within wedge" design C. Up to ANSI Class 300 D. Up to 10,000 PSIG (69 MPa)
Design Temperatures:	A and B. Cryogenic to 500°F (260°C) C. −20 to 1125°F (−29 to 607°C)
Rangeability:	A. 10:1 B. 20:1 C. Up to 50:1 is claimed; see Section 6.7
Characteristics:	See Figure 6.23a
Capacity:	A. $C_v = 45\ d^2$ B. $C_v = 30\ d^2$ C. $C_v = (6 \text{ to } 10)\ d^2$ See Table 6.23b
Leakage:	A and B. ANSI Class I or II with metal seat; better with soft seat or lining C. ANSI Class IV; see Table 6.1gg for definitions
Materials of Construction:	A and B. Ductile iron, cast iron, carbon steel, 304, 316, 317 stainless steel, Alloy 20, Hastelloy B or C. Seating can be metal to metal, nylon, or RTFE C. Body: Ductile iron, bronze, carbon steel, stainless steel, aluminum, Monel Trim: Stainless steel is standard, which can be chrome-plated for hardness or Teflon-coated for corrosion resistance; Monel or Hastelloy trims are also available
Costs:	The cost of V-insert-type slide gate valves is similar to, but generally less than that of, single-seated globe valves, which are given in Figure 6.19b. The cost of plate and disc valves is given in Table 8.23j.

INTRODUCTION

The knife gate-type slide gate valves are relatively inexpensive, have high capacity, and are suited for slurry and dirty services. On the other hand they have poor control characteristics, do not provide tight shut-off, and are not suited for corrosive services. The V-insert type variation of this design has similar features, but as illustrated in Figure 6.23a, has better control characteristics.

The positioned sliding disc designs are ideal for high-pressure (up to 10,000 PSIG), cavitating, abrasive, or erosive services, but are relatively expensive and are not suited for sludge, slurry, viscous, or fibrous services. The multiport plate and disc type valves are similar, but provide superior control characteristics. These valves are available as pump governors or as unusually high rangeability (> 200:1) control valves in sizes from 0.5 to 6 in.

SLIDING GATE VALVE DESIGNS

Knife Gate Valves

Changing the process fluid's flow rate by sliding a plate past a stationary hole is one of the oldest and most basic approaches to throttling flows. The most common valve, the sliding gate valve, operates like this. Although occasionally used for automatic control, it is not considered to be a throttling control valve. It is a form of "guillotine"-type gate valve (Figure 6.23c) and is much used in the pulp and paper industry due to its shearing ability and nonplugging body design.

The "slab-type" sliding gate is provided with a round opening (Figure 6.23d) and therefore its characteristics are determined by the two converging circles. Its characteristics approximates equal-percentage behavior up to about 70% of its flow capacity, and above that it becomes nearly linear. The flow rate of 70% is reached by opening the valve to about 30% of its stroke.

On critical services, such as in catalytic cracking, reforming, isomerization, or coal gasification applications, the "double" gate valves are often considered (Figure 6.23e). In this

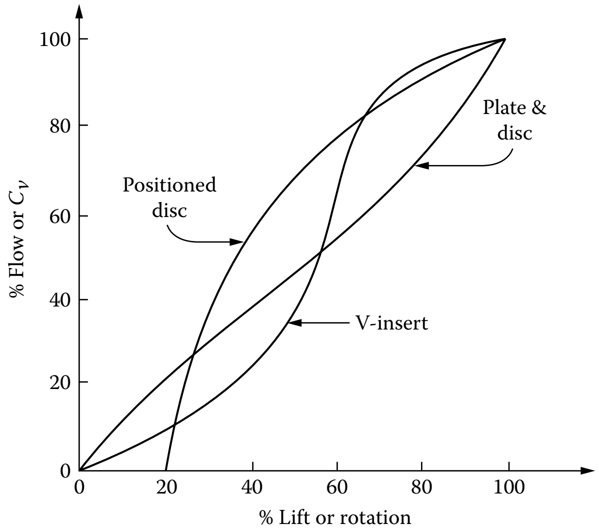

FIG. 6.23a
The characteristics of the various types of sliding gate-type valve designs.

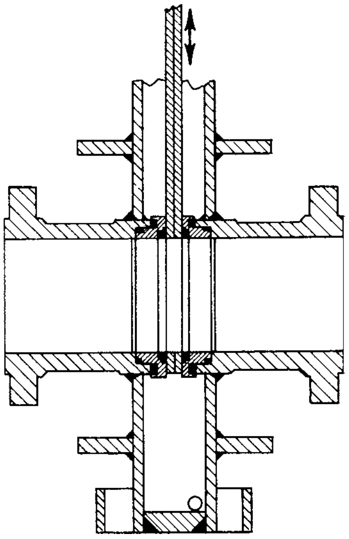

FIG. 6.23d
The design of a slab-type sliding gate valve.

design a "wedge" is provided within the wedge-shaped sliding gate. This inner wedge forces the two sliding gates on its two sides against the two seats, thereby guaranteeing tight closure.

V-Insert Type The addition of a V-shaped insert (Figure 6.23f) in the valve opening creates a parabolic flow characteristic. As shown in Figure 6.23a, this characteristic is somewhat similar to that of the V-ported globe valve. The performance of these valves is much dependent on the type of actuator and positioner used, because the quality of control is dependent upon the ability to provide very accurate positioning of the sliding gate.

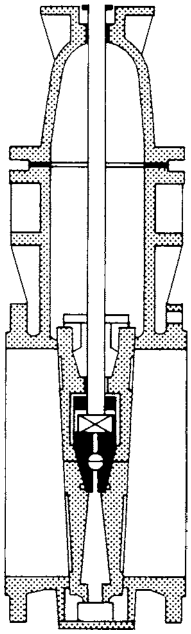

FIG. 6.23e
The design of the double gate valve, which is also called the "wedge in the wedge" design. (Courtesy of Zimmermann & Jansen Inc.)

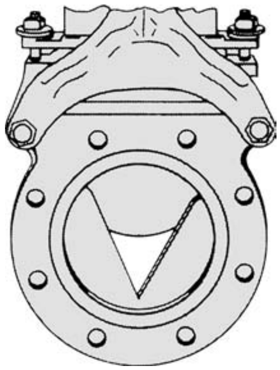

FIG. 6.23f
Sliding gate valve with V-insert.

Positioned-Disc Valves

Rotation of a movable disc with two holes, which if rotated can progressively cover two holes in the stationary disc, can successfully throttle flow (Figure 6.23g). This variable choke was designed to control flow from high-pressure oil wells.

The use of ceramic or tungsten carbide discs allows it to handle pressures up to 10,000 PSIG (69 MPa). Such valves are presently furnished in 1 and 2 in. (25 and 50 mm) sizes with areas from 0.05 in.^{2} with 0.25 in. hole (32 mm^2 with 6.3 mm hole) to 1.56 in.^{2} with two 1 in. holes (1006 mm^2 with two 25 mm holes).

An angle version of this valve design is used for proportioning control, with an actuator capable of controlling the discharge flow at quarter-turn movement. Both linear and rotary type actuators can be used. The valve opening (the relationship between the discs) remains in the last position if power fails.

A stepping actuator (Figure 6.23h) positions the inner valve disc in 1° increments as a function of a pneumatic controller input to a double-acting, spring-centered piston. Rotation occurs through a rack and pinion assembly. Limit

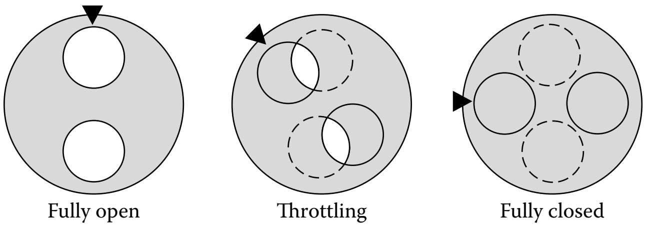

FIG. 6.23g
High-pressure process streams can be throttled by the positioned-disc-type slide gate valve.

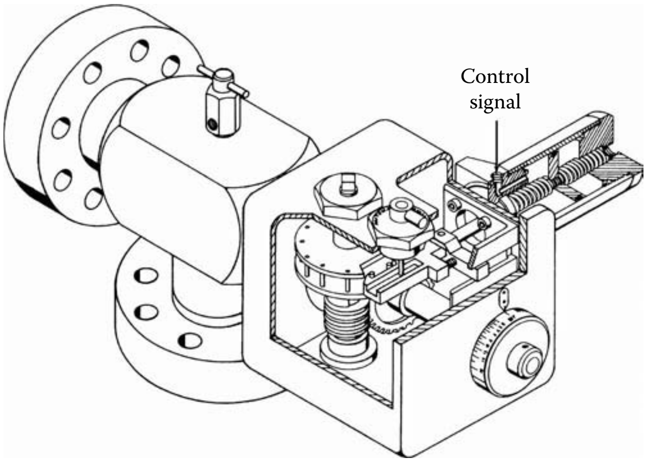

FIG. 6.23h

switches are provided, and a stepping switch can be used for position transmission and for position feedback in automatic control systems.

Plate and Disc Valves

A wide variety of flow characteristics are available using a stationary plate in the valve body and a disc that is moved by the valve stem. The plate (Figure 6.23i) is readily replaceable by removing a flanged portion of the body, which retains the plate with a pressure ring. Areas of the plate are undercut to reduce friction. A circumferential groove provides flexibility and allows the plate to remain flat in spite of differential pressures or expansion or contraction of the body. The stem contacts the disc by a pin through a slot in the plate.

The disc is held in contact with the plate by upstream pressure and by retaining guides. The contacting surfaces of the disc and plate are lapped to light band flatness. The chrome-plated surface of the stainless steel plate has a hardness comparable to 740 Brinell to resist galling and corrosion and obtain smooth movement of the disc. The material, with the registered name of Jordanite, is reported to have an extremely low coefficient of friction, is applicable to high-pressure drops, and has great resistance to heat and corrosion.

Flow occurs through mating slots in the disc and the plate. Positive shut-off occurs when the slots are separated (Figure 6.23i). Flow increases on an approximately linear relationship until the slots are lined up for maximum flow. Capacities are about $C_v = 6.5\ d^2$ through the 2 in. (50 mm) size and about $C_v = 12\ d^2$ through the 6 in. (150 mm) size.

Stem travels to obtain full flow are very short due to the slot relationship, and low-lift diaphragm actuators can be used for positioning. Forces needed for positioning are low, requiring only sufficient power to overcome friction between the plate and disc, which is right-angle motion and not opposed to the direction of flow.

Valve bodies are offered in sizes between $^1/_4$ and 6 in. (6.3 and 150 mm) and with ratings through 300 PSIG (2.1 MPa), depending on the material, with a selection of trims and packings. Many styles of actuators are used, including one with a thermal unit and cam actuation. This body design has been adapted for extensive use in self-contained pressure or temperature regulators.

This valve is also used to control the steam flow to steam-driven pumps, so as to maintain the pump discharge pressure constant. The sizes and costs of these pump governors are given Table 6.23j.

INTRODUCTION

Dampers and louvers are used to control the flow of gases and vapors. These streams usually flow in large ducts at relatively low static pressures. There are both "commercial" and "process control" quality dampers on the market. Commercial-quality units are used for the less-demanding applications, such as heating, ventilation, and air conditioning (HVAC), while the process control-quality units can handle higher pressures, higher temperatures, and corrosive vapors. The process control-quality units also can provide superior leakage and control characteristics.

Dampers are also used to control the flow of solids or to throttle the capacity of fans and compressors. There is no

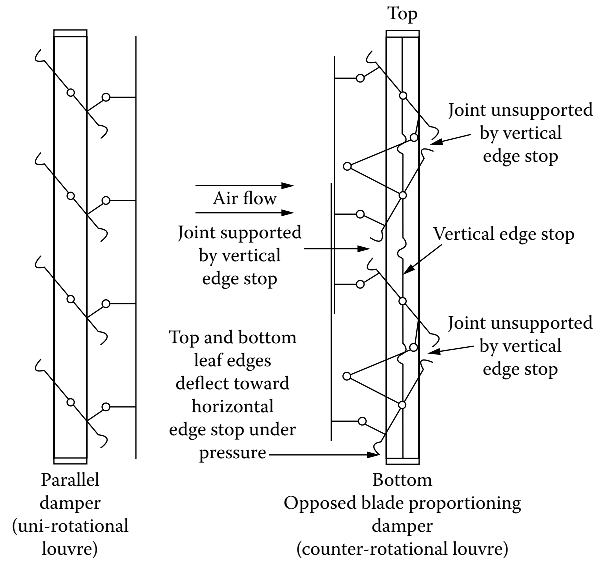

FIG. 7.1a

The designs of the parallel-blade and opposed-blade dampers, which are also referred to as uni-rotational and counter-rotational louver designs.

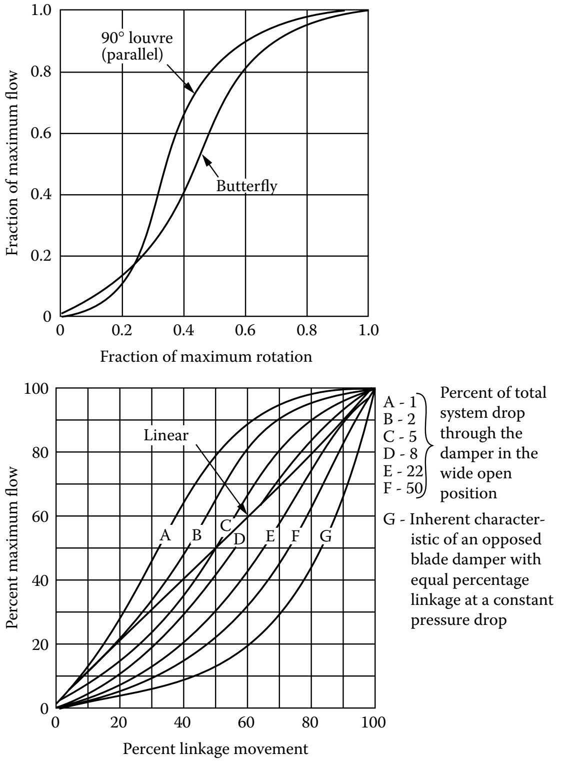

FIG. 7.1b

The flow characteristics of a parallel-blade damper are similar to those of a conventional butterfly valve (see top part of this figure). The flow characteristics of an opposed-blade damper approach equal-percentage characteristics when the total system pressure drop is through it and it shifts its characteristics toward quick opening, as the damper receives less and less of the total pressure differential.

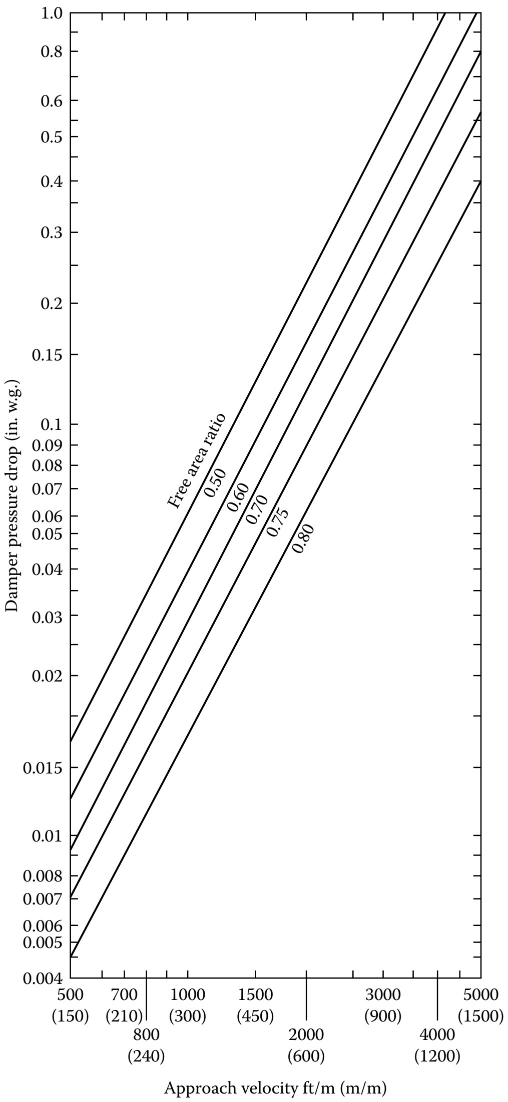

FIG. 7.1c

Pressure drop through wide-open dampers. The free-area ratio of an open damper is the total open area between the blades, divided by the nominal area.

clear distinction between butterfly valves and butterfly dampers or between slide-gate valves and guillotine dampers. The design features of these dampers are quite similar to their control valve counterparts, which are discussed in Chapter 6.

Dampers in general are large in size, and their operating and shut-off pressures are limited to lower values. The diameters of the largest dampers can exceed 20 ft (6 m).

DAMPER DESIGNS

Dampers and louvers can be grouped according to their shapes into parallel-blade, disc and multiple-disc, radial vane, and variable-orifice designs. Within each design category, there can be subdivisions according to leakage rates, materials of construction, actuator designs, or accessories provided.

Parallel-Blade Dampers and Louvers

Multiblade dampers consist of two or more rectangular vanes mounted on shafts that are one above the other, which are interconnected so they rotate together (Figure 7.1a). The vanes are operated by an external lever, which can be positioned manually, pneumatically, or electrically. In the uni-rotational louver (parallel damper) design, the vanes remain parallel at all rotational positions. In a counter-rotational louver (opposed blade), alternate vanes rotate in opposite directions. Both designs are illustrated in Figure 7.1a.

Flow guides are sometimes installed between adjacent vanes in order to improve the effectiveness of throttling. In the top of Figure 7.1b, the blade-angle vs. flow characteristics of a parallel-blade damper and a butterfly valve are shown. The sensitivity of this design is very high at mid-flow while the last 30° of rotation is relatively ineffective. The flow characteristics of butterfly valves are similar though somewhat superior to those of louvers.

The lower portion of Figure 7.1b shows an opposed-blade damper with equal percentage linkage. As less and less of the total system pressure drop is assigned to the damper, the characteristics of this damper shift toward quick opening.

Figure 7.1c gives the pressure drop across wide-open dampers. Ideally the wide-open pressure drop should be between 4 and 8% of the pressure difference across the closed damper. If the damper is sized so that closed pressure difference is between 12 and 25 times the pressure drop, when the damper is open, its apparent characteristic will be nearly linear (see curves C and D in Figure 7.1b).

Figure 7.1d provides some dimensional data for standard commercial damper frames, including their areas.

Low-Leakage Designs The parallel-blade damper cannot provide tight shut-off because of the long length of unsealed seating surfaces. The leakage characteristics of unsealed standard dampers are given in the lower portion of Figure 7.1e. In low-leakage damper designs, blade seals are installed along the seating surfaces of the blades, resulting in the reduced leakage characteristic shown in the upper portion of Figure 7.1e.

There are a number of variations in the blade-edge seal designs. Some of these designs are illustrated in Figure 7.1f.

Corrosion Resistant Designs For corrosive services, both the parallel- and the opposed-blade designs are available in sizes from 12 by 24 in. up to 60 by 120 in. These units are made of fiberglass-reinforced polymer with 304 stainless steel hardware. Some design variations are shown in Figure 7.1g.

Actuators and Accessories Damper actuators can be manual, electric, hydraulic, or pneumatic. Standard pneumatic actuators vary their effective diaphragm areas from 2 to 24 in.^{2} (13 to 155 cm^2), while their stroke lengths range from 2 to 6 in. (51 to 152 mm). The amount of force they produce ranges from about 10 to 300 lbf (4.5 to 136 kgf). The standard spring ranges for dampers include the spans of 3–7, 5–10, and 8–13 PSIG (0.2–0.48, 0.34–0.68, and 0.54–0.88 bars). Electronic actuators can be operated by 4 to 20 mA DC analog or by digital signals.

For more accurate throttling, the actuators can also be provided with positioners. If remote indication of damper status is desired, limit switches can be installed to detect the blade angle. These can be pneumatic sensors of nozzle backpressure or mechanically actuated position sensors. The damper position switch can be furnished with an adjustable mounting flange, which allows the unit to be mounted through a duct wall with the trip lever positioned so that it is actuated by the damper blade itself.

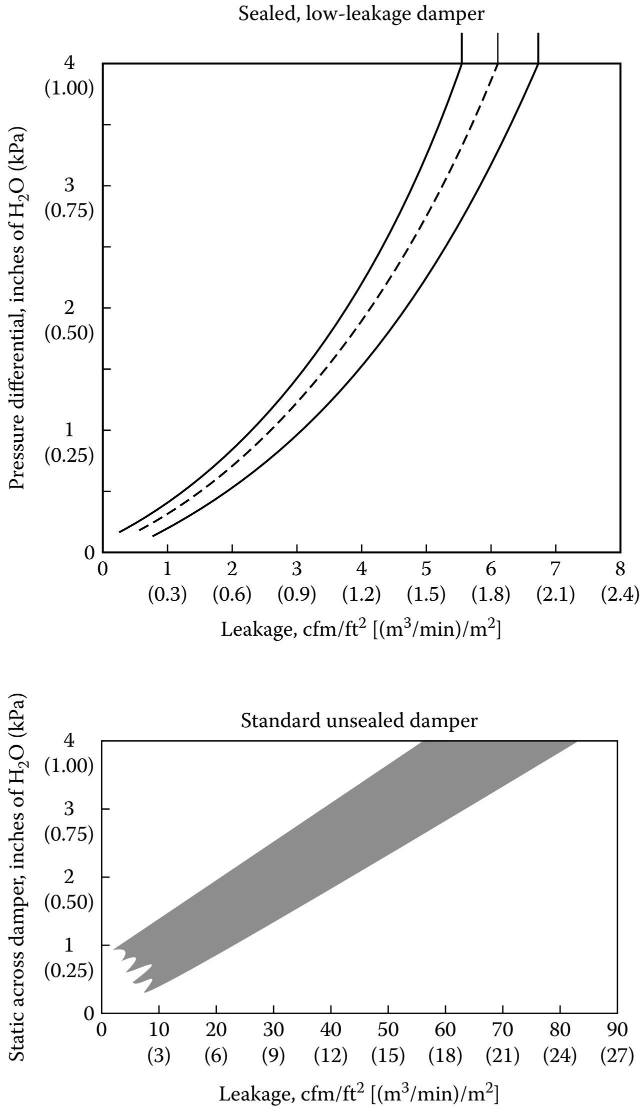

FIG. 7.1e
The leakage rates through sealed, low-leakage dampers are shown in the top, while the leakage rates of unsealed dampers are given in the bottom portion of the figure. (Courtesy of Honeywell and Ruskin, formerly Johnson Controls.)

Rotating Disc Dampers

The rotating disc damper designs are very similar to the butterfly valve designs, which were discussed in detail in Section 6.17. These dampers are usually installed in circular ducts and can be operated both manually or automatically. A corrosion-resistant version of this design is made of fiberglass-reinforced plastics materials and is illustrated in Figure 7.1h.

Multiple-Disc Dampers

A unique variation of the butterfly design is the multiple rotating disc damper. In this design several disc elements are distributed over an area (Figure 7.1i). One advantage of this configuration is improved flow control characteristics,

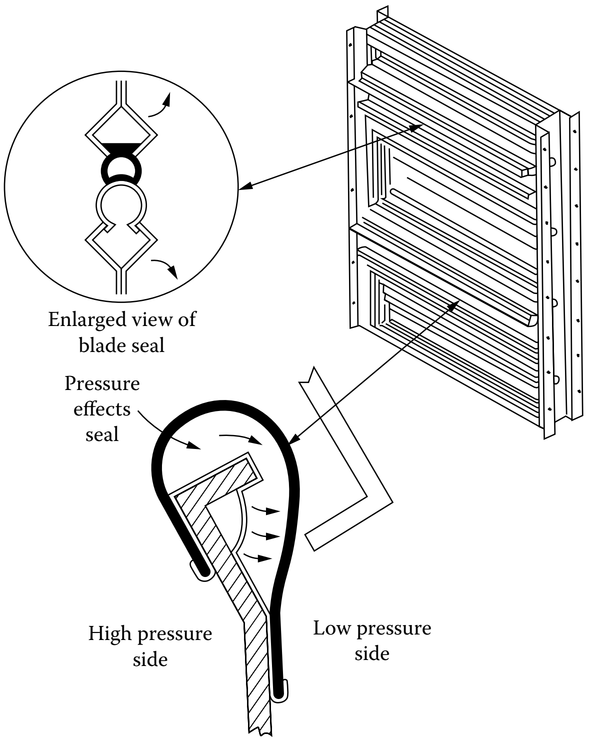

FIG. 7.1f
Low-leakage damper designs tend to increase the efficiency of HVAC systems. In this figure, two blade-edge seal designs are illustrated. (Courtesy of Honeywell and Ruskin, formerly Johnson Controls.)

because each disc can have its own unique spring range and failure position.

Another major advantage is the substantial reduction in leakage compared to the parallel-blade design. At a static pressure of 3 in. H_2O (0.75 kPa) the leakage can be estimated as 0.01% of full damper capacity, which corresponds to about 0.5 SCFM (2.5 $l/s/m^2$) leakage per ft^2 (0.092 m^2) of damper area.

Fan Suction Dampers

On blowers and fans, when throughputs must be controlled, radial vane dampers can be utilized. The damper consists of a number of radial vanes arranged to rotate about their radial axis (Figure 7.1j).

The radial vane dampers do not provide high-quality control, and their closed position leakage rates are also high. Their control applications include furnace draft control.

Usually a positioner is furnished with these units, which provides a linear relationship between the control signal and the blade pitch angle. In certain packages the positioner is factory set in the reverse acting mode, meaning that an increasing control air signal will reduce the air flow by decreasing the blade pitch. In such packages, one has to install a reversing relay between the positioner and the actuator, if direct action is desired.

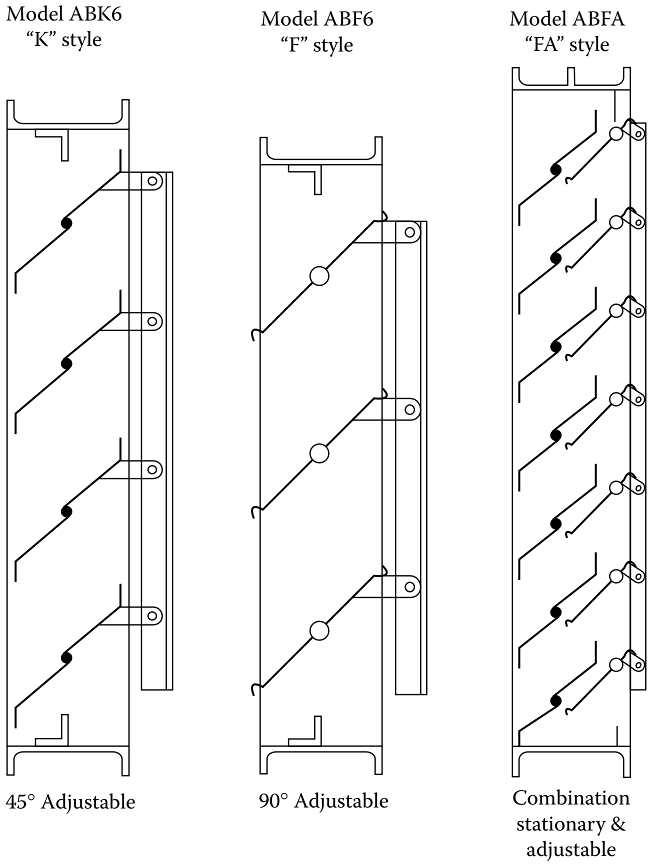

FIG. 7.1g
Corrosion-resistant fiberglass-reinforced polymer damper designs for both adjustable and stationary applications. (Courtesy of Polymil Products Inc.)

Variable-Orifice Dampers

Variable-orifice dampers use the same principle as the iris diaphragm of a camera. In order to achieve control action, the closure element moves within an annular ring in the damper body and produces a circular flow orifice of variable

FIG. 7.1h
Corrosion-resistant single-disc damper (Courtesy of Polymil Products Inc.)

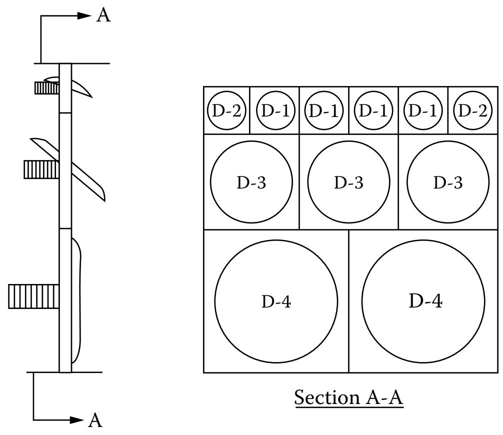

FIG. 7.1i
Multiple-disc dampers provide better sealing and control characteristics.

diameter (Figure 7.1k). The flow characteristics are similar to those of a linear valve.

However, tight shut-off is not possible, and leakage rates are comparable to or greater than those of a butterfly valve of equal size. Maximum pressure differential is limited to approximately 15 psid (104 kPa). Dual valve units can be provided with a common discharge port for applications involving the blending of two streams.

For solids service, the variable-orifice valve can be used for throttling, if the valve is installed in a vertical line. In horizontal lines, the shutter mechanism of the valve forms a dam, which makes the valve unsuitable for solids service. Standard sizes range from 4 to 12 in. (100 to 300 mm).

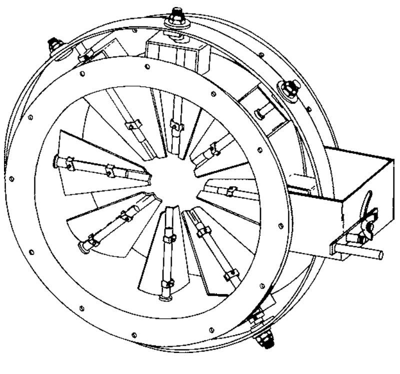

FIG. 7.1j
Radial vane dampers are used to throttle the flow on the suction side of air fans and blowers.

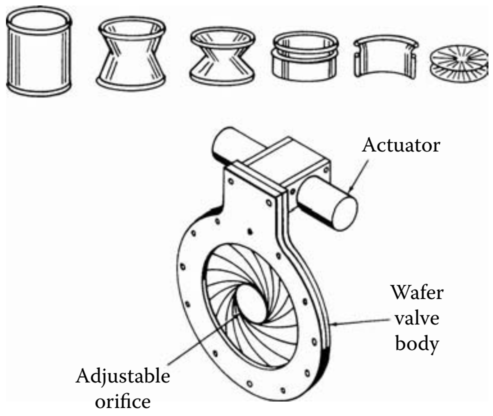

FIG. 7.1k
Variable-orifice or iris damper. The sleeve can be made of nylon or of other materials and is provided with a built-in retaining ring at each end. When the upper end is fixed and the lower end is rotated, this gradually reduces the orifice opening. At 180° of rotation the orifice is completely closed. If the sleeve is first turned back on itself, partly "inside out," the effect of rotation is exactly the same, but operates in a much more compact form, as a pleated duplex diaphragm.

CONCLUSIONS

Dampers are suitable for control of large flows at low pressures where high control accuracy is not a requirement. Typical applications of these units include air conditioning systems and furnace draft control. Variable-orifice or iris dampers are smaller than other dampers, offer better control quality, and can also be used to control vertical solid flows.

INTRODUCTION

Devices for modulating the flow of electrical heating power can be grouped into on/off and proportional control devices. Examples of on/off final control elements include solid-state relays (SSRs) or solid-state contactors (SSCs) and electromechanical power relays or contactors. Proportional power controllers are mostly silicon-controlled rectifiers (SCRs), with some saturable core reactors, power amplifiers, and a few ignitrons also still being used.

An SCR or thyristor is a semiconductor device that switches AC power on and off. On/off control always produces a cyclic

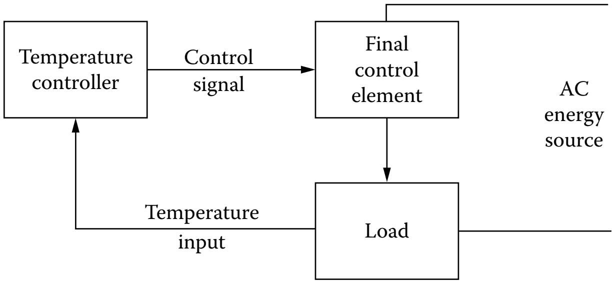

FIG. 7.2a
Temperature control loop, using electric energy modulation as the means of control.

response, while properly tuned proportional throttling control improves control quality by eliminating cycling. SCRs are almost silent in operation and can eliminate the switch-on surge.

Electric power throttling devices are often used as the final control elements in temperature control loops, as shown in Figure 7.2a. The load, to which the electric power is throttled by this final control element, can be an electric or ultraviolet heater, but can also be a variable-speed motor or any other electric load. A comparison of the characteristics of the various electric energy modulation devices is summarized in Table 7.2b.

ON/OFF POWER CONTROL

Electric circuits can be opened and closed as a function of the value of temperature or other controlled variables. Such on/off control devices have been discussed in several sections of the three volumes of this handbook. In the *Process Measurement* volume, Section 2.7 covered flow switches, Section 4.11 discussed temperature switches, and Section 5.13 dealt with pressure switches. Relays and contactors are covered in Chapter 5 of this volume.

The common feature of these on/off devices is that they apply electric power intermittently and therefore cause cycling in the controlled variable, which usually is temperature. This mode of control is acceptable only in such secondary processes as HVAC, where steady and close control is not required and cycling can be tolerated.

THROTTLING POWER CONTROLLERS

A power controller contains solid-state switching devices, heat sinks, protection circuits, and the electronics to control the solid-state switching devices. The power controller accepts standard industrial control signals, which can either be analog, such as 0–5 mA, 1–5 mA, 4–20 mA, 0–5 V, 0–10 V, or digital and which controls the power or voltage delivered to an electrical load in proportion to the control signal.[1]

For temperature control applications both the saturable core reactors and the silicon-controlled rectifiers (SCRs) are used. Both will be described below.

Saturable Core Reactors

A saturable core reactor is a device consisting of an iron core, an AC or gate winding, and a control winding (Figure 7.2c). The impedance of the gate winding can be changed by means of the magnetic flux produced by the DC current in the control winding. A DC control signal of a few watts can therefore control hundreds of kilowatts of AC power. Because the control signal requires watts of power, a magnetic amplifier is always used to boost the control signal from the process controller up to the power level required by the control winding of the saturable core reactor.

Saturable core reactors are relatively inefficient (90%), large in size, and require water or air cooling, depending upon their power rating. Their main advantage is their immunity to modest transients and overloads. Well-designed SCRs can offer similar reliability at greater efficiency and reduced size.

The main advantage of saturable core reactors is that it is not possible to burn out the unit. Even if the controlled electric heater is short-circuited, it will not allow enough current to flow to burn out the reactor. The disadvantages of the saturable core reactors, in addition to their size and weight, is that they cannot adjust the line voltage from 0 to 100%.

Because the reactor relies on the impedance of its core to attain the shut-off power, a shut-off condition will still

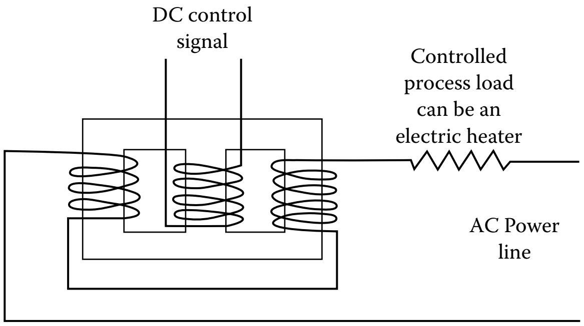

FIG. 7.2c
The basic components of a saturable core reactor controller.

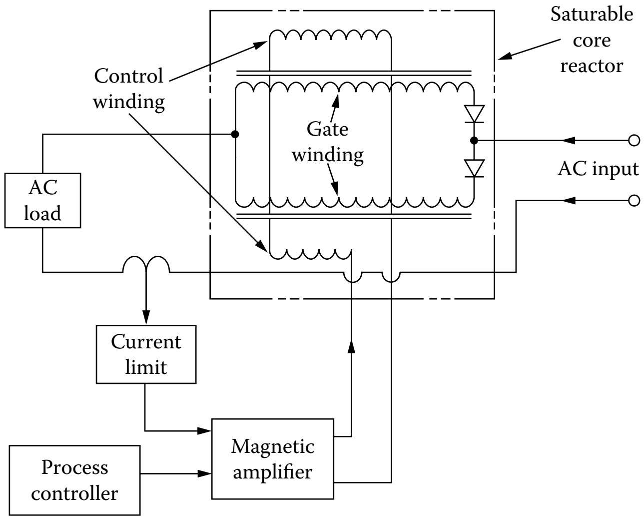

FIG. 7.2d
Current limiting applied to a saturable core reactor control loop.

yield about 3% of full power. Similarly, because the reactor depends on the saturation of its core to provide full power, this full power state usually yields only about 90% of full power. Therefore, when the control signal is 0, the load voltage is about 5%, and when the control signal is 100%, the load voltage is only about 90% of the line voltage.

As a consequence of this limitation, the use of saturable reactors requires a very good understanding of the nature of the load, because the saturable core reactor must be so selected that the load wattage and voltage will always be within 3 and 90% of its power control range. In order to reduce the severity of this limitation, reactors can be tapped for several ratings.

Saturable core reactors can be provided with current limiting by means of a current transformer and an appropriate input to the magnetic amplifier. A diagram of a typical saturable core reactor design is shown in Figure 7.2d.

SCR Power Controllers

The power switching element in most power controllers is a silicon-controlled rectifier—thus the general term "SCR power controller." The SCR is a four-layer solid-state silicon structure consisting of alternating layers of negatively and positively doped material. It is a three-terminal device consisting of an anode, a cathode, and a gate, encapsulated and bonded to a thermally conductive base (Figure 7.2e).

In order for the SCR to conduct, the anode must be positive with respect to the cathode and a trigger signal at the gate must initiate conduction. Once the gate has been pulsed by a DC voltage, conduction is self-sustained until the current flow through the SCR tries to reverse. When current attempts to reverse, the SCR "commutates" and returns to the blocking state and will remain "off" until triggered again, provided the anode is positive with respect to the cathode. In this manner an SCR can efficiently control loads from a few hundred watts to megawatts of electrical energy.

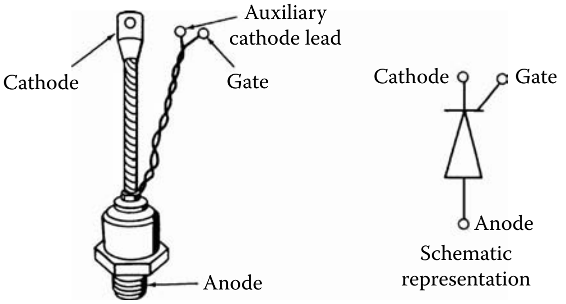

FIG. 7.2e
The components of a silicon-controlled rectifier.

For DC applications, two SCRs are combined with two diodes to provide a full wave rectified, modulated output. For AC loads, two SCRs are connected in an antiparallel fashion to provide modulated AC output.

Below a kilowatt, some AC power controllers use a triac as the power switching element. A triac is a four-layer device with three terminals that behave as a pair of SCRs connected in an antiparallel fashion. Power controller configurations for DC loads, as well as SCR and triac AC loads, are shown in Figure 7.2f.[2]

SCR-type power controllers operate either by turning on each AC cycle for part of the full cycle (phase-angel firing) or by sending only a percentage of the full cycles to the load (zero-voltage firing). Zero-voltage firing is like turning a switch on and off while the power is off. Phase-angle firing can be compared to opening and closing a switch while the power is on.

Relative to the saturable core reactors, the SCRs are superior in the following ways: They are smaller in size and weight; they have higher efficiencies because complete shut-off of electric heaters can be attained; and they do not require load matching, but are able to control any load that is below their rating. The disadvantages of SCRs are due to their being semiconductor devices, which necessitates that they be protected against transient surges, high inrush currents, load short circuits, over-temperatures, and other circuit component failures.

Phase-Angle-Fired SCR Controllers An SCR, once gated properly, will continue to conduct until the current through it goes to zero. Phase-angle-fired units modulate the power delivered by triggering the SCR between 180° and 0° in the appropriate half cycle of the AC supply. As shown in Figure 7.2g, the point at which the SCR is triggered is defined as the firing angle. The SCR will deliver power to the load until the end of the half cycle. Thus, for half power the SCR is gated on at 90°; for 75% power the firing angle is gated at 60°; and the full-power firing angle is 0°.

The same action occurs for the negative half cycle, thus resulting in the waveforms shown. Thus, by varying the point in each half cycle where the SCRs are turned on, the average power delivered to the load can be varied from zero to full power, in proportion to the control signal, with infinite resolution.

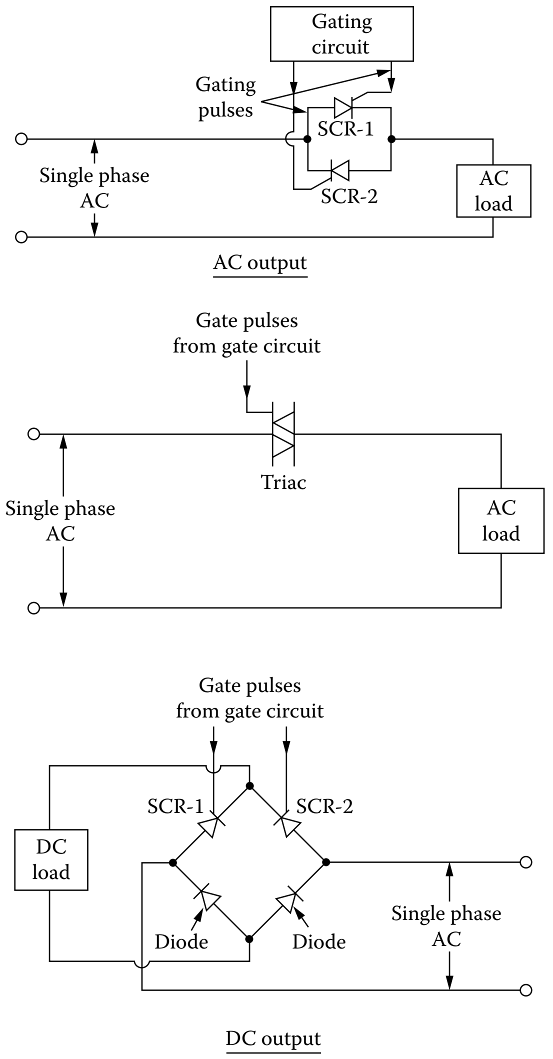

FIG. 7.2f
Power controller configurations: SCR and triac circuits for AC loads on the top and SCR control circuits for DC loads at the bottom.

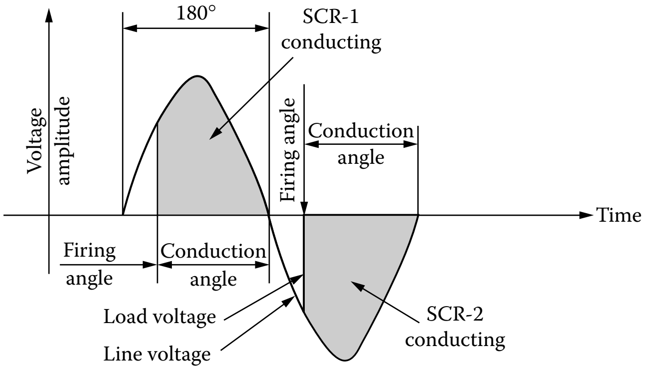

FIG. 7.2g
Definition of firing and conduction angles.

Radio Frequency Interference (RFI): Phase-angle firing can generate radio frequency interference and power line spikes, which can cause interaction between controllers if two or more of them operate on the same line. Because a phase-angle-fired SCR power controller switches from the off state to the on state very quickly (less than 1 ms) at substantial voltage levels, harmonics in the radio frequency area of the spectrum are created. This radio frequency interference can interfere with proper control loop performance. In severe cases or sensitive applications, filtering of the RFI by means of line chokes and bypass capacitors may be necessary.

Current Limit Feature: With the addition of a current transformer and some control circuitry, an adjustable current limit feature can be used with phase-angle-fired power controllers for loads that exhibit high inrush currents. These types of loads are heaters whose cold resistance is very low compared to the resistance at normal operating temperatures.

Current limiting works by always gating the SCRs on at a 180° firing angle, then moving the firing angle back toward that desired by the control signal. As the firing angle is backed away from 180°, the current is monitored and will be kept below the preset current limit before the firing angle is permitted to back away toward higher current output firing angles. This feature is also useful for transformer-coupled loads to ensure that the transformer is not driven into saturation and drawing excessive current.

Soft Start Feature: With phase-angle-fired power controller units, a soft start feature will start the firing angle at 180° and ramp up slowly (typically 0.5–1 sec) to the firing angle desired by the control signal. This feature can be incorporated with little or no additional control circuitry and is usually standard on most phase-angle-fired power controllers. It helps to prevent high inrush currents experienced with transformer-coupled loads, coupled loads, and nonlinear heating elements.

ZERO-VOLTAGE-FIRED SCR CONTROLLERS

In zero-voltage-fired power controllers the SCRs are gated on at the beginning of each half cycle. Thus, each SCR will conduct for a full cycle. Generally, power modulation is accomplished by varying the number of full half cycles on vs. the number of full cycles off over some time base (usually 0.5–1 sec).

If we assume a 1 sec time base, then at 50% power the load would receive 30 full cycles on and 30 full cycles off. At 20%, power would be on for 12 full cycles and off for 48 full cycles. Sometimes zero-voltage-fired units are called burst-fired units because in this type of unit the load receives a burst of energy followed by some off time.

Some units proportion energy without a fixed time base by varying both the on time and the off time. For this type of unit, 50% would have one full cycle on and one full cycle off, 20% would be one full cycle on and four full cycles off. Typical waveforms of both methods are shown in Figure 7.2h.

Because a zero-fired SCR controller gated the SCR on at the beginning of the cycle, current limiting cannot be done with

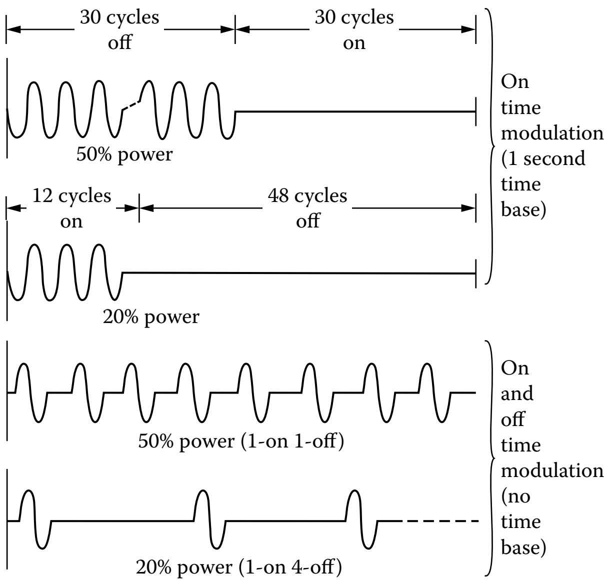

FIG. 7.2h
Output waveforms when zero-voltage firing is used.

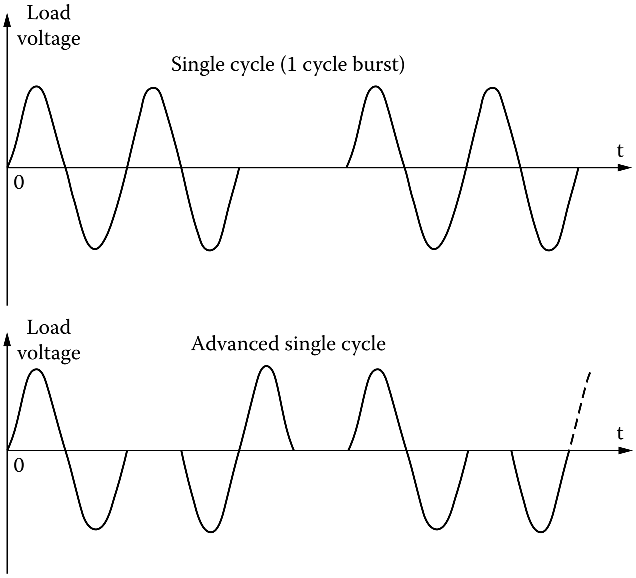

FIG. 7.2i
On top, the conventional single cycle firing method is illustrated, while on the bottom the advanced half cycle firing is shown. (Courtesy of Invensys Eurotherm Controls.)

this type of unit. For this reason zero-fired units are usually applied to resistive loads and not transformer-coupled loads.[3]

Because the SCR is gated at or near zero voltage, almost no RFI is generated by this type of SCR power controller. This is the chief advantage of this type of SCR unit over the phase-angle-fired type.

Controlling Infrared Tungsten Heaters

Infrared radiation occurs at wavelengths from 0.76–1000 μm. The *radiant* heat output of an IR heat source relates to the fourth power of its temperature, and the wavelength of IR radiation depends on the temperature of the heat source. The wavelength of the IR radiation also determines its ability to penetrate or to be absorbed. The shorter wavelengths emitted by tungsten lamps at 4000°F are more penetrating than those emitted by nickel chrome filaments operating at 1800°F.

Different processes benefit differently from the use of different wavelengths. For example, the heating of transparent materials such as water requires longer wavelengths. On the other hand, the drying of paint benefits from the greater penetration of shorter wavelength IR radiation.

Traditional IR Controls The traditional method of controlling IR heaters was by phase-angle-fired SCRs. They provided smooth, stable application of the power, and their soft start eliminated inrush problems.

This method also had the disadvantages of higher equipment cost and higher electricity consumption, because of the reduced power factor. In addition, phase-angle firing required larger transformers due to harmonics, and it also generated RF interference, which can harm the electronics equipment.

Advanced Half Cycle Firing and V^2 Power Control Figure 7.2i illustrates both the conventional single cycle and the advanced half cycle firing. In single cycle firing the on and off times are reduced to a single whole cycle of the AC supply. In contrast, the advanced method switches half cycles and, thereby, reduces the off time at 60 Hz to 8.33 ms. This not only reduces flicker, but provides a more stable heater temperature, as the tungsten filament has less time to cool.

One possible disadvantage of the half cycle firing method is the generation of DC current or voltage if the number of switched positive and negative half cycles is not equal. To eliminate this requires intelligent half cycle firing.

The relationship between tungsten filament temperature and radiated energy output is not linear, but the relationship between power output and the square of the voltage (V) is linear, as shown in Figure 7.2j. Therefore, for the best overall performance of IR heater controls, the intelligent half cycle firing should be combined with voltage-squared power control.

Common SCR Limitations

Regardless of the type of power controller chosen, some common limitations exist that require protective devices or circuitry. These are usually provided by the manufacturer and some of them are described below.

Transient Voltage Protection SCRs can be damaged by the line voltage transients that exceed the voltage capability of the device. Most power controllers offer metal oxide varistor (MOV)

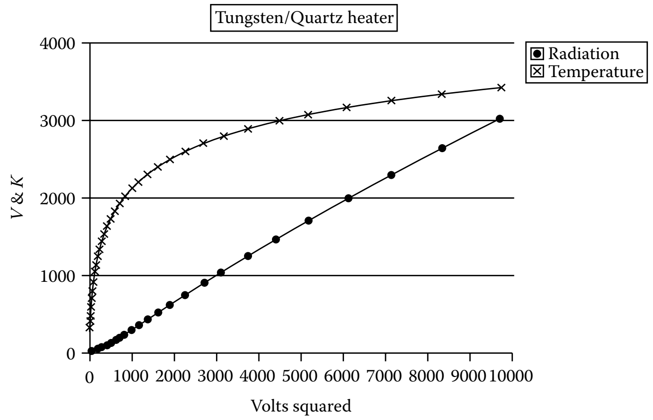

FIG. 7.2j
The radiated energy related linearly to the square of voltage. (Courtesy of Invensys Eurotherm Controls.)

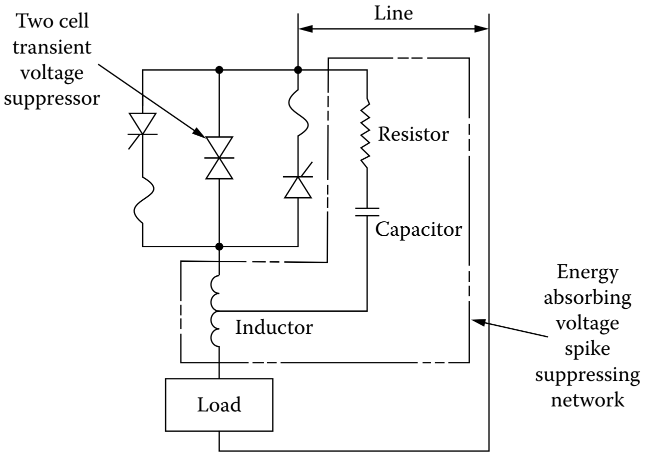

FIG. 7.2k
Energy-absorbing network using voltage spike suppressors.

protection circuitry across the SCR. The MOV will short-circuit the voltage spike around the SCR and prevent a false turn-on or permanent damage to the device.

Current Limit Fuses SCRs will fail due to load shorts, just as mechanical contactors will. SCRs have fault current ratings that are specified by the terms I^2T and I surge. These ratings allow proper selection of the special fuses that clear in less than a half cycle in order to protect SCRs. The I^2T and I surge value of the fuse should be less than that of the SCR it is to protect.

dv/dt Protection A large change in a short period of time can cause problems with SCR performance. High rates of voltage change (dv/dt) can trigger an SCR into an unscheduled turn-on by inducing internal gate trigger currents via interjunction capacitance. Transformer-coupled loads can present dv/dt problems due to a lagging current in the inductive load. In this case the SCR will not commutate (turn off) when the gate trigger is stopped.

Transient voltage spikes are also a form of dv/dt problems. To prevent dv/dt problems, gate-to-cathode capacitors are used to shut internally coupled gate currents from the gate, or R-C snubber circuits are used in parallel with the SCR (Figure 7.2k).

di/dt Protection A high anode current flow during the turn-on of the SCR can stress the junctions of the device. If a load requires near-rated current before the entire junction area of the SCR is turned on, then the current density in the partially conducting junction is too high. This can cause localized heating and eventually lead to failure of the device. Usually, gate drive circuitry ensures good junction turn-on with a large fast-rising trigger pulse.

If a load is purely resistive, then for phase-angle-fired units some small inductance should be put in a series with the load, to prevent di/dt problems around a 90° firing angle. Usually zero-fired power controllers do not have di/dt problems, because the voltage is near zero when the SCR is turned on.

Cooling and Heat Sinking The temperature of an SCR will increase during normal operation due to the power dissipated in it. This power loss stems from the fact that there is a voltage drop of approximately 1 V, which the device is conducting. The current that an SCR can safely carry is dependent on the heat sinking provided. Operating at excessive temperatures will cause failures.

Most power controllers up to 20 kW are convection cooled. Fan cooling is usually required for units between 30 and 500 kW. Above 500 kW water cooling is employed to maintain safe operating temperatures for the SCR. Suppliers can also supply thermostats mounted to the heat sinks to signal if the temperature of the SCR is getting too high.

IGNITRON TUBE

Ignitron tubes, in function, are similar to the SCRs, but quite different in construction. As shown in Figure 7.2l, the ignitron is a mercury arc rectifier consisting of a graphite anode, a cathode containing a pool of mercury, and an electrode called

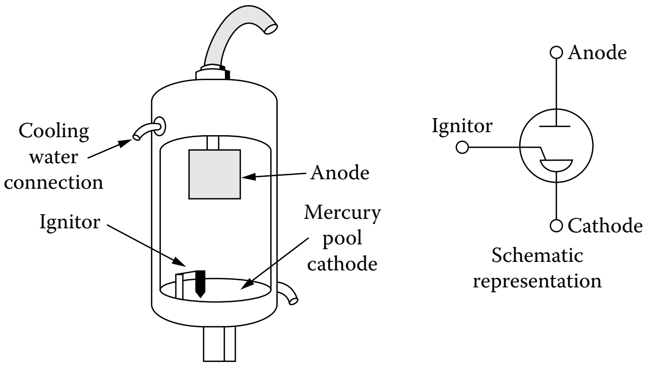

FIG. 7.2l
Ignitron tube.

the ignitor. Ignitron operation is achieved by applying a DC voltage pulse to the ignitor. The arc produces a large number of mercury ions that permit current to flow from anode to cathode, if the required potential exists. The ignitron can be subjected to 200% overloads for up to a minute without damage.

Because of the lower efficiency of the ignitron, the amount of cooling required here is much greater than for an SCR. Normally, forced air or water cooling must be employed with the ignitron. In general, the ignitron is inferior to SCR in terms of size, efficiency, life expectancy, and vibration resistance. It is for these reasons that ignitrons have largely been replaced by SCRs even on existing installations.

POWER AMPLIFIER

A power amplifier is a combination of active devices, transistors, operational amplifiers or tubes, and passive elements, resistors, capacitors, and inductors to yield power amplification with certain characteristics such as linearity, frequency response, and gain. Such amplifiers are not usually used as final control elements. Reproduction of an input waveform, while important in communications, is not necessary in process control, where only modulation of power is desired. For this reason the previously discussed devices offer more cost-effective and efficient solutions than does the power amplifier.

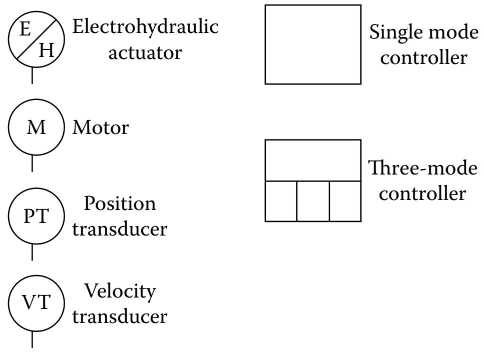
7.3 Linear and Angular Positioning of Machinery

D. S. NYCE (2005)



Flow sheet symbols

Range:	*Linear position:* Linear motion is typically driven through the use of a leadscrew, ballscrew, or worm drive, which are available with ranges from less than an inch (< 25 mm) to over 20 ft (> 6 m). Linear sensors for position feedback in the lower range include LVDTs, magnetic, and optical encoders. Longer stroke linear feedback devices include encoders and magnetostrictive position transducers. Optical encoders are practical up to 6 ft (2 m). Magnetostrictive position transducers can be used up to 60 ft (20 m). *Angular position:* Gearboxes are normally used to transmit rotary motion, but direct drive is also used. The motion, often driven by a stepper or DC motor, can be 0–360°, or can be multiturn or continuous rotation. Typical angular feedback sensors have a range of 270–360° rotation, and when using a 360° sensor, the turns can be counted for multiturn applications.
Inaccuracy:	A complete control loop for one axis of motion comprises several components, typically including a motor, motor driver, controller, and one or more feedback elements. The position inaccuracy is the sum of errors from all the above-listed components. There are both static and dynamic sources of error. Generally speaking, inaccuracy can range from about 1.0%, in systems where speed or cost are the driving factors, down to less than 0.01% where precision is the main consideration.
Costs:	A combination of motor and controller can range from less than $200 for a stepper motor and open-loop printed circuit controller card, to well over $1000 for a linear motion stage with motor, driver, controller, and feedback element.

OPEN- AND CLOSED-LOOP POSITIONING

Movable components of industrial machinery can require positioning in relation to the three linear axes (*x*, *y*, and *z*), and in rotations about these same axes. Normally, for a particular movable component, the motion is desired in relation to only one or two axes, and the machine is designed to minimize unwanted motion in relation to the remaining axes.

Positioning systems can use either an open-loop or a closed-loop control system. In an open-loop system, such as can be built utilizing a stepper motor or piezoelectric actuator, the drive system can output a precise predetermined command for movement. In such a system, moving to a new position then is accomplished by consecutively executing a given number of predetermined steps. In open-loop positioning, there is no sensor that is continuously detecting the resulting position, and therefore no control is exercised during the move. The motion continues until the control input is discontinued, or until a limit switch is activated.

In closed-loop motion control, the position of the moving part is continuously detected and reported. Based on this feedback, the position and velocity of movement can both be controlled. The reported position can be continuously compared to the desired position, and the component can be moved in a direction that will reduce the error. This is called servo control. Figure 7.3a shows a block diagram of a basic closed-loop motion control loop, which continues to adjust the component's positions, from the beginning of the motion until it is completed as commanded.

The input (or desired) position is compared to the actual position, which is reported by the feedback device. The difference between these positions is the error, *E*. The error signal can be positive or negative, where the sign indicates the direction. The error signal is amplified (the amplification factor is called gain) and used to drive the motor.

The complete control system for positioning on an actual control axis includes several levels of control loops, which are acting in a synchronized manner, as shown in Figure 7.3b. The intermediate control loops are called embedded loops, and together they guarantee that the original command for a specified movement is correctly completed.

In this example, the position input (set point) is compared to the detected actual position by the feedback sensor. The detected difference is used to generate a velocity command. A differentiator determines the actual rate of change in the position of the controlled component. This derivative of the position feedback signal is used as the velocity feedback. The velocity error (the difference between the desired and the actual velocities) becomes the input to the motor driver. The motor driver is provided with a current feedback from the DC motor circuit to maintain continuous control of the motor.

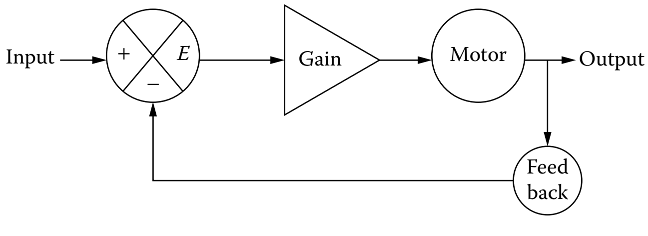

FIG. 7.3a
Basic block diagram of a closed-loop motion control system.

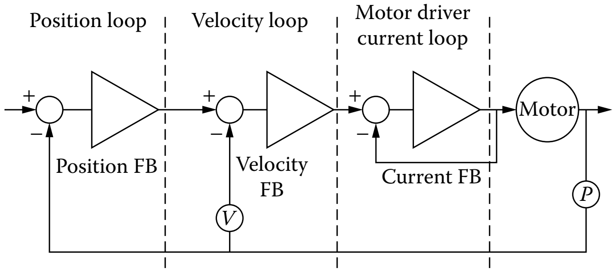

FIG. 7.3b
Motion system with embedded loops.

Any command for a movement that is executed under closed-loop control will result in a *motion profile*. This profile defines how the component is intended to be moved. Figure 7.3c illustrates a standard trapezoidal velocity profile.

In Figure 7.3c, the velocity is zero when the component to be moved is in its starting position, but is not moving yet. As time passes, the velocity of the component is ramped up at a constant acceleration until a limiting velocity is reached. This velocity remains constant until the desired end (stopping) position is approached. When it does, the velocity is reduced at a constant rate of deceleration until zero velocity is reached as the moved element arrives at the end position.

POSITIONING SYSTEM COMPONENTS

In closed-loop systems for positioning of industrial machinery, one of the components used is a motor or actuator. The motor driver receives its commands from a controller. When the controller receives a command to initiate a move, it compares the real-time readings of position or velocity to the

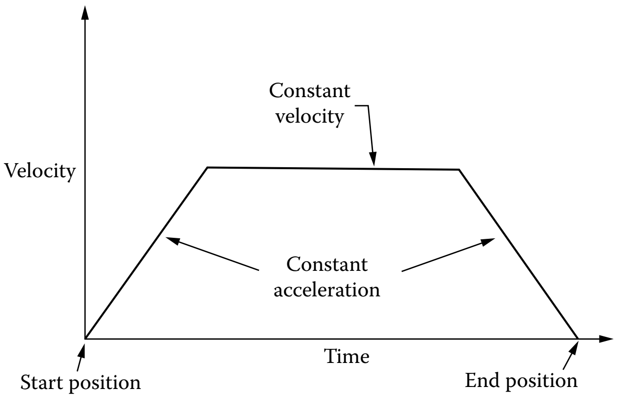

FIG. 7.3c
The standard velocity profile is trapezoidal.

desired values in the move command and sends the appropriate signal to the motor driver.

The motor driver adjusts the driving current (or other power source used) to operate the motor in the direction and at the rate that are commanded by the controller. The motor moves the machine axis, and one or more feedback devices report the actual position and speed back to the controller. The components in such control loops will be described in more detail in the following paragraphs.

Motors and Actuators

The power supply required for moving components can be electrical, hydraulic, or pneumatic. Of the three, electric drives are the most popular.

Hydraulic actuators are fast and powerful and can provide stiffness. These properties result from the incompressibility of the hydraulic fluid and from the energy stored as the momentum of the moving fluid, but the use of hydraulic actuators also necessitates the use of hydraulic pumps and plumbing. The disadvantages of hydraulic actuators is their greater space requirement, audible noise, and potential for leakage.

Pneumatic actuators are not as powerful or fast as hydraulic ones, but can still handle the less demanding applications that do not require much stiffness in the holding position. Compared to hydraulic designs, one advantage of the pneumatic actuators is that they do not leak oil.

Electric motors and actuators are the most widely used and are available in the largest variation of designs. The electric motor can either be synchronous types of stepper motors utilizing permanent magnet, variable reluctance and hybrid designs, or DC motors of the brushed or brushless types.

Electric Motors

Permanent Magnet Stepper Because opposite magnetic poles attract and like ones repel each other, stepper motors can use magnetic fields to move a rotor with respect to a stator by the exploitation of magnetic attraction and repulsion. An electrical pulse sent to a stepper motor causes it to rotate by a small amount, or step. The number of pulses received results in a corresponding amount of motion, and the frequency of the pulses determines the speed of that motion.

In a permanent magnet-type stepper, the permanent magnets are located on the rotor. The movement of the rotor magnets is caused by the magnetic fields of the stator coil windings. By energizing four stator fields in sequence, rotation at 90° intervals is achieved. Some permanent magnet steppers use 45° steps.

Externally mounted electronic circuits direct which stator windings will receive each pulse. This pulse direction or switching is called commutation. When at rest and receiving no pulses, the stepper has a holding torque that tends to maintain the last position, even when no power is being applied.

Variable Reluctance Stepper Variable reluctance steppers have many more poles of permeable material on the rotor. These are formed by teeth, each of which forms a permanent magnetic pole when energized by the nearby stator coil. The teeth align themselves with the respective poles of the stator windings. This provides a finer resolution per step, typically 15° or less.

Hybrid Synchronous Stepper Hybrid synchronous steppers have a high number of permanent magnetic teeth on the rotor, with an equally high number of teeth magnetized by the stator windings. The stator windings can be driven in either direction, forming either a North or South magnetic pole. This further improves resolution over either the permanent magnet or variable reluctance types of stepper motors.

Microstepping Even higher angular resolution is possible through a technique called microstepping. Instead of applying full power to one set of windings and no power to the others, microstepping involves the provision of percentages of power to more than one set of windings. This enables the determination of positions in-between the normal steps. When microstepping, more power is used due to the powering of more coils at any given time. Also, there is no holding torque in a microstepped position when power is lost (the holding torque will act to maintain the closest normal step position).

Brushed DC Motors The brushed DC motor has been around for a long time. It is simple and cheap, and its speed and torque are easily controlled. The magnetic field of the stator (stationary field) is produced by field windings or by permanent magnets.

Most DC motors of up to a few horsepower are made by using permanent magnets for the stator field. The armature field is the moving field associated with the rotating shaft. It is generated by windings on the rotor. Due to the two magnetic fields of the stator and rotor, the rotor moves toward alignment of the fields (North attracting South poles). A larger number of poles in the rotor and stator fields results in a more smoothly operating motor.

The electric current powering the rotor fields must be constantly switched as pole alignment is approached, in order to maintain rotation. The switching is called commutation. A set of stationary conductive brushes rubs onto contacts near one end of the rotating shaft to provide connection to the rotor coils.

Torque is easy to control because it is directly related to the armature current. Speed is easy to control because it is related to the voltage. One disadvantage of DC brushed motors is the wear of the brush material, requiring maintenance and generating dust. Another is the electrical noise generated during the commutation. In addition, it is difficult to maintain smooth operation when controlling at low speeds.

Brushless DC Motors Brushless DC motors have most of the same attributes as the brushed type, except that they do not have brush wear. They are more expensive and more complex because of the electronics of the brushless commutation. They operate in the same way as a brushed type, but use sensors to indicate the rotational position of the armature. The armature field is generated by permanent magnets, and the stator fields use coil windings. When the armature sensors indicate that the next set of stator field windings need to be energized, an electronic switching circuit makes the change.

Motor Drivers

Once the motor type and size are selected, a suitable motor driver is needed. The motor driver must accommodate the performance and power requirements of the specific motor to be used. This relationship can be complex.

The motor driver is an amplifier that converts the signal from the controller into the voltage and current signals needed to drive the particular motor type. It is usually best to select a compatible motor driver model that is supplied or recommended by the motor manufacturer. Sometimes the motor driver is mounted inside the motor housing, so that the motor and drive are purchased as a single unit.

Controllers

The positioning servo controllers can use the types of position and velocity control loops that were shown in Figures 7.3b and 7.3c or can use proportional, integral, derivative (PID) controls.

In a proportional-only controller (P), the controller output is equal to the error signal multiplied by the gain (the gain is usually signified as “A”), as was shown in Figure 7.3a. So, the farther away the positioned component is from the desired (commanded) position, the greater will be the amplitude of the motor drive output signal.

The gain can be set high in order to obtain a fast response, but this can result in more overshoot, which occurs if the motion continued past the commanded position and has to come back in order to reach it. If the gain is set low, then the positioning accuracy may suffer because the positioning is too slow or there is not enough power to overcome friction and reach the exact position as commanded.

A PID control solves these problems, because it does not only respond to the state at the moment, but its integral mode also looks at the past history or error, while its derivative mode predicts and corrects for potential future errors. The derivative mode responds to the rate of change of position so that the speed of changing the position can be increased faster than that which is possible with proportional gain control only. The integral function responds to the lower frequency requirements, including that of a steady state, to apply enough restoring force to reach and maintain the desired final position. In a PID control, the proportional, integral, and derivative modes are all incorporated into the gain function, A.

Sensors for Feedback

In a closed-loop control system, position feedback to the controller is required. For velocity feedback either a velocity sensor can be used, or the velocity can be obtained by taking the derivative of the position signal. Popular position feedback devices include potentiometers, optical and magnetic encoders, linear variable differential transformers (LVDTs), and magnetostrictive position transducers. Potentiometers and encoders can be linear or rotary.

A rotary type of LVDT is called a rotary variable differential transformer (RVDT). It is possible to make rotary magnetostrictive position transducers, but these are not common as yet. Magnetostrictive position transducers are normally used only for linear measurements. They are very cost effective for longer strokes, because the rod assembly is relatively inexpensive when compared to the electronics head.

Potentiometers Potentiometers detect the position by making physical contact with the moving component. A potentiometer utilizes a conductive element and a metallic contact that traverses over the range of positions that the measured component can travel. It is a contact device, meaning that the metal contact rubs against the resistive element. This also means that the contact and element are subject to wear during normal use.

There are three electrical connections to a potentiometer, whether it is a linear or a rotary measuring device. Two connections are made to the ends of the resistive element, and the third to the moving contact, called the wiper. The resistive element is mounted in a housing that includes an internal structure to guide the wiper carrier for even wiper contact along the element surface. An actuator rod is often attached to the wiper carrier, and this is used to provide a mechanical connection to the moving part that is to be measured (Figure 7.3d).

A DC voltage is normally applied across the resistive element, and the voltage of the wiper is the position measurement signal. Some potentiometers can have a calibrated accuracy on the order of 0.1%, but the wear of the rubbing parts can require frequent maintenance. Potentiometers are used in lower cost systems where long-term reliability is not as important as initial system cost. The other position sensors listed here are noncontact, so they have nearly unlimited lifetime.

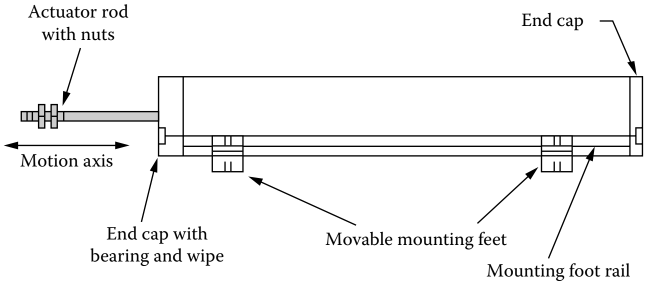

FIG. 7.3d
Components of a linear potentiometer position transducer.

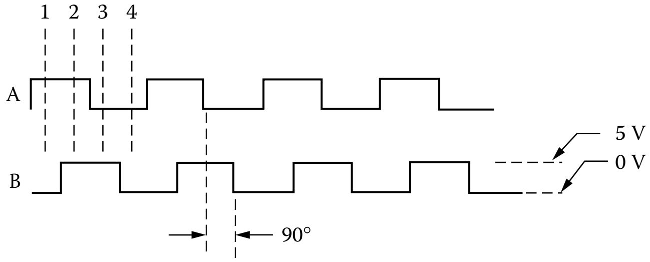

FIG. 7.3e
Incremental encoder pulse trains, showing the output trains A and B, which are separated by 90°.

Encoders Position can be detected by optical or magnetic encoders, which generate pulses in proportion to the amount of movement detected. Encoders can be incremental or absolute reading. An incremental encoder outputs a number of pulses corresponding to the amount of motion. There are usually two outputs, called A and B, that are separated in time by 90° in order to indicate the direction of travel. This is shown in Figure 7.3e.

The two outputs being separated by 90° are called quadrature outputs. A counter counts up all of the increment and decrement counts to arrive at the total count that represents the present position. There are four states of the combination of A and B levels per the 360° of one cycle. The phase relationship between outputs A and B during a state change indicates the direction of motion (increment or decrement of the count).

The drawback of an incremental encoder is that the count can be corrupted by power interruption or electrical noise. Then, in order to restart the system, it needs to be homed in order to re-establish the zero count position. A pictorial representation of an incremental rotary optical encoder is shown in Figure 7.3f.

In an optical encoder, a linear pattern or rotor disk is provided with adjacent transparent and opaque sections, allowing pulses of light to reach the detectors as the move progresses. These light pulses produce the electrical output pulses that indicate the linear or angular position change and direction.

An absolute encoder is more complex than an incremental one, in that it must have a number of light paths and light detectors equal to the number of bits of resolution, but it has the advantage of maintaining an accurate position even through power loss and other disturbances.

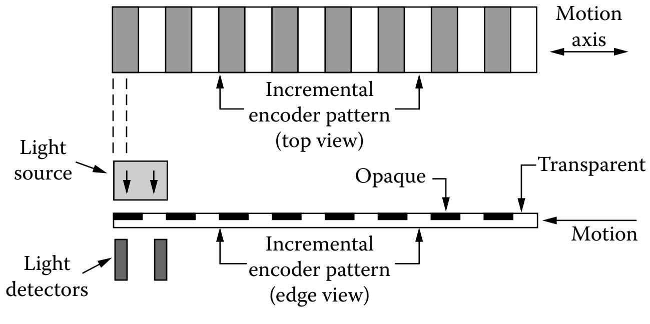

FIG. 7.3f
Incremental rotary optical encoder.

FIG. 7.3g
The outside appearance of a typical LVDT-type position sensor. (Courtesy of Revolution Sensor Company.)

A rotary encoder is often attached to the motor shaft. Linear encoders can be mounted so that they directly measure the output axis, eliminating errors due to gear backlash.

Although Figure 7.3f illustrates an encoder with optical sensors, encoders are also available with magnetic sensors. In a linear magnetic encoder, a tape is laid out along the axis of the motion and read by a reading head that moves with that axis. Alternatively, the tape and reading head can be incorporated into a slide assembly and purchased as a unit.

LVDT A linear variable differential transformer is suitable for measuring relatively short travel distances at high accuracy, in the range of microinches (or microns) to several inches (≈100 mm). As shown in Figure 7.3g, an LVDT is usually cylindrical in shape and is provided with a core that moves into the center bore of the cylinder.

An LVDT consists of three symmetrically spaced coils, which are carefully wound onto an insulated bobbin.[1] As shown in Figure 7.3h, the primary coil is in the center and it is surrounded by the two secondary coils.

The primary coil is driven by an AC waveform, usually a sine wave of 250 Hz to 10 kHz. The two secondaries are connected in series-bucking so that the output is also an AC waveform. The secondary difference output is demodulated and amplified to produce a DC output voltage. The output

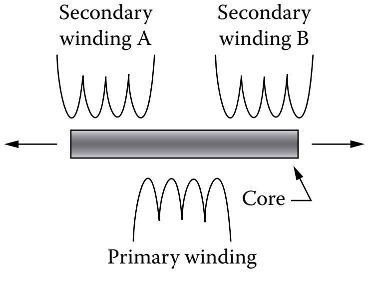

FIG. 7.3h
The primary and the two secondary windings of an LVDT.

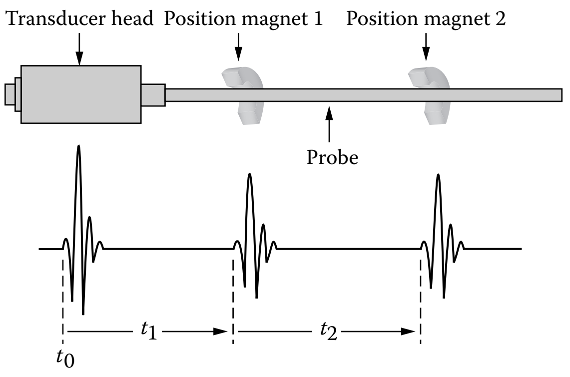

FIG. 7.3i
The components of a magnetostrictive position transducer.

voltage amplitude indicates the magnitude of the position, and its polarity indicates the direction from the center or null.

The AC waveform generator, demodulator, and amplifier comprise a signal conditioner. The signal conditioner may be purchased as a separate component when using an AC LVDT. Alternatively, if a DC LVDT can be used, it includes the signal conditioner within the same housing as the LVDT.

Magnetostrictive Position Transducer A magnetostrictive position transducer can have as high a resolution as 1 μ and a range from less than an inch (< 25 mm) to over 60 ft (> 20 m). Errors as low as 0.01% of range are typical. Figure 7.3i illustrates that it consists of a transducer head, a probe section, and one or more position magnets.

The transducer probe houses a waveguide made from magnetostrictive material and measures the location of a permanent magnet called the position magnet. A magnetostrictive material is one that changes shape or size when magnetized.

The operating sequence is such that at time t_0 in Figure 7.3i, the electronics module within the transducer head applies a current pulse to the waveguide, which forms a magnetic field around it. At the location of the position magnet, the interaction of the two fields imparts a mechanical torsion onto the waveguide due to the vector sum of the fields. The torsional force travels as a sonic wave along the length of the waveguide at a speed of approximately 9000 ft/s (3000 m/s). For each measurement cycle, one current pulse is applied, which instantaneously forms a magnetic field on the full length of the waveguide. The torsion pulse is generated at the location of the position magnet.

At the time of applying the current pulse, an electronic timer is also started. When the above-mentioned sonic wave is detected at the transducer head, the timer is stopped.[2] The elapsed time indicates the location of the position magnet (time t_1 or $t_1 + t_2$, in Figure 7.3i).

The update sequence can occur at frequencies of up to 4 kHz, depending on the length of the sensing probe. Magnetostrictive position transducers are accurate and are very cost effective, especially for longer stroke lengths of over 3 ft (> 1 m). They also have the capability to read the location of more than one position magnet while using only one sensing probe. This reduces system cost.

COMMUNICATION PROTOCOLS

Positioning systems can use a network communication configuration, where the components operate as nodes on a network. Alternatively, they can use a direct backplane interface, where the motion control system uses a PC card that plugs into a PC bus. Wireless communication networks are not yet fast enough to allow these sensors to be used in closed-loop position control.

Network communications protocols include ARCnet, CANbus, Device net (a version of CANbus), Ethernet, Profibus, IEEE 1394 (Firewire), IEEE 1451, Interbus-S, SERCOS, and Seriplex, among others.

PC bus-type protocols include the normal backplane ISA/EISA (PC-XT/AT) connection for a PC, Mac PCI (Nubus) for Macintosh computers, Multibus, PC 104, PCI bus, compact PCI (cPCI) bus, PCMCIA, VME bus, and VXI.

Each of the above communication protocols have fairly sophisticated definitions, and so the reader is directed to contact the product manufacturers to determine which are available in the specified product, and to learn about the advantages offered by each in the particular application. For a detailed description of network and bus protocols, the reader can also refer to the third volume of this handbook, *Process Software and Digital Networks.*

CONCLUSIONS

A motion control system comprises of a matched set of components including a motor, motor drive, feedback device, controller, and software. The best approach to implementing such a system is to first specify a motor and drive that are capable of meeting the performance requirements. Once they are specified, select the remaining parts of the system to match the requirements of the motor and drive combination with the help of their manufacturer, because the manufacturer can select the compatible components for optimum performance.

Often a custom system will be used. In addition to the performance of the control axis, networking capability, user interface, and environmental considerations should also be addressed.

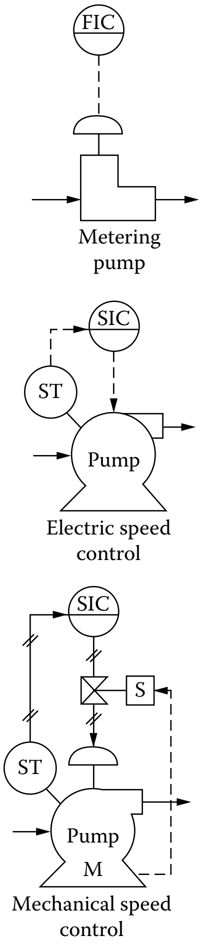
7.4 Pumps as Control Elements

A. BRODGESELL (1970) **R. D. BUCHANAN** (1985)
B. G. LIPTÁK (1995) **I. H. GIBSON** (2005)



Flow sheet symbols

Types of Pumps:	A. Radial-flow pumps B. Axial- and mixed-flow pumps C. Peripheral or regenerative turbine pumps D. Pitot or jet pumps E. Progressing cavity pumps F. Flexible-rotor pumps G. Peristaltic pumps H. Gear pumps I. Plunger and piston pumps J. Diaphragm pumps K. Eductors L. Blow-egg and air lifts *Note:* Types A, B, and E are available in both conventional and submersible designs.
Rangeability:	*Variable-speed drives*: From 4:1 to 40:1 (electrical types), from 4:1 to 10:1 (mechanical designs), up to 40:1 (hydraulic types).
Metering pumps:	Can exceed 100:1 combining variable speed and variable stroke.
Efficiencies:	Pump efficiencies range from 85% for large-capacity centrifugals (types A and B) to below 50% for many of the smaller units. For types I and J, the efficiency ranges from 30% and up, depending on power and number of heads. For type J the efficiency is at most 30%, and for other types as low as 25%.
Materials of Construction:	For water using type A or B pumps: normally bronze impellers, bronze or steel bearings, stainless or carbon steel shafts, cast iron housing. For industrial process services, stainless steel and cast steel. For corrosive services, engineering plastic materials are common.

Costs: Varies with size and horsepower. For example, type A pumps cost from $650 to more than $34,000. Typically, a type A 10 hp (7.5 kW) sewage pump might cost $5000 for a horizontal and $4000 for a vertical model. A 10 hp (7.5 kW) type F ejector costs about $24,000, but to do the same work as the type A pump, a 30 hp (22 kW) $47,000 ejector is needed. A 10 hp (7.5 kW) type I, J, or K sludge pump costs about $12,000. Prefabricated stations (including pump) range from $13,000 to $100,000. The cost is $2700 for a pneumatic metering pump and $5400 for type K metering pump with positioner. The cost of stainless steel pumps is three to four times that of cast iron or bronze-fitted pumps. The purchase cost of a submersible pump is higher than that of one of the “dry pit” types, but the total installed cost is lower because there is no need for both a dry and a wet well (Figure 7.4k).

Partial List of Suppliers: There are a multitude of pump manufacturers throughout the world, many of whom make a variety of types. Because pumping is the primary means of liquid transportation in most processes, pumps are important parts of control systems. The various pump control systems will be discussed in Chapter 8; the features and designs of variable-speed drives are covered in Section 7.10; and metering pumps have been discussed in Section 2.14 of the *Process Measurement and Analysis* volume of this fourth edition of the handbook. Therefore, the main emphasis of this chapter will be to describe the features and selection of conventional (centrifugal, reciprocating, screw) pumps and their applications. In addition, this section will also briefly discuss metering pumps for the benefit of those who do not have access to *Process Measurement and Analysis.*

ROTODYNAMIC OR CENTRIFUGAL PUMPS

Types A, B, C, and D of the feature summary (Table 7.4a) fall within this classification, which is the most common type of pump. In the form of tall, slender, deep well submersibles, they pump clear water from depths greater than 2000 ft (600 m). Horizontal centrifugals with volutes almost the size of a man can pump 9000 gpm (0.57 m^3/s) of raw sewage through municipal treatment plants. Few applications are beyond their range, including flow rates of 1–100,000 gpm (3.78 lpm to 6.3 m^3/s) and process fluids from liquefied gases through clear water to all but the densest sludge.

Radial-Flow

Radial-flow pumps are designed to throw the liquid entering the center of the impeller or diffuser out into a spiral volute or bowl. The impellers may be closed, semi-open, or open, depending on the application (Figure 7.4b). Closed impellers have higher efficiencies and are more popular than the other two types. They can readily be designed with nonclogging features. By using more than one impeller the discharge head characteristics can be increased, in proportion to the number of impellers. These pumps may be of horizontal or vertical design. Multiple stage designs with up to 99 impeller/volute assemblies on a single shaft are available, though not common. Flow can be throttled, but many pumps have a minimum

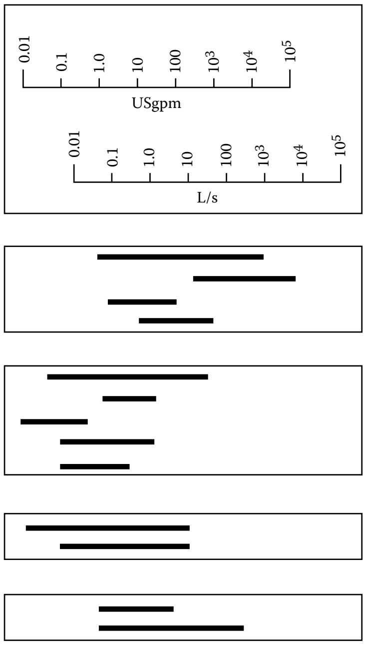
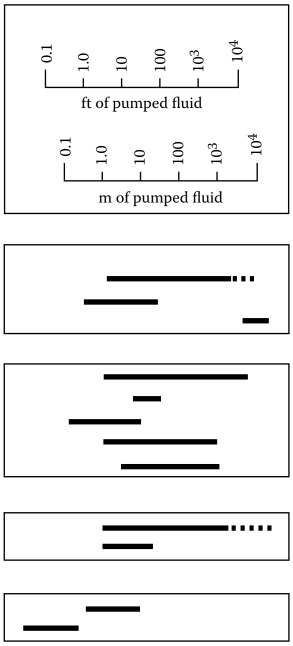
For liquid pumped — *Capacity range*



Developed head range



flow below which they become bistable, flipping between zero and a much higher flow. In some cases, this may be as high as 75–80% of design rate.

Axial- and Mixed-Flow

Axial-flow (propeller) pumps, although classed as centrifugals, do not truly belong in this category because the propeller thrusts axially rather than throwing the liquid outward. Impeller vanes for mixed-flow centrifugals are shaped so as to provide partial throw, partial push of the liquid outward and upward. Axial-flow and mixed-flow designs can handle huge capacities but only at the expense of a reduction in discharge heads. They are constructed vertically. The head/flow characteristic is such that throttling the flow is usually undesirable, and bypassing or speed control is a better control strategy.

Peripheral or Regenerative Turbine

Peripheral turbine pumps (Figure 7.4c) are low-flow/high-head devices that require very little positive suction head. The fluid enters an annular space near the periphery of the rotor, which has a large number of slots. The fluid is carried around by the rotor, gaining pressure as it circulates in the rotor slots, and is discharged after traveling about 300° around the casing. A small single-stage impeller can provide up to 500 ft (150 m) head.

Pitot or Jet Pumps Pitot pumps (Figure 7.4d) provide extremely high head, up to 5000 ft (1500 m), at relatively low flow rate. The pump has an internal cylindrical casing that rotates at high speed, with a fixed pitot pickup inside. The discharge

from the pitot exits on the impeller axis, coaxial with the suction connection.

Applications Most liquids and wastes can be pumped with centrifugal pumps. It is easier to list the applications for which they are not suited than the ones for which they are. They should not be used for pumping (1) very viscous industrial liquids or sludges (the efficiencies of centrifugal pumps drop to zero, and therefore various positive displacement pumps are used), (2) low flows against very high heads (except for deep well applications, the large number of impellers needed put the centrifugal design at a competitive disadvantage), and (3) low to moderate flows of liquids with high solids contents (except for the recessed impeller type, rags and large particles will clog the smaller centrifugals). For low flow and high head, the turbine and the jet pump designs may be competitive with positive-displacement types up to 400 hp (300 kW).

POSITIVE-DISPLACEMENT PUMPS

Rotary Pumps

Progressing Cavity Pumps Invented by R. Moineau in 1930, progressing cavity pumps have a helical metal rotor within a (usually) elastomer stator with a bihelical bore; the rotor is connected to the rotating drive through a sealed universal joint set or a flexible shaft enabling the rotor to nutate as it rotates. The resulting motion causes a series of trapped cavities to progress axially through the pump. Such pumps offer unusual capabilities in handling fragile products (small live fish can pass through them) and can be classed as semipositive displacement; the capacity is largely proportional to rotational speed; though slippage increases above a value depending on the tightness of fit of the rotor in the stator. The pumps must not be run dry, as this will rapidly damage the stator, but will act as vacuum pumps provided there is enough liquid to lubricate the system. They are therefore capable of suction lift equivalent to about 90% of the vapor pressure of the liquid. They find application in paste and slurry handling service, as well as small high-lift submersible and down-hole pumps. Variants with hopper/auger feed will handle filtercake and similar extremely high viscosity products. Multistage variants utilize a single, long rotor and a series of standard stator units. Other variants exist with an n-start helical rotor and $n + 1$-start stator, which have even less pulsation than the standard design. The progressive cavity pump with VSD can be one of the most useful tools for a control system engineer, offering a simple alternative to centrifugal pump, control valve, and check valve in a single package. A single-stage pump is capable of producing a differential of up to about 62 psid (430 kPa).

Flexible-Rotor Pumps A cylindrical metallic housing with diametric suction and discharge connections contains a multivaned elastomer rotor, eccentrically mounted (Figure 7.4e). As the rotor turns, the volume between the vanes increases to a maximum as the set of vanes pass the suction connection, trapping a volume of liquid, and then diminishes to a minimum as the trapped volume passes the discharge connection. The pump is reversible.

Peristaltic Pumps Widely used in laboratory applications, the peristaltic pump has an elastomer tube. held inside a cylindrical retainer and a set of spring-loaded rollers that trap a series of volumes of fluid in the tube as they rotate, transferring liquid from the suction to the discharge (Figure 7.4f). These commonly have multiple heads on a single variable-speed drive mechanism and will accept a variety of different bore tubes, enabling a variety of reagents and samples to be fed proportionately to analytical equipment. They are also used for industrial purposes, handling material such as nitric and hydrofluoric acids. Pumps will handle both liquids and gases,

and available capacities vary from fractions of a milliliter/minute to 1400 gph (90 lpm).

Gear Pumps

Gear pumps are available in a multitude of variations. Most designs have a pumping chamber with a pair of meshed gears; as the gears rotate, liquid is trapped between the housing and the gear teeth, being carried from the suction chamber to the discharge chamber. As the gear teeth engage, the liquid is forced out of the discharge port. Another common design is the “star and moon” with a planetary gear and a quarter-moon-shaped stationary component inside a driven ring-gear.

Reciprocating Pumps

Almost all reciprocating pumps are either metering or power pumps. The steam-driven pump is historically interesting but rarely used. Most frequently a piston or plunger is utilized in a cylinder, which is driven forward and backward by a crankshaft connected to an outside drive. Metering pump flows can readily be adjusted by changing the length and frequency of strokes of the piston. The diaphragm pump is similar to the piston type, except that instead of a piston, it contains a flexible diaphragm that oscillates as the crankshaft rotates. Diaphragm pumps commonly have a buffer hydraulic fluid to transfer the force to the diaphragm.

Smaller units may be solenoid driven or use pneumatic power.

Plunger and diaphragm pumps can feed metered amounts of chemicals (acids or alkalis for pH adjustment) or can also pump sludge and slurries. Plunger pumps commonly come as simplex (one head), duplex (two head) or triplex (three head). The triplex design, with the piston throws operating at 120° to each other, minimize pulsation in suction and discharge, and acceleration losses in the suction lines. Pulsation dampers are commonly fitted to further reduce these effects.

Variable-capacity hydraulic pumps utilize a variable-angle swashplate to alter the stroke of a set of pistons (commonly five) in a common assembly. Fitted with an integrated hydraulic servomechanism, these can be set up to provide constant discharge pressure/variable flow, or constant power (flow × pressure). This design can also be used as a reversible variable-speed hydraulic motor.

AIR PUMPS AND AIR LIFTS

This method of pumping (type L) employs a receiver pot, into which the wastes flow by gravity, and an air pressure system that transports the liquid to a treatment process at a higher elevation. A controller is usually included, which keeps the tank vented while it is filling. The level controller energizes a three-way solenoid valve when it is full to close the vent and open the air supply to pressurize the vapor space in the tank.

The air system may use plant air (or steam), a pneumatic pressure tank, or an air compressor directly. With large compressors, a capacity of 600 gpm (2.28 m^3/min) with lifts of 50 ft (15 m) may be obtained. The advantage of this system is that it has no moving parts in contact with the waste and thus no impellers to clog. Ejectors are normally more maintenance free and longer lived than pumps.

Condensate Pumps

A related device can be used to transfer steam condensate at subatmospheric pressure to a condensate return system, by injecting live steam above the condensate surface. When the vessel is empty, the vapor space is connected to the steam space of the heater to equalize pressure and allow the condensate to refill the vessel (Figure 7.4g).

Air Lifts

Air lifts consist of an updraft tube, an air line, and an air compressor or blower. Air is blown into the bottom of the submerged updraft tube, and as the air bubbles travel upward, they expand (reducing density and pressure within the tube), inducing the surrounding liquid to enter. Flows as great as 1500 gpm (5.7 m^3/min) may be lifted short distances in this way. Air lifts are of great value in waste treatment to transfer mixed liquors or slurries from one process to another.

DESIGN OF PUMPING SYSTEMS

In order to choose the proper pump, the conditions that must be known include capacity, head requirements, and liquid characteristics. To compute capacity, one should first determine the average flow rate for the system and then decide if adjustments are necessary. For example, when pumping wastes from a community sewage system, the pump must handle peak flows that are roughly two to five times the average flow, depending on the size of the community. Summer and winter flows and future needs may also dictate capacity, and the population trends and past flow rates should be considered in this evaluation.

Head Requirements

Head describes pressure in terms of height of fluid. It is calculated by the expression:

$$\text{head in feet} = \frac{\text{pressure (psi)} \times 2.31}{\text{specific gravity}} \qquad \mathbf{7.4(1)}$$

The discharge head on a pump is a summation of several contributing factors: static head, friction head, velocity head, and suction head.

Static head (h_d) is the vertical distance through which the liquid must be lifted (Figure 7.4h).

Friction head (h_f) is the resistance to flow caused by the friction in pipes. Entrance and transition losses may also be

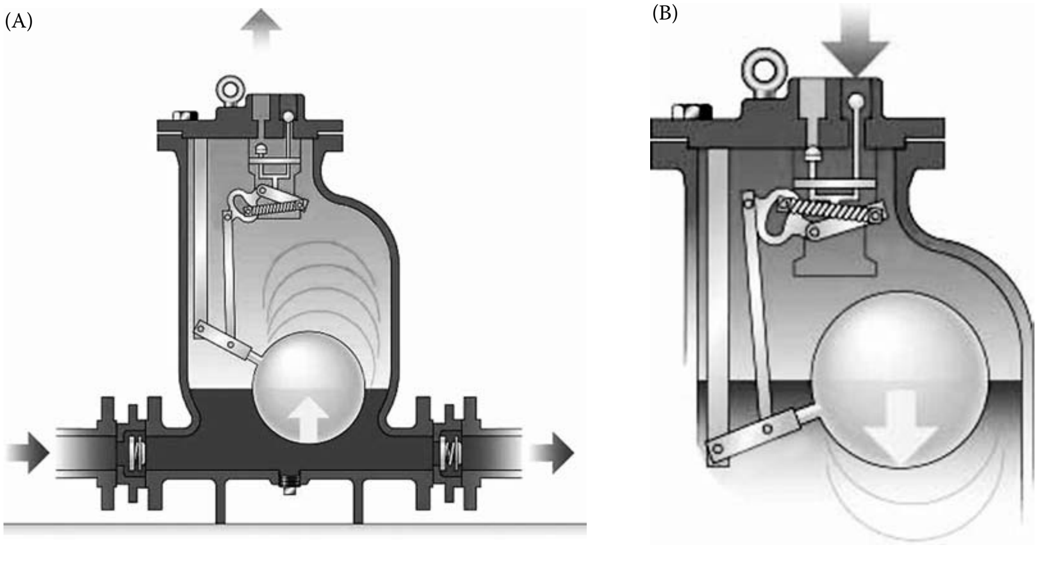

FIG. 7.4g

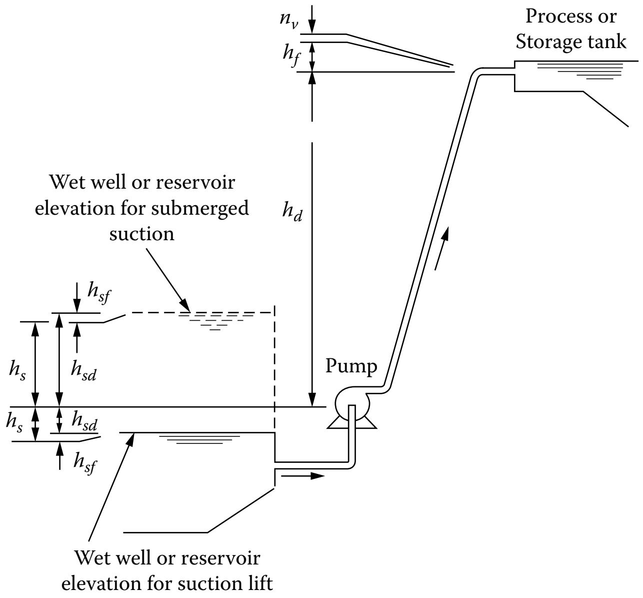

FIG. 7.4h

Determination of pump discharge head requirements. Legend: h_v = velocity head; h_f = friction head; h_d = static head; h_s = suction head; h_{sd} = suction side static head; h_{sf} = suction side friction head.

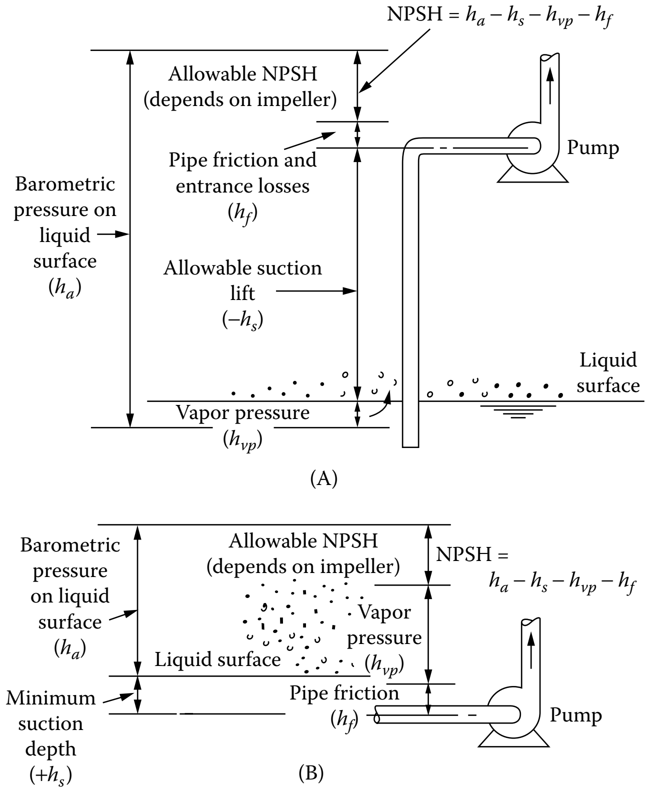

FIG. 7.4i

Role played by NPSH in determining allowable suction lift: (A) pump with suction lift, (B) pump with submerged suction but high vapor pressure (possibly hot water).

included. Because the nature of the fluid (density, viscosity, and temperature) and the nature of the pipe (roughness or straightness) affect the friction losses, a careful analysis is needed for most pumping systems, although for smaller systems, tables can be used.

Velocity head (h_v) is the head required to impart energy into a fluid to induce velocity. Normally this is quite small and may be ignored unless the total head is low.

Suction head (h_s), if there is a positive head on the suction side (a submerged impeller), will reduce the pressure differential that the pump has to develop. If the liquid level is below the pump, the suction lift plus friction in the suction pipe must be added to the total pressure differential required.

Total head (H) is expressed by

$$H = h_d + h_f + h_v \pm h_s \qquad \textbf{7.4(2)}$$

NPSH Calculation

The suction lift that is possible to handle must be carefully computed. As shown in Figure 7.4i, it is limited by the barometric pressure (which in turn is dependent on elevation and temperature); the vapor pressure (also dependent on temperature); friction and entrance losses on the suction side; and the net positive suction head (NPSH)—a factor that depends on the shape of the impeller and is obtained from the pump manufacturer.

In order for the pump to be able to “pull in” the pumped fluid, the net positive suction head available (NPSHA) for the particular installation must be greater than the NPSH that the pump requires. The NPSH values for the particular pump are obtained from the pump curve (Figure 7.4j), while the available NPSH is calculated according to the following equation:

$$\text{NPSHA} = h_a(+\text{ or }-)h_s - h_{vp} - h_f \qquad \textbf{7.4(3)}$$

where

h_a = the absolute pressure (in feet) at the surface of the source of the pumped liquid. If the source is atmospheric, h_a = 33.96 ft.

h_s = the static head of the installation, which is the vertical distance between the pump inlet and the surface of the liquid on the supply side. It is positive if the liquid level is above the pump inlet, and it is negative if it is below.

h_{vp} = the vapor pressure of the pumped fluid (in feet) at the operating temperature. The h_{vp} rises with temperature, and $h_{vp} = h_a$ when the liquid reaches its boiling point.

h_f = the suction side friction head in feet. This term increases with the square of flow and reflects the pressure drop through all pipes, valves, and fittings

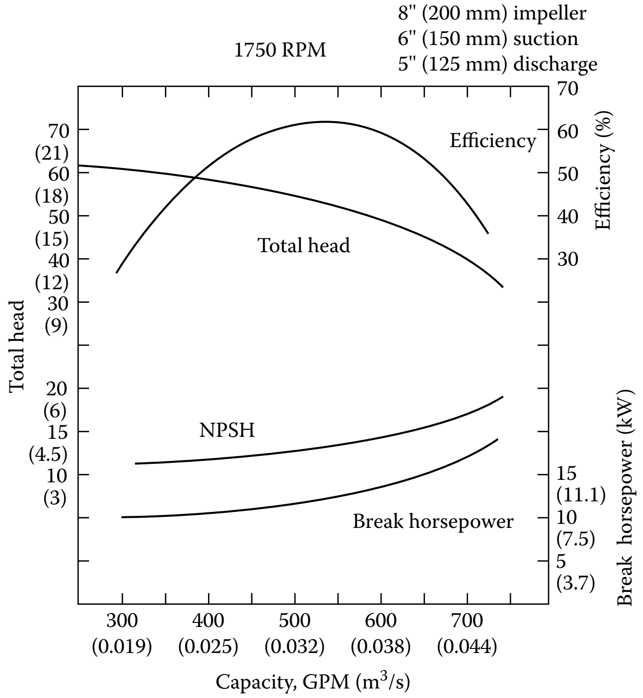

FIG. 7.4j
Typical pump curve for a single impeller.

on the suction side of the pump. When dealing with reciprocating pumps, the suction column is accelerated and decelerated with each stroke, and the head required to accelerate the suction column must be included.

If it is desired to convert NPSHA from feet to PSI, the NPSHA given in feet should be multiplied by the specific gravity of the fluid and should be divided by 2.31. (When converting to metric units, ft = 0.3048 m and PSI = 6.9 kPa.)

It is generally sufficient to calculate the available NPSH at maximum flow rate, because at that flow, the suction side friction head (h_f) is maximum and the NPSHA value is likely to be minimum. The NPSH required (NPSHR) of the pump rises with flow (Figure 7.4j). Therefore, if NPSHA exceeds NPSHR when the flow is maximum, it will exceed it by an even greater margin as the flow drops.

Specific Speed

The rotational speed of the impeller affects capacity, efficiency, and cavitation. Even if the suction lift is within permissible limits, cavitation can still occur, because additional static head is converted to velocity head as the fluid is accelerated in the pump.

The specific speed of the pump can be found using Equation 7.4(4).

$$\text{specific speed, } N_s = \frac{\text{RPM} \times \sqrt{\text{capacity (gpm)}}}{H^{3/4}} \qquad \textbf{7.4(4)}$$

Charts are available showing the upper limits of specific speed for various suction lifts. Caution: In metric units, specific speed values are NOT the same as in U.S. units, as the relationship is not dimensionally consistent.

Horsepower

The power required to drive the pump is called brake horsepower. It is found by solving Equation 7.4(5).

$$\text{BHP} = \frac{\text{capacity (gmp)} \times H\text{(ft)} \times \text{Sp. Gr.}}{3960 \times \text{pump efficiency}} \qquad \textbf{7.4(5a)}$$

In metric units,

$$\text{Power (kW)} =$$

$$\frac{\text{capacity (m}^3\text{/h)} \times H\text{(Nm/kg)} \times \text{density (kg/m}^3\text{).}}{3.670 * 10^5 \times \text{pump efficiency}} \qquad \textbf{7.4(5b)}$$

or

$$\text{Power (kW)} = \frac{\text{capacity (m}^3\text{/h)} \times H\text{(kPa)}}{3600 \times \text{pump efficiency}} \qquad \textbf{7.4(5c)}$$

Installation Considerations for Wastewater Pumping Stations

The typical designs for wastewater pumping stations are shown in Figure 7.4k. In selecting the best design for a particular application, the following factors should be considered:

1. Many gases are formed by domestic wastes, including some that are flammable. When pumps or other equipment are located in rooms below grade, the possibility of explosion or the build-up of these gases exists, and ventilation is extremely important. Similarly, such gases may be toxic (hydrogen sulfide) and asphyxiant (methane, carbon dioxide).
2. When pumping at high velocities or through long lines, water hammer can be a problem. Valves and piping should be designed to withstand these pressure waves. Even for pumps that discharge to atmosphere, check valves should be chosen so as to cushion the surge.
3. Bar screens and comminutors are undesirable because they require maintenance, but they may be necessary for small centrifugal pump stations where the flow might get clogged.
4. Pump level controls are not fully reliable because rags can short electrodes and hang on floats. Purged air systems (air bubblers) require less maintenance but need an air compressor that must operate continuously. Therefore, it is important to provide maintenance-free instrumentation.

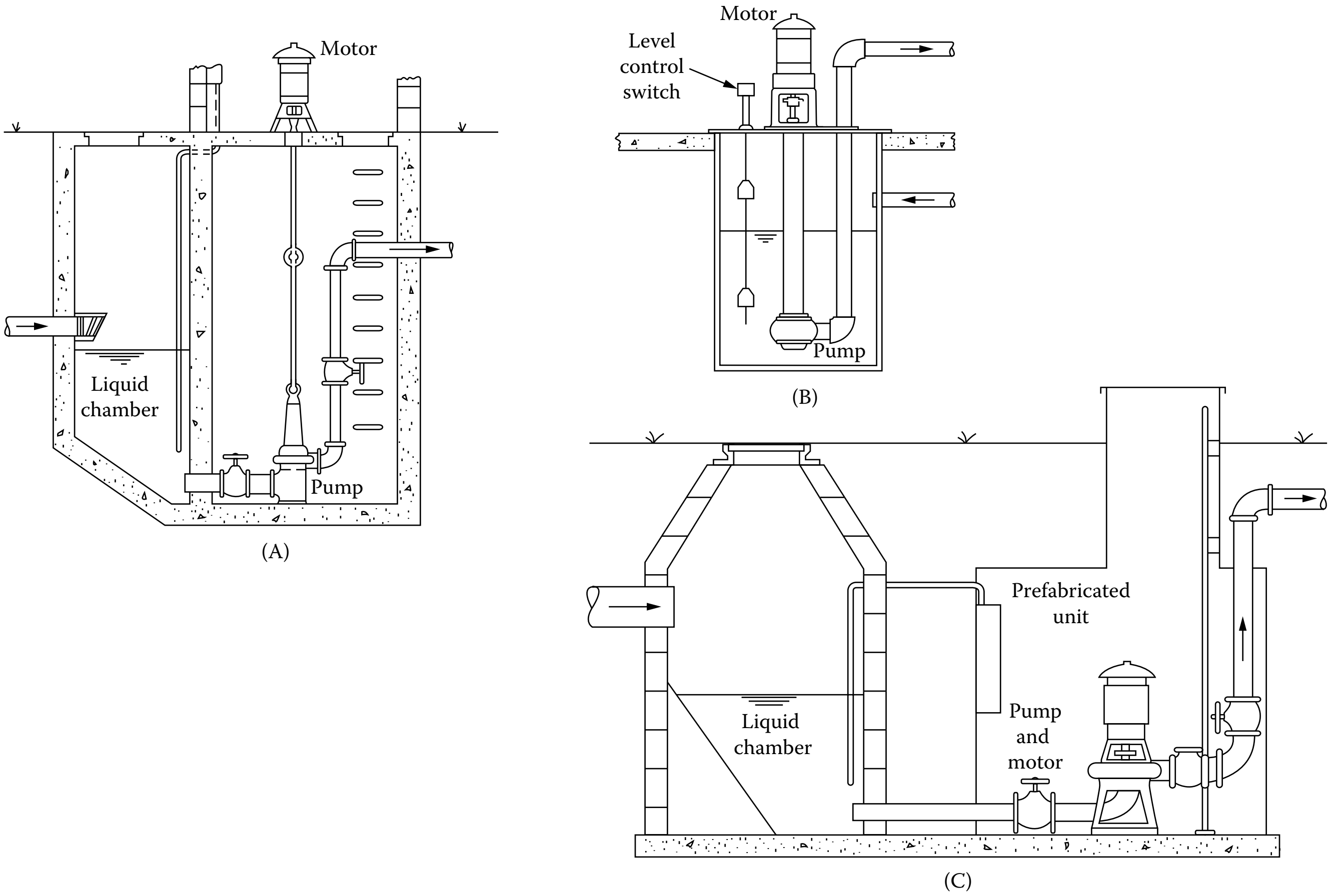

FIG. 7.4k
Pumping stations: (A) dry well design, (B) wet well design, (C) prefabricated pumping station.

5. Charts and formulas are available for sizing wet wells, but infiltration and runoff must also be taken into account.
6. Sump pumps, humidity control, a second pump with alternator, and a pump hoisting mechanism are desirable.
7. Most sewage utilities prefer the dry well designs for ease of maintenance.

METERING PUMPS

Flow control of liquids can be accomplished by means of pumps that incorporate the measurement and control element in a single unit. Metering pumps are designed to provide measurement and control of the process. For a measurement-oriented discussion of these pumps, refer to Section 2.14 in the *Process Measurement and Analysis* volume of this handbook.

Plunger Pumps

Plunger pumps are suitable for use on clean liquids at high pressures and low flow rates. A typical plunger pump is shown in Figure 7.4l. The pump consists of a plunger, cylinder, stuffing box, packing, and suction and discharge valves. Rotary motion of the driver is converted to linear motion by an eccentric. The plunger moves inside the cylinder with reciprocating motion, displacing a volume of fluid on each stroke.

Stroke length, and thus the volume delivered per stroke, is adjustable. The adjustment can be a manual indicator and dial, or for automatic control applications, a pneumatic actuator with positioner can be provided. Stroke adjustment alone offers operating flow ranges of 10:1 from maximum to minimum. Additional rangeability can be obtained by means of a variable-speed drive. A pneumatic stroke positioner used in conjunction with a variable-speed drive provides rangeability of at least 100:1. In the case of automatic stroke adjustment and variable speed, the pumping rate can be controlled by two independent variables, or the controller output can be "split-ranged" between stroke and speed adjustment.

The reciprocating action of the plunger results in a pulsating discharge flow, as represented in Figure 7.4m by the dotted simplex curve. For applications where these flow pulsations cannot be tolerated, particularly if a flow measurement is required, pumps can be run in duplex or triplex arrangements. With the duplex pump, two pump heads are

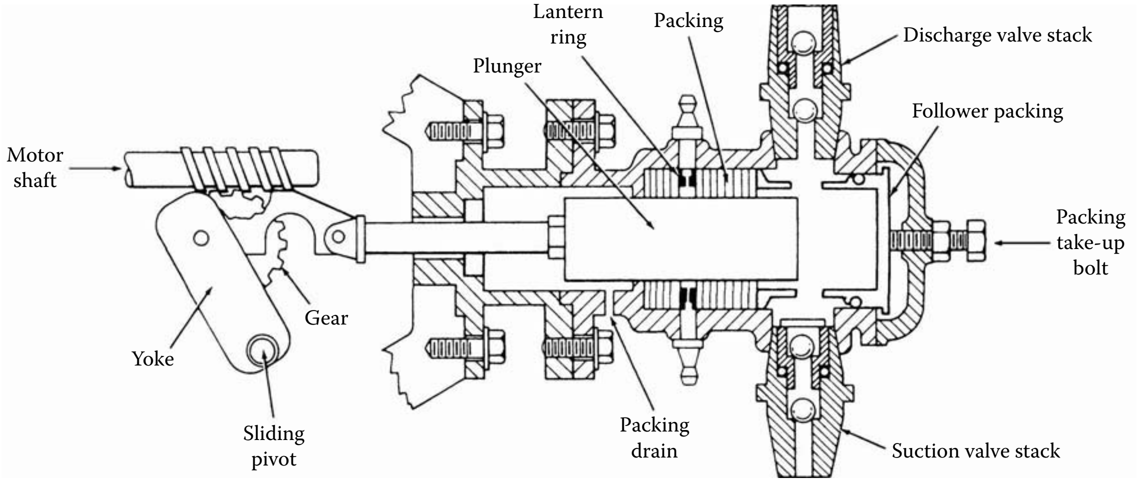

FIG. 7.4l
Plunger- or piston-type metering pump.

driven off the same motor, and the discharge strokes are phased 180° apart. With a triplex arrangement, three pump heads are driven by one motor and the discharge strokes are 120° apart. Both the duplex and triplex pumps provide a smoother flow than the single pump, as shown by the dashed and solid curves of Figure 7.4m.

For blending two or more streams, several pumps can be ganged to one motor. Stroke length adjustment can be used to control the blend ratio, and drive speed can control total flow. However, in this case rangeability is sacrificed for ratio control.

Pumping efficiency is affected by leakage at the suction and discharge valves. These pumps are therefore not recommended for fluids such as slurries, which will interfere with proper valve seating or settle out in pump cavities.

Diaphragm Pumps

Diaphragm pumps use a flexible diaphragm to achieve pumping action. The input shaft drives an eccentric through a worm and gear. Rotation of the eccentric moves the diaphragm on the discharge stroke by means of a push rod. A spring returns the push rod and diaphragm during the suction stroke. A typical pump is shown in Figure 7.4n.

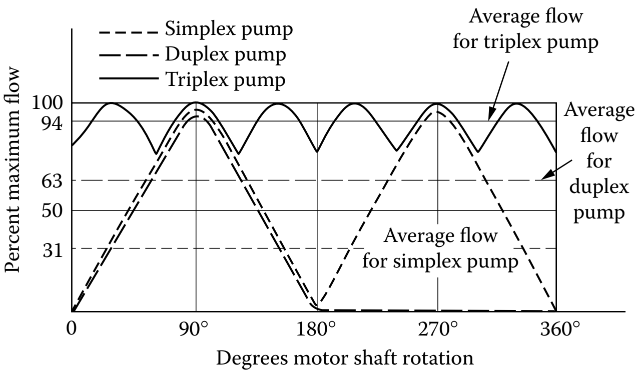

FIG. 7.4m
Flow characteristics of simplex and multiple plunger pumps.

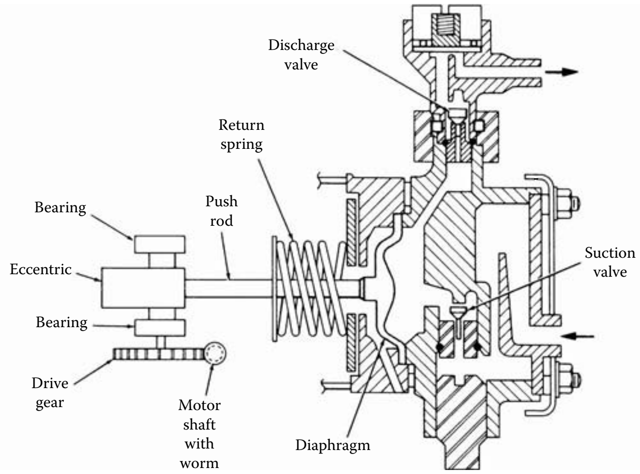

FIG. 7.4n
Diaphragm-type metering pump.

Operation of the diaphragm pump is similar to that of the plunger pump; however, discharge pressure is much lower due to the strength limitation of the diaphragm. Their principal advantage over plunger pumps is lower cost. Designs with two pumps driven by one motor can be used to advantage for increased capacity or to smooth out flow pulsations. By combining automatic stroke length adjustment with a variable-speed drive, operating ranges can be as wide as 20:1. These pumps can be used only on relatively clean fluids, because solids will interfere with proper suction and discharge valve seating or may settle out in the pump cavities.

The weakness of the diaphragm pump design is in the diaphragm, which is operated directly by the push rod. The diaphragm has to be flexible for pumping and yet strong enough to deliver the pressure. The strength requirement can

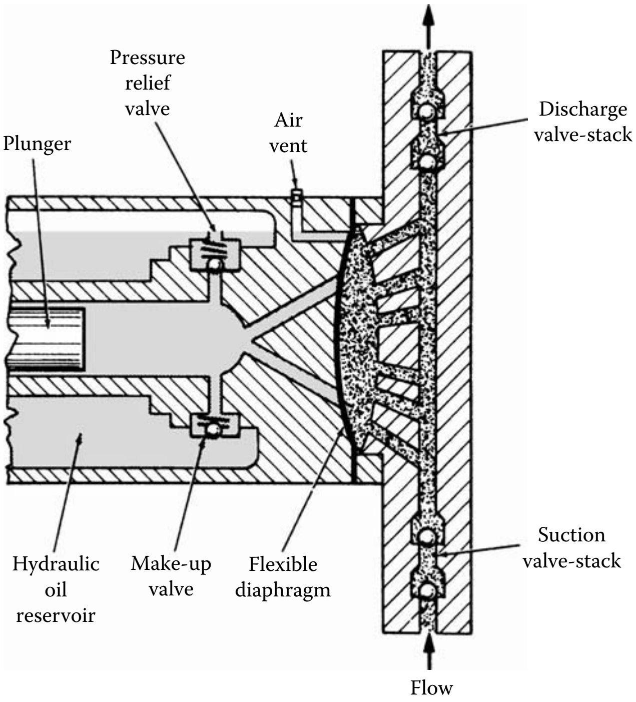

FIG. 7.4o
Diaphragm pump operated with hydraulic fluid.

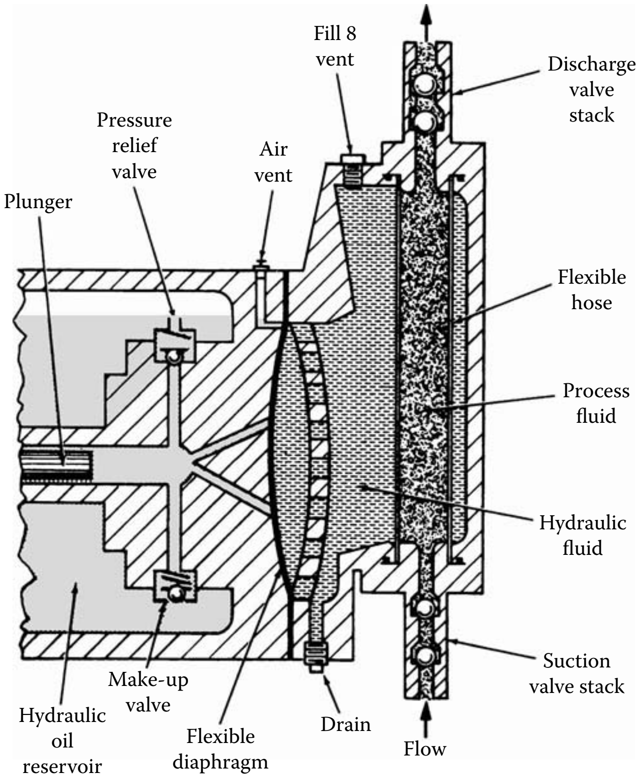

FIG. 7.4p
Diaphragm pump operated with hydraulic fluid and flexible hose element.

be reduced by using a hydraulic fluid to move the diaphragm, thereby eliminating the high differential pressures across it. This design consists basically of a plunger pump to provide hydraulic fluid pressure for diaphragm operation and the diaphragm pumping head (Figure 7.4o). The forces on the diaphragm are balanced, and discharge pressures comparable to plunger pumps are possible. The volume pumped per stroke is equal to the hydraulic fluid displaced by the plunger, and this volume is controlled by the stroke length adjustment as in the plunger pump.

A pump design using a flexible tube to achieve pumping action is shown in Figure 7.4p. Motion of the plunger displaces the diaphragm, which in turn causes the flexible tube to constrict, forcing fluid in the tube to discharge (similar to the operation of a peristaltic pump). This design is better suited for use on viscous and slurry liquids than the previously discussed types because the flow path is straight with few obstructions and no cavities; however, seating of the valves can still be a problem.

Pneumatic Metering Pumps

Pneumatically operated plunger-type (Figure 7.4q) and bellows-type metering pumps are also available for use when liquids in small quantities need to be injected at high pressure. The pneumatic timer is adjustable between 4 and 60 strokes per min, while the stroke length is also adjustable from 1/4 –1 in. (6–25 mm). When at the end of the stroke, the pressurized air-operated plunger has displaced the process fluid through the discharge check valve, the piston trips the vent valve, which resets the timer and allows the spring to return the piston to the starting position.

Pneumatic metering pumps are available in all stainless steel construction, require no lubrication, can be provided with plungers of 1/8 – 1/2 in. (3–12 mm) diameter, and can deliver flows from 0.1–60 gpd (0.4–225 lpd) at pressures up to 5000 PSIG (3.4 MPa). Until recently, natural gas was frequently used as the motive fluid for odorant injection pumps of this type. While this has the advantage that no other utilities are required, it releases methane to the atmosphere, and this is illegal in many places.

Installation Considerations

In order to ensure a properly working installation, a number of factors associated with the physical installation and with the properties of the fluid must be considered. Some factors that can contribute to a poor installation include:

1. Long inlet and outlet piping with many fittings and valves
2. Inlet pressure higher than outlet pressure
3. Pocketing of suction or discharge lines
4. Low suction head or suction lift

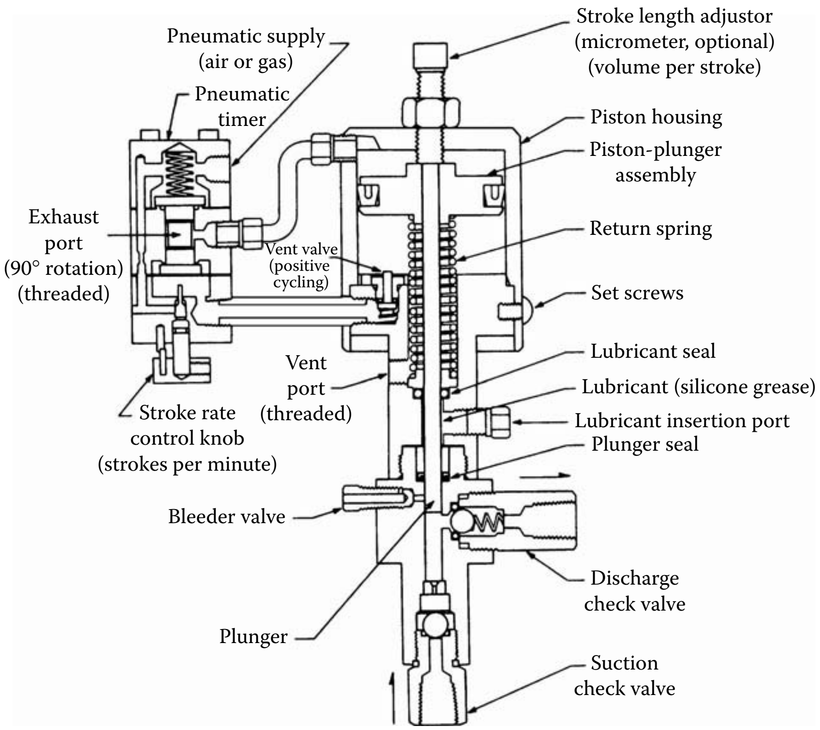

FIG. 7.4q

Pneumatically operated plunger-type metering pump. (Courtesy of Linc Mfg.)

A tortuous flow path in the pump suction or discharge can be troublesome when the fluid handled contains solids, is of high viscosity, or has a high vapor pressure, or if the suction head available is low. Generally, valves that offer a full flow path (such as ball valves) are preferred. Needle valves should be avoided. If the inlet pressure is higher than discharge, the fluid may flow unrestricted through the pump. Spring-loaded check valves at the pump are undesirable because the spring loading stops the ball check from rotating and from finding a new seating surface, for increased valve life. For such applications the installations shown in Figures 7.4r and 7.4s offer solutions.

In Figure 7.4r, the piping arrangement will supply the head to prevent through flow and siphoning. The height of the liquid should be varied depending on pump capacity and fluid velocity. This dimension varies between 2 and 10 ft (0.6 and 3 m) and increases with capacity and velocity. Figure 7.4s illustrates the use of a spring-loaded back-pressure valve to overcome the suction pressure. For this installation a volume chamber (gas-filled bladder) to dampen pulsations should be placed between the pump discharge and the valve.

Dissolved or entrained gases in the fluid can destroy metering accuracy, and in quite small volume they can stop pumping action entirely, as the gas volume is compressed before the fluid can exit through the discharge check valve. Figure 7.4t illustrates an installation design to vent entrained gases back to the fluid hold tank.

It is always desirable to locate the pump below and near the fluid hold tank. Under these conditions the fluid will flow by gravity into the pump suction and loss of prime is unlikely. If the pump cannot be located below the hold tank, other measures must be taken to prevent loss of prime.

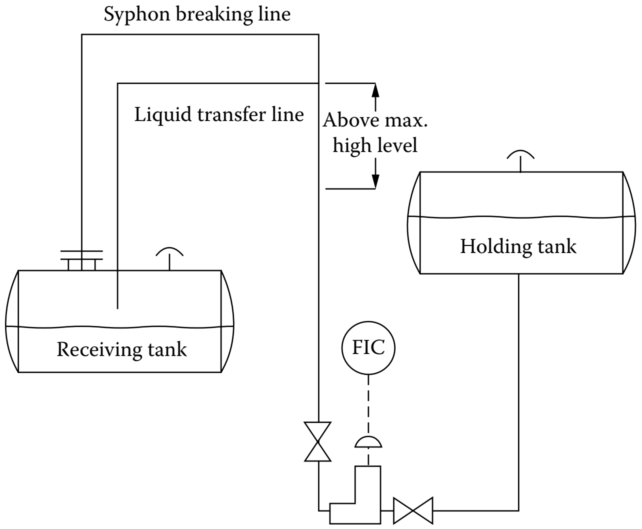

FIG. 7.4r

Piping arrangement to prevent through flow and siphoning.

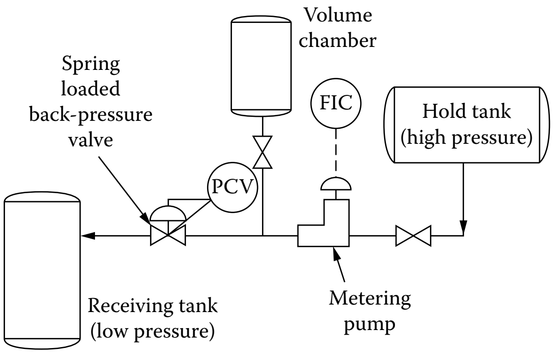

FIG. 7.4s
Metering pump with artificial head created by back-pressure valve.

NPSH and Pulsation Dampening

In order for the pump to operate properly, the net positive suction head must be above the minimum practical suction pressure of approximately 10 psia (69 kPa abs). The available net positive suction head is given by Equation 7.4(6).

$$\mathrm{NPSHA} = P - P_v \pm P_h - \sqrt{\left(\frac{lvGN}{525}\right)^2 + \left(\frac{lvC}{980Gd^2}\right)^2} \qquad \mathbf{7.4(6)}$$

where

P = feed tank pressure (psia)
P_v = liquid vapor pressure at pump inlet temperature (psia)
P_h = head of liquid above or below the pump centerline (psid)
l = actual length of suction pipe (ft)
v = liquid velocity (ft/s) at maximum piston speed (see Figure 7.4m)
G = Liquid specific gravity
N = number of pump strokes per minute
C = viscosity (centipoise)
d = inside diameter of pipe (in.)

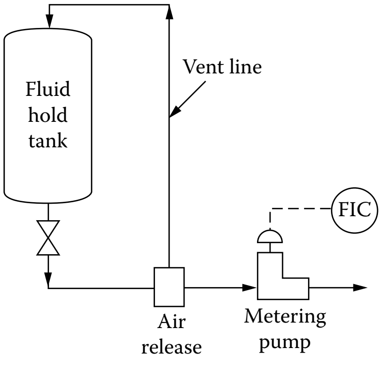

FIG. 7.4t
Elimination of entrained gases in metering pump installations.

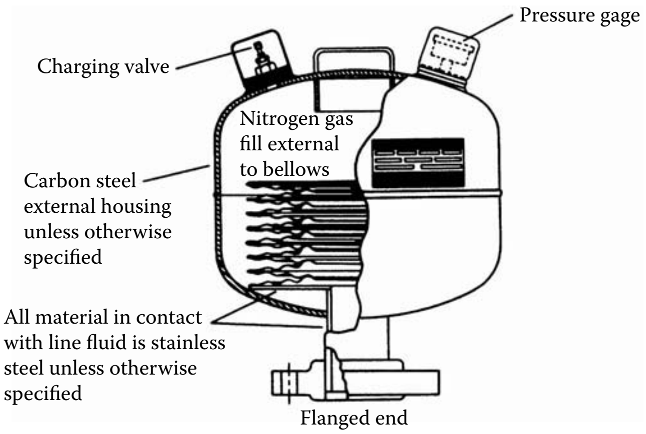

FIG. 7.4u
Pulsation dampener will suppress the pressure surges caused by positive displacement pumps. (Courtesy of the Meraflex Co.)

For liquids below approximately 50 centipoise (0.05 Pa·s), viscosity effects can be neglected, and Equation 7.4(6) reduces to

$$\mathrm{NPSHA} = P - P_v \pm P_h - \frac{(lvGN)}{(525)} \qquad \mathbf{7.4(7)}$$

The calculated value to NPSHA must be above the minimum suction pressure required by the selected pump.

In addition to multiple pumping heads, a pulsation dampener can be used on the pump discharge to smooth the discharge flow pulsations. The pulsation dampener is a pneumatically charged diaphragm chamber that stores energy on the pump discharge stroke and delivers energy on the suction stroke, thus helping to smooth the flow pulses. In order to be effective, however, the dampener volume must be equal to at least five times the volume displaced per stroke (Figure 7.4u), and the precharge pressure matched to the discharge pressure. Suction dampeners are also used to minimize the acceleration losses in the suction line if the NPSHA is close to the minimum, particularly for simplex and duplex designs; triplex designs are less sensitive. When handling flammable fluids, the piping code may call for the use of excess-flow valves in the suction line, to shut off the tank if the line ruptures. The use of these on a simplex or duplex reciprocating pump suction needs sizing for the maximum pump suction flow, not the average value.

OPPOSED CENTRIFUGAL PUMPS

The opposed centrifugal pump is not a control element but is an adaptation of a centrifugal pump to flow control. This method of control is particularly suitable for coarse, rapidly settling slurries at low flow rates. In such services the conflicting requirements of control at low flow and the need for a large free area to pass the solids may make it impossible

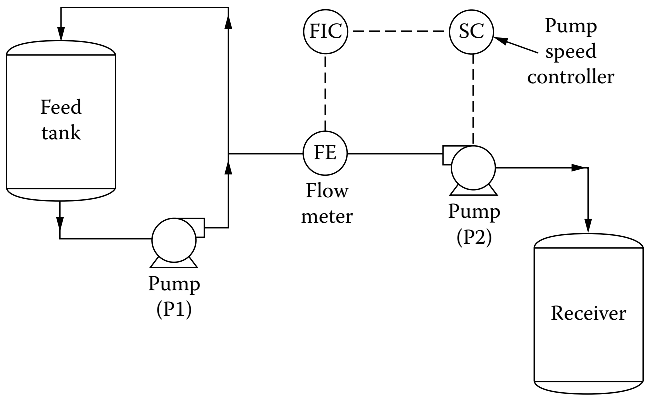

FIG. 7.4v
Opposed centrifugal pump as final control element.

to find a suitable control valve. A system that requires a small quantity of slurry to be fed to a receiving vessel under controlled conditions is depicted in Figure 7.4v. Pump P_1 continuously circulates the slurry from the feed tank at high velocity. A branch line from the discharge of P_1 is connected to the opposed centrifugal pump P_2. Pump P_2 is connected in opposition to the direction of slurry flow and provides a pressure drop to throttle flow. A variable-speed driver on pump P_2 throttles the pump pressure drop so as to keep the flow constant. At full speed the pressure difference across P_2 is sufficient to stop the branch line slurry flow completely. A magnetic flowmeter or some other suitable device can be used to measure the slurry flow. A VSD can be used to vary pump speed in response to the flow controller output signal.

A related approach utilizes a progressing-cavity pump as the restriction element, close-coupled to the circulating line and preferably discharging freely from the drive end. This does not need the flowmeter, as it is effectively positive displacement at low head, and flow is proportional to speed.

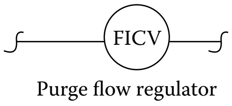
7.5 Regulators—Flow

G. F. ERK (1985, 1994) **B. G. LIPTÁK** (1995) **T. J. BAAN** (2005)



Purge flow regulator

Flow sheet symbol

Types:	A. Rotameters, purge flowmeters (variable area) B. Chromatographic flow controller C. Variable, spring-loaded, and flexible orifice flow regulator D. Thermal mass flow controller
Design Pressures:	A. Up to 600 PSIG (4.1 MPa) B. 500 PSIG (3.45 MPa) C. Industrial flow regulators are available for maximum working pressures up to 3600 PSIG (2.07 MPa) at 100°F (38°C). Oil flow controllers are available for up to 3750 PSIG (26 MPa) D. From 20 PSIG (138 kPa) minimum to 1000 PSIG (6.9 MPa) maximum
Design Temperatures:	A. Standard units for 200°F (93°C) B. Barstock units, brass 180°F (82°C), stainless steel 250°F (121°C) C. Standard units up to 400°F (204°C) D. Standard units from 41 to 149°F (5 to 65°C); special up to 302°F (150°C)
Materials of Construction:	A. Glass, aluminum, brass, carbon steel, stainless steel, or PTFE-PFA B. Brass or 316 stainless steel with a choice of elastomeric O-rings C. Typically brass, copper, ductile iron, or steel bodies with stainless steel internals D. 316 SS, corrosion-protected steel, nickel, Inconel, elastomer seals
Flow Rates:	A. For liquids from 0.01 cc/min and for gases from 0.5 cc/min and up. A standard 1/4 in. (6 mm) unit can have a 0.05–0.5 gpm (0.2–2 lpm) range on liquid or a 0.2–2 SCFM (0.3–3 m^3/hr) range on gas service. Off-the-shelf 2 in. meters for liquids 0.25–120 gpm (35–440 lpm), range for gas service 1.2 SCFM (2.1 m^3/hr) to 250 SCFM (420 m^3/hr) B. Chromatographic applications in the cc range C. Water regulators for standard HVAC applications are available with settings from 0.5 to 150 gpm (2 to 600 lpm), while oil flow regulators are available with ranges from 0–5 to 0–800 gpm (0–20 to 0–3200 lpm). Industrial units cover liquid ranges from 0.02 to 550 gpm (0.1 to 2000 lpm) and gas ranges from 0.2 to 6000 SCFM (6 slpm to 170 m^3/m) D. Full scale for gases from 10 sccm to 1000 slm (35 SCFM). Special units up to 1900 slm (500 SCFM)
Sizes:	A. Typically from 1/2 to 2 in. (3 to 50.8 mm) connection size B. 1/2 in. FNPT C. 0.5 in. to 6 in. (12 to 150 mm) D. 1/8 in. (3.2 mm) to 3/4 in (19 mm) compression fittings, 3/4 in. FNPT
Inaccuracy:	A,B. 2–5% of full scale C. 1.5% of full scale for industrial designs, 5% of full scale for HVAC designs D. 1% of full scale
Costs:	A. A typical 65 mm scale glass tube meter with a brass or aluminum built-in needle valve costs about $80. An all-stainless steel 150 mm scale rotameter with a 16-turn precision valve with 1/4 in. (6 mm) connections costs about $350. 65 mm and 150 mm purge flow regulators with built-in differential pressure controllers cost $600 and $650, respectively. B. Brass barstock $100, stainless steel barstock $150

C. HVAC units in smaller sizes and larger quantities are under $100
D. A standard thermal mass flow controller for gases costs $1100

INTRODUCTION

For the general subject of flow measurement, please refer to Chapter 2 of the first volume of this handbook. In this section a number of self-contained flow regulators/controllers are described. Their common feature is that the flow sensor, the flow controller, and the flow control valve (in other words, the whole control loop) are combined into a single unit.

The design variations covered in this section include the purge flow regulators, which detect the flow by using a rotameter (variable area flowmeter), the various flow regulator valves used in chromatography, the various adjustable-orifice flow regulators that reduce their internal opening to flow when their inlet pressure rises and thereby keep the flow relatively constant, and the thermal mass flow controllers used as accurate regulators of gas flows.

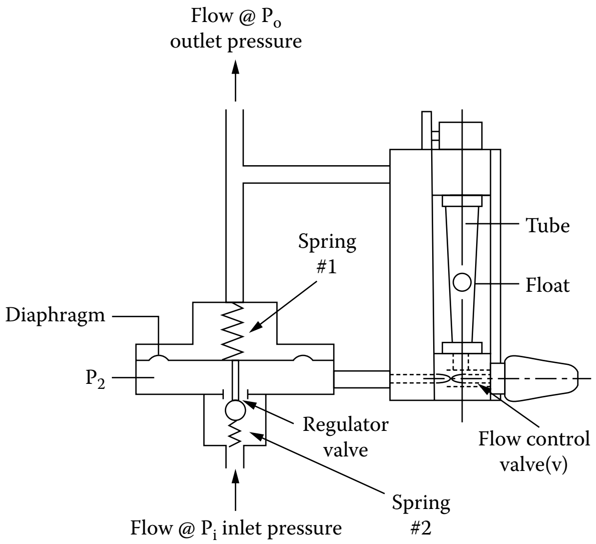

FIG. 7.5a
The main components of the illustrated purge flow regulator are a glass tube rotameter, an inlet needle valve, and a differential pressure regulator. (Courtesy of Krone Inc.)

PURGE FLOW REGULATORS

When a variable area flowmeter is combined with a differential pressure regulator (Figure 7.5a), it becomes a self-contained flow controller. The purge flow is fixed by adjusting springs #1 and #2 for a particular pressure difference, usually in the range of about 60–80 in. (150–200 cm) of water. This constant pressure drop ($P_2 - P_o$) is then maintained across the flow control valve (V). The configuration in Figure 7.5a maintains the outlet pressure (P_o) constant by compensating any variation in the inlet pressure P_i by changing the regulator valve opening.

Other purge flowmeter designs are also available that work in a reverse configuration by keeping the inlet pressure P_i constant and allowing the outlet P_o to vary. In these designs the constant pressure drop across the valve (V) is maintained to equal ($P_i - P_2$) instead of ($P_2 - P_o$) being kept constant. The gas flows through purge flow controllers are usually adjustable in a range of 0.2–2 SCFH (6–60 slph). The error or inaccuracy is usually 5% of full scale over a range of 10:1. The standard pressure and temperature ratings are 150–300 PSIG (1–2 MPa), and 212–572°F (100–300°C).

Figure 7.5b illustrates how a needle valve can be placed at the inlet or the outlet of a variable area flowmeter and the pressure difference controlled across this assembly. The main applications of purge flow regulators are to introduce small gas or liquid purge streams into pressure taps, where for reasons of corrosion or plugging protection it is desirable to do so. As the interest in these applications is only to make sure that there is some flow, the typical ±5% of full-scale error in these units is acceptable.

FLOW REGULATORS FOR CHROMATOGRAPHS

Another self-contained flow regulator valve design is shown in Figure 7.5c. It is designed to accurately adjust and maintain small gas and liquid flows. This design utilizes a nonrising stem and features a positive, direct mechanical means of adjusting a sliding tapered needle that virtually prevents sticking caused by foreign matter in the fluid stream. These barstock valves are available in straight line or 90° configurations, and are particularly suitable for the precise control requirements in chromatography.

VARIABLE-ORIFICE FLOW REGULATORS

These are mature devices that have not changed much during the last decades. One of their simplest versions is a thick rubber orifice (Figure 7.5d). It has such a geometry that it is deflected as the pressure drop increases in such a way that with a rising pressure drop, the opening to the flow is reduced.

Such flexible orifices, which inversely vary their openings with the pressure of the water supply, are used in HVAC distribution and other water balancing applications, such as in showers, appliances, filters or sprinklers. These units can be mounted inside 1/2 and 3/4 in. fittings. Different orifices are available for approximately maintaining crude flows at 2, 2.5, 3, 3.5, 4, 5, 6, 7, 8, 9, and 10 gpm, while the inlet pressure varies between 15 and 125 PSIG (103 and 870 kPa). The cost of these fittings is a few dollars.

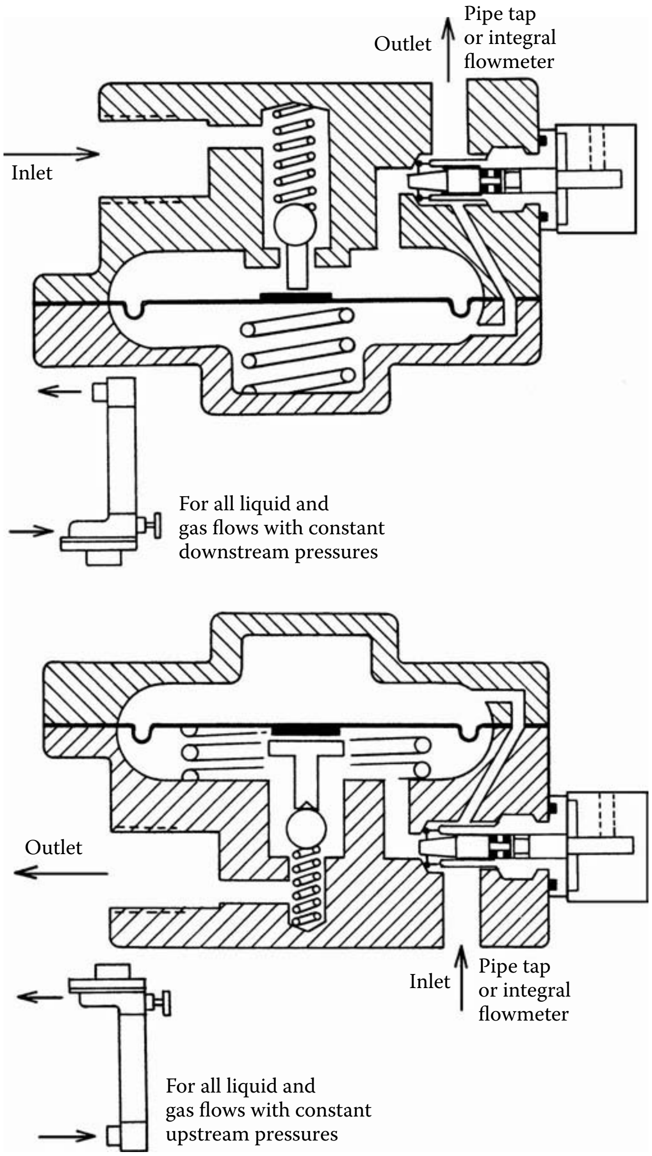

FIG. 7.5b
Purge flow rate can be regulated by maintaining the differential pressure across a variable area flowmeter constant. The d/p regulator is located at the inlet of the rotameter (top) if the downstream pressure is constant, and at the outlet (bottom) if the upstream pressure is constant.

HVAC Balancing Flow Regulators

The purpose of the flow regulator shown in Figure 7.5e is to balance the water flow to the various heating/cooling coils in large HVAC systems, where the water pressure varies on the different floors of a building. In order to keep the flow constant while the inlet pressure varies, it is necessary to vary the orifice opening as a function of pressure.

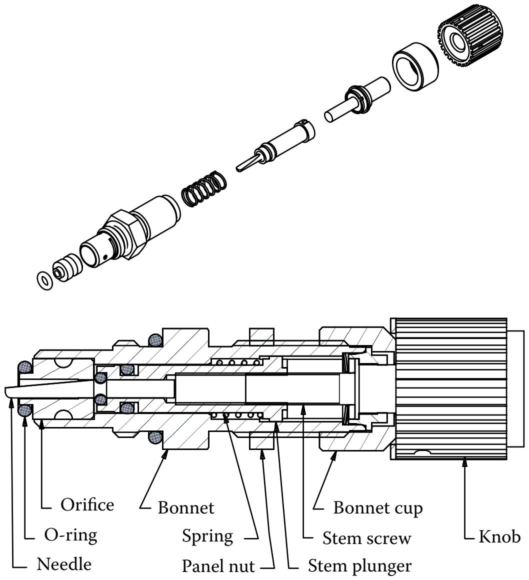

FIG. 7.5c
Nonrising stem-type valve cartridge. (Courtesy of AALBORG Instruments.)

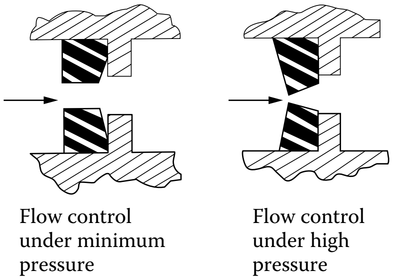

FIG. 7.5d
Flexible-orifice-type flow regulator, which is used to balance the flow of shower and sprinkler heads or in HVAC applications.

The inner flow element of the regulator illustrated in Figure 7.5e is pushed against a spring by the flowing water. When the water pressure is low (minimum pressure drop), the spring forces the element out and exposes the maximum number of flow openings to the water. As water pressure rises, the element is pushed in against the spring and therefore fewer orifices are available for the water to pass through. This increases the pressure drop across the regulator, while keeping the flow rate relatively constant.

Units are available in sizes up to 3 in. (75 mm) and with flow settings up to 200 gpm (600 lpm). The spring should be selected to match the probable pressure drop variation in the system. Springs are available with 14, 32, 57, and 128 psid (96, 220, 393, and 883 kPa) ranges.

Another flexing action flow regulator consists of an automatic control valve with an elastic diaphragm-orifice combination. This design permits passage of small particles, sludge, thread chips, and rust impediments and minimizes the need

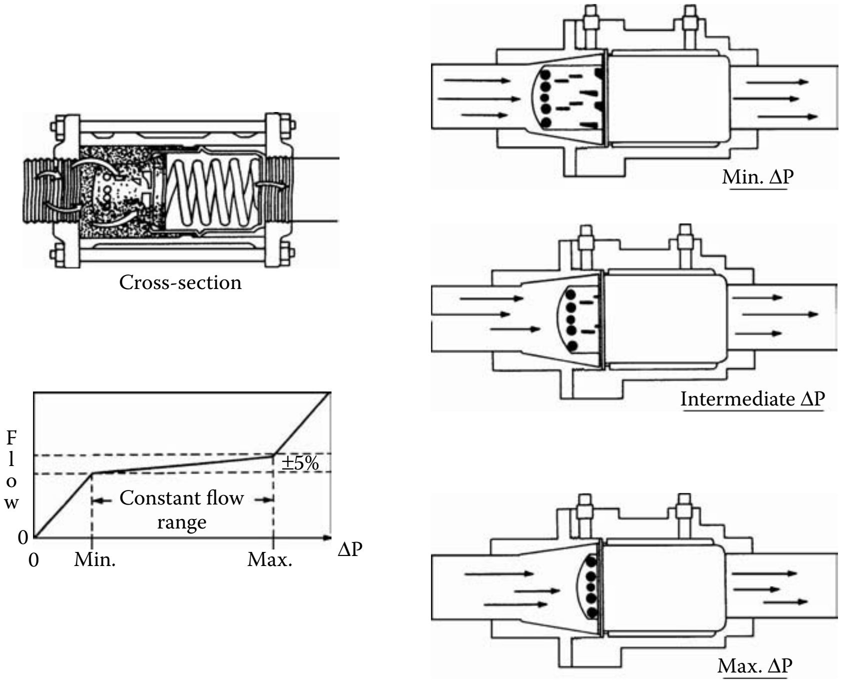

FIG. 7.5e
As inlet pressure rises, the orifice element is pushed in against the spring, thereby exposing fewer openings to the flow and as a result increasing the pressure drop so as to maintain the flow relatively constant. (Courtesy of Griswold Controls.)

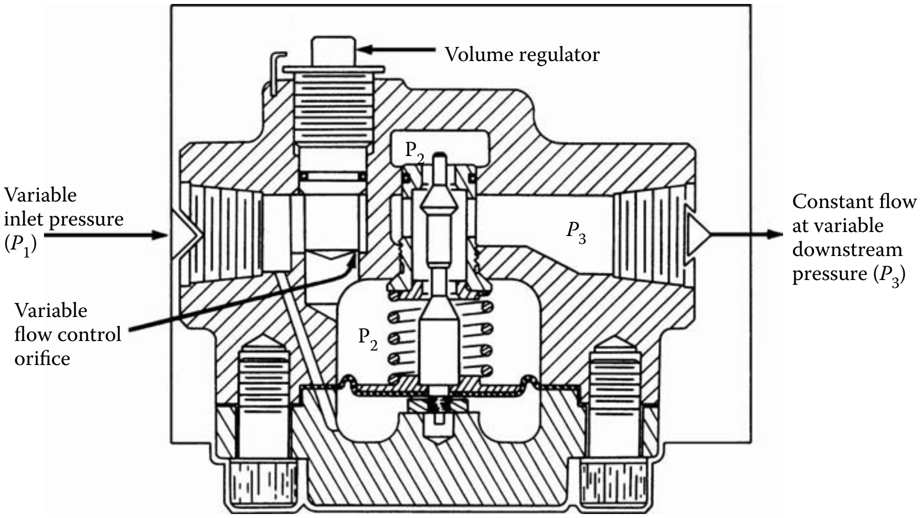

FIG. 7.5f

Oil flow regulator keeps the pressure difference ($P_1 - P_2$) constant across the flow control orifice and thereby allows for the maintenance of constant flow even when the inlet or outlet pressures vary. (Courtesy of Taylor Valve Technology, Inc., formerly Taylor Tools.)

for strainers. The operation is quiet and the flow is maintained within a 5–10% error.

Oil Flow Regulator

Figure 7.5f depicts a flow controller, which is used to regulate the flow of high-pressure oil. In this design, flow is maintained constant by keeping the pressure drop across a manually adjustable internal orifice constant. This way either the upstream or downstream pressures can vary without affecting the flow.

The internally controlled differential pressure ($P_1 - P_2$) can be as low as 15 psid (103 kPa) and the flow will still be maintained approximately constant when the overall differential ($P_1 - P_3$) is several thousand psid. These units are available in sizes from 0.5–4 in. (12–102 mm) and can control flow ranges from 0–5 to 0–400 gpm (0–20 to 0–1514 lpm). These units have been designed for high-pressure operation and are suited for working pressures up to 3750 PSIG (26 MPa).

Industrial Flow Regulators

Self-contained flow-rate controllers usually combine an adjustable orifice and an automatic internal regulating valve in a single body. Differential pressure across the adjustable orifice is automatically maintained constant, regardless of the orifice opening. Therefore, the total flow rate is directly proportional to the area of the orifice.

The orifice and the automatic differential pressure regulator are usually enclosed in a single housing with a calibrated flow-rate indicating dial. A regulator that is provided with an external needle valve with the differential pressure controller is also available. This provides some flexibility in adjusting flow rates remotely.

A flow-rate controller of this type is shown in Figure 7.5g. Here, the metering orifice is formed by an arcuate slot in a cylinder (orifice sleeve) and a second slot is provided in an inner (orifice) cylinder around which the first (orifice sleeve) can be rotated. When the two slots match or coincide, the orifice has its maximum open area; when the outer sleeve is rotated, the open length of the slot and the open area decrease in proportion to the angle rotation of the sleeve. When the outer sleeve is rotated to 160°, the open orifice area is reduced to 0.

This automatic differential pressure regulator includes an impeller, spring, valve sleeve, and valve tube. The impeller disc reciprocates in the upper part of the orifice sleeve, driven by the balance between the forces due to the differential pressure across the orifice ($P_U - P_D$) and the spring. The impeller is rigidly connected to the valve sleeve. It closes or opens the valve ports as dictated by the force balance, maintaining the orifice differential pressure and holding the orifice flow at the valve determined by the differential pressure and the orifice area.

Advantages and Limitations Advantages of the self-contained flow-rate controllers are as follows:

1. Provides reasonably accurate flow-rate control by means of a self-operated single unit.
2. Does not require straight pipe runs upstream or downstream of the unit.
3. No utility requirements to operate the unit (no electric power or pneumatic or hydraulic fluids).
4. Maximum speed of response, because control occurs at the point where the measurement is made.

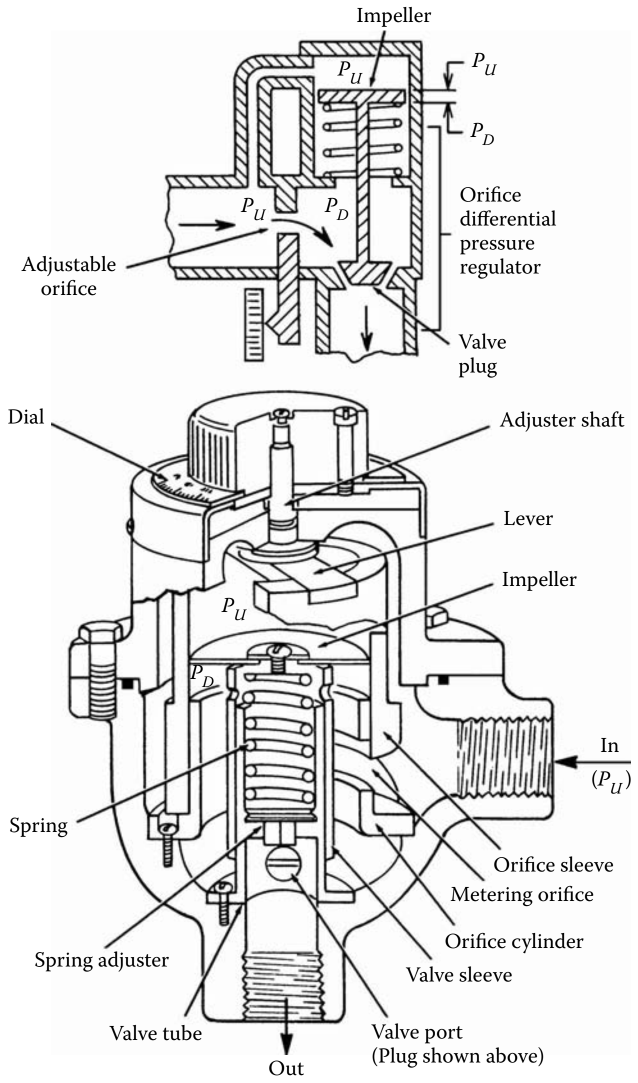

FIG. 7.5g
Industrial flow regulator.

5. Flow scale is linear and, therefore, adjustment rangeability is better than with square root scales.
6. Simple design and few parts with little calibration and adjustment requirements.
7. Low oscillation or hunting phenomena in liquid service.
8. Turndown ratio can be up to 25:1 or better.
9. Large pressure drops have minimal effects.
10. On clean water services, both the first and maintenance costs are low.

Disadvantages include that the regulator requires a fairly high minimum pressure drop to work properly and that it can only be used on clean fluids.

Typical applications include the controlling of the flow of sealant fluids to the rotating seals on centrifugal pumps, compressors, turbines, and other rotating machinery. Another application is in pressure filtration, where a self-contained flow-rate controller will keep the filter effluent flow rate constant as the pressure drop across the filter increases with increasing filter cake build-up. Other applications can involve blending, batch control, and hydraulic oil flow control, where constant flow rates to various components must be maintained.

Gas Flow Applications For accurate flow-rate control in gas flow applications, the variations in the upstream pressure and temperature should be minimized. To determine the capacities of a particular regulator, manufacturers provide gas flow equivalent graphs. These graphs show values in gpm of water. All capacity data are based on water for purposes of standardization and convenience.

Water is normally used as the test fluid for factory calibrations. Graphs are also available for air, hydrogen, natural gas, nitrogen, and oxygen. For other gases, a factor (C) determined from its specific gravity is applied to the capacity data given for air. Hence, at a given pressure and temperature, the gas flow = (air flow) × C, where

$$C = \frac{1}{\sqrt{\text{S.G. of gas}}} \tag{7.5(1)}$$

The error in regulating the flow is usually less than 1.5% of set point. In some applications it is desirable to set the regulated flow rate remotely. Pneumatic and electric actuators are available for this purpose.

THERMAL MASS FLOWMETERS

For the regulation of small gas flows, complete mass flow control packages using thermal flow detectors are available. Thermal flowmeters are discussed in detail in Section 2.13 of the *Process Measurement* volume of this set of handbooks, and therefore are only briefly discussed here.

In order to make the heat-transfer-type flowmeter also suitable for the measurement of larger flow rates, the bypass design illustrated in Figure 7.5h has been introduced. The flow sensor in the bypass consists of two self-heated resistance thermometers wound around a thin-walled tube.

When there is no flow, the two heaters raise the tube temperature by about 70°C above ambient in a symmetrical manner (solid line in the upper part of Figure 7.5h) and there is no temperature difference between the two sensors. As the gas starts to flow, the molecules will carry the heat downstream (dotted line on Figure 7.5h) and the two sensors will register a temperature difference, which is directly proportional with the mass flow of the gas.

The thermal flowmeter tubes in these bypass units are small capillary tubes, usually under 0.125 in. (3 mm) diameter. They ensure laminar flow over the full operating range

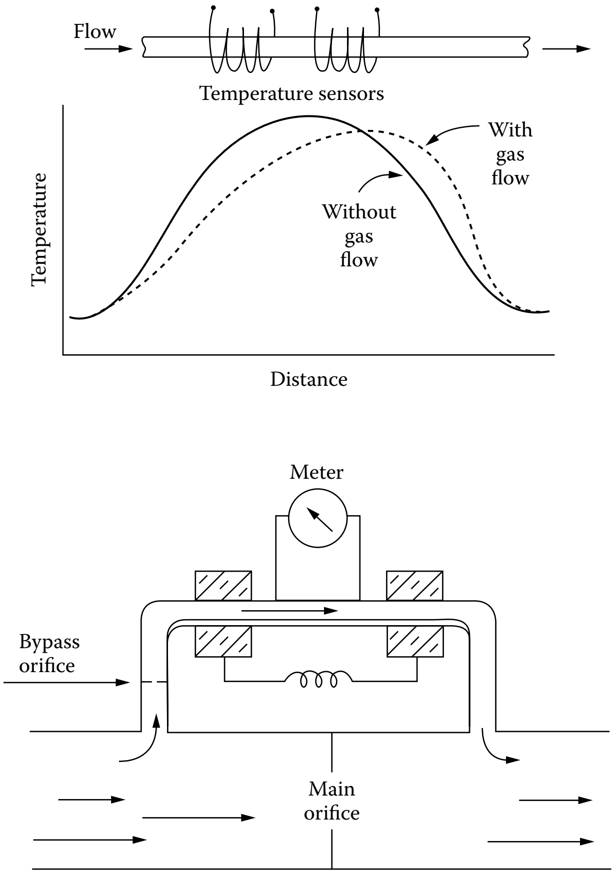

FIG. 7.5h
The operation of a bypass-type thermal flowmeter. (Courtesy of Mykrolis Corporation, formerly Tylan General Corp.)

of the meter. Their small size is advantageous in minimizing the electric power requirement and also in increasing their speed of response but necessitates the use of upstream filters to protect them against plugging. Some of the units also require up to 45 PSIG (3 bars) pressure drop in order to develop the laminar flow conditions at which they operate.

These units are also available as complete control loops, with sensor, controller, and automatic control valve and LCD readouts, all assembled into a single unit (Figure 7.5i). The cost of these units is competitive, and therefore if it is sufficient to control the flow of small gas streams within an error of ±1% of full scale, these units are a good selection.

These mass flow controllers are usually equipped with electromagnetic, fast response control valves, but slow response thermal-expansion-type control valves can also be used, if the fast response would result in over- and undershooting of the set point. Thermal-expansion-type valves are operated without seals and therefore without friction or wear. In this design, the controller heats the stem of a thermal expansion valve and the expanding stem moves the valve plug toward the seat, thereby closing the valve. Because of this nature of the valve actuator, it takes 5–30 sec to bring the flow to set point.

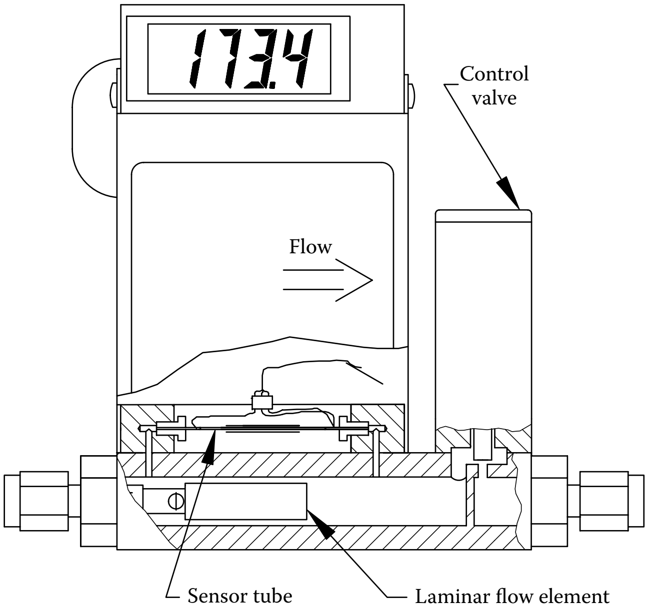

FIG. 7.5i
Bypass-type thermal mass flow controller with built-in readout. (Courtesy of AALBORG Instruments.)

In the microprocessor-driven mass flow controllers, firmware enables these digital devices to perform an array of functions that are unavailable with analog controllers. Intelligent mass flow controllers incorporate automatic zeroing, totalizers with set, start/stop, read, start at preset flow, and stop at preset volume capabilities.

Typically, up to ten primary gas flow calibrations may be stored in their memory. In addition, 256 gas coefficients are provided to convert between calibrating and other gases. High/low flow alarms, up to ten user-programmable flow ramping patterns, self-diagnostics, choice of engineering units, PID auto-tune, and dry contact closures are now standard in digital devices.

"Smart" mass flow controllers typically have one of the following digital interfaces: RS-232, RS-485, Device Net, and PROFIBUS. Because of the requirements of the semiconductor industry, thermal mass flow controllers are now optionally available with clean room assembly and all metallic O-ring features. Another new development is the increasing use of IP65 (NEMA4/12) water- and dust-resistant enclosures.

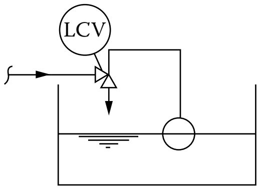
7.6 Regulators—Level



Flow sheet symbol

B. G. LIPTÁK (1969) **G. F. ERK** (1985, 1995)
M. D. CHAPMAN, B. G. LIPTÁK (2005)

Pressure in Vessel:	Up to 500 PSIG (3.5 MPa) with float type; atmospheric for diverter and altitude valves
Maximum Pressure Drop through Valve:	100 psid (0.7 dMPa) for float type; 50 psid (0.35 MPad) for diverter or altitude valves
Design Temperature:	Up to 450°F (232°C) with float type; ambient for altitude valves; up to material selected on diverter valves
Materials of Construction:	Iron, steel, stainless steel for float type; unlimited for diverter valves; cast iron for altitude valves
Range:	Normally less than 12 in. (300 mm) for float type; diverter valves essentially on/off; altitude valves practically on/off (some regulate)
Valve Sizes:	1/2 to 42 in. (12.5 to 1050 mm) for float and diverter type; 2 to 42 in. (50 to 1050 mm) for altitude valves
Cost:	Float-type control valves are basically globe valves in which the spring-and-diaphragm actuator has been replaced by a float operator. Therefore, their costs are similar to the costs of globe valves, which for carbon and stainless steel valves are given in Table 6.19b. In cast iron, a 3/4 in. (18 mm) valve with a float costs about $300, while a 30 in. (750 mm) altitude valve with multiple control functions can cost over $50,000

INTRODUCTION

Regulators are self-contained mechanical devices, while controllers require an external (pneumatic, hydraulic, or electric) energy source. Float-type level regulators have been around for a long time and have not changed much in the last couple of decades. The use of these devices is limited to clean liquid services and to applications where the offset that is inherent in the operation of any proportional-only regulator can be tolerated.

In the designs that are described in this section, the energy source for the regulator's operation is either the static and kinetic energy of the flowing stream or the buoyant force generated by the fluid inside the process vessel.

Three basic level regulator designs will be described: the float level control valves, the solid-state diverter valves, and the altitude valves.

FLOAT-TYPE LEVEL REGULATORS

In the float-type level control valves, mechanical linkages transmit the movement of the level float to the final control element (control valve) and thereby serve to regulate the flow to or from the vessel in such a manner that the level is maintained relatively constant. In order to evaluate the advantages and disadvantages of such a device one needs to consider the following:

1. Offset due to load changes, hysteresis, dead band, and span
2. Float power limitations
3. Stuffing box arrangements on pressurized vessels
4. Installation requirements

The Phenomenon of Offset

When process load (flow) changes, a plain proportional controller is not capable of keeping the controlled variable (level) on set point, because it first needs an error to develop, before it can change the valve opening. Therefore, as illustrated in Figure 7.6a, when the load changes, a permanent offset (deviation from set point) will occur.

The proportional band or gain of the control loop shown in Figure 7.6a can be defined as the level change that will result in fully stroking the inlet valve. As shown, the valve stroke from open to close is 1 in. (25 mm) and the level change required to stroke the valve is 7 in. (175 mm). The ratio *A*/*B* is the gain of the regulator. If $A = B$, the gain is 1 or the proportional band is 100%. If a small change in level results in a large change in valve opening ($B/A < 1$), the regulator has a high gain (narrow proportional band) and if $B/A > 1$ (the gain is less than 1), the proportional band is over 100%.

Proportional sensitivity (K_c) can be defined as the percentage change in flow rate through the valve that will result from a 1% change in liquid level in the tank. In the illustrated example, a 7 in. (175 mm) change in level will move the valve from fully closed (no flow) to fully open (maximum flow of 10 gpm or 40 lpm). Therefore, the proportional sensitivity is:

$$K_c = \frac{q}{h} = \frac{10}{7} = 1.4 \text{ gpm/in.} \qquad 7.6(1)$$

If the flow controller in the discharge pipe from the vessel maintains an outflow rate of 5 gpm (19 lpm), at steady-state conditions, the flow into the vessel has to match that flow rate. Therefore, if the process load is 5 gpm, the level in the tanks at steady state is

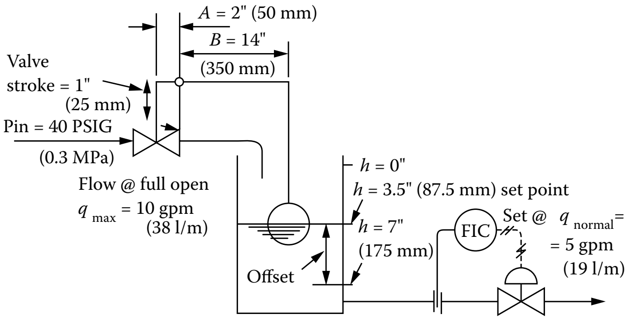

FIG. 7.6a

Illustration showing why in a float-type level regulator an offset is unavoidable if a load change occurs.

$$h = \frac{q \text{ normal}}{K_c} = \frac{5}{1.4} = 3.5 \text{ in.} \qquad 7.6(2)$$

When a load change occurs, either because the operator changed the FIC set point or because the liquid supply pressure at the inlet of the regulator valve changed, the result will be a permanent offset in the tank's level. Assuming, for example, that the header pressure is reduced from 40 PSIG (276 kPa) to 10 PSIG (69 kPa), and therefore the maximum flow through the control valve when fully open drops from 10 gpm (40 lpm) to 5 gpm (20 lpm), the new proportional sensitivity of the process becomes

$$K_c = \frac{q}{h} = \frac{5}{7} = 0.7 \text{ gpm/in.} \qquad 7.6(3)$$

Therefore, in order to obtain the previous outflow of 5 gpm (20 lpm) under these new conditions, the float of the level regulator has to sink until the valve is fully open. This occurs at

$$h = \frac{q \text{ nomal}}{K_c} = \frac{5}{0.7} = 7 \text{ in.} \qquad 7.6(4)$$

Therefore, the level of 3.5 in. that was previously maintained cannot be kept under these new load conditions and a permanent offset error of 3 (87.5 mm) will result in the controlled level. The amount of offset can be reduced by increasing the gain (reducing *B*/*A*) but it cannot be fully eliminated.

If the proportional band was reduced from 700 to 100% ($B/A = 1$), the proportional sensitivity would be increased by a factor of seven ($K_c = 4.9$), and the permanent offset would be reduced to 1/2 in. (12.5 mm). On the other hand, with a wider proportional band (*B*/*A* increased), the permanent offset would also rise.

Span, Dead Band, and Hysteresis

In all instruments that have boxes, pivots, and mechanical linkages, before motion can occur, the "break-away torque" has to be overcome, and therefore they all have some dead band. In addition, in such devices the direction of motion will influence the force-to-motion relationship, which will cause hysteresis. Both hysteresis and dead band are substantial in float-type level control valves.

The span of these blind, self-contained level control devices is adjustable, but the maximum control range is normally less than 12 in. (300 mm).

Power Generated by the Float

The buoyant force generated by the float is a function of the float volume and of the fluid density. The power that is

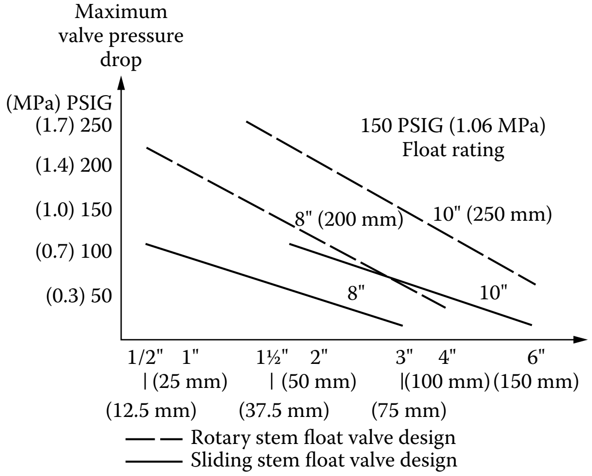

FIG. 7.6b
The maximum pressure difference against which the float-type level regulator can close is a function of both the valve size and the stem design.

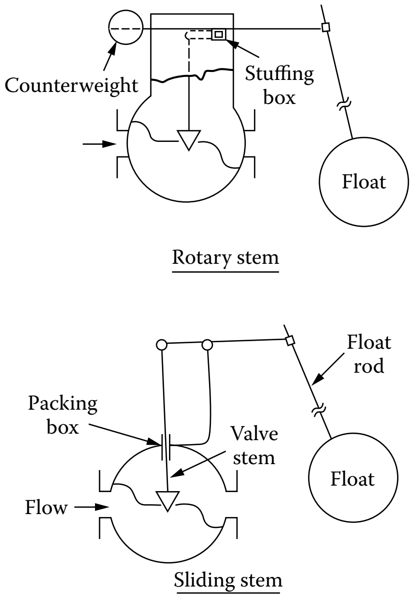

FIG. 7.6c
Of the total power generated by the float, the rotary stem design leaves more to overcome the process fluid forces at the valve plug because it has less friction than the sliding stem design.

available to operate the float or to close the valve against the static pressure in the supply header is substantially less than the buoyant force, because the float weight has to be subtracted from the gross buoyant force. The friction losses in the stuffing boxes, pivots, and mechanical linkages also reduce the net power available.

In addition, the total float volume cannot be used for sizing because the float is only partially submerged when it operates the valve. For example, an 8 in. (200 mm) diameter float with 150 PSIG (1.04 MPa) pressure rating, when totally submerged in water, has a gross buoyancy of 9.5 lb_f (42.3 N). After subtracting the float weight, the net total buoyancy is 6 lb_f (26.7 N). If the float design pressure is 500 PSIG (3.45 MPa), the net buoyancy is reduced to 4.5 lb_f (20 N). This net force is then amplified through the mechanical levers, while some of it is used to overcome the friction of the components.

Figure 7.6b shows the relationship between the size of the valve and the maximum pressure drop against which the valve is able to close. As one would expect, a larger float is required to operate the same size valve against a higher pressure drop.

As shown in the figure, there is a substantial difference between the limitations of the rotary and sliding stem valve designs. The rotary stem design shown in Figure 7.6c has less friction than the sliding stem design because of the relatively low friction of its lubricated stuffing box and therefore can handle higher pressure drops.

Specific Gravity and Temperature Effects

Specific gravity (SG) is the ratio of the process fluid density to that of 60°F (15.6°C) water at sea level. The buoyant force generated by a float is a function of the difference between the specific gravity of the float (SG_f) and the specific gravity of the process fluid (SG_p). The point at which the process fluid begins to lift the float and therefore change the valve opening is also affected by the float's specific gravity in relation to the process fluid's specific gravity.

The float will sink in the process fluid if its specific gravity is higher than that of the fluid ($SG_f > SG_p$) and therefore such float cannot be used at all. The specific gravity of the float must always be lower than that of the process fluid ($SG_f < SG_p$). The float will generate more buoyant force as the difference ($SG_f - SG_p$) rises.

So, for example, a float with a specific gravity of 0.6 in water with a specific gravity of 1.0 has to be submerged to about 60% of its volume before it will become buoyant and begin to lift. If that float is 8 in. (200 mm) in diameter, the water level has to rise to 4.8 in. (122 mm) before the float begins to generate a buoyant force to move the valve stem. In comparison, if the same 8 in. (200 mm) diameter float was used in diesel fuel oil with an SG of 0.82, the float will need to be submerged to a depth of 5.9 in. (150 mm) above the bottom of the float before buoyant force is generated.

The process fluid temperature will also affect the float buoyancy, because temperature affects the specific gravity of the fluid. Using the same 8 in. (200 mm) diameter float as an example, it was estimated above that cold water at a specific gravity of 1.0 will start to generate buoyant force when the level has risen to 4.8 in. (122 mm). In contrast, if the water is heated to 176°F (80°C) the specific gravity drops to 0.97, and therefore the float will only start to generate buoyancy force when the level has risen to 5 in. (127 mm) above the bottom of the float.

One can approximate the depth to which the float has to be submerged before it starts to generate a buoyant force as

$$\text{Zero buoyant force level} = (D)(\text{SG}_f/\text{SG}_p) \qquad \textbf{7.6(5)}$$

where:
D = float diameter

Stuffing Boxes

Displacer and float-type level transmitters and controllers are described in the *Process Measurement* volume of this handbook. Sections 3.7 and 3.8 in that volume cover units that are isolated from the process vessels by means of frictionless seals. The seals on the float-type level control valves are not frictionless. The rotation caused by float motion is transmitted through a stuffing box to the mechanical levers that operate the valve.

The stem friction in the stuffing box is reduced by the use of a lubricated fitting, which can be refilled while the unit is in service. The design of the fitting is such that it lubricates the total region of metal-to-metal contact. Ball bearings are normally provided in these stuffing boxes to absorb radial and thrust loads, and thereby reduce stem friction. When repacking is needed, it can be done by breaking the packing gland union on the stuffing box and by replacing the package without removing the unit from the vessel.

With operating temperatures below 30°F (–1.1°C) or above 450°F (232°C), radiation fins are provided between the vessel and the packing box to cool the assembly by the air at ambient temperature.

Installation

The installation of float control valves on open vessels is shown in Figure 7.6a, and the regulator can be as simple as the float valve shown in Figure 7.6d.

When the vessel is pressurized, one option is to use a flange-mounted unit, where the float is inserted into the vessel through a nozzle (Figure 7.6e). In this configuration, the vessel has to be drained before the float regulator assembly can be removed for repairs or maintenance.

In this configuration, the stuffing box is perpendicular to the float arm. The proper balance of linkage, turnbuckle, float, and inner valve weights is achieved by adjusting the counterweights. The connecting rod between the float assembly and the valve should be of minimum length and needs to be carefully aligned to avoid binding during float travel.

In Figure 7.6f, the stuffing box is screwed directly into the flat vessel wall. The float has to be installed from the inside, and the vessel must be drained for servicing.

The external cage can also be utilized, as shown in Figure 7.6g. Here the float level regulator chamber is provided with isolation valves so that the instrument can be

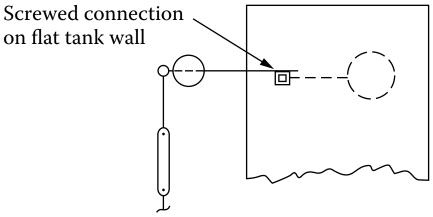

FIG. 7.6f
Direct mounting of float into coupling on tank wall.

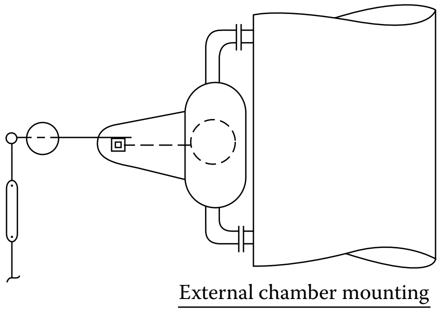

FIG. 7.6g
The mounting of a float level regulator on a pressurized tank in an external chamber.

removed from the tank and serviced without disruption of the process.

The maximum recommended length for the connecting rod with the turnbuckle is about 8 ft (2.4 m). If the vertical distance between float assembly and valve is greater than that, a mechanical lever system cannot be used and the use of a regular level control loop has to be installed.

The float assembly with rotating stem stuffing box can also be provided with a pneumatic pilot. Its main advantage is the increase in the available power to operate the valve and the ease of sensitivity adjustment. As shown in Figure 7.6h, these pilot-operated valves can be very large, up to 48 in. (1.22 m). Such a valve weighs 21,000 lb.

The float-type level switches and transmitters are discussed in Section 3.8 of the first volume of this handbook. They are available in electric or pneumatic designs Their sensitivity adjustment is simpler than of the mechanical unit, because the power required to operate the valve need not be furnished by the float. The float assembly can also be used for level alarming. In that design, a switch is actuated by the rotating stem instead of by mechanical levers.

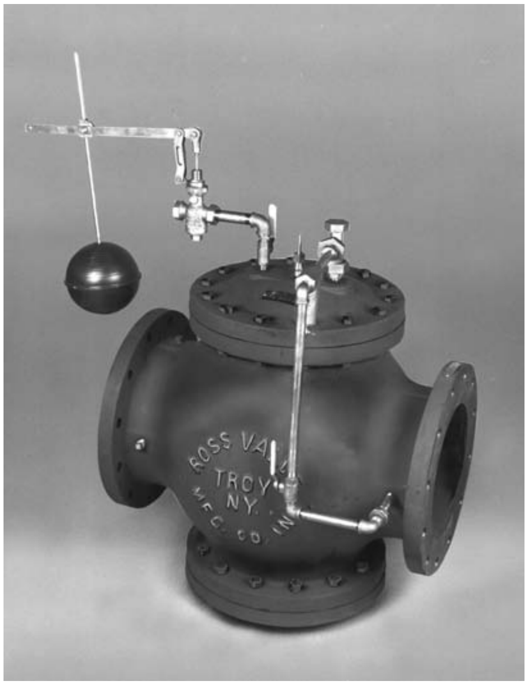

FIG. 7.6h
Pilot-operated regulator valves are not limited by the buoyant force of the float and can be very large. (Courtesy of Ross Valve Mfg. Co.)

Conclusions

Float-type level regulators can be used where the quality of control is not critical and the narrow span, offset, dead band, and hysteresis that are inherent in such regulators can be tolerated. Because of the large number of moving parts, pivots, levers, and the stuffing box, the device requires regular maintenance and should be used only on clean fluids where material build-up will not interfere with the operation of the moving parts.

The use of these level controllers is limited because they are blind, are not frictionless, and the physical relationship between valve and float is restricted. The economy of this design must also be balanced against the limitations of float power and the limitations in the available materials of construction. The industrial applications of float-type level controllers are therefore quite limited. On the other hand, they are still used on open water tanks, such as cooling tower basins, where the lack of readily available or economical external power sources does not limit the use of this design.

DIVERTER VALVES

This solid-state level regulator has no moving parts and utilizes fluidics principles. This valve works uses the Coanda effect, namely that a fluid stream will attach itself to the nearest side wall. Figure 7.6i illustrates such an on/off level control valve, where one wall of the diverter is closer to the incoming fluid stream than the opposite sidewall. On the closer side wall, a level sensing dip pipe is connected to the control port of the diverter.

When the level in the vessel is below the dip tube opening, air from the atmosphere enters the dip tube. The air is entrained into the control port, causing the inlet jet to detach

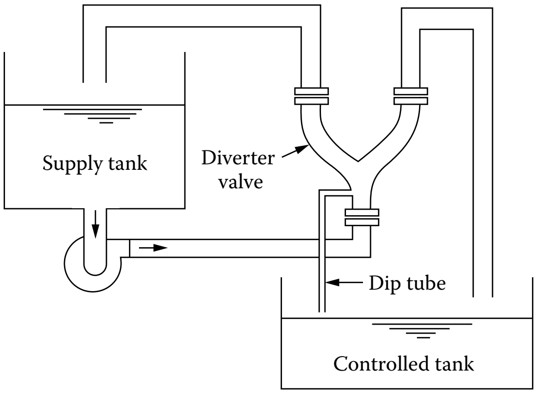

FIG. 7.6i
On/off level control using a solid-state diverter valve.

itself from the adjacent side wall and to attach itself to the opposite side wall, thereby diverting the full flow to the controlled vessel. As the level in the controlled vessel rises, it will eventually cover the end of the dip tube, thereby cutting off the air flow to the control port. As soon as this occurs, the flow stream will attach itself to the "favored" side wall and will divert the full flow back to the supply tank for recirculation. Having no moving parts, the on/off cycling of the valve has no harmful effects.

It is the shape of the flow passage that makes the valve function. With no plugs or packing, as in conventional valves, the unit is essentially maintenance-free. The valve is not affected by vibration or temperature (operating or ambient) and requires no external power source for operation. The flow stream is diverted in one tenth of a second, and the valve can be manufactured out of metal, plastic, or ceramic material. The design is streamlined without shoulders or pockets and so is recommended for use not only on clean liquids, but also on fluidized solids and slurries. It should be noted, however, that for proper operation the dip tube and the control port must be open; any material build-up in them will interfere with the functioning of the device.

When the solid-state diverter valve is considered for control application, the effect of back-pressure must be carefully considered. Outlet pressures other than atmospheric should be evaluated as to their effect on tight shut-off and on the safe-failure position.

The solid-state diverter valves can also be used for throttling instead of on/off control. In such a design, there are two ports for each leg of the valve, and the quantity of air entering the ports determines the ratio between the streams leaving through the two legs. For throttling control, the back-pressure in the controlled leg cannot be more than half of the inlet pressure to the valve in order not to spill into the unused leg.

The solid-state diverter valve is a reliable on/off control device for atmospheric vessels containing hot or cold, corrosive or noncorrosive clean liquids. Its application in pressurized vessels or with hard-to-handle process fluids is not recommended.

ALTITUDE VALVES

Altitude valves are installed in supply lines to elevated basins, tanks, or reservoirs for the purpose of holding the reservoir level constant and to prevent overflow. No external energy source is required because the power for operation is gained from the pressure of the process fluid.

One of the simplest versions of this design is shown in Figure 7.6j. The purpose of this valve is to admit water into the elevated tank until a preset level is reached and to close at that point to prevent overflow. The hydraulic head in the elevated tank is balanced by the setting spring of the pilot. When the tank water level exceeds the setting of the spring, the pilot diaphragm is moved down, closing the drain port and opening the main line pressure to apply its force to the top piston. Because the top area of the piston is greater than the bottom, the main valve closes.

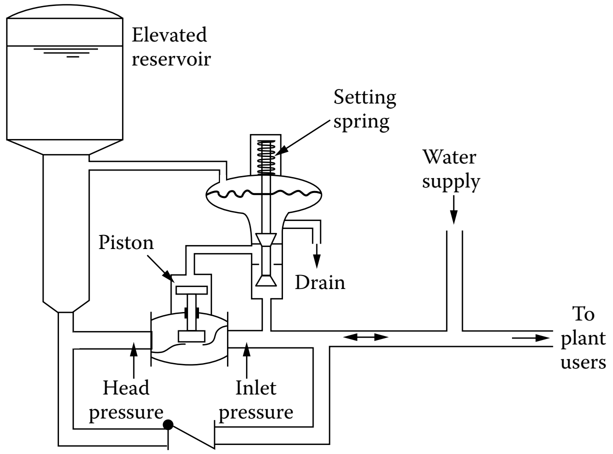

FIG. 7.6j
Typical altitude valve installation. When the reservoir level is high, the pilot opens the water supply to the top of the piston in the main valve, which closes the water supply to the reservoir.

If the head in the tank decreases, the setting spring moves the diaphragm up, closing the main line pressure connection and opening the drain port on the pilot. This results in removing the pressure from the large end of the piston, thereby opening the main valve to supply additional water to the head tank.

Where this type of altitude valve is used, discharge from the tank is handled by a swing check valve in a bypass line around the altitude valve or by a separate line from the tank to the plant. With the check valve as shown in the figure, water will flow from the head tank to the plant whenever the demand for water used exceeds the supply available. When the plant demand falls back below the capacity of the supply, the check valve closes and the water is made up in the tank under the control of the altitude valve.

Altitude valves are multipurpose devices, and with the addition of pilots, they can satisfy a number of requirements, in addition to the simple on/off level control described above.

All altitude valves close on high tank level to prevent overflow, but they can have other features as well:

1. The valve can have a delayed opening so that it opens only when the tank level has dropped below the control point by a set amount.
2. Instead of on/off action, the valve can be closed gradually to eliminate pressure shock (water hammer).
3. Instead of opening on low level, the valve can stay closed until the water supply pressure drops below the head pressure of the tank. With this unit, there is no need for the check valve in the bypass as shown in Figure 7.6j, because the valve is designed for two-way flow, allowing the water to return from the tank when the distribution or supply pressure drops below that of the tank head.

4. The valve can be modified to delay its opening until the supply or distribution pressure has dropped to an adjustable preset point.
5. By using another combination of pilots, the valve will open on low level, but only to the extent needed to maintain constant inlet pressure to the valve (which is the distribution pressure to the plant).
6. The unit can be provided with an additional check valve feature. In this arrangement, the valve operates as described, except that it closes if the distribution pressure drops to a predetermined low point due to line breakage or other reasons.
7. When used on aerator basins with high supply pressures, the altitude valve can also act as a pressure reducer. In this case, the valve will open on low level only to the extent needed to provide a permissible outlet pressure for the aerator nozzles.

As far as accessories are concerned, all altitude valves can be provided with solenoid pilots to close the valve on a remote electrical signal. Limit switches can also be furnished to give remote indication of valve position (whether open or closed).

The use of altitude valves is recommended for locations where only hydraulic power is available to operate large water valves controlling the level in storage reservoirs. They are not applicable to level control in pressurized vessels. The materials of construction of these units restrict their applications to water service. Due to the substantial number of components and moving parts, they require periodic cleaning and maintenance. Protection against freezing of stationary sensing lines is also required. In line sizes greater than 12 in. (300 mm), there is some economic advantage to using butterfly valves with hydraulic pilots.

INTRODUCTION

The pressure regulator is a complete pressure control loop, incorporating a sensor, a controller, and a valve. It is called a regulator (and not a controller) because it is mechanical and self-contained, requiring no external energy source.

In this section, first a comparison is drawn between regulators and controllers. This is followed by a description of the operating characteristics of pressure regulators, giving particular emphasis to the subjects of droop, noise, and stability. Next, the specific designs and their variations will be described, including such specialized units as the safety shutoff regulators used in gasoline station applications.

REGULATORS VS. CONTROL VALVES

In many applications, pressure can be controlled by either a regulator or a full control loop. In making the choice, the design engineer should consider their relative merits, which are listed in Table 7.7a.

Particularly in the smaller sizes, regulators usually cost less than a control loop consisting of a control valve, transmitter, and controller. Regulators are less expensive to buy, install, and maintain. But when the application requires a larger valve, the economics begin to change and, in sizes over 4–6 in. (100–150 mm), might favor of control valves.

Regulators have a built-in controller and do not require an air supply. This results in savings in both purchase and installation costs. As a consequence, regulators are not subject to air-supply failure. In applications where the fail-safe feature is essential or in locations that are remote from a source of compressed air, this is an important consideration. On the other hand, diaphragm failure in a regulator usually results in the opening of the valve, which can be unsafe.

Control Valves

Control valves are used with an external controller. The controller can be provided with one, two, or three control modes and can operate in either the automatic or the manual mode. Figure 7.7b illustrates a simple, proportional-only controller.

TABLE 7.7a
Comparison between Regulators and Control Valves

Regulators	*Control Valves*
Lower cost (in small sizes and ordinary materials of construction)	Higher cost
Smaller size	Larger and heavier
Lower installation cost	Higher installation cost due to size and weight
No air supply required	Requires air connections
Built-in controller	External controller
Limited materials of construction	Practically no limit on materials of construction
No remote control; set point adjustment is at regulator location	Local or remote control; remote/manual control possible
Single mode (proportional only) with associated droop	Varied control modes possible
Most fail open; relief valve is recommended	No limitation in fail-safe
Limited accessories	Wide variety of accessories
Limited interchangeability	Possibility of interchangeability among services
Fewer applications	More (and more complex) applications

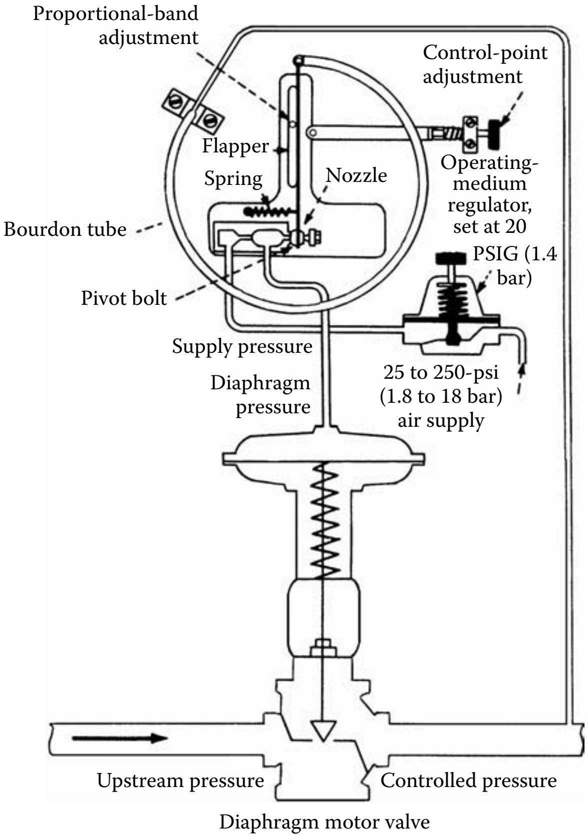

FIG. 7.7b
The main components of a proportional-only, pneumatic pressure control loop.

The valve itself can be made from castable metal, and it may be lined. Control valves can be provided with the failure position, which makes the operation of the process the safest. Valve accessories include positioners, limit switches, manual handwheels, and solenoids. These can be interchangeable with the accessories on valves in the plant, thereby reducing spare-parts requirements.

In a regulator, the set point is integral, and remote set point adjustment is usually not possible. All regulators are single mode (proportional only) and therefore they all have a set point droop, which results in an offset if the load (throughput) changes. The available regulator materials of construction are limited, as is interchangeability with other services. Accessories are not available.

In contrast with regulators, regular control loops are more expensive to purchase, install, and maintain. The control valves are less compact, require more space for installation, and require a source of compressed air for their operation.

REGULATOR APPLICATIONS

On steam-driven pumps, pump governors frequently regulate the suction or discharge pressures by modulating steam flow. On purging applications, differential-pressure regulators are

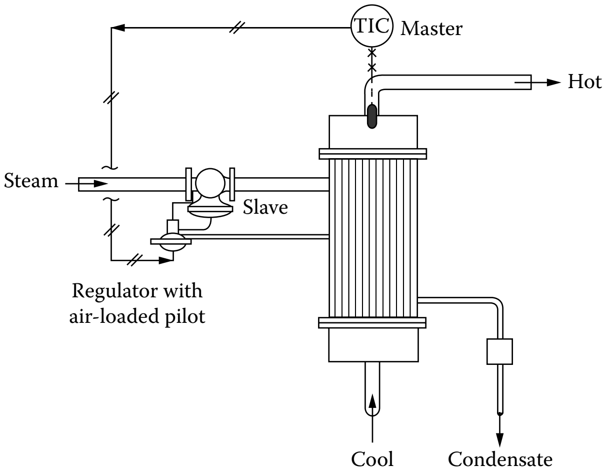

FIG. 7.7c
Because of its speed of response, a pressure regulator provides an ideal slave controller in a cascade loop.

used to keep the purging media at a pressure higher than that of the process. This same regulator is also used in air bubbler-type level measurement systems. A differential-pressure reducing valve can also be used to provide constant water flow for wet-bulb humidity detection.

Oil-burner back-pressure regulators are installed in the oil return line. Their settings are modified according to the steam pressure in the boiler. The regulator stem is discontinuous to permit both low- and high-fire pressure adjustments.

Pressure regulators have been successfully used as cascade slaves receiving their set points from temperature control masters. Figure 7.7c illustrates such an installation on a steam-heated water heater. The air-loaded pressure regulator is extremely fast and corrects for load changes or steam-supply pressure variations almost instantaneously. This is exactly the kind of performance that is required from a cascade slave.

In this arrangement, the work that the temperature controller (master) has to do is much reduced because its task is reduced to compensate for the nonlinearity of the heat transfer curve by adjusting the set pressure.

Gas Industry Applications

In addition to regulators available for general service, the gas utility industry uses an extensive family of regulators designed specifically for gas service. The types of regulators for these services are tabulated in Table 7.7d.

There are basically two types of pressure regulators: the flow type and the dead-end type (Figure 7.7e). The flow type can reduce the flow to zero, but cannot allow for flow reversal. This is acceptable for most applications except for the dead-ended air pressure control services. For them, if the outlet pressure is too high then the air has to be released to the atmosphere.

Pressure regulators perform well on gas control applications. Stable control is provided because the regulator response is usually much faster than that of the process, and the deviation from set point (droop or offset) can be kept small, because the gain is high (20 or more) and therefore the amount of offset is low. These performance characteristics will be discussed in more detail later.

TABLE 7.7d
Regulators Used in the Gas Industry

Application Pressures	*Inlet Pressures*	*Outlet*
Appliance	8 in. H_2O (2 kPa)	3–4 in. H_2O (0.75–1 kPa)
Household	2–100 PSIG (13.8–690 kPa)	5–8 in. H_2O (1.25–2 kPa)
Community of users, 60 PSIG (414 kPa)	Up to 200 PSIG (1380 kPa)	3 in. H_2O to 60 PSIG (0.75–414 kPa)
Transmission line take-off, PSIG in two stages	Up to 1200 PSIG (8.28 MPa)	100–1000 PSIG (690 kPa–6.9 MPa)
Transmission line take-off to individual user	Up to 1500 PSIG (10.35 MPa)	3–600 PSIG (20.7–4140 kPa)

A frequent problem in the gas industry is the need to accurately regulate to very low pressure levels while using a relatively high supply pressure. Shutting off against such pressure requires a relatively large force. Because the regulated pressure is low, it must be amplified by using both large diaphragm areas and mechanical amplification.

Liquid Pressure Regulation

The use of pressure regulators on liquid pressure control applications is not as likely to provide good control. This is because on noisy (very fast) liquid processes, the regulator is not likely to be fast enough to eliminate noise and, in fact, might amplify it. Generally it is better to control such processes with low gain (wide proportional) and long integral mode settings. Such settings are not available in regulators, as regulators are high gain, basic proportional controllers.

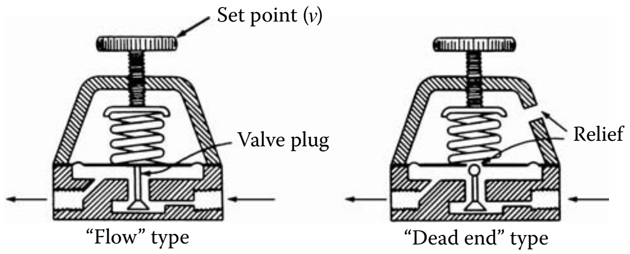

FIG. 7.7e
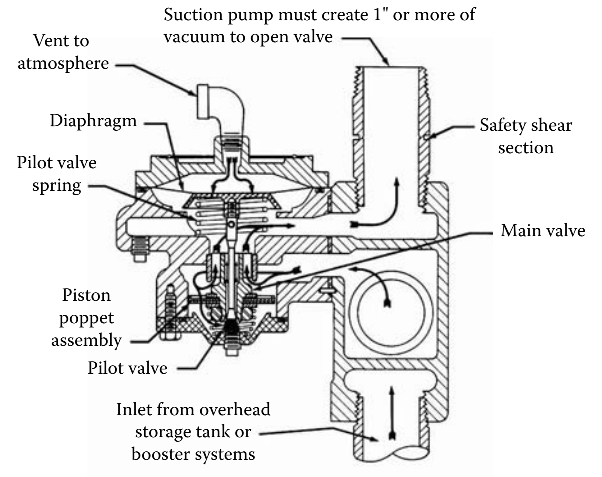
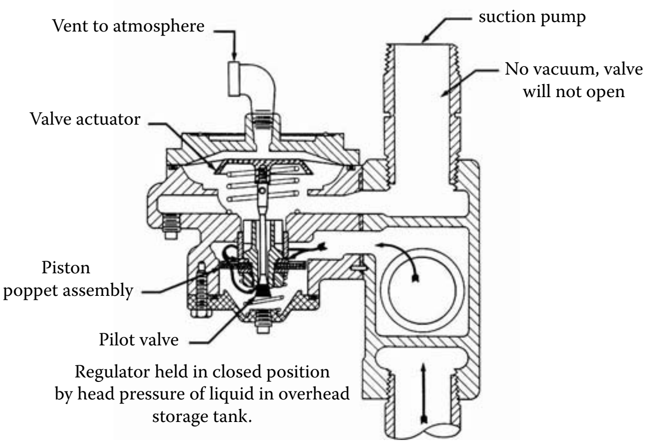
Pressure regulators can be either the flow type or the dead-end type. Dead-end units are used on air applications where the relief of excess pressure to the atmosphere is also needed.



Open position



Closed position

FIG. 7.7f

Safety regulators serve to protect gasoline dispensers at gas stations. The regulator is installed below the pump in the dispenser cabinet. It can open only if the gasoline pump is on, because the pump's suction generates a vacuum. If the safety shear section is broken, the vacuum is lost and the regulator shuts off, preventing a spill. (Courtesy of Tokheim Corp.)

Another reason why the use of regulators is usually not a good choice for liquid pressure control is that regulators do not provide tight shut-off. Therefore overpressuring of the system due to leakage can occur when the supply regulator is not fully closed, while there is no demand for the controlled fluid.

Gas Station Safety Regulators

A variety of pressure regulators have been designed to meet specific safety concerns in different operations. One such concern is the spilling of gasoline at gas stations if a truck accidentally backs into a dispenser unit and thereby breaks the gas pipe. The safety regulator shown in Figure 7.7f has been designed to protect against such an occurrence. The regulator is installed in the ground, below the gas dispenser unit, on the suction side of the gas pump.

When the gas pump is off, the regulator is closed. When the gas pump starts, its suction pulls a vacuum below the diaphragm of the regulator and opens it. If at any time the safety shear section of the outlet of the regulator (suction of the gas pump) is damaged, the vacuum is lost and the atmospheric pressure closes the regulator. When the gasoline is supplied from overhead tanks, the blocked-in gasoline contained in the piping between the shut-off valve at the tank and the regulator can be exposed to thermal expansion. In order to protect from mechanical damage, thermal expansion relief valves must be installed.

Pressure Surge Relief Valves

The pressure surge relief valve assembly shown in Figure 7.7g is designed to open and regulate flow and velocity in crude oil pipeline applications when the upstream pipeline pressure reaches a specified set point. The pressure surge relief control consists of a main valve body assembly for relieving flow, a hydraulic cylinder for actuator thrust, and a control manifold assembly to control modulation of the main valve in relation to the surge pressure level above the set point. The main valve trim limits the flow velocity through the valve that should yield smooth and quiet operation. The pipeline fluid and its pressure level are used to control the surge relief function.

The control element is a three-way pilot-operated hydraulic valve that senses the upstream pressure. The three-way valve directs fluid pressure to either the top or bottom of the hydraulic actuator to modulate the main valve movement. A spring assembly above the hydraulic actuator, which provides main valve seating load when closed, can ensure a Class VI leakage requirement. The spring is sized to also permit the main valve to open when pressure of the pipeline exceeds the set point. If the pipeline pressure is less than the relief pressure, the three-way valve blocks the pipeline fluid.

When the set point pressure is exceeded, the three-way valve vents the top of the hydraulic actuator and pressurizes the bottom to open the main valve. The fluid from the top of the hydraulic actuator is vented to the main valve bonnet, which is open to the downstream pressure via a balanced plug. The valve characteristics are nearly linear; the flow through the valve is nearly in linear proportion to the valve stroke (Figure 7.7h). The capacity of the three-way valve is such that the main valve will fully open in about 4 sec. The speed of closing can be adjusted by changing the flow rate into the top of the hydraulic cylinder.

PRESSURE REGULATOR DESIGNS

The self-contained pressure regulator is simple, dependable, rugged, and inexpensive. Energy from the flowing fluid operates it. The pressure acts on the diaphragm, which moves the

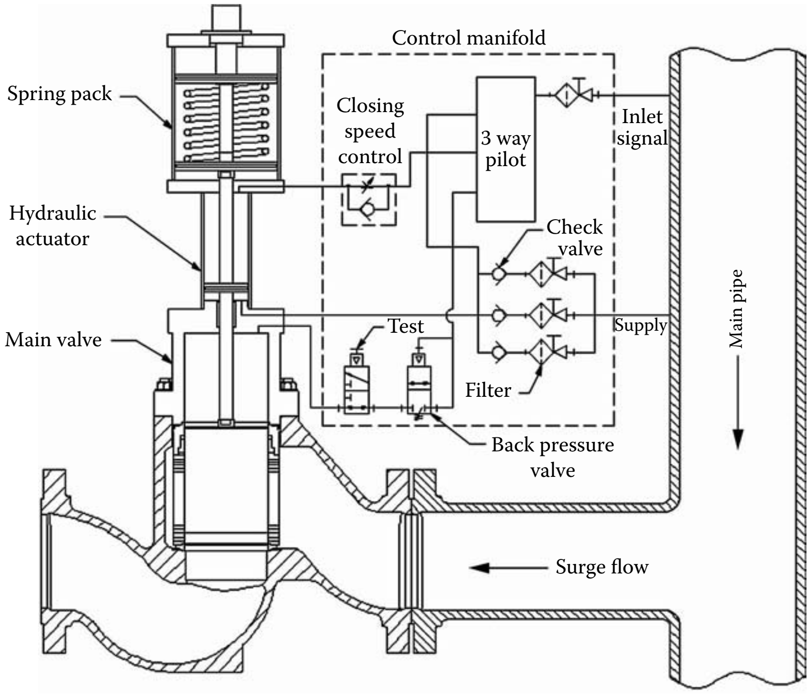


FIG. 7.7g
Schematic for a modulating crude oil pipeline application of a surge pressure relief valve (Courtesy of Control Components.)

valve plug (by compressing the spring). The initial spring compression sets the pressure at which the valve begins to open. For each pressure on the diaphragm, there is a corresponding seat position, or valve opening.

Figure 7.7i shows that the diaphragm is the "brain" of the regulator. It compares the set point that is converted into a spring force to the regulated pressure that is converted into a force by the diaphragm itself. It adjusts the valve opening to reduce the error between the two. The diaphragm comprises a feedback device, an error-detecting mechanism, and an actuator. Figure 7.7i shows a spring-loaded pressure-reducing valve. In other regulator designs, pressure regulators can also be loaded by weights or by gas pressure.

Regulators are also available to control back-pressure, differential pressure, or vacuum and can control the pressure of gases, vapors, and liquids. The self-contained regulator has no adjustments in terms of capacity (i.e., reduced valve trim) or in terms of tuning (proportional band and reset adjustments). It has a fixed proportional band of about 5%, or a gain of about 20. There are many different regulator types and designs available. Descriptions of the most common designs will be given later.

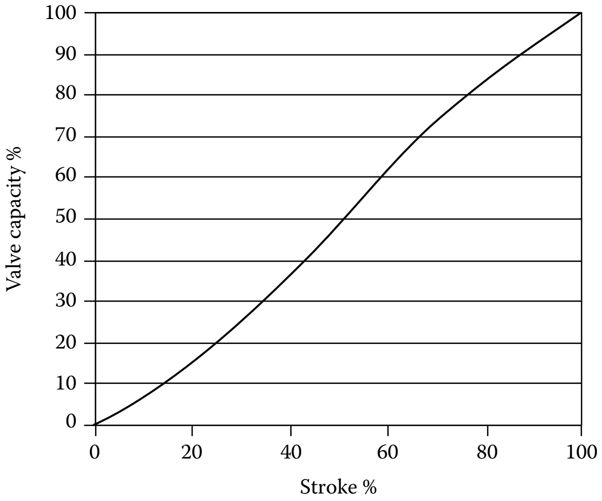

FIG. 7.7h

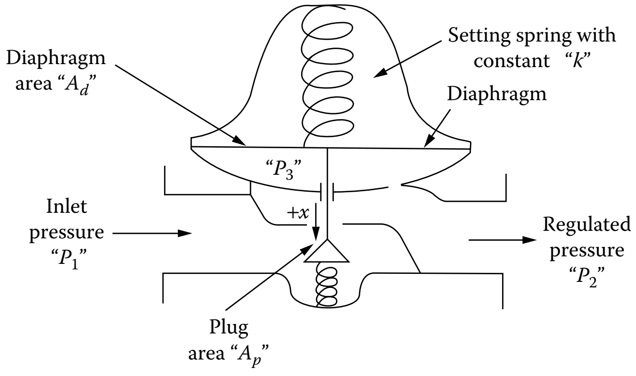

FIG. 7.7i
The basic components and operation of a spring-loaded pressure-reducing valve.

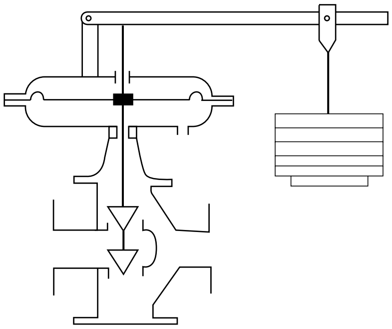

FIG. 7.7j
Weight-loaded pressure regulator with the external pressure tap below the diaphragm.

Weight-Loaded Regulators

The force in a spring changes as the spring is compressed. In a weight-loaded regulator, however, a weight provides a constant actuating force on the diaphragm, thus minimizing droop. Set-point changes are accomplished by adding weight or by changing the weight position (Figure 7.7j). Weight-actuated regulators are used to regulate gas pressures at 1 PSIG (6.9 kPa) or below when load changes are slow. It is not recommended for service where mechanical shock or vibration are present or for regulation of incompressible fluids.

Spring-Loaded Regulators

Spring-actuated regulators are used more than any other type because of their economy and simplicity. They also have an extremely fast dynamic response. Disadvantages include high droop, awkward set-point adjustment, and sensitivity to shock and vibration.

The "air regulator" is a common type of spring-loaded regulator. It is a 1/4 in. (6.25 mm) air pressure regulator used to reduce instrument air pressure to a level compatible with pneumatic instruments. The term "air set" is also applied to these regulators. Bleed-type regulators have the ability to relieve excess regulated pressure (Figure 7.7e). This design is recommended for dead-end (no flow) service. Various manufacturers supply air regulators having capacities from 10–60 SCFM (280–1680 lpm). These regulators are usually provided with an integral filter, hence the name "filter regulator."

Figure 7.7k shows one design of a spring-actuated regulator. The valve is normally closed. Turning the set-screw compresses the spring and opens the valve. Increasing downstream pressure acts beneath the diaphragm, thus raising it and closing the valve. Spring compression is adjusted to provide the desired downstream pressure at the demand flow.

When vacuum is to be regulated, the spring force is applied in the opposite direction than in case of the regulation of positive pressures. Figure 7.7l shows a spring-actuated vacuum pressure regulator.

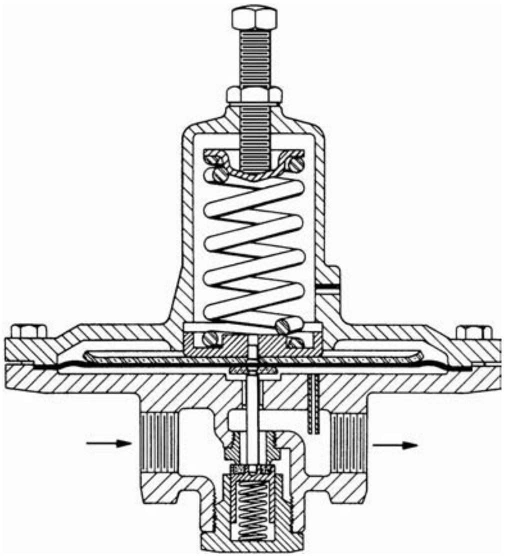

FIG. 7.7k
Spring-loaded pressure regulator.

Figure 7.7m illustrates a differential-pressure regulator that can be used to maintain a certain pressure difference between two streams.

Pilot-Operated Regulators

The pilot-loaded regulator is a two-stage device. The first stage contains a spring-actuated pilot regulator that controls pressure on the diaphragm of the main regulating valve. The second stage contains a spring-actuated regulator that controls the main valve stem. One advantage is that the actuating fluid operating the first-stage (pilot) regulator is at the upstream pressure. This provides a higher level of force to

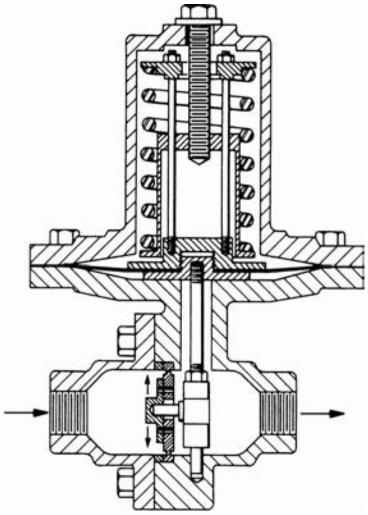

FIG. 7.7l
Spring-loaded vacuum regulator. (Courtesy of Jordan Valve.)

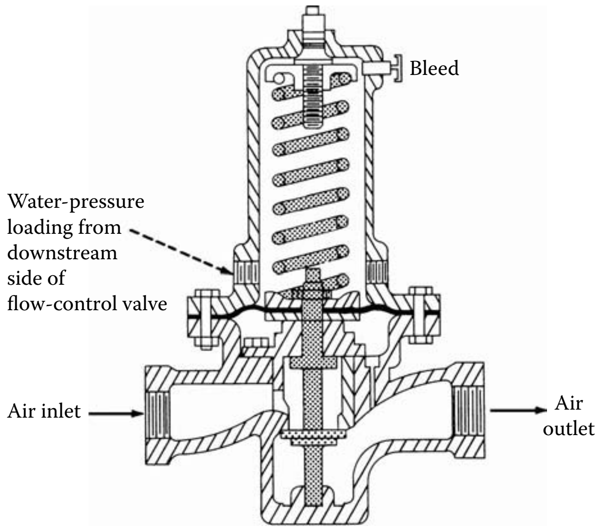

FIG. 7.7m
This differential-pressure regulator maintains a fixed pressure difference between a water pressure reference and the air pressure at its outlet.

the actuating mechanism. Travel is very short and that reduces droop. More accurate regulation is possible with this design.

Figure 7.7n shows that the pilot regulator can be external or internal. It controls pressure to a diaphragm operating the main valve. In some designs a piston can be used in place of the diaphragm. Pilot-operated regulators use the difference between upstream and downstream pressures for actuation. Therefore, a minimum differential is required for proper operation.

Pilot-operated regulators provide accurate regulation for a wide range of pressures and capacities. They are more expensive than spring-loaded regulators but also provide more capacity. Because the small passages and ports can become plugged, these regulators can only be used with clean fluids. Their dynamic response is slower than with the spring-loaded designs.

Externally piloted regulators are available in a wide range of sizes. One advantage of this design is that the pilot regulator can be mounted at a distance from the main valve, thereby keeping the control pilot in an accessible location away from possible pipeline shock and vibration. Such location of the remote pilot also simplifies its maintenance.

Figure 7.7o illustrates an internally piloted regulator operated by a remote set-point air signal. This design offers the convenience of remote set-point adjustment at distances up to 500 ft (150 m), but the requirement for compressed air makes it more expensive to operate than the use of spring-loaded regulators.

Table 7.7p provides some data that can help the design engineer in deciding when to use spring-loaded and when to select pilot-loaded regulators for a particular application.

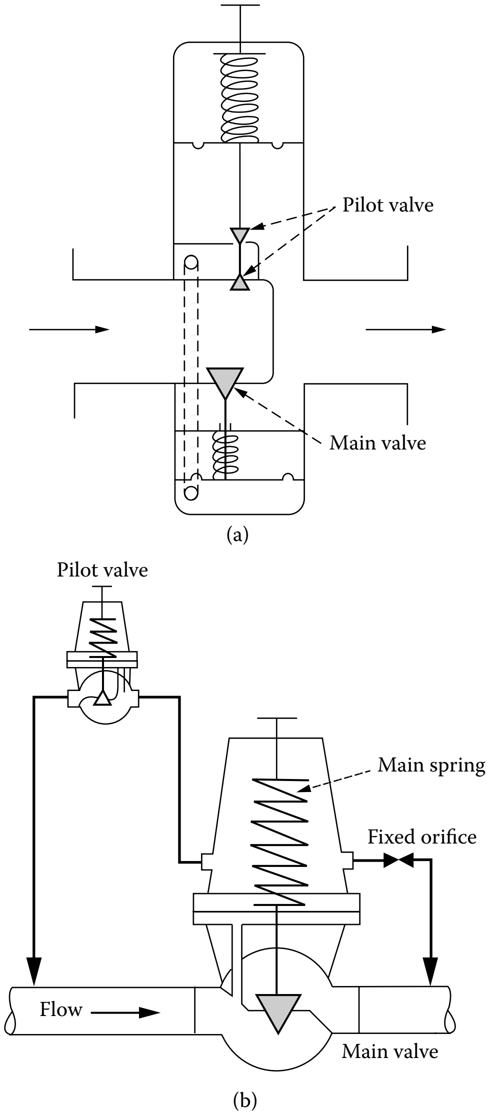

FIG. 7.7n
Pilot-operated regulators can be provided with integral or external pilots.

REGULATOR CHARACTERISTICS AND SIZING

Seating and Sensitivity

As shown in Figure 7.7i, the balance of forces on the valve stem is

$$kx = A_p(p_1 - p_2) - A_d p_3 \qquad \mathbf{7.7(1)}$$

where

k = spring constant (lb$_f$/in. or N/m)
x = valve stem movement (in. or mm)
A_p = port area (in.^{2} or mm^2)

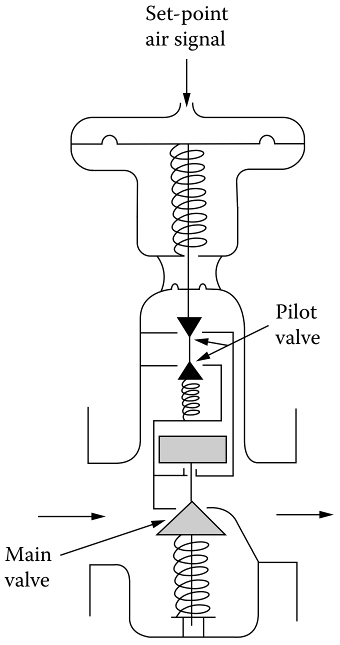

FIG. 7.7o
Remote set point provided by pneumatic loading of an internally piloted regulator valve.

p_1 = inlet pressure (PSIG or Pa)
p_2 = outlet pressure or regulated pressure (PSIG or Pa)
p_3 = diaphragm back-pressure (PSIG or Pa)
A_d = diaphragm area (in.^{2} or mm^2)

Inserting into Equation 7.7(1) the typical values of a typical regulator application will likely result in a relatively large product of $A_p(p_1 - p_2)$ as compared to $A_d p_3$. In other words, the actuating force is comparatively low, and a balanced plug is desirable because it eliminates the term $A_p(p_1 - p_2)$.

TABLE 7.7p
Regulator Selection for Various Service Conditions

Recommended Regulator Type	*Magnitude of Pressure Reduction*	*Supply Pressure Variations*	*Load Variations*
Spring-loaded	Moderate	Small	Moderate
Spring-loaded	Moderate	Large	Moderate
Pilot-operated	Moderate	Large	Large
Pilot-operated	Large (in one stage)	Moderate	Large
Pilot-operated first stage	Large (in two stages)	Large	Large (in first stage)
Spring-loaded or pilot-operated	Large (in two stages)	Large	Moderate (in second stage)

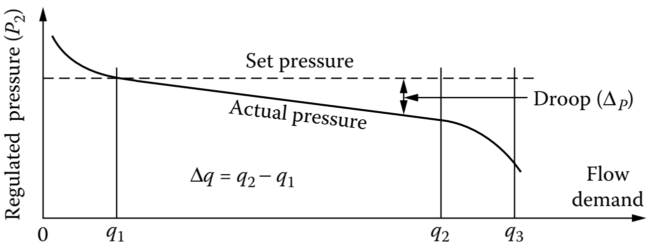

FIG. 7.7q
The actual value of the regulated pressure equals the set pressure only at minimum flow (q_1), and once the flow rises above it, the actual controlled pressure drops. This "droop" or offset is permanent and increases with flow.

Figure 7.7j shows an essentially balanced, double-seated plug valve design, which is limited to continuous service because it cannot provide tight shut-off.

Figure 7.7k shows a sliding gate mechanism that is also balanced, but this design is not suited for applications with high pressure drops. Analysis of the regulator as a feedback mechanism shows that the balanced plug reduces sensitivity to variations in supply pressure.

Intermittent service requiring tight shut-off necessitates using a single-seated valve. Balancing pistons, diaphragms, and ingenious seating configurations can be used to provide a balanced plug in a single-seated design, but these devices are more complex and costly. In valves with port diameters of 1 in. (25 mm) or less, the ratio of diaphragm area to port area can be made large enough so that balancing is not required for moderate pressure drops.

Droop or Offset

The regulator is a complete, self-contained feedback control loop with proportional-only control action. Thus, the regulated pressure will be offset by changes in the load disturbance variables (flow demand, in the case of a pressure-reducing valve). The offset in regulated pressure with changing flow is called droop. It can be expressed as follows:

$$\Delta p = \frac{(kx/q)(p_1^2 - p_2^2)}{kxp_2 + A_d(p_1^2 - p_2^2)} \Delta q \qquad \textbf{7.7(2)}$$

where

q = throughput and the other letters are as defined in connection with Equation 7.7(1).

Equation 7.7(2) shows that the droop or offset is a function of the operating pressures and of the regulator design parameters such as spring rate k, valve lift x, and diaphragm area A_d.

Size and economic considerations limit the length of the spring (for low spring rate) and also limit the diaphragm area. Low lift (x) is necessary to reduce diaphragm fatigue as well as minimize droop. Figure 7.7q illustrates the phenomenon of droop.

Equation 7.7(2) applies to the flow range of q_1 to q_2 in Figure 7.7q. This is the operating span of the regulator. While ideally linear, the operating span takes on many shapes in practice because of valve plug flow characteristics and varying effective diaphragm areas. The valve is fully open at q_2 and acts as a fixed orifice restriction from q_2 to q_3. The span from 0 to q_1 is dominated by flow-generated pressure forces on the plug, and q_1 is considered to be the minimum controllable flow rate. The minimum flow rate is a function of plug design and is typically 5–10% of maximum capacity q_2.

Therefore, a pressure regulator cannot control pressure at a set value. All it can do is travel on its operating curve (shown in Figure 7.7q) and provide a pressure that this curve dictates as a function of flow. In order to provide tight shutoff, extra force is needed and therefore the pressure difference on the diaphragm must rise. Consequently, at near-zero flow the regulated pressure will rise.

What the manufacturers call the "set point" of the regulator is in fact is the pressure at minimum flow (q_1). To call this value the set point is not correct, because this "set point" varies with flow (Figure 7.7q). A more accurate designation would be to call this point the "zero droop" (zero offset) point or to call it the upper end of the pressure throttling range, because as the flow increases the actual controlled pressure drops.

From Figure 7.7q, the reader should conclude that the maximum regulator capacity is not at full valve opening (q_2), but at the minimum pressure, which the process can tolerate as the droop increases with flow. Reliable data on droop vs. flow is therefore essential to check if regulator performance will be satisfactory.

Minimizing Droop Regulator designs that minimize droop are available. Many of them place the feedback sensing line at a point of high velocity, either in the throat of a slight restriction or in the middle of the flowing fluid (Figure 7.7k). The latter design uses the aspirating effect.

Droop compensation can also be provided by a moving valve seat, which is called a pressure-compensating orifice, that moves with upstream pressure. The roll-out diaphragm that reduces its effective area with spring compression also acts to reduce droop. These devices allow the specification of the droop curve for limited flow spans.

Noise

High velocities of compressible fluids are primarily responsible for noisy regulator installations, a continuing source of complaint. Aerodynamic noise caused by high-velocity gas flow in the valve body has been identified as the principal source of irritating "screaming." The volume of the gas increases in proportion to the ratio of inlet to outlet pressure. Gas velocity increases in proportion to the volume increase if the cross-sectional area of the regulator outlet port does not also increase.

Increased velocity raises the pressure drop until sonic velocity is reached. A tapered pipe expander downstream from the valve will increase the sonic velocity (Mach 1) to supersonic velocities (Mach 2 to Mach 3). Velocities above sonic result in noise, because a major portion of the energy conversion takes place downstream of the valve plug. The static pressure build-up in the downstream piping can far exceed its pressure rating and can cause "choking" (reduced capacity) of the regulator due to the downstream static pressure.

Sonic velocity is known to occur when downstream pressure is less than 50% of upstream pressure. Because changes in flow path direction also contribute to noise, a maximum gas velocity of 200 ft/s (60 m/s) (below ground, 500 ft/s, or 150 m/s) has been recommended. Gas velocity in regulators is difficult to calculate because of interaction between velocity, pressure drop, and cross-sectional area. Many manufacturers provide tables of maximum capacities for quiet operation.

Calculating Velocity In order to avoid noise, the gas velocity should be kept under the sonic velocities at the regulator outlet. Because velocity is difficult to calculate (see Section 6.14), sonic velocity can be avoided by limiting pressure reduction to less than the critical ratio of 2:1.

Higher pressure ratios can be handled if several regulators are installed in series. Two to three stages are common to reduce noise and to improve regulation. In these installations a slightly less than critical reduction is made in the second of the two stages, or in the second and third of three stages, with the remainder of the reduction taking place across the first stage.

Eliminating changes in flow direction will also reduce noise. Therefore, it is recommended to use as much straight pipe as practical on both sides of the regulator. The use of mufflers can also be considered.

Water hammer can also cause noise in regulators on liquid service when the valve is opened or closed too quickly. When a valve closes quickly, a pressure wave is generated as the moving water column hits the closing plug. This pressure wave travels upstream at sonic speed and is reflected by the first solid surface with which it comes in contact. If, by the time this pressure wave returns, the valve is closed, vibration results.

Water hammer is eliminated by slowing valve closure or by reducing the distance (L) between the reflecting surface and the valve so that the valve closure time (t) is more than $2L$ divided by the speed of sound.

Cavitation

Cavitation is caused by localized vaporization as the pressure at the vena contracta drops below the vapor pressure of the flowing fluid. As the pressure recovers after the vena contracta, these vapor bubbles collapse and can cause vibration damage and valve-metal erosion.

The energy for the increase in flow velocity at the valve's vena contracta is obtained from the pressure (potential energy) of the flowing fluid, causing a localized pressure reduction. If this localized pressure falls below the vapor pressure of the fluid, it causes temporary vaporization.

Cavitation damage always occurs downstream of the vena contracta, where the pressure recovery occurs in the valve. It is in this area where the vapor bubbles collapse. Destruction is due to the implosions that generate the extremely high-pressure shock waves in the substantially incompressible stream (Figure 6.1w). When these waves strike the solid metal surface of the valve or downstream piping, the damaged metal surface will give a cinder-like appearance. Cavitation is usually coupled with vibration and makes a sound like that of rock fragments or gravel flowing through the valve.

Cavitation can be eliminated by altering either the valve, the process, or the installation. The various anticavitation valve designs such as the labyrinth (Figure 6.1y) are usually not available for regulators. Therefore, cavitation in regulators must be eliminated by changing either the process or the installation.

Anticavitation Designs A slight reduction of operating temperature can usually be tolerated from a process point of view, and this might be sufficient to lower the vapor pressure sufficiently to eliminate cavitation. Similarly, increased upstream and downstream pressure, with ΔP unaffected, can also relieve cavitation. Valves subject to cavitation should be installed at the lowest possible elevation in the piping system. Moving the valve closer to the pump will also serve to increase both upstream and downstream pressures.

If cavitating conditions are unavoidable from the process condition's point of view, then it is actually preferable to have not only cavitation but also some permanent vaporization (flashing) through the valve. This can usually be guaranteed by a slight increase in operating temperature or by decreasing the outlet pressure. Flashing eliminates cavitation by eliminating pressure recovery.

Another way to eliminate cavitation is to install two or more regulators in series. Cavitation problems can also be alleviated by absorbing some of the pressure drop in breakdown orifices, chokes (Figure 6.1cc), or partially open block valves upstream of the pressure-reducing valve. The amount of cavitation damage is related to the sixth power of flow velocity or to the third power of pressure drop. This is the reason why reducing ΔP by a factor of two, for example, will result in an eightfold reduction in cavitation destruction.

In some high-pressure let-down stations, it might not be possible to eliminate cavitation accompanied by erosion or corrosion, or both. In such installations, one ought to consider the use of inexpensive choke fittings (shown in Figure 6.1cc) instead of control valves. The fixed chokes can be of different capacities and be isolated by full-bore on/off valves, providing a means of matching the process flow with the opening of the required number of chokes. If *n* chokes are installed, this will allow for operating at (2^n-1) flow rates. If, for example, the chokes discharge into the vapor space of a tank, this will minimize cavitation damage because the bubbles will not be collapsing near any metallic surfaces.

Sizing and Rangeability

Oversizing is the most common error in regulator selection. The droop characteristic makes a larger valve attractive, because a greater capacity is obtainable for the same droop. The larger valve also reduces noise because of its larger passages. These apparent advantages are offset by higher cost, severe seat wear, and poor regulation.

The limitation on sizing is rangeability. Rangeability varies from 4 to 1 for a steam regulator, which cannot be operated close to its seat because of wire drawing, to over 50 to 1 for an air regulator. Figure 7.7q illustrates rangeability (q_2/q_1). Minimum flow, q_1, is 5–10% of q_2, depending on the seat configuration.

Maximum flow is not necessarily q_2 but is determined by maximum acceptable droop. A typical rangeability is 10 to 1. An oversized regulator may not be able to control at the minimum flow because it falls outside its rangeability.

Regulators are sized on the basis of tabulated data or valve coefficients (C_v) provided by the manufacturer. Size is chosen to accommodate the maximum flow at minimum pressure drop. The valve should ideally operate at 50–60% open under normal conditions. Catalog information must be used judiciously, because capacity and droop may be specified at different points. Rated capacity might result in too high a velocity, or the (external) pressure feedback tap might have been located at a different point during testing than in the application.

Rangeability is increased by using two regulators in parallel. In such installations the pressure setpoint of one regulator is set 10% higher than the other, so one regulator will be wide open while the other modulates under high load conditions. As demand is reduced, the second regulator will close and the first will modulate. Leakage in the second regulator must be a minor portion of the capacity of the first regulator.

Stability

Stability of the regulator installation depends on the open loop gain. For the regulator shown in Figure 7.7i, open loop gain is defined as

$$K_o = \frac{A_d(p_1^2 - p_2^2)}{kxp_2} \qquad \textbf{7.7(3)}$$

where K_o is the open loop gain. Comparing this equation with the one given earlier for droop, it is apparent that any changes that might decrease droop would increase the open-loop gain and decrease stability, as expected in a feedback mechanism. Because the regulator has no controller mode adjustments, the maker must choose design parameters that will provide an adequate compromise between droop and stability. It can thus be expected that the open-loop gain of some applications will be too high, resulting in a noisy and cycling pressure regulator.

Guidelines for a stable installation are few. Difficulties are generally found after installation. Because the regulator has no adjustments it is costly to correct problems. The following steps can be considered in stabilizing an installed regulator: (1) Relocation of the pressure-sensing tap. (2) Redesign of the downstream piping to provide more volume. (3) Restricting the pressure feedback line, either by a needle valve in an external line or by filling an internal line and redrilling it to provide a smaller hole.

Safety

Diaphragm rupture is the most common failure in a regulator. Most regulators fail full open upon diaphragm failure, which is usually an unsafe condition. A relief valve on the regulated pressure side is recommended if it is unsafe to allow the increase in regulated pressure to the level of the supply pressure.

In installations where it is imperative that the user continue to be supplied even on a regulator failure, two regulators can be placed in series. In such installations, the second regulator should have a set point that is 10% higher than the first, so that it will remain wide open under normal circumstances. If the first regulator fails, the second will take over pressure regulation.

Installation

Regulator installation is generally easier than regulator selection. The following installation suggestions will help ensure satisfactory regulator performance:

1. Steam regulators should be preceded by a separator and a trap.
2. All regulators should be preceded by a filter or strainer.
3. A valve bypass is recommended where it is necessary to service the regulator while continuing to supply users.
4. Use straight lengths of pipe upstream and downstream to reduce noise.
5. External feedback lines should be 1/4 in. (6.25 mm) pipe or tubing.
6. Locate the pressure feedback tap at a point where it will not be affected by turbulence, line losses, or sudden changes in velocity. A distance of 10 ft (3 m) from the regulator is recommended.

ISA SPECIFICATION FORM (TABLE 7.7s)

Compiling the information necessary to specify a regulator is best done with the aid of a tabulation sheet. Many large companies have their own customized forms. A general-purpose form standardized by the Instrumentation, Systems and Automation Society, formerly the Instrument Society of America (ISA) is provided below with the instructions for completing ISA Form S20.51. The ISA SP20 Committee is currently updating all of the S20 Instrument Specification Forms.

Instructions for ISA Form S20.51

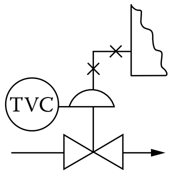
1–4. Identification and service/location. It is assumed that each tag number is for a single valve.
5. Pressure reducing, back-pressure control, or differential pressure regulator.
6. Globe, or Manufacturer's Standard (MFR. STD.).
7. Body connection size and inner valve size.
8. Guiding may be top, top and bottom, skirt, or MFR. STD. Select single or double port, if applicable.
9. Specify screwed (NPT), flanged, or weld end, and flange rating, such as 150 lb ANSI.
10–11. Specify materials.
12. Write in "yes" or use checkmark if required.
13. Quick open, equal percent, linear, etc.
State Characteristic:

L = Linear
LV = Linear V Port
EP = Equal Percentage
EPT = Equal Percentage Turned
EPB = Equal Percentage Balanced
Q = Quick Opening
Or use your own code and identify in notes.

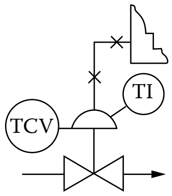
14. Refers to seal between body and top works, such as diaphragm, stuffing box, etc.
15. Refers to seat, plug, stem; in general, all internal wetted parts.
16. Use only to specify soft seat; otherwise material will be same as trim specified in line 14.
17. Use if required.
18. Max. allowable sound level dBA 3 ft from pipe and 3 ft downstream of the valve outlet.
19. Actuator may be spring type or springless pressure balanced.
20. The pilot is an integral or external auxiliary device that amplifies the force available through an operating medium, usually air.
21. Give pressure available and specify medium.
22. Refers to valve pressure sensing system. Specify whether controlled pressure is sensed internally or by means of an external line requiring an additional piping connection.
23–24. Specify diaphragm material and pressure or temperature limits, if applicable.
25. Range over which pressure setting can be made.
26. Specification of set pressure does not apply to factory setting. This must be called for specifically, if required.
27. Specify filter regulator, with or without gage, if required for air supply to pilot. Write "yes" or use checkmark.
28–29. Specify if strainer is to be furnished with valve. Write "yes" to check off, or give style or model number.
30–33. Options available in gas regulators. On line 30, specify "bug-proof" if required. Specify accessories on lines 32–33.
34. State liquid, steam, gas units (gpm, lb/hr, ft^3/min., etc.)
35. Name of fluid and state, whether vapor or liquid, if not apparent.
36. State maximum quantity required by process and corresponding C_v.
37. State operating quantity required by process and corresponding C_v.
38. The manufacturer shall fill in the valve C_v and F_L (liquid pressure) recovery factor without reducers or other accessories.
39. Operating inlet pressure and pressure differential with units (psia, PSIG, inches H_2O, or Hg). Note at this point that one might consider how minimum conditions will fit the sizing.
40. Maximum inlet pressure if different from normal.
41. State the maximum pressure drop in shut-off position to determine proper actuator size. This is actual difference in inlet and outlet pressure stated in psi, inches of H_2O or H_g, etc.
42. State °F or °C.
43. State operating specific gravity and molecular weight.
44. State operating viscosity and its units. State flash at valve outlet, i.e., of max. flow that will be flashed to vapor because of the valve pressure drop.
45. In the case of vapors, state the superheat, and in the cases of liquids, state the solids, if present.
46. Note vapor pressure of fluid as well as the critical pressure.
47. Give manufacturer's predicted sound level dBA.
48. Complete when available.

7.8 Regulators—Temperature

L. S. DYSART (1970, 1985) **B. G. LIPTÁK** (1995, 2005)



Blind temperature regulator



Temperature regulator with direct indicator

Flow sheet symbols

Size:	From 1/4 to 2 in. (6.25 to 50 mm) standard, special up to 6 in. (150 mm)
Features:	Two- or three-way designs with direct or reverse action, only proportional mode of control and the only adjustment capability being the changing of set point. Bulb pressure may exceed 1000 PSIG (6.9 MPa)
Ranges:	Overall: –25 to 480°F (–31.7 to 248.9°C) Individual: 1) 10 to 65°F (–12 to 18°C) 2) 40 to 100°F (4 to 38°C) 3) 70 to 145°F (21 to 63°C) 4) 110 to 170°F (43 to 77°C) 5) 130 to 190°F (54 to 88°C) 6) 170 to 240°F (77 to 116°C) 7) 220 to 275°F (104 to 135°C) 8) 270 to 340°F (132 to 171°C)
Spans:	Standard from 40 to 70°F (22.2 to 38.8°C); special up to 100°F (55.6°C)
Materials of Construction:	Body in iron, bronze, steel, or stainless steel; bulb in copper, steel, stainless steel, or coated with PVC, Teflon, and so on, tube in copper or stainless steel
Tubing Length:	Usually 10 ft (3 m) with 50 ft (15 m) being the maximum
Base Cost:	\$500 for standard unit in 1/2 in. (12.5 mm) size; \$1200 for standard unit in 2 in. (50 mm) size. For larger sizes and carbon or stainless steel materials, refer to the costs of globe valves given in Figure 6.19b in Chapter 6.

INTRODUCTION

Because they require no external power supplies (electricity, air, and so on), regulators are described as "self-actuated." They actually "borrow" thermal energy from the controlled medium to obtain the required forces. Temperature regulators are self-contained mechanical devices that provide fixed, narrow band proportional control action. They are referred to as temperature control valves (TCVs). Their operation is similar to that of a thermostat throttling a temperature control valve, except that the throttling control feature is part of their actuator.

This means that they are not capable of maintaining a set point, because in order to change the valve opening, first the measured temperature has to change. Therefore, all they can do is follow an operating line that relates the valve opening (load) to the controlled temperature (measurement). This phenomenon has been discussed in detail in connection with pressure regulators (Figure 7.7q) and thermostats (Figure 7.9c) and therefore will not be repeated here.

The difference between the temperature setting and the actual process temperature is called the "offset" of the regulator. Because of this offset, the resulting temperature control is not very accurate, and therefore these regulators are used only in such secondary applications as HVAC.

The temperature is detected by measuring the thermal expansion of the filling material in the bulb, which is inserted into the controlled process. Table 7.8a lists the thermal expansion coefficients of a variety of substances at 20°C (64°F). These values vary with temperature.

TABLE 7.8a
Thermal Expansion Coefficients of Different Substances (Values are given in cubic units, giving the incremental change of volume of a unit volume in response to a 1°C increase in temperature)

Substance	*Cubic Expansion* ($\times 10^{-4}$)	*Substance*	*Cubic Expansion* ($\times 10^{-4}$)
Acetone	14.9	Mercury	1.8
Air	36.7	Nickel	0.13
Aluminum	0.23	Nitrogen	36.7
Brass	0.19	Oxygen	36.7
Carbon dioxide	37.3	Platinum	0.089
Chloroform	12.8	Quartz	0.006
Copper	0.15	Steel	0.12
Ethyl alcohol	11.2	Tin	0.27
Ethyl ether	16.6	Toluene	11.2
Glass (regular)	0.085	Tungsten	0.035
Glass (Pyrex)	0.036	Turpentine	9.7
Glycerine	5.0	Water	2.1
Hydrogen	36.6	Xylene	11.3
Invar	0.009	Zinc	0.26

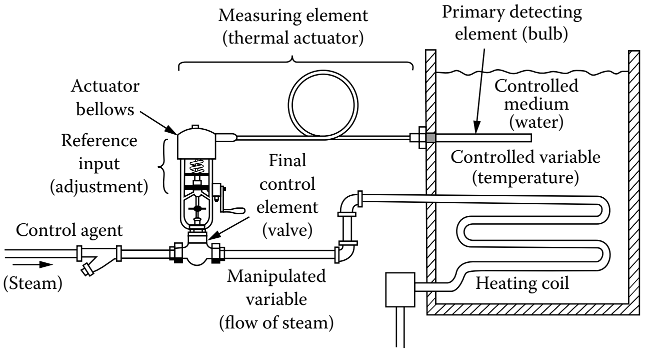

FIG. 7.8b
The main components of a self-actuated temperature regulator.

As shown in Figure 7.8b, the temperature regulator consists of three main components: 1) the temperature detecting element (bulb), 2) the measuring element (thermal actuator) and the reference input (adjustment), and 3) the final control element (valve). These three components will be discussed in that order.

Control Quality

Only the proportional mode is available in all temperature regulators. The proportional band is not adjustable in the field but is determined by various design factors, and it generally varies in direct proportion to the valve size and lift. For example, a typical 1 in. (25 mm) vapor pressure actuated regulator, using a double-seated valve, has a mid-range throttling range (full open to full closed) of 7°F (3.9°C), and a similar 2 in. (50 mm) regulator has a throttling range of 11°F (6.1°C).

The relationship between proportional band, gain, and throttling range is explained in Section 7.9, in connection with Figure 7.9c. Because thermostats and regulators do not have a set point but only an operating line, therefore the controlled temperature changes as the valve opens or closes. The maximum error—the maximum offset—is half the throttling range.

Response time of temperature regulators is much longer than that of pneumatic or electronic control loops. TCV time constants vary widely with design factors such as actuator bellows size (area), valve size (lift), transmission tube length, bulb size, and material (heat conductivity). The time constant of a typical regulator is likely to be in the range of 30–90 sec. Although the time constant can be reduced to under 10 sec, this can only be done under favorable conditions.

TYPES OF TEMPERATURE REGULATORS

Temperature regulators are usually depicted on a flowsheet by a TCV symbol, emphasizing the fact that most of these units are blind. A regular temperature control loop (depicted as TIC or TRC on the flowsheet) is superior not only because it indicates the measurement (which the TCV can also do, but providing indication is a special feature), but also because TICs are not limited to plain proportional control and therefore are capable of maintaining their set points without offset.

Two types of TCV regulators are available: direct-actuated and pilot-actuated. They are distinguished by the way in which the valve (the final control element) is actuated.

Direct- and Pilot-Actuated

In the direct-actuated type, the power unit (bellows, diaphragm, and so on) of the thermal actuator is directly connected to the valve plug and develops the force and travel necessary to fully open and close the valve (Figure 7.8c). Direct-actuated regulators are generally simpler, lower in cost, and more truly proportional in action (with somewhat better stability).

In the pilot-actuated design, the thermal actuator moves a pilot valve, internal or external (Figure 7.8d). This pilot controls the amount of pressure energy from the control agent (fluid through valve) to a piston or diaphragm, which in turn develops power and thrust to position the main valve plug. The pilot may be internal or external. When external, independently acting multiple pilots are also available.

Compared to direct-actuated TCVs, pilot-actuated regulators have smaller bulbs, faster response, and narrower proportional band, and they can handle higher pressures through the valve. Pilot-actuated regulators can also handle interrelated functions through use of multiple pilots, such as temperature plus pressure plus electric interlocks.

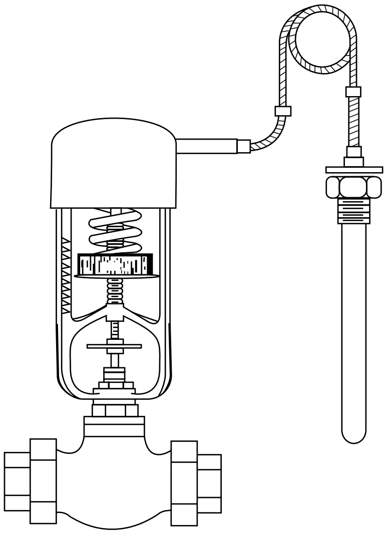

FIG. 7.8c
Direct-actuated temperature regulator.

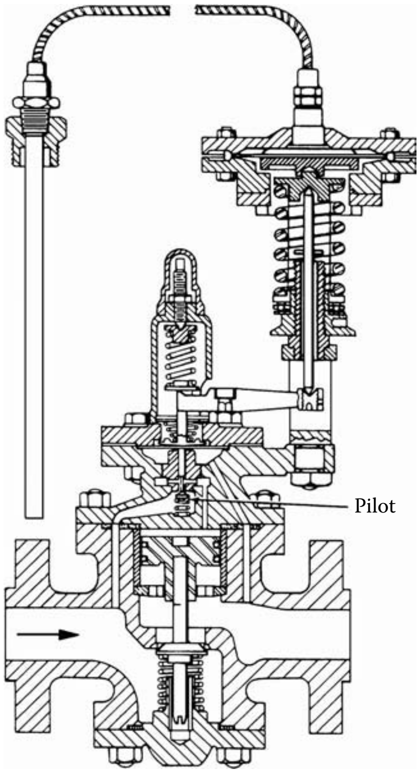

FIG. 7.8d
Pilot-actuated temperature regulator.

There are two styles of temperature regulators: self-contained and remote-sensing. Which one is appropriate depends on the location and structure of the measuring element (thermal actuator).

Remote or Internal Element

In remote-sensing regulators, the bulb (the primary detecting element) is separate from the power element (bellows and so on) of the thermal actuator and is usually connected to it by flexible capillary tubing (Figures 7.8b and 7.8c). This type of TCV measures and regulates the temperature of the process by throttling the heating or cooling medium (the control agent).

Self-contained regulators contain the entire thermal actuator within the valve body, and the actuator serves as the primary detecting element (Figure 7.8e). Thus, the self-contained style can sense only the temperature of the fluid that is flowing through the valve. That fluid is both the controlling agent and the controlled medium. The device regulates the temperature of the fluid by regulating the fluid's flow. Self-contained regulators are generally provided with liquid expansion or fusion-type thermal elements.

One common application for an internal sensor-type temperature regulator is illustrated in Figure 7.8f. Here the goal is to keep the tracing tubes full of steam while draining off only the condensate. The internal sensor-type TCV valve guarantees this, because if it is set at 200°F (93°C), it will open

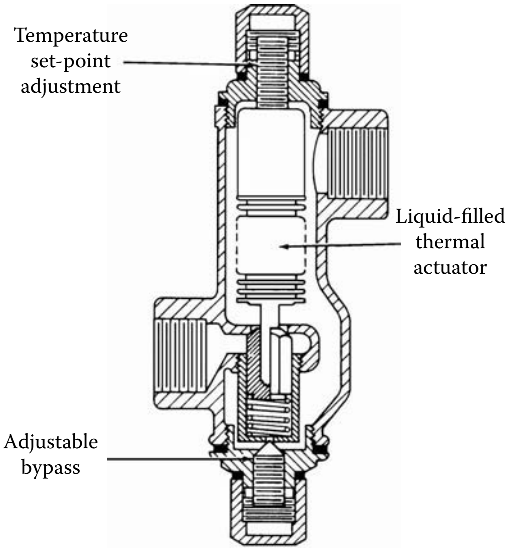

FIG. 7.8e
Internal element type self-contained temperature regulator.

only when it detects a lower temperature, thereby releasing condensate, and will close when the temperature rises above that setting, thereby preventing the release of steam.

The self-contained style is simpler, frequently lower in cost, and "packless" (has no stem sliding through the valve body "envelope"), but it is limited to such uses as regulating the temperature of coolant (water, and so on) that is leaving the engine, compressor, and exothermic process.

Accessories and Special Features

Temperature indication is available with most vapor pressure actuated regulators (Figure 7.8o). It usually consists of a pressure gauge sealed in the thermal system and calibrated to correspond to the particular range (charging liquid) used. Inaccuracy is about ±2% of indicated span.

Fail-safe design is available as a special version of the vapor pressure regulator. Here failure (loss of fill) of the thermal actuator produces downward movement of the valve stem; i.e., the valve goes to the "safe" position, producing shut-off of the heating medium or full flow of the cooling medium, depending on valve action. Adjustable ranges are short (approximately 30°F, or 16.7°C), and valve actuating force is rather low, because the actuator works on the subatmospheric portion of the nonlinear vapor pressure curve of the filling medium.

Manual handwheels are available in a few regulator versions (Figure 7.8o). These are useful to manually override the element, to provide a minimum valve position, or for emergency operation.

Combination temperature/pressure control is available in the pilot-actuated regulator. This is accomplished in two ways. In the external pilot version (Figure 7.8d), two separately adjusted pilot units are piped in series in the pilot pressure line. The temperature pilot modulates the flow of heating medium (control agent) to regulate the process temperature, while the pressure pilot limits the discharge pressure from the main valve to its setting under maximum load conditions.

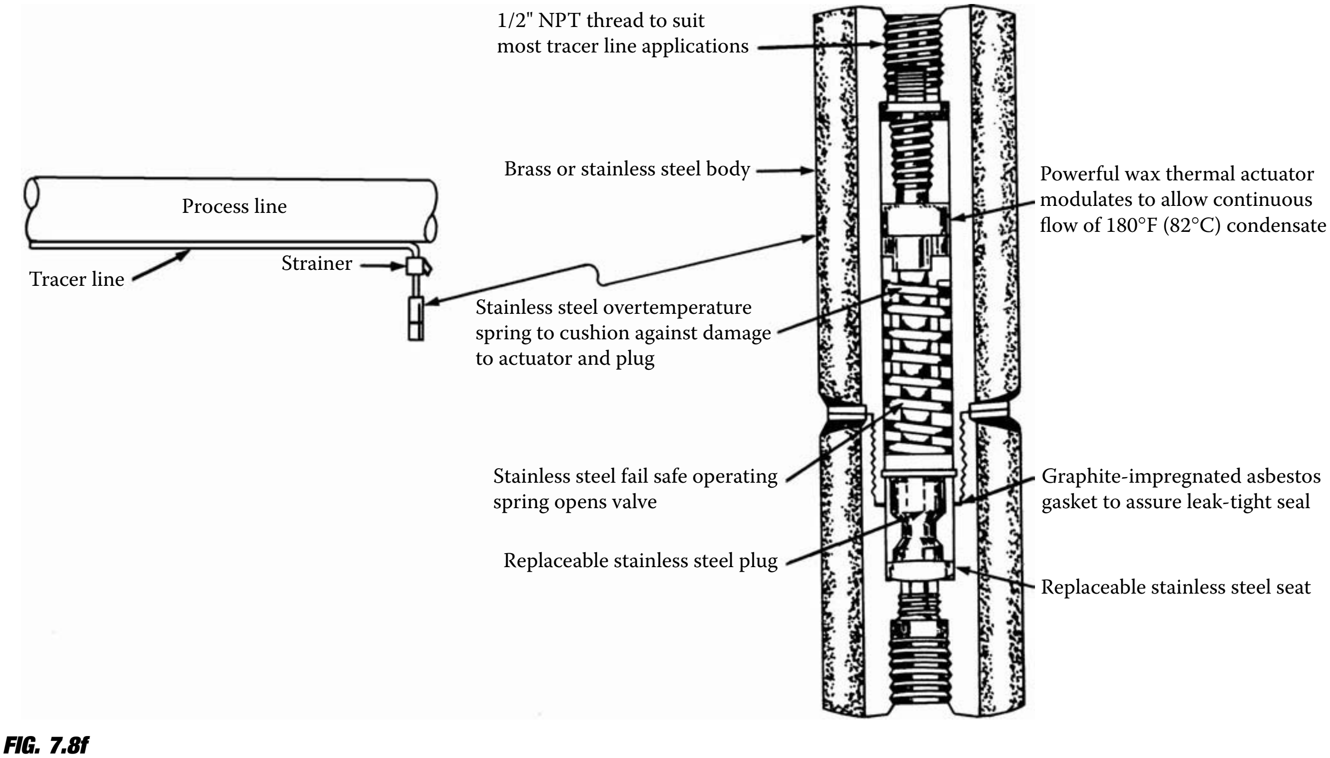

FIG. 7.8f
A temperature regulator can be used in place of a steam trap. It will guarantee that the tracer line is always full of steam and only the condensate is drained, because it opens at a low enough temperature where steam cannot exist. (Courtesy of Ogontz Controls Co.)

In the internal pilot version, the two pilot elements are cascaded; i.e., the temperature element mechanically changes the setting of the pressure element from zero at no load to the maximum pressure for which the pressure pilot is set at full load.

THERMAL SYSTEMS

There are four classes of "filled system" thermal actuators that are used in temperature regulators. They all develop power and movement proportional to the measured temperature, and hence temperature regulators are proportional controllers. For a detailed discussion of filled thermal systems, refer to Section 4.6 in the *Process Measurement* volume of this handbook.

Gas-filled systems (SAMA Class III), bimetal, and "differential expansion" thermal elements are usually not used in temperature regulator valves.

Bulbs, Wells, Fittings

The temperature-sensitive element, the bulb, comes in many sizes and shapes to handle the many different applications. It is good practice to use the largest bulb that will do the job. This will cut down on ambient temperature errors and permit smaller spans and longer capillaries.

Plain bulbs are used where the measured medium is not under pressure and will not harm the bulb material. If this is not the case then a separate well to protect the bulb from the process medium is needed. This, of course, will slow down the response time even more than the 4–7 sec speed of response range.

Speed of Response The speed of response generally doubles with the doubling of bulb diameter and tends to be the fastest with vapor or gas and the slowest with liquid filling, with mercury and Class IID vapor filling in the middle. When thermowells are added to the bulb, speed of response slows as follows: 12–24 sec for 0.25 in. (6 mm), 20–35 sec for 3/8 in. (9 mm), 25–50 sec for 0.5 in. (13 mm), and 40–75 sec for 3/4 in. (19 mm) diameters. Figure 7.8g illustrates a filled bulb installed in a thermowell.

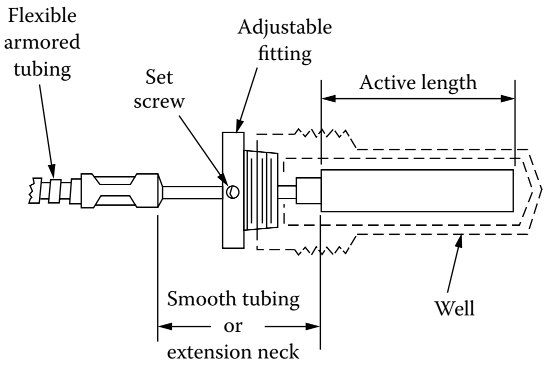

FIG. 7.8g
The main components of a thermal bulb installation with adjustable fitting and well.

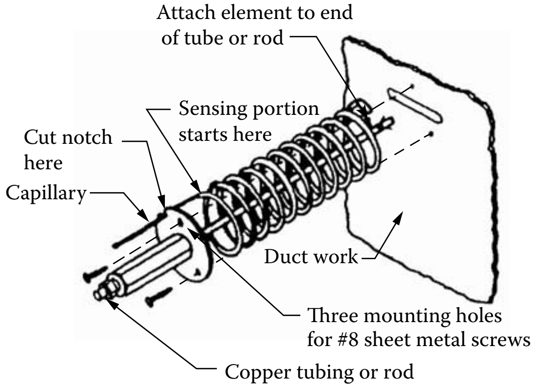

FIG. 7.8h
Averaging capillary-type sensing element for air duct installation. (Courtesy of Johnson Controls.)

Higher speed of response can be obtained with a long, thin, bendable bulb used to sense the average temperature in large areas. Another way of presenting a long bulb is by coiling it. For use in low-velocity gas flow temperature measurement, the coil is set at the factory and cannot be uncoiled (Figure 7.8h).

The primary sensing element of temperature regulators is usually called the bulb in remote sensing designs. The following forms, sizes, fittings, and materials are available.

Bulb Forms and Sizes The cylindrical bulb form is usually standard and is suitable for most liquid control requirements (Figure 7.8i). For faster response in air or gas, a cylindrical form with metal fins is utilized. Other increased surface forms

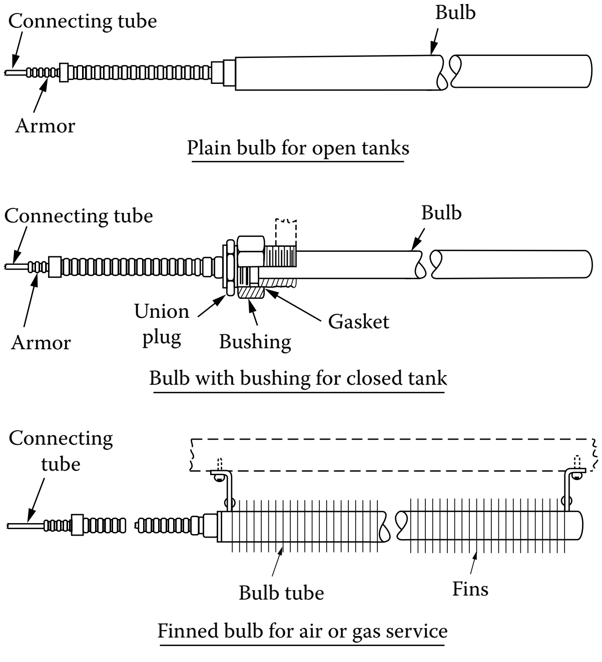

FIG. 7.8i
Thermal bulb designs for open tank (top), closed tank (center), and air service installations.

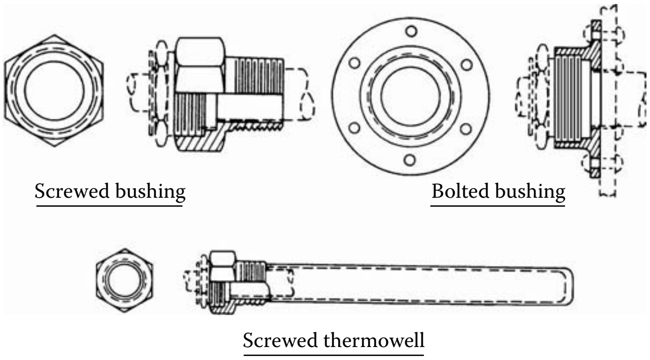

FIG. 7.8j
Thermal bulb design variations.

are the precoiled bulb (for liquid expansion and hot chamber classes) and the tubular bulb. The tubular bulb is made from a substantial length of flexible tubing, to be formed and supported in the field, for example, in and across a duct or wrapped around piping. Other forms include those with dead (inactive) extensions and flexible extensions.

Because of widely varying regulator designs and bulb volume requirements, no bulb dimension standards have been developed. Bulb sizes vary between the extremes of 1/2 in. (12.5 mm) diameter by 9 in. (225 mm) long and 1 1/2 in. (37.5 mm) diameter by 36 in. (900 mm) long. Most bulbs range from 3/4 × 9 in. to 1 1/4 × 24 in. (18.7 × 225 mm to 31.25 × 600 mm) long. Some manufacturers will vary the diameter and length combination to fit special needs.

Fittings and Pressure Ratings For open tank use, no fittings are needed. For pressure vessel or pipeline installations, the use of the union-type screwed bushing is most common (Figure 7.8j). These are generally ground joint unions but are sometimes gasketed. Wells, or sockets, are also available for higher pressure ratings, corrosion protection, and to maintain the integrity of the pressure vessel or system during service. Sanitary fittings are also available.

Bulbs are used in built-up assemblies and are available in copper or in other materials at an extra cost. Table 7.8k gives a list of the available bulb materials and their temperature and pressure ratings.

Capillary Tubing The tubing that transmits the pressure from the bulb to the actuator bellows is usually covered with armor (spiral or braided) for mechanical strength. A tube with 3/16 in. (4.69 mm) OD and approximately 0.050 in. (1.25 mm) wall thickness is common.

The relatively fragile thin-wall capillary should be protected by a flexible armored stainless steel or by PVC-covered bronze tubing. An extension neck to the bulb prevents the tubing from being immersed directly in the measured medium. Bendable smooth steel tubing might also be used for capillary protection.

The standard tubing material is copper with brass armor, but stainless steel (tube or armor), lead-coated copper, and PVC- or Teflon-coated copper or stainless steel are also available.

Standard tubing length is 10 ft (3 m). Longer or shorter lengths are also provided, but lengths above 50 ft (15 mm) are not recommended because of increased mechanical hazards and slow response.

Vapor-Filled System

Still extensively used are the vapor fillings, but these too are limited in their usefulness. The vapor-filled system is limited

TABLE 7.8k
Construction Materials and Other Features of Thermal Bulbs

			Rating	
Bulb Material	*Assembly*	*Fittings*[5]	*Pressure*[1], *PSIG (MPa)*	*Temperature, °F (°C)*
Copper, brass	Brazed	Brass	700 (4.8)	300 (148.9)
Stainless steel[2]	Welded	Stainless steel	1100 (7.6)	600 (315.6)
Steel	Welded	Steel, stainless steel	1000 (6.9)	600 (315.6)
Lead[3]	Fusion	Lead	50 (0.35)	250 (121.1)
Monel	Welded	Monel	1000 (6.9)	600 (315.6)
PVC-coated[4]	Fusion	None	—	160 (71)
Teflon-coated	Shrinking	None	—	300 (148.9)

1. Average, based on 1 in. (25 mm) diameter bulb. Larger diameters have lower ratings.
2. Type #316 is available.
3. Some lead bulbs are sheathed over copper.
4. Coatings are usually over copper, but may be over other materials.
5. Wells for sockets are available in all metals. The use of copper bulbs with other well materials is usual.

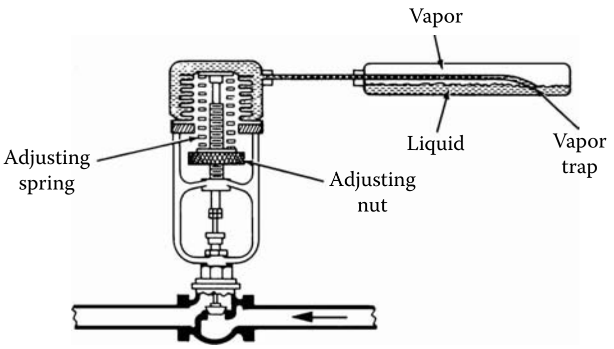

FIG. 7.8l
The main components of a self-actuated temperature regulator using a vapor-filled actuator and thermal element.

due to its nonlinearity and its potential for problems caused by cross-ambient operation or by errors due to elevation.

The operation of the vapor pressure class (SAMA Class II) is illustrated in Figure 7.8l. The thermal actuator, having been evacuated to eliminate the contaminating effect of air and other gases and vapors, is partially filled with a volatile liquid. Liquids used are chemically stable at temperatures well above the range used.

The bellows and tubing usually contain liquid only, if the process temperature is above ambient, although with ambient conditions *above* the set point of the regulator they may contain vapor only—*never both* under conditions of normal operation. If the bulb contains the liquid-vapor interface, the pressure within the actuator is the vapor pressure of the fill liquid at the bulb temperature. This vapor pressure increases with rising temperature and acts on the bellows against the spring force of the adjustment to produce the power required to reposition the valve plug.

Figure 7.8m shows the temperature to vapor-pressure relationship of the various charging liquids used, each having a different vapor pressure curve and atmospheric boiling point. Different ranges are achieved by using different liquids and not by changing springs.

Ranges of Adjustment Ranges of adjustment from –25 to 480°F (–31.7 to 248.9°C) are commonly available, and common spans are in the order of 40 to 60°F (22 to 33°C). In some special cases, involving small short-stroke valves, longer spans up to 100°F (55.6°C) can be furnished. Other

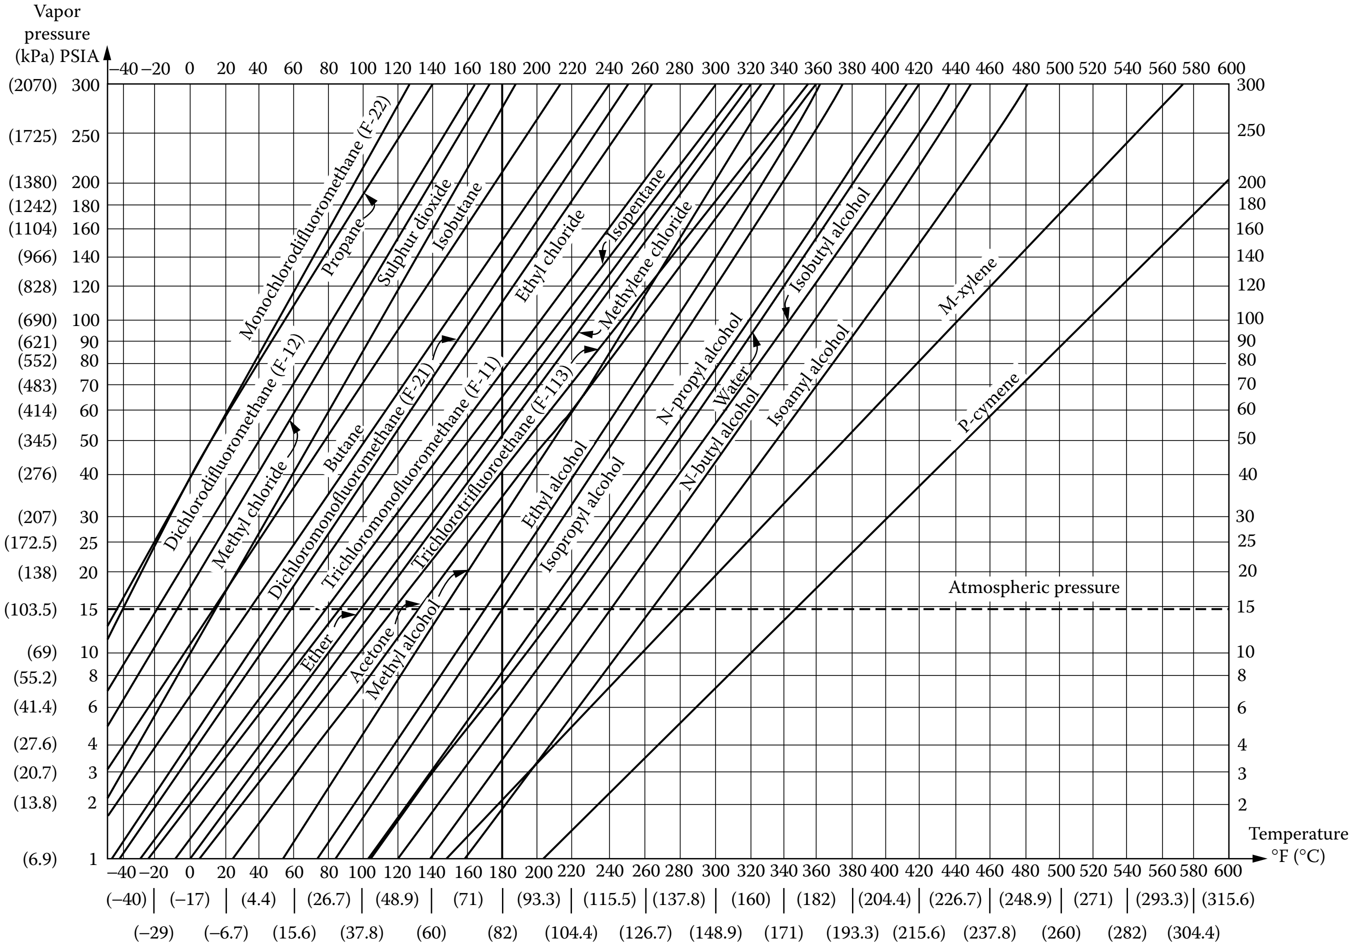

FIG. 7.8m
The relationships between vapor pressure and temperature for a variety of filling liquids.

special designs have shorter ranges of 25 to 30°F (13.9 to 16.7°C).

Adjustment of vapor pressure actuated regulators is accomplished by changing the initial thrust of the adjusting spring (Figure 7.8h). Turning the adjusting nut toward the bellows to compress the spring increases the spring thrust. This requires an increased pressure to start valve movement and thus effects a higher temperature setting. Lowering the adjustment to decompress the spring permits motion of the stem with lower actuator pressure, thereby lowering the set temperature.

The rate of the adjusting spring (force required per inch of spring compression) is an important factor in determining the length of adjustment span as well as the proportional band of a regulator. The stiffer the spring, the longer the span or range, but also the larger the proportional band (lower the gain).

Refrigerant Controls A specialized application of vapor-filled TCVs is the control of heat exchangers that are cooled directly by refrigerant. As the cooling effect is obtained from the evaporation of the refrigerant, these heat exchangers operate the same way as do the evaporators on chillers. As shown in Figure 7.8n, the refrigerant control valve is operated by a diaphragm actuator that compares two pressures: P_1 is the pressure in the temperature bulb, and P_2 is the refrigerant vapor outlet pressure in the equalizer line. The valve is balanced when P_1 equals the sum of the force produced by P_2 and that of the spring.

If the cooling load on the cooler exceeds the refrigerant supply, the refrigerant vapor outlet temperature rises, causing an increase in the vapor pressure inside the thermal bulb (P_1). When P_1 exceeds P_2 plus spring force, the diaphragm in Figure 7.8n moves down, which in turn moves the push rod down and opens the valve. As the refrigerant valve opens, more refrigerant is evaporated, and therefore more cooling is done by the exchanger. As a result, the vapors leaving the evaporator become cooler, P_1 drops, and the force balance on the diaphragm is reestablished.

Inversely, if the cooling load on the evaporator drops, the refrigerant flow becomes excessive for that load, and therefore the temperature at the bulb drops. This results in a drop in P_1 and the closing of the valve until the force balance on the diaphragm is reestablished.

The pressure drop variation across the evaporator tends to assist in the above-described operation. This is the case because when the required refrigerant flow is rising, the pressure drop across the evaporator is also rising, and consequently P_2 is dropping. The drop in P_2 has the same effect as the rise in P_1; that is, they both open the valve. Inversely, when the refrigerant flow is dropping, P_2 is rising, and thereby it assists in closing the valve.

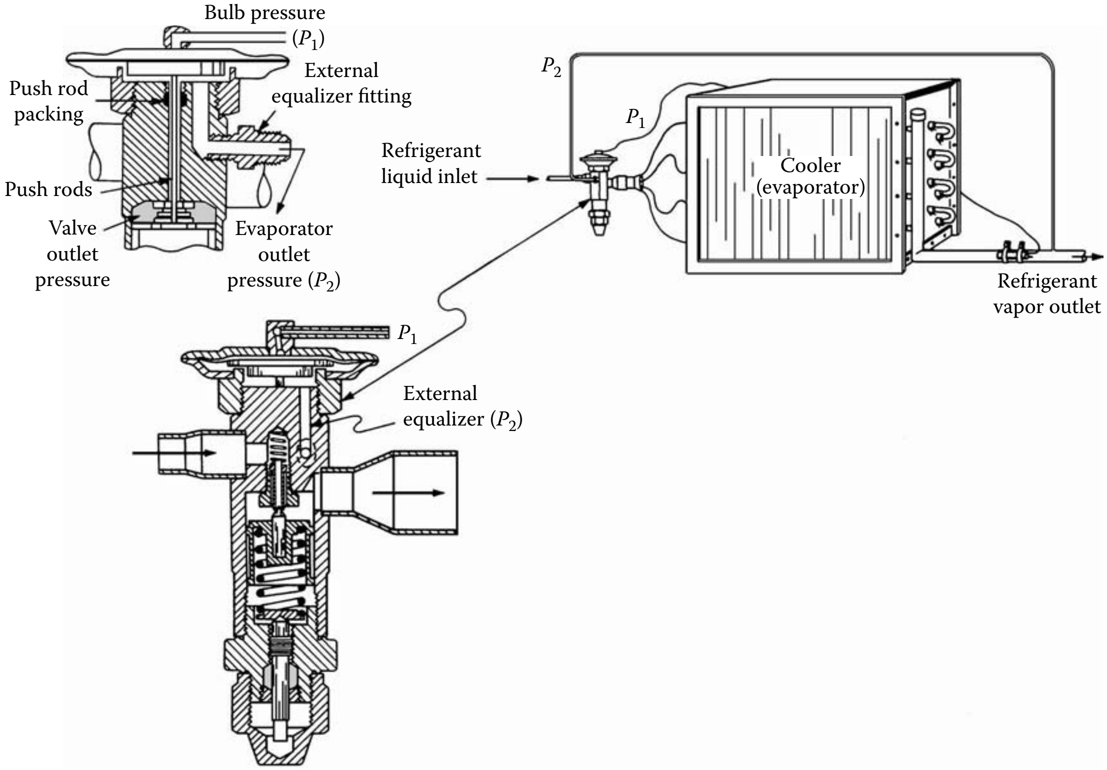

FIG. 7.8n
Temperature regulators provided with refrigerant-filled bulbs admit as much refrigerant liquid into the evaporator as the load demands. (Courtesy of Sporlan Valve Co.)

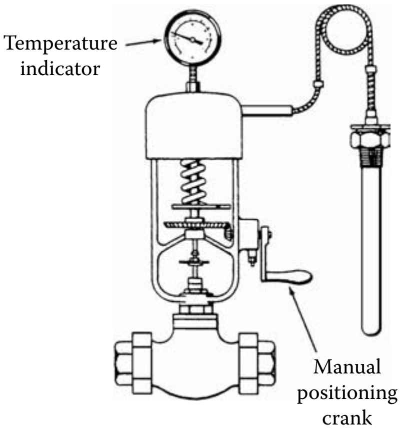

FIG. 7.8o
Accessories such as indicator and handwheel can be provided with the temperature regulators.

The temperature regulator described in Figure 7.8n, therefore, matches the refrigerant flow to the varying coolant demand of the process, while maintaining some superheat in the refrigerant vapor leaving the evaporator. If the cooler is properly sized, this guarantees that the refrigerant liquid will never spill into the outlet line.

Special Features Weight-and-lever adjustment, once very common, is seldom used today because of problems of position, location, and general vulnerability of the moving lever. Here, the force produced by the weight acting on an adjustable length lever or "movement" arm opposes the thrust produced by the thermal actuator. Increasing the length of the lever raises the setting. Because the force of the weight-and-lever system has no "rate" (being almost constant for a given setting), the proportional band of a weight-adjusted regulator is narrower than for a spring-adjusted design.

Overtemperature protection is standard in most regulators of the vapor pressure class. It consists of a special spring-loaded and compressible "overrun" section of the actuator stem. When increasing temperature produces a force beyond that for normal control action, this overrun compresses. The added movement of the actuating bellows drains the remaining liquid from the bulb, and pressure then follows the gas law instead of the vapor pressure curve. This provides protection up to 100°F (55.6°C) above the top end of the range.

Temperature indication is available as a special feature (Figure 7.8o). Generally, this is simply a compound pressure gauge, sealed in the thermal system and responding to the changing pressure of the fill. The dial is calibrated to correspond to the temperature-pressure curve of the particular fill (change) and, therefore, "reads" the bulb temperature. In some designs the thermometer has its own sensing elements, with a separate bulb contained in or attached to the regulator bulb. Improved characteristics are claimed for this design. In either case, the "thermometer" is in the order of approximately ±2% inaccuracy. Thermometers are furnished with both Fahrenheit and Celsius calibration.

Bulb Size Actuator bellows design (diameter, area, length, etc.) is the major factor in determining the characteristics of the vapor pressure regulator. A small bellows, having limited power and stroke, results in a compact actuator, successful only for small valves and on moderate to low pressures.

Increasing bellows size makes direct actuation of larger valves possible at higher pressure levels. However, because the bellows movement requires the transfer of some liquid from the bulb to the bellows (equal to the volumetric displacement), larger bellows require larger bulbs. In general, larger bellows result in shorter adjustable ranges but also narrower proportional bands. Some manufacturers offer a choice of designs based on bellows size in order to offer different characteristics.

Bulb size of the vapor pressure regulators is governed by the volumetric displacement of the bellows (area × valve travel) and varies with actuator design and with valve design and size. It is also affected by the possible need to operate under "cross-ambient" condition, i.e., with ambient temperature either above or below the regulator's set point.

This requirement produces a bulb substantially larger than that used where the ambient temperature will always be either above or below the range of the regulator. *The use of vapor-filled thermal elements on cross-ambient applications is generally not recommended.* Bulb sizes of this class range from 1/2 in. (12.5 mm) OD by 6 in. (150 mm) OD by 36 in. very small units to 1 1/2 in. (37.5 mm) OD by 36 in. (900 mm) long in large valves with cross-ambient fill.

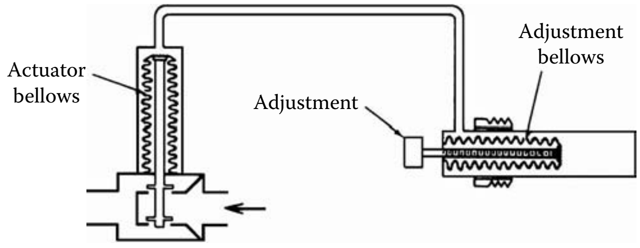
Bulb construction for vapor pressure regulators includes a "vapor trap" (Figure 7.8l). This serves to give the best possible response by ensuring liquid transfer of pressure changes from bulb to bellows. Because the end of the vapor trap tube must always be in liquid, it requires that the installation of the bulb be made in accordance with markings on the bulb. For installations where the tube connection end of the bulb is below the horizontal, the extended vapor trap must be omitted.

Advantages of vapor pressure regulators are (1) ambient temperature has no effect on calibration, and (2) there is a wide choice of designs, characteristics, ranges, and special features available.

Liquid-Filled System

The use of mercury filling has been discontinued in most industrial applications because of health concerns. The use of both mercury and liquid fillings have also lost ground because of the expense associated with compensating for the ambient effects on the capillary and because of the errors caused by elevational differences between bulb and readout.

The operation of the liquid expansion class (SAMA IB) is illustrated in Figure 7.8p. The thermal actuator is completely filled with a chemically stable liquid. Changing temperature



Uniform liquid expansion per degree temperature rise at sensing bulb compresses valve actuating bellows to control flow of heating or cooling medium

FIG. 7.8p
Liquid-filled thermal actuator and sensing element.

at the bulb produces a volumetric change, which causes the small-area bellows to move in a corresponding direction, thereby moving the valve. The force and action are positive and linear, limited only by the components of the element, chiefly the actuator and adjustment bellows.

Ranges are from 0 to 300°F (–17.8 to 148.9°C) with spans generally from 30 to 50°F (16.7 to 27.8°C). The special 100°F (55.6°C) spans are sometimes furnished with very small, short-stroke valves. The different ranges (not field-changeable) are achieved by filling procedure and sealing temperature. Hydrocarbon fills are generally used. Mercury is no longer used as a filling fluid for regulators because of cost and hazards.

Adjustment is achieved by moving the actuator bellows relative to the valve plug (Figure 7.8b) or by using a separate adjusting bellows (Figure 7.8p). This adjustment bellows transfers liquid into the actuator bellows to lower the set point, or vice versa. The adjustment may be located at the bulb or at the valve, or it may be separate from both.

The proportional band is generally wider than with other classes of actuators (lower gain), and it is a direct function of bulb volume to actuator bellows area.

Overtemperature protection, which permits overtravel of the bellows, allows an uncontrolled temperature to overrun the set point by up 50°F (27.8°C). Ambient temperature effect on the liquid in the tubing, bellows, and adjustment is minimized by design, but wide ambient swings do introduce errors.

Packless construction (no moving stem through the body envelope) is a feature of this class of regulator. However, they must not be used in applications involving corrosive fluids. Temperature indication is not generally available.

Advantages of the liquid expansion class regulators include a positive actuating force, linear movement, and packless design.

Hot Chamber System

The hot chamber class of regulator has no corresponding SAMA designation. This thermal actuator is partially filled with a volatile fluid (Figure 7.8q) and has some characteristics common to the liquid expansion class. Rising temperature at the bulb forces liquid into the actuator bellows (the "hot chamber"). There, the heat of the control agent, always at a temperature substantially above the regulator range, flashes the liquid into a superheated vapor. The pressure increase in the bellows causes the valve to move against a return spring.

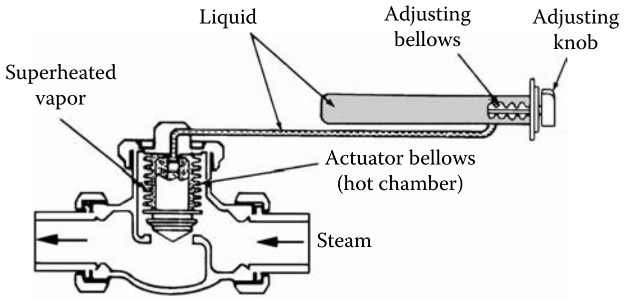


FIG. 7.8q
The sensing element and the actuator of a hot chamber-type temperature regulator.

Hot chamber regulators are available in sizes from 1/2 to 1 1/2 in. (12.5 to 37.5 mm). Because of practical considerations, only direct-acting designs are available (close on rising temperature), and they are limited to use on steam at pressures up to 75 PSIG (518 kPa). Theoretically, other designs are also possible.

Ranges are from 30 to 170°F (–1.1 to 76.7°C) (to 200°F, or 93°C, in special cases) with spans from 30 to 60°F (16.7 to 33.3°C). Adjustment is achieved by the use of adjusting bellows that are usually located at the bulb but may be separate and remote.

Ambient temperature effects are minimized by design, but wide ambient swings are nevertheless detrimental. Effects of steam supply pressure variations are partially self-compensating.

Bulbs (thermostats) take several forms. For steam space heating systems, the wall-mounting types or duct-mounting types are common, while for liquid heating the cylinder types with pressure-tight bushings are utilized.

Advantages of the hot chamber class include calibrated knob and dial adjustment, good response and good proportional characteristics, packless design, and compact construction.

Fusion-Type System (Wax-Filled)

The fusion class of regulator does not have a SAMA equivalent. In the least common class, the compact element is filled with a special wax containing a substantial amount of copper powder to improve its rather poor heat-transfer characteristics (Figure 7.8r). A considerable and positive volumetric increase occurs in the wax as temperature rises through its fusion or melting range. This volumetric change produces a force used for valve actuation through the ingenious arrangement of a sealing diaphragm that acts to compress a rubber plug that "squeezes out" the highly polished stem (Figure 7.8r). This

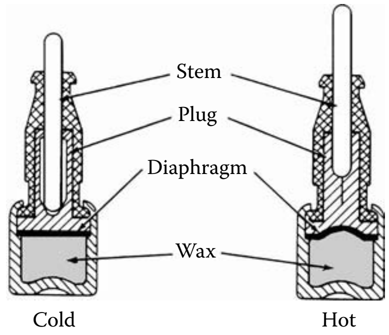

FIG. 7.8r
Wax-filled, fusion-type thermal element.

element has more hysteresis and dead band than the other classes.

Different waxes, such as natural waxes, hydrocarbons, silicones, and mixes of these are available that provide a variety of operating (control) spans between 100 and 230°F (55.6 and 127.8°C).

No adjustment of set point is provided, because the fusion (melting) span of the wax is narrow, from 6 to 14°F (3.3 to 8.3°C). A heavy return spring, which is always present in the regulator, forces the rubber components of the element to follow the wax fill on falling temperature.

Remote bulb designs are not offered because they would provide no advantages over the other three classes. Thus, fusion class regulators are available only in "self-contained" styles (Figure 7.8s).

Overtemperature protection up to 50°F (27.8°C) above the operating span is provided by the flat temperature expansion curve of the wax above its melting range.

Valve sizes are from 1 to 6 in. (25 to 150 mm), with the majority being of the three-way valve design in sizes from 2 to 6 in. (50 to 150 mm).

Advantages of fusion class regulators lie in their compact size and low cost of the thermal element, even where multiple elements are required to stroke larger valves.

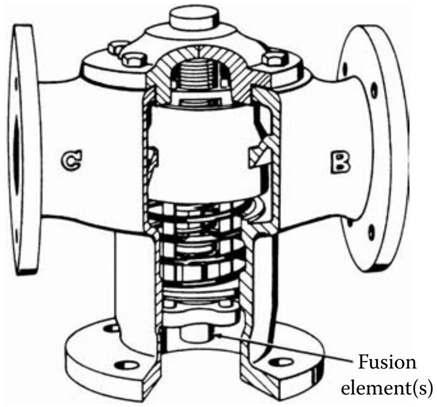

FIG. 7.8s
Self-contained temperature regulator with wax-filled (fusion-type) element.

THE REGULATOR VALVE

Further discussion here is limited to some special forms of valves and to factors relating to selection and use due to force limitation of the thermal actuator. For a detailed discussion of the features of globe valves, refer to Section 6.19.

Valve action refers to the relationship of stem motion to plug and seat position. A direct-acting valve closes as the stem moves down into the valve. A reverse-acting valve opens as the stem moves down. A three-way valve combines these, one port (or set of ports) opening and the other port(s) closing on downward movement.

A direct-acting valve on heating service will reduce the flow rate of the heating medium if the controlled temperature increases. Therefore, heating control is accomplished by a direct-acting regulator, in combination with a direct-acting valve.

Cooling control is most frequently achieved by a reverse-acting regulator with a reverse-acting valve to increase the flow of coolant on rising temperature. However, on constant coolant flow systems, a direct-acting regulator with its valve in a bypass line is occasionally used to vary the flow through the heat exchanger.

A three-way valve provides positive control of such a cooling system by giving a full range of flows through the two legs of the cooling circuit (exchanger and bypass). This gives good temperature control, but wastes energy. Mixing of two media at different supply temperatures to control the mixed temperature is also accomplished with three-way valves.

Single- and Double-Seated Valves

Single-seated valves are desirable for minimum seat leakage in the closed position. The pilot-actuated regulators always use single-seated valves (Figure 7.8t). On direct-actuated types, the use of single-seated valves is limited to a 2 in. (50 mm) maximum for two reasons: (1) the required full-open lift (approximately 1/4 of valve size) and (2) the closing force required (full port area times maximum pressure drop across the valve). A single-seated valve with piston-balanced plug (Figure 7.8t) eliminates the closing force problem but requires slightly higher full-open lift.

Double-seated valves are most common on direct-actuated regulators in sizes up to 4 in. (100 mm). The reasons for this include their low full-open life (approximately 1/8 of valve size) and minimum closing force requirement. The unbalanced area of double-seated valves is the difference between the two port areas, which is approximately 6% of the larger of the two — hence, the term "semibalanced" is used for double-seated valves (Figure 7.8u).

Three-Way Valves

Three-way valves used with temperature regulators are of three basic designs (Figure 7.8v). Smaller valves (to 2 in., or

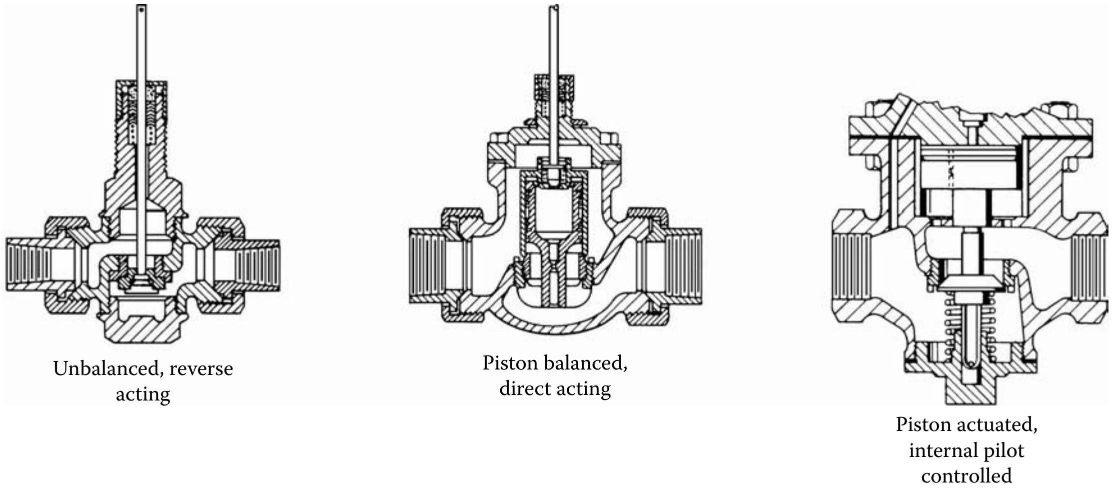

FIG. 7.8t
Three designs of single-seated, two-way regulator valves.

50 mm) are of the "unbalanced" single-seated construction with a common plug moving between two seats. In sizes from 2 to 6 in. (50 to 150 mm) there are two designs. A sleeve-type plug (requiring a body seal) moves between two seats and provides near balance of closing forces, but it requires typical single-seated lift. A semibalanced design, essentially two double-seated valves for each flow path with connected plugs, gives both low lift and low seating force. This construction is somewhat more expensive, however.

Plug guiding is considered to be a less important factor with regulators than with control valves, because the applications involve relatively low pressures and velocities. Therefore, many direct-actuated single-seated valves are only stem guided. Most double-seated valves are seat ("wing") guided, but some top- and bottom-guided designs are also in use. Pilot-actuated valves are generally well guided, as are the piston-balanced valves.

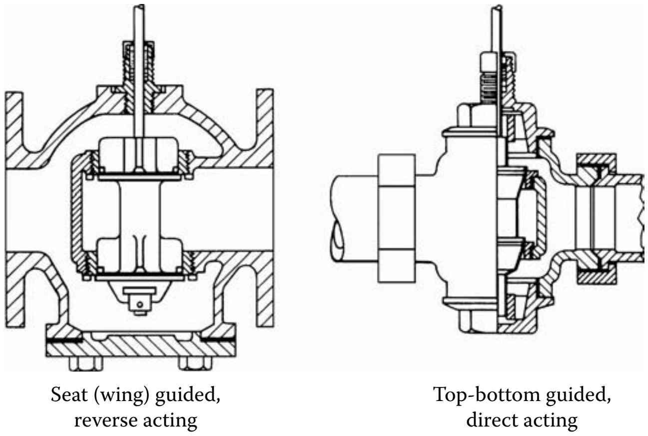

FIG. 7.8u
Double-seated, two-way regulator valves with direct (right) and reverse (left) action.

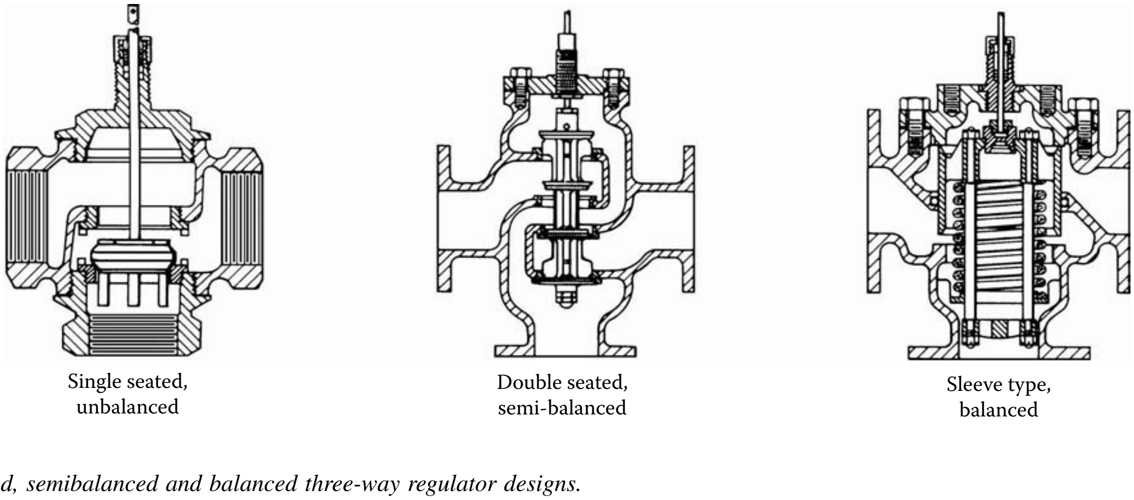

FIG. 7.8v
Unbalanced, semibalanced and balanced three-way regulator designs.

Valve Features

Flow Characteristics Most regulator valves are of the quick-opening type in order to use the shortest practical lifts. On special basis, low-lift plugs are available in some small single-seated valves and also in a few double-seated valves. As was explained in Sections 6.1 and 6.7 in Chapter 6, the ideal valve characteristic for temperature control loops is equal percentage. This is another reason why TCV regulators are not used on critical temperature control applications.

Materials and Connections Standard materials used in body construction are bronze in sizes below 2 in. (50 mm) and cast iron in larger sizes. Steel and stainless steel are considered to be special body materials. The standard bronze valve trim is used with pressure drops below 50 psid (345 kPa), while stainless steel is recommended for greater drops.

On low-pressure and -temperature services, composition discs can be used for tight shut-off. Stellite or hardened alloy trim for extreme service is available as special, though some pilot-actuated designs offer it as standard. Monel and other special alloys are available for specialized services, such as seawater applications.

To lessen the chance of installation damage, union ends are usual for 1/2 to 1 1/2 in. (12.5 to 37.5 mm) valves (in some cases 2 in., or 50 mm). Flanged ends are standard in sizes 2 in. (50 mm) and larger.

Pressure Rating The pressure rating of a temperature regulator is frequently determined more by limitations in the thermal actuator power (seating force) than by the design and materials of the valve body and trim. Therefore, while catalogs will usually state the maximum temperature and pressure rating for the valve, they should also give a lower recommended maximum pressure limit for a direct-actuated regulator. This will usually decrease as valve size increases, and it should be given full cognizance.

With pilot-actuated valves and piston-balanced valves (direct actuated), the actuator limitation is not a factor. However, regulators are seldom available or recommended for pressures above 250 PSIG (1.7 MPa).

Valve Capacity and Leakage The valve capacity data published by manufacturers is reasonably accurate, having been determined by recognized test procedures (Section 6.6 in Chapter 6). Most manufacturers publish capacity tables for common fluids, from which the full-open capacity figures can be read directly for various supply pressures and pressure drops. In a few cases, the information takes nomographic form. Some list the valve capacity factor C_v for each valve size and type.

Regulators should not be considered as positive shut-off devices. However, in "as new" condition, leakage across seats in the closed position for metal-seated valves may be expected to be 0.02% of full capacity for single-seated and 0.5% for double-seated regulators. Single-seated valves with composition discs can be nearly "dead tight" or "bubble tight."

CONCLUSIONS

Because the characteristics of a regulator cannot be altered in the field, greater care must be taken in the proper evaluation and selection than would be the case when using a complete temperature control loop with adjustable control mode or modes.

In general, temperature regulators are most successful on control applications having high "capacitance" (slow processes), such as heated or cooled storage tanks, process ovens, and dryers, or on applications with small load changes, such as metal treating (cleaning and plating) tanks.

Proper installation includes the selection of a good location for the bulb, where process temperature changes can be sensed quickly, but away from potential damage by moving equipment. Regulators in sizes 2 in. (50 mm) and greater should be installed upright in horizontal lines. Strainers should be installed for the protection of all regulators.

Regulator maintenance is minimal. Direct-actuated regulators with packed valve stems may require occasional lubrication and infrequent replacement of packing and cleaning or polishing of stem. Pilot-actuated regulators with piston-actuated valves (Figure 7.8d) may require programmed cleaning to remove "glaze" and deposits that would cause the piston to stick. Depending on the service, occasional examination and servicing of valve seats may be required to maintain needed tightness.

Relative to using full-temperature control loops, the advantages and limitations of temperature regulators can be summarized as follows: Advantages include low installed cost, ruggedness, simplicity, low maintenance, and no need for an external power source. The limitations include the fixed gain and the resulting offset, the local set point, the limited and narrow ranges, the slow response, the limitations in size and operating pressures, and requirements for a relatively large bulb.

7.9 Thermostats and Humidistats

B. G. LIPTÁK (1985, 1995, 2005)

Types:	A. Conventional HVAC thermostats B. Advanced, digital, intelligent thermostats C. Conventional HVAC humidistats D. Advanced, digital humidistats
Standard Ranges:	A. 45 to 85°F (7 to 29°C) for heating and from 55 to 105°F (13 to 40°C) for cooling services B. 40 to 90°F (5 to 32°C) to 23 to 122°F (-10 to 50°C) or higher C. 15 to 95% RH D. 0 to 100% RH
Inaccuracies:	Sensor Error: A. ±1°F (0.5°C) B. ±0.5°F (0.28°C), even better with RTD-based digital units C. ±3 to 5% RH D. ±2% RH (some w/1% resolution) Offset Error: A. ±1 to 5°F (0.5 to 2.8°C) B. Zero with integral C. ±2 to 10% RH D. Zero with integral
Air Capacities:	Relay types (high volume): 10 to 30 SCFH (0.3 to 0.84 m^3/hr) Non-relay types (low-volume): 1 SCFH (0.028 m^3/hr)
Costs:	A. Room thermostat $50 to $100. Low-volume, proportional, pneumatic room thermostats cost $75 to $125; high-volume, proportional, dual room thermostats for heating/cooling and with automatic changeover cost $175 to $250; averaging, proportional thermostats for duct mounting cost about $150; on/off electric thermostats can be obtained for $100 or less B. Microprocessor-based on/off home thermostats cost $100 to $200, programmable microprocessor-based energy-saver thermostats cost $200 to $400; C. Proportional, pneumatic room humidistats cost $200 to $250; duct-mounted, proportional, pneumatic humidistats cost about $300; on/off electric humidistats can be obtained for about $100, HVAC transmitter $600 to $800. D. For the costs of higher-quality humidity instruments see Section 8.32 in the *Process Measurement* volume of this handbook (Note: Installed total costs can double the hardware costs listed above.)

INTRODUCTION

There is an overlap between the measurement and the control of room temperature and humidity. The first volume of this handbook on *Process Measurement and Analysis* covers these topics from the measurement perspective in Sections 4.11 and 8.32. In this section, the emphasis will be placed on the control capabilities of these devices.

Thermostats and humidistats have been developed to serve the heating, ventilating, and air conditioning (HVAC) industry. While energy costs were low, the consideration of performance was secondary to the purchase price of these devices. When energy costs increased, new, better-quality units were developed, but the conventional HVAC devices still remain in use in existing systems and in new installations, where the designers are less sensitive to the quality of performance. In this section, the conventional quality units and the more advanced designs are both described.

On/off and throttling devices are both referred to as thermostats or humidistats. Therefore, both versions will be discussed, but more emphasis will be placed on the throttling-type designs. First the narrow proportional band controllers, the stats, will be described. After that, the various thermostat and humidistat designs will be covered.

ACCURACY OF THERMOSTATS AND HUMIDISTATS

Conventional

In conventional HVAC thermostats and humidistats, the total error is the sum of the sensor error and of the offset error. Even after individual calibration, the sensor error of conventional thermostats cannot be reduced to less than ±1°F (±0.55°C) for thermostats or to ±5% relative humidity (RH) for humidistats. Added to the sensor error is the offset error, which increases as the throttling range increases. This, for conventional thermostats, can be as high as ±5°F (±2.8°C) and ±20% RH for humidistats. If the two errors are additive, the total errors of conventional units can approach ±6°F (±3.3°C) and ±20–25% RH, respectively.

In conventional HVAC electrical thermostats or humidistats, the total error is the sum of three components. The first error component is the element error, which is the same as the sensor error in pneumatic designs. The second error component is the mechanical differential set in the thermostat switch, which does not modulate the final control element, but turns it on and off. The differential (or bandwidth) can vary for the thermostats from 0.5 to 10°F (0.3 to 5.6°C) and for humidistats from 2 to 50% RH.

The third error component is due to the fact that turning on a heat or humidity source does not instantaneously return the space to within the control differential. Instead, conditions will continue to deviate further for a while. The total error resulting from these three contributing factors can be as high as for HVAC pneumatics, although if the final control elements are sized large enough and if the control differential is set small, electrical units are likely to outperform their pneumatic counterparts.

Advanced

If space conditions are to be accurately maintained, such as in clean rooms where the temperature must be controlled within ±1°F (±0.55°C) and the humidity must be kept within ±3% RH, neither of the above designs is acceptable. In such cases it is necessary to use a resistance temperature detector (RTD)-type or a semiconductor transistor-type temperature sensor and a proportional-plus-integral thermostat controller, which will eliminate the offset error. This can be most economically accomplished through the use of microprocessor-based thermostats that communicate with sensors over data highways.

The performance of advanced, microprocessor-based digital units is much better than that of conventional thermostats. The error in an RTD-based digital thermostat is around 1% of span. Similarly, the resolution of a digital hygrometer is around 1%.

THERMOSTATS

Conventional thermostats are usually uncalibrated devices, and their manufacturers usually do not guarantee their accuracy. This is a limitation, because it is possible to have some

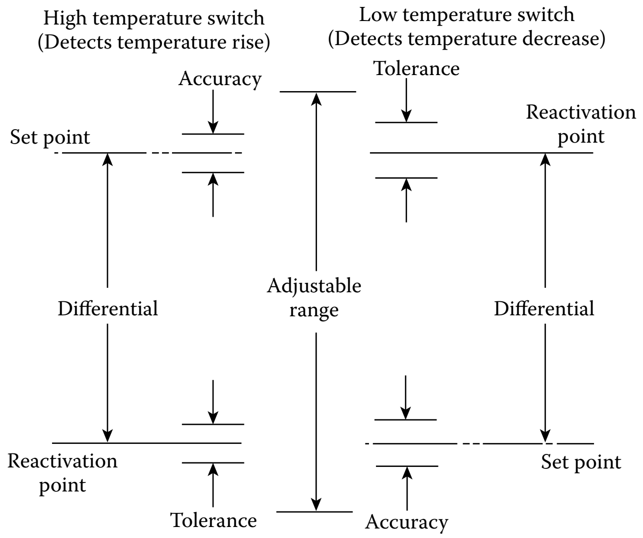

FIG. 7.9a

A cooling thermostat operates as a high-temperature switch, and a heating thermostat functions as a low-temperature switch.

thermostats with as much as 5–10°F (3–6°C) error in their measurement. In the last decades, a new generation of thermostats have been introduced that guarantee to limit their error to 1°F (0.6°C) or less.

ElectroMechanical Designs

There is little difference between a two-position thermostat and a temperature switch. A thermostat that is controlling the heating of a space operates like a low-temperature switch, and a cooling thermostat operates as a high-temperature switch (Figure 7.9a).

The movement produced by a bimetallic temperature sensor or by the expansion of a humidity-sensitive element can be used to build two-position controllers. The electric thermostats in Figure 7.9b illustrate the various differential gaps in two-position control. The thermostat on the left operates load contacts directly from the bimetallic element.

The set point is adjusted by setting one contact or by repositioning the whole bimetal element. The gap in this arrangement is theoretically zero, although in actual practice there is a very small gap due to contact "stickiness."

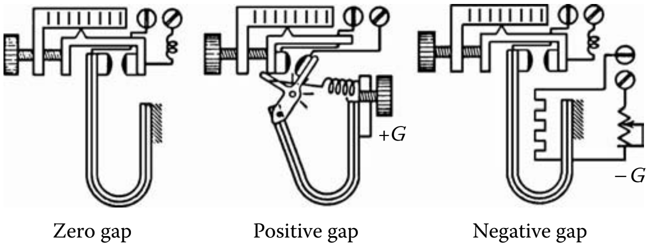

FIG. 7.9b

Design variations of electrical two-position thermostats.

A positive differential gap is often necessary in two-position control in order to save wear on the control apparatus. The mechanism shown in Figure 7.9b employs a toggle action to produce a positive gap. The gap is adjustable by the tension of the spring, because this determines the suppressive (hysteresis) force acting on the element.

A negative differential gap is often used on domestic thermostats in order to reduce an abnormally long period of oscillation. An auxiliary heater operated by the load contacts turns on a small heater within the thermostat when the contact is made. Thus, the bimetal element opens the load contact before the actual room temperature attains the same point. The load contact make point is normal. This is sometimes termed "anticipation."

There are many forms of two-position thermostat- or humidistat-type controllers for both domestic and industrial applications. These offer many arrangements of load contacts, set point, and differential gap. Generally, a solenoid valve or an electrical heating element, motor, or other power device is operated by the controller.

For floating controller action, a neutral zone is usually necessary. This is obtained by a second contact position in the controller and is often obtained with two independently set on/off control mechanisms.

Single-speed floating control can be achieved by means of the same equipment as for two-position control with an electric-motor-operated valve. The difference lies only in the speed of operation of the motor or valve actuator. In two-position control the valve stroke is 120 sec or less. In single-speed floating control, the valve stroke is usually 120 sec or more. An electrical interrupter is sometimes employed in conjunction with the motor to decrease the speed of opening and closing the valve.

Electrical/Electronic Design Features

The most common thermostat is the low-voltage unit that uses external interposing relays to control heating or cooling equipment (typically 24 VAC). Other models include:

Line voltage units that directly control AC circuits (120 or 240 VAC).
Heating only or heating/cooling models.
Digital or analog indication of room temperature.
Bimetallic, filled system or electronic sensing elements.
Direct or reverse acting.
Local or remote set point.
Local set points may be external or internal and may be key protected.
Limited control range thermostats allow the occupant of an office to move the set point to any value desired, but will disregard any setting that exceeds the limit value.
Programmable set-back models with 24-hour or 7-day programs.

Microprocessor-Based Units

A *smart thermostat* is usually a microprocessor-based unit with an RTD-type or a transistorized solid-state sensor. It is usually provided with its own dedicated memory and intelligence, and it can also be provided with a communication link (over a shared data bus) to a central computer. Such units can minimize building operating costs by combining time-of-day controls with intelligent comfort gap selection and with maximized self-heating.

Microprocessor-based units continue to incorporate new features. These are programmable devices with memory and communication capability. They can be monitored and reset by central computers using pairs of telephone wires as the communication link. Microprocessor-based units can be provided with continuously recharged backup batteries and with accurate electronic room temperature sensors. They can also operate without a host computer (in the "stand-alone" mode). In this case the user manually programs the thermostat to maintain various room temperatures as a function of the time of day and other considerations.

Control by Phone

In the year 2000, the first residential gateway for the HVAC industry's new open communications standard for residential environmental control was introduced. This gateway enables secure, remote access to residential HVAC systems via touch-tone telephone, standard phone line, and pass code. Some systems offer either "dial-in" or "dial-out" functions. Owners can call in to check the temperature, change the status of their HVAC system, and perform other thermostat-related functions.

These telephone access modules enable monitoring of the building's temperature and its heating/cooling equipment. It can report when a furnace filter needs replacing or an electronic air cleaner's cells need cleaning. And it can call up to three phone numbers to immediately alert the owner, contractor, or others of problems, such as freezing temperatures or an extended power outage.

The Proportional-Only Controller

A thermostat or humidistat is a simplified controller, having only one control mode—proportional—that is narrow and fixed. The pressure of the output signal from a pneumatic "stat" is a near straight-line function of the measurement, described by the following relationship:

$$O = K_c(M - M_0) + O_0 \qquad \textbf{7.9(1)}$$

where

O = output signal

K_c = proportional sensitivity (K_c can be fixed or adjustable depending on the design)

M = measurement (temperature or relative humidity)

M_0 = "normal" value of measurement corresponding to the center of the throttling range

O_0 = "normal" value of the output signal, corresponding to the center of the throttling range of the control valve (or damper)

Throttling Thermostats are distinguished from other controllers in that they provide proportional action only and that their proportional band (gain) is narrow and fixed. In this section, the operation of thermostats will be described on the basis of their pneumatic designs, but all concepts and features that are discussed are equally applicable to analog or digital electronic thermostats, also.

A conventional pneumatic room thermostat might have a set point range of 55–85°F (13–29°C) and a *fixed sensitivity* (gain) of 2.5 psi/°F (0.3 bar/°C). Assuming that this thermostat operates a control valve having a 9–13 PSIG (0.6–0.9 bar) spring range, we can convert the fixed sensitivity of 2.5 psi/°F into a percent-proportional band value that is better understood by instrument engineers.

Sensitivity (or gain) is stated as the ratio between a change in measurement and a change in the corresponding controller output. A 1°F (0.56°C) change in measurement is 3.3% of the measurement range of 30°F (55–85°F, or 13–29°C), while the 2.5 psi change in controller output is 62% of the controller output range of 4 psi (9–13 PSIG). If a 3.3% change in input results in a 62% change in output, that is a gain of 62/3.3 = 19. Converting this typical thermostat gain to proportional band, we get:

$$P = \frac{100}{G} = \frac{100}{19} = 5.3\% \qquad \textbf{7.9(2)}$$

If a thermostat is controlling a valve or a damper, one needs to determine K_c, M_0, and O_0 in Equation 7.9(1) in order to draw the straight-line relationship between measurement and output signal. Figure 7.9c illustrates the behavior of a control loop consisting of a direct acting thermostat, having a fixed K_c of 2.5 PSIG/°F (0.3 bar/°C), a "normal" measurement value of M_0 = 72°F (22ºC), and a damper spring range of 8–13 PSIG (0.55–0.9 bar). This combination results in a normal output signal: O_0 = 10.5 PSIG (0.73 bar).

Does it Have a Set Point? It is a common error to call M_0 in Figure 7.9c the set point of that thermostat. Stats do not have setpoints in the sense of having a predetermined temperature value to which they would seek to return the condition of the controlled space. (One must add integral action in order for a controller to be able to return the measured variable to a set point after a load change.)

M_0 does not represent a set point; it only identifies the space temperature that will cause the cooling damper in Figure 7.9c to be 50% open. This can be called a "normal" condition, because relative to this point the thermostat can both increase and decrease the cooling air flow rate as space temperature

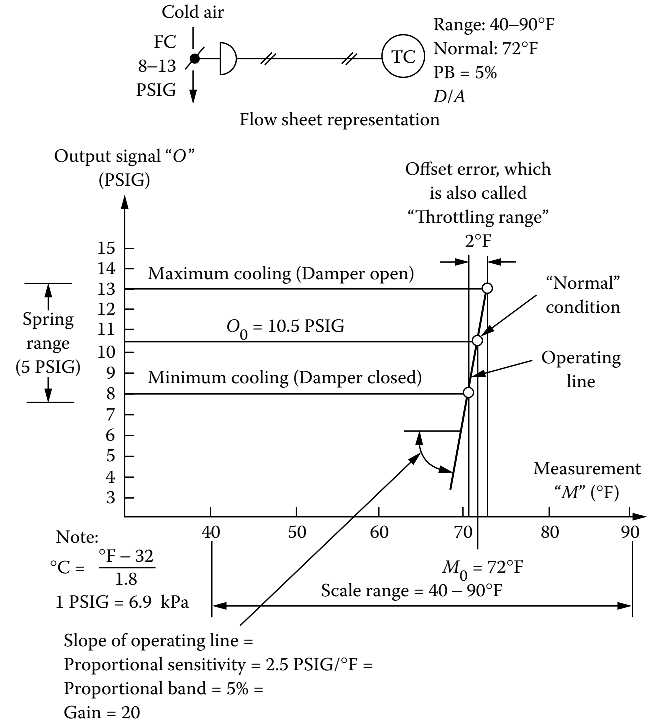

FIG. 7.9c
Operating characteristics of a narrow and fixed proportional band, pneumatic thermostat.

changes. If the cooling load doubles, requiring the damper to be fully open, this cannot take place until the controlled space temperature has first risen to 73°F (23°C). As long as the cooling load remains that high, the space temperature must also stay up at the 73°F (23°C) value.

Similarly, the only way this thermostat can reduce the opening of the cooling damper below 50% is to first allow the space temperature to drift down below 72°F (22°C). Therefore, stats do not have set points, but they have throttling ranges, and if a throttling range is narrow enough, this gives the appearance that the controller is keeping the variable near set point, when in fact the narrow range allows the variable to drift within limits.

Offset Error This controller has a fixed proportional band of 5%; it is is very sensitive, has a small "offset," and, as its gain is fixed, it cannot be tuned. Let us examine the consequences of these characteristics separately. A sensitive controller is suited for the control of very slow, large-capacity processors. Temperature control in the HVAC industry usually fits that description, and therefore thermostats with fixed, high gains can give acceptable results, if space temperature can change only very slowly. On the other hand, such thermostats cannot control spaces with fast dynamics (short time constants) and will cycle or lose control when applied to such service.

The "offset" inherent in all proportional controllers is not a serious drawback because the resulting error is small, due to the narrowness of the proportional band. Assuming that the thermostat output is set at 11 PSIG (0.76 bar) when the error is zero (thermostat is on set point), we can calculate the maximum error due to offset. When there is no error, the control valve is 50% open (output is 11 PSIG, or 0.76 bar).

As the load changes, an error must be allowed to develop in order for the valve opening to change. Assuming that the valve has been correctly sized and is large enough to handle all expected loads, the maximum error due to offset will be that deviation that is required to move the valve from half to full opening. If the thermostat's sensitivity is 2.5 PSIG/°F, this 2 PSIG (0.14 bar) change in thermostat output will occur when the deviation from set point is 0.8°F (0.4°C).

Therefore, this is the size of the permanent offset error for a gain of 19:1. There is an inverse linear relationship between gain and offset error, such that if the gain is cut in half, the offset error will be doubled. From the above discussion it might be concluded that the conventional room thermostat is a good selection for the HVAC-type applications and that more expensive instruments, such as PID controllers, would not necessarily improve the overall performance.

Throttling Range, Gain, or Sensitivity The control response of thermostats is described by the slope of the operating line in Figure 7.10c. This slope is described in different ways depending on the industry and manufacturer involved. People in the process control fields tend to be more familiar with terms such as "gain" and "proportional band," while people working in the HVAC field are more used to the terms "proportional sensitivity" or "throttling range."

All of these terms describe the same slope shown in Figure 7.9c and they are also defined below:

The ***throttling range*** is the gap within which the space conditions are allowed to drift as the final control element is modulated from fully closed to fully open (2°F or about 1°C in Figure 7.9c). Figure 7.9d describes the throttling range of a 3–13 PSIG (0.2–0.9 bar) thermostat.

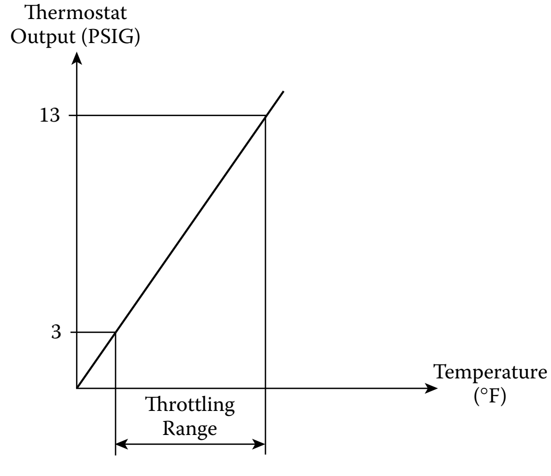

FIG. 7.9d
The throttling range of a 3–13 PSIG (0.2–0.9 bar) thermostat.

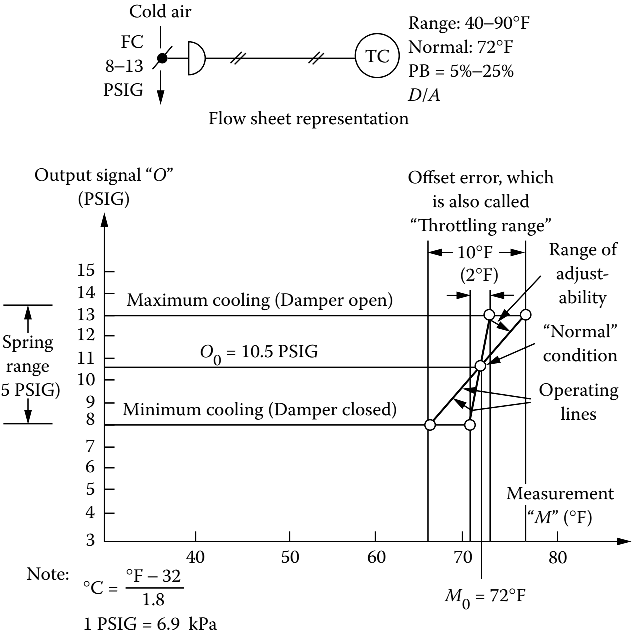
Proportional sensitivity is the amount of change in the output signal pressure that results from a change of one unit in the measurement (2.5 PSIG/°F in Figure 7.9c).

Gain is the ratio between the sizes of the changes in control output and measurement input. In case of Figure 7.9c, a 100% change in output (5 PSIG, moving the damper from fully open to fully closed) will result from a 2°F (1°C) change in measurement, which represents only 4% of the thermostat span of 40–90°F (6.6–32°C). Therefore, the gain of this thermostat is 25.

Proportional band (PB) is related to gain as follows: PB = 100/G = 100/25 = 4%. Therefore, the proportional band of the thermostat in Figure 7.9c is 4%.

Having defined the "normal" conditions (M_0 and O_0) and also the slope of the operating line, the behavior of the thermostat is now fully defined.

Gain or Sensitivity Adjustment The simplest thermostats are manufactured with fixed sensitivities. Such a unit was illustrated in Figure 7.9c, having a fixed proportional sensitivity of 2.5 PSIG/°F (0.3 bar/°C). Control flexibility is improved in those designs where the proportional sensitivity is adjustable. Figure 7.9e illustrates a thermostat with a 5:1 range of gain adjustment, which is typical to standard thermostats. Lowering the proportional sensitivity tends to improve stability, but it also increases the offset error due to the widening of the throttling range.



Range of adjustability:
Offset error or throttling range: 2 to 10°F (1.1 to 5.6°C)
Proportional sensitivity: 2.5 to 0.5 PSIG/°F (31 to 6.3 kPa/°C)
Proportional band: 5% to 25%
Gain: 20 to 4

FIG. 7.9e
The features and characteristics of a thermostat with adjustable sensitivity.

Thermostat Action and Spring Range

The thermostat in Figure 7.9c is said to be direct acting (D/A) because its output signal is increased as the measurement rises. If, instead of the Fail Closed damper, a Fail Open damper were used, a reversal in the thermostat action would be required, because now maximum cooling would take place when the thermostat output signal is low. Hence, in that case a reverse-acting (R/A) thermostat would be used, and the left-to-right slope of the operating line in Figure 7.9c would change to right-to-left.

Spring Ranges The operating line in Figure 7.9c varies with the spring range of the final control element. The typical spring ranges that are available are listed below:

Fail Closed HVAC Quality Dampers

A—3 to 7 PSIG (0.2 to 0.5 bar)
B—5 to 10 PSIG (0.35 to 0.7 bar)
C—8 to 13 PSIG (0.55 to 0.9 bar)

HVAC Quality Valves

D—Fail Open, 4 to 8 PSIG (0.9 t 0.55 bar)
E—Fail Closed, 9 to 13 PSIG (0.6 t 0.9 bar)
F—Three-way, 7 to 11 PSIG (0.5 to 0.76 bar)

Speed or Blade Pitch Positioners (Fail Closed)

G—3 to 15 PSIG (0.2 to 1.0 bar)

Figure 7.9c illustrated the operating line of a thermostat with a 2.5 PSIG/°F (0.3 bar/°C) proportional sensitivity in combination with a final control element having a type *C* spring. If the range spring of the final control element is changed, this would also change the operating lines, as illustrated in Figure 7.9f.

From Table 7.9g, it is obvious that the range spring selection can substantially affect the throttling range and the apparent proportional band. The wider the throttling range, the larger the control error (offset or drift away from the "normal" measurement value). On the other hand, the wider the throttling range, the more stable (less cycling) the final control element is likely to be.

Therefore, the trade-off is between lower stability or higher offset error. By narrowing the spring ranges to 4 or 5 PSIG (0.3 or 0.35 bar), the conventional HVAC control manufacturers have selected lower stability as the more acceptable of the two undesirable options. The process control industry has made just the opposite choice, as shown in Figure 7.9f by the 12 PSIG (0.8 bar) spring line (type *G*). This selection stems from the desire to maximize stability while being unconcerned with offset error because it was eliminated by the addition of the integral mode.

Thermostat Design Variations

Figure 7.9h illustrates the design of the simplest thermostat that is manufactured. This fixed-proportional controller uses

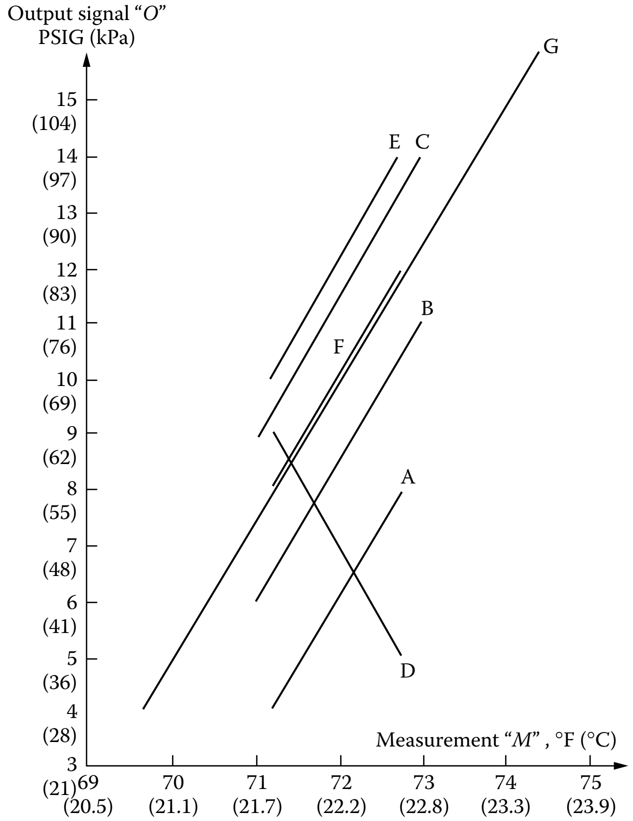


FIG. 7.9f

Illustrating the effect of damper or valve spring range on the gain or throttling range of the thermostat.

a flapper arrangement, which moves in front of a nozzle as the temperature detected by a bimetallic element changes relative to the manually adjusted "normal" value. Air at about 20 PSIG (140 kPa) is supplied through a restriction to the open nozzle, the back-pressure of which is inversely proportional to the distance between nozzle and flapper.

Because the A/B ratio is fixed in Figure 7.9h, the proportional sensitivity (K_c = change in output pressure per °F measured) is also fixed. Figure 7.9q describes a humidistat design in which the proportional sensitivity is adjustable.

Due to the small restriction and small nozzle openings in Figure 7.9h, the resulting output airflow is rather small, around 1.0 SCFH (0.028 m^3/hr). This type of design is also referred to as "nonrelay" or "low volume" design. The 1.0 SCFH air capacity can be insufficient to fill connecting tubing and operate final control elements. In order to increase the air capacity of a thermostat, a booster or repeater relay can be added.

Such "relay type" or "high-volume" thermostats will usually provide an output airflow of 10–30 SCFH (0.3–0.84 m^3/hr), which is sufficient for most applications. In the case of the relay-type design (Figure 7.9q), the nozzle back-pressure, instead of operating a final control element directly, is sent to the bellows chamber and acts against the bellows. Because the bellows has some stiffness (spring gradient), the pilot valve plug is positioned between the inlet and outlet ports in accordance with the nozzle back-pressure. A low nozzle back-pressure positions the valve plug to the left, throttles the exhaust port, and causes a high output pressure.

The advantages of adding the pilot are (1) the actuating signal vs. output pressure relationship can be made linear, and (2) the capacity for airflow can be considerably increased.

Special-Purpose Thermostats

Application engineers can choose from a fairly large variety of design features when specifying thermostats, because they can not only be electromechanical, pneumatic, or electronic, but they can also

- be indicating or blind
- be direct or reverse acting
- automatically switch their actions in response to a pneumatic or electronic signal
- have bimetallic, filled, or electronic sensing elements
- have local or remote set points
- have their set points under key, concealed, or externally adjustable.

Advanced Features If the set point of a pneumatic thermostat is adjusted remotely by an air signal, each 1 PSIG (0.07 bar)

TABLE 7.9g

Thermostat Gain (Proportional Sensitivity) and Throttling Range as a Function of Its Spring Range

Range Spring Type	PB (%)	GG	Proportional Sensitivity PSIG/°F (bar/°C)	Throttling Range °F (°C)	"Normal" Output PSIG (bar)	Spring Range PSIG (bar)
A	3.2	31	2.5 (0.3)	1.6 (0.9)	5.0 (0.35)	3–7 (0.2–0.5)
B	5.0	20	2.5 (0.3)	2.0 (1.1)	7.5 (0.52)	5–10 (0.35–0.7)
C	5.0	20	2.5 (0.3)	2.0 (1.1)	10.5 (0.72)	8–13 (0.55–0.9)
D	3.2	31	2.5 (0.3)	1.6 (0.9)	6.0 (0.4)	4–8 (0.3–0.55)
E	3.2	31	2.5 (0.3)	1.6 (0.9)	11.0 (0.76)	9–13 (0.6–0.9)
F	3.2	31	2.5 (0.3)	1.6 (0.9)	9.0 (0.6)	7–11 (0.5–0.76)
G	9.6	10	2.5 (0.3)	4.8 (2.7)	9.0 (0.6)	3–15 (0.2–1.0)

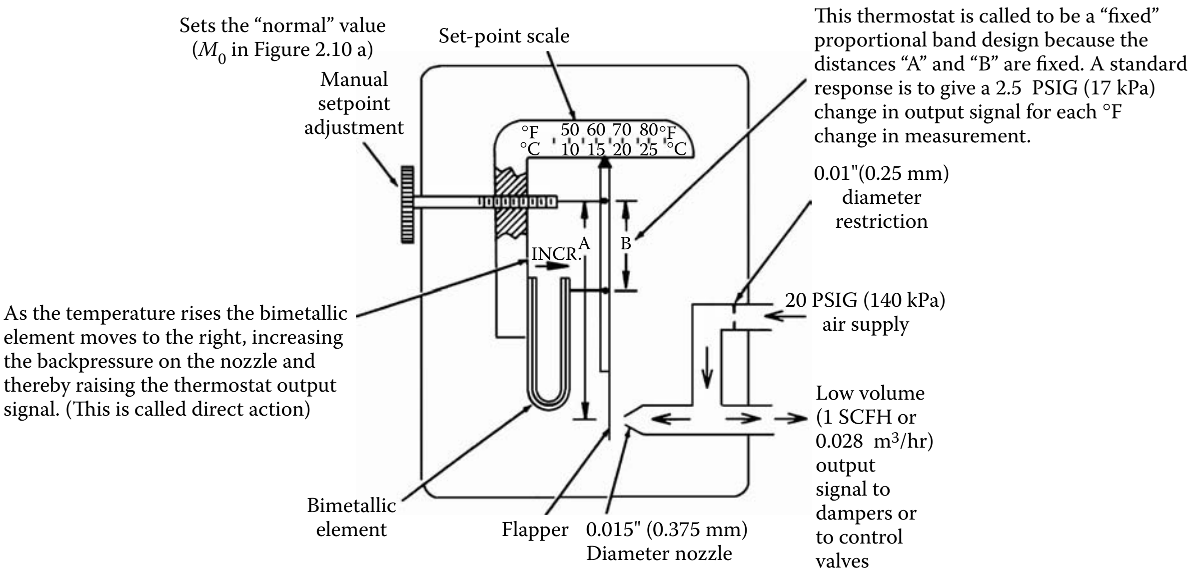

FIG. 7.9h

Direct-acting bimetallic thermostat with manual set point and fixed proportional band. The output airflow is limited because no booster relay is included. For this reason, it called a "low-volume" thermostat.

change in set point pressure will move the set point by an adjustable preset amount. The range of this adjustment is usually from 0.15–1.4°F (0.1–0.8°C) per 1 PSIG (0.07 bar). If the set point is to change as a function of the time of day, a timer can automatically operate a solenoid and thereby switch the set-point signal.

Some of the more recently developed and more advanced thermostat features include:

Dual Set Points Dual set point thermostats will switch their settings in response to a change in the air supply pressure. Both set points can be manually adjustable, with the day setting made by external thumbwheel and the night setting concealed internally.

One design variation is a dual thermostat that has two set points, one corresponding to the minimum, the other to the maximum allowable space temperature. These thermostats can use their dual outputs to operate a variable air volume (VAV) damper to cool the space and a reheat coil to heat it (Figure 7.9i).

In other control systems the dual outputs of the thermostat can be used to throttle the hot or the cold water to condition the air being supplied to the room (Figure 7.9j).

Night–Day or Set-Back These thermostats will operate at different "normal" temperature settings for day and night. They are provided with both a "day" and "night" setting dial, and the change from day to night operation can be made automatic for a group of thermostats.

The *pneumatic day–night* thermostat uses a two-pressure air supply system, the two pressures often being 13 and 17 PSIG (89.6 and 117 kPa) or 15 and 20 PSIG (103.35 and 137.8 kPa).

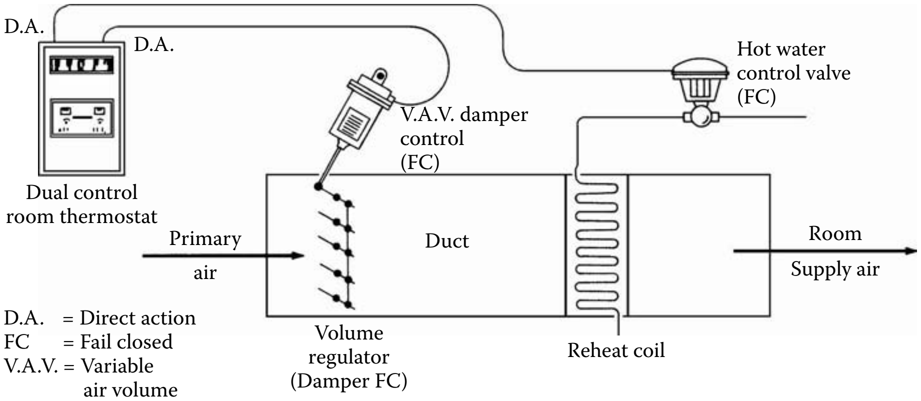

FIG. 7.9i

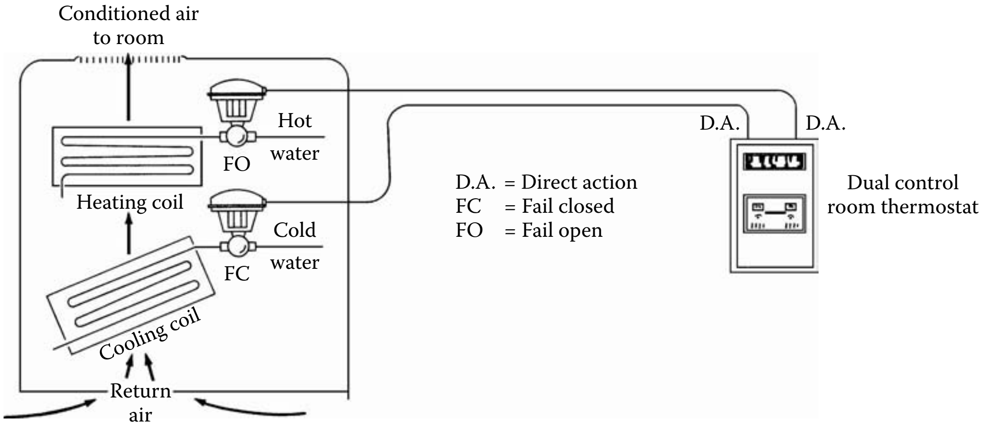

FIG. 7.9j
Dual thermostat installed to control a heating and a cooling coil. (Courtesy of Powers Controls.)

Changing the pressure at a central point from one value to the other actuates switching devices in the thermostat and indexes them from day to night or vice versa. Supply air mains are often divided into two or more circuits so that switching can be accomplished in various areas of the building at different times. For example, a school building may have separate circuits for classrooms, offices and administrative areas, the auditorium, and the gymnasium and locker rooms. In some of the electric designs, dedicated clocks and switches are built into each thermostat.

Heating–Cooling or Summer–Winter This thermostat can have its action reversed and, if desired, can have its set point changed by means of indexing. It is used to actuate controlled devices, such as valves or dampers, that regulate a heating source at one time and a cooling source at another. It is often manually indexed in groups by a switch, or automatically by a thermostat that senses the temperature of the water supply, the outdoor temperature, or another suitable variable.

In the heating–cooling design there frequently are two bimetallic elements, one being direct acting for the heating mode, the other being reverse acting for the cooling mode. The mode switching is done automatically in response to a change in the air supply pressure, similarly to the operation described for the day–night thermostats.

Limited Control Range These thermostats allow the occupant of an office to move the set point to any value desired, but will disregard any setting that exceeds the limit value. For example, in heating applications, the limit could be 74°F (23°C). In this case the space temperature will be limited to a maximum of 74°F, regardless of the setting by the occupant. In the cooling season the minimum limit value of 75°F (24°C) can be set for cooling. This is done internally without placing a physical stop on the setting knob.

Zero Energy Band Control The idea behind *zero energy band* (ZEB) control is to conserve energy by not using any when the room is comfortable. Zero energy band thermostats will provide heating when the zone temperature is below 72°F (22°C) and will provide cooling when it is above, say, 78°F (25.6°C) (these are adjustable settings), and in between, they will neither heat nor cool.

One way to achieve this goal is to use the dual thermostat illustrated in Figures 7.9i and 7.9j. If in these installations a single set-point thermostat was used instead of a dual one, energy would be wasted, because as soon as heating was stopped, cooling would be initiated (Figure 7.9k). This is wasteful, as no energy needs to be added or removed from a space that is comfortable as it is (within the ZEB band). This approach can reduce the yearly operating cost by up to about 33%.

ZEB control can be accomplished in one of two ways. The dual set-point approach is shown on the right of Figure 7.9l. The single set-point and single output approach is illustrated on the left side of Figure 7.9l.

In the single set-point, spilt-range configuration, the cooling valve fails closed and is shown to have an 8–11 PSIG (0.55–0.76 bar) spring range, while the heating valve is selected to fail open and has a 2–5 PSIG (0.14–0.34 bar) range. Therefore, between 5 and 8 PSIG (0.34 and 0.55 bar) both valves are closed, and no pay energy is expended while the thermostat output is within this range. The throttling range is usually adjustable from 5–25°F (3–13°C). Thus, if the ZEB is 30% of the throttling range, it can be varied from a gap size of 1.5°F (.85°C) to 7.5°F (4.2°C) by changing the throttling range (or gain).

ZEB control can also allow buildings to become self-heating by transferring interior heat to the perimeter. (For a detailed discussion of self-heating, see Section 8.2.)

Slave or Submaster This thermostat has its set point raised or lowered over a predetermined range, in accordance with variations in the output from a master controller. The master controller can be a thermostat, manual switch, pressure controller, or similar device. For example, a master thermostat measuring outdoor air temperature can be used to adjust a submaster thermostat controlling the water temperature in a heating system. Master–submaster combinations are sometimes designated as single-cascade action.

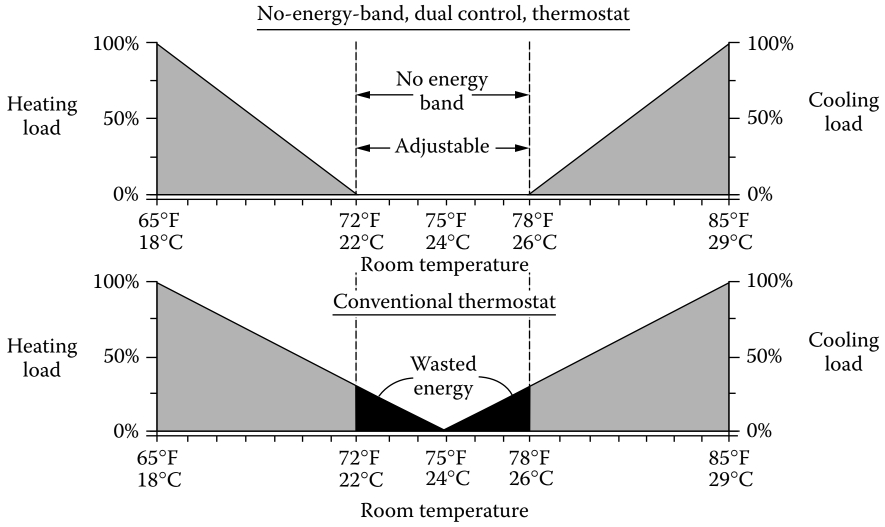

FIG. 7.9k
Energy can be saved by neither cooling nor heating a space if its temperature is within a zone that is comfortable.

When such action is accomplished by a single thermostat having more than one measuring element, it is known as compensated control.

Split-Range Control *Multistage* thermostats are designed to operate two or more final control elements in sequence. While the split-range approach is a little less expensive than the dual set-point scheme (shown on the right of Figure 7.9l), it is also less flexible and more restrictive. The two basic limitations of the split-range approach are:

1. The gap width can only be adjusted by also changing the thermostat gain; maximum gap width is limited by the minimum gain setting of the unit.
2. In this design, the heating valve must fail open, which is undesirable from an energy conservation point of view.

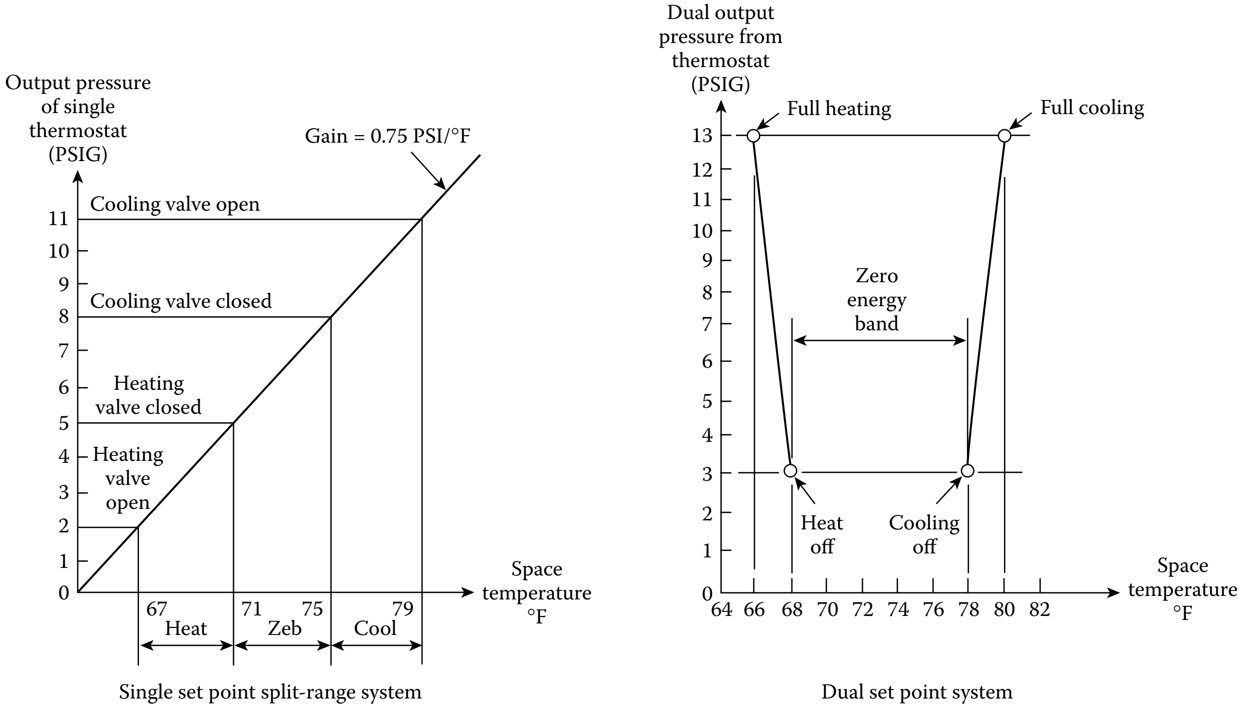

FIG. 7.9l
The zero energy band (ZEB) can be obtained by single set-point split-range design (left) or by dual set-point system (right).

These limitations are removed when a dual set point, dual output thermostat is used. Here both valves can fail closed and the bandwidth is independently adjustable from the thermostat gain. The gains of the heating and cooling thermostats are also independently adjustable. In Figure 7.9l, the heating thermostat is reverse acting and the cooling thermostat is direct acting.

For a detailed discussion of controlling and optimizing HVAC systems, refer to Section 8.2.

HUMIDISTATS

Basically the same design variations are available for humidity control as have already been discussed in connection with thermostats. By replacing the temperature sensor element, such as a bimetallic spring, with a humidity-sensitive sensing element, such as a polymer, a humidistat can be obtained.

A *wet-bulb* thermostat is also often used for humidity control with proper control of the dry-bulb temperature. A wick, or other means for keeping the bulb wet, and rapid air motion to ensure a true wet-bulb measurement are essential.

A *dew-point* thermostat is a device designed to control from dew-point temperatures.

Just like thermostats, humidistats can also be on/off, pneumatic, electric, electronic, or microprocessor-based digital. For the design features of these and for a discussion of the nature of fixed and narrow proportional control and the resulting offset, the reader is referred to the previous paragraphs.

Thermometers and hygrometers can also be combined into single instruments, and their microprocessor-operated versions can also be provided with memory, so they can recall past temperature and humidity records and can allow remote access to such data.

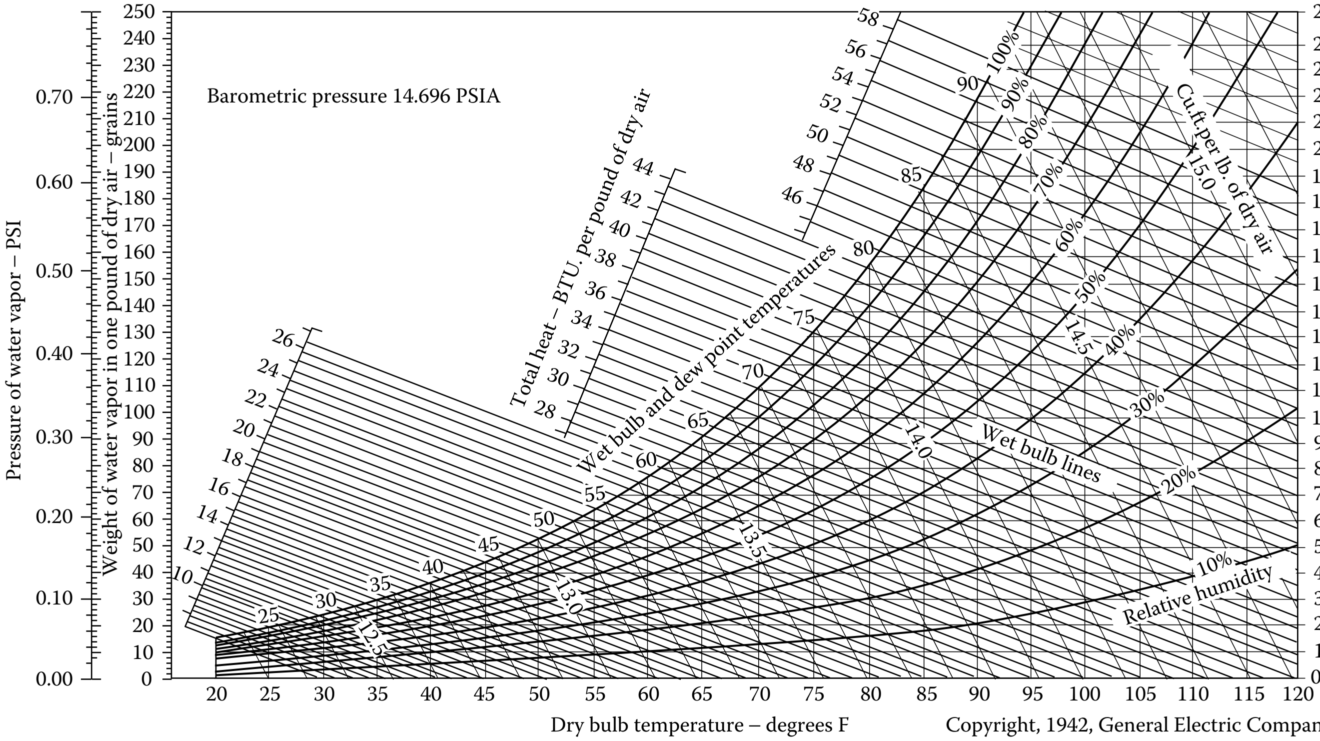
Relative Humidity Sensors

Humidity refers to the water vapor contained in the air at a particular temperature. Warm air has a greater capacity for water vapor than does cold air. Relative humidity is the mole fraction of moisture in air to the mole fraction of moisture in a saturated mixture at the same temperature and pressure. In other words, RH is the ratio of how much water vapor is in the air vs. the maximum it could contain at the particular pressure and temperature.

Relative humidity is the ratio of the actual partial pressure of the water vapor to the saturation vapor pressure at a particular temperature. Therefore, in a room that has 50% RH at 20°C, the RH will drop to 37%, if the temperature rises to 25°C. (Note that temperature has no effect on the dew point temperature, which in the above example stays constant at 9.3°C.)

Relative humidity can be calculated using the wet and dry bulb temperature readings, or relative humidity can be read from a psychrometric chart such as the one shown in Figure 7.9m.

The sensor in a humidistat can be moisture-sensitive hair, cellulose, synthetic polymer fiber, surface conductivity, or resistance or capacitance elements. Other, more accurate



Copyright, 1942, General Electric Company

FIG. 7.9m

One can read the relative humidity of air from the above psychrometric chart if one knows any two of the air properties shown in the chart.

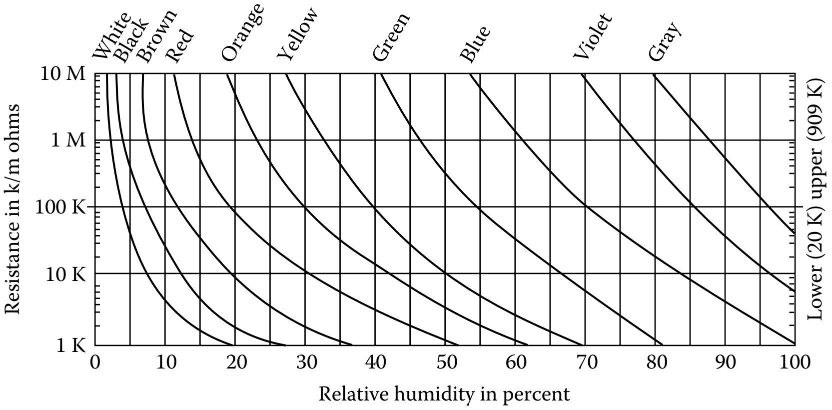


FIG. 7.9n
The chart describes the RH-to-resistance relationship of ten color-coded Dunmore sensor elements. (Courtesy of Ohmic Instruments Co.)

humidity and moisture sensors are also available and are discussed in detail in Section 8.32 in the first volume of this handbook.

Cellulose Hygrometers Cellulose strips or other shapes are used to measure humidity. Like human hair and synthetic materials, cellulose changes its dimensions as the water vapor concentration varies. This elongation has been used to build dial and digital indicators and also relatively inexpensive HVAC-type thermostats, transmitters, and recorders. The operation of the cellulose element instruments involves the detection of dimensional change of the element.

Solution Resistance Elements (Dunmore Cells) The Dunmore sensor consists of a wire grid on a insulating substrate that is coated with lithium chloride solution. Lithium chloride is hygroscopic and therefore takes up moisture from the air. The resulting resistance of the sensor is an indication of the relative humidity in the air. One disadvantage of this otherwise widely used, inexpensive, and good sensor is its narrow range.

Figure 7.9n illustrates the ranges of ten color-coded elements that are used by one manufacturer to cover the full range of 0–100% RH. Wide-range Dunmore sensors can be configured by placing several narrow-range elements in a single housing and connecting them to a microprocessor-based readout.

Polystyrene Surface Resistivity (Pope Cells) The Pope cell is similar to the Dunmore element, but instead of lithium chloride solution it uses polystyrene as a substrate for the conductive wire grid. In this design the polystyrene is treated with sulfuric acid, which produces a thin hygroscopic layer on its surface.

Changes in humidity cause large changes in the impedance of this layer, and because the operating portion of the sensor is only its surface, its speed of response is fast — only a few seconds. An AC-excited Wheatstone bridge circuit can be used to measure the impedance. The output signal is nonlinear and can cover a range of 15–99% RH. This type of humidity probe can be mounted on the wall or in ducts (Figure 7.9o).

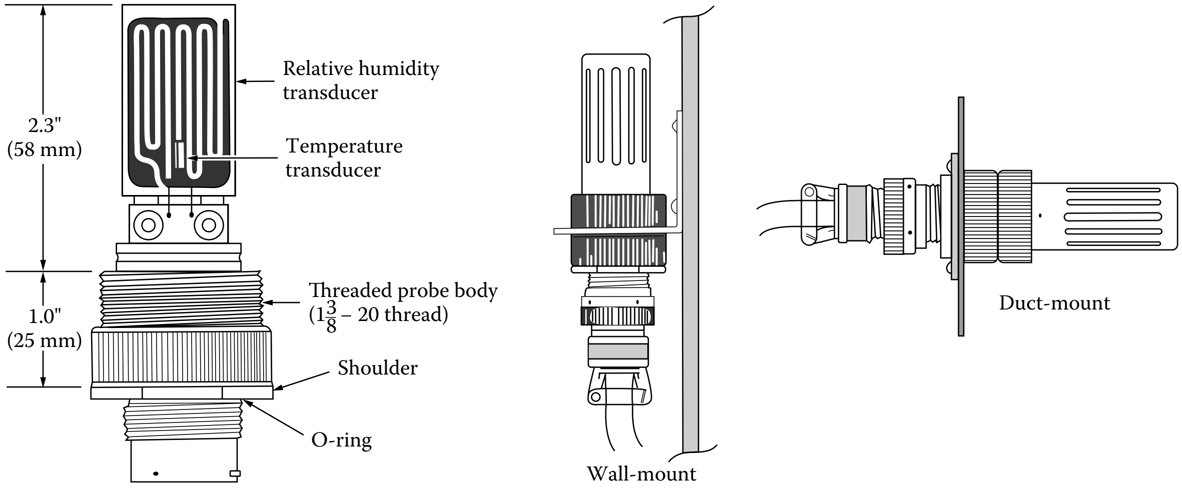

FIG. 7.9o

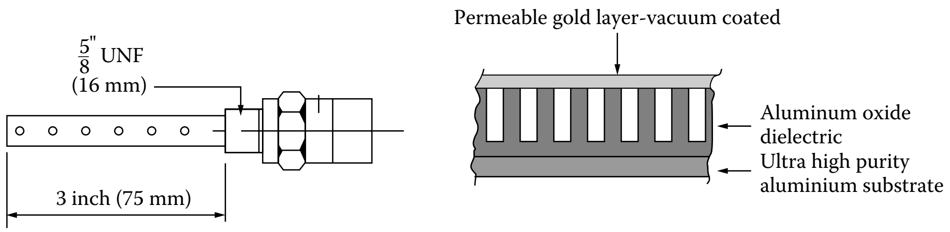

FIG. 7.9p
Thin-film aluminum oxide capacitance element packaged as a probe. (Courtesy of Michell Instruments Ltd.)

Thin-Film Capacitance The largest number of manufacturers use some form of a capacitance measurement to detect humidity or dew point in air.

Metal Oxide Sensor One variation is to form a capacitor by depositing a layer of porous aluminum oxide on a conductive aluminum substrate and coating the oxide with a thin film of condensation from evaporated gold. The aluminum substrate and the gold film serve as the electrodes of the capacitor (Figure 7.9p).

When exposed to air, the water vapors penetrate through the gold layer into the aluminum oxide dielectric and are absorbed by it. The amount of water absorbed determines the capacitance registered by the sensor. Some suppliers "dope" the aluminum oxide dielectric with lithium chloride to extend its range down to dew points of –94°F (–70°C). The disadvantages of lithium chloride doping include the need for individual calibration, the slowing of the response, and the potential for shorting due to condensation.

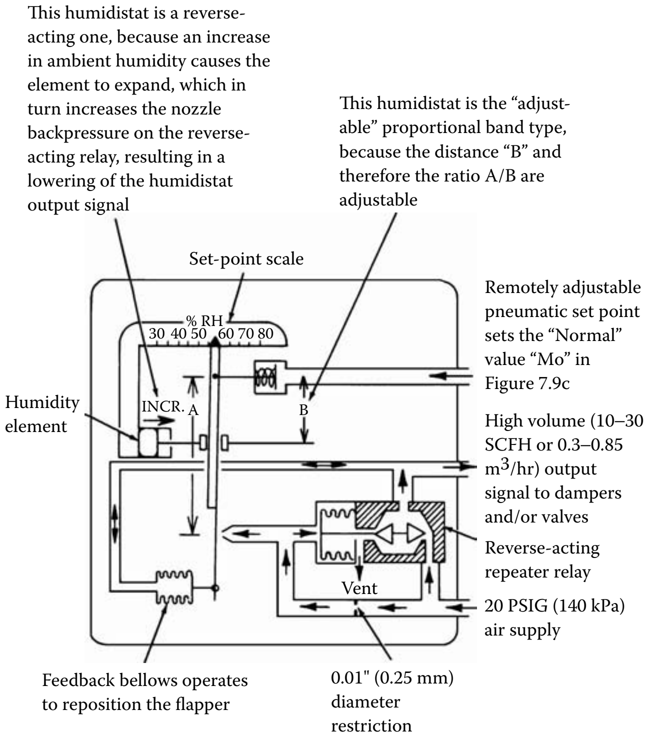
The accuracy of the aluminum oxide moisture sensor is low; each sensor requires a separate calibration curve, which is nonlinear; and the unit must be periodically recalibrated to compensate for aging and contamination. These sensors are designed for low dew-point measurements, but can be disabled if exposed to high humidity or if wetted. The advantages of these sensors include their small size, their probe-type packaging, and the fact that their measurement range is wide and is well suited for the detection of low dew points. As a consequence of these characteristics, they are widely used in such applications as HVAC, where cost is the primary concern and accuracy of measurement is not critical.

Polymer Sensor Design variations of the capacitance-type humidity sensor include the replacement of aluminum oxide dielectric with hygroscopic polymer dielectrics. These units consist of a capacitive polymer sensor bonded to a resistive temperature sensor. The polymer sensor detects humidity directly, while dew point is calculated by a microprocessor, which also reads the temperature. These sensors are claimed to provide better linearity and allow the use of longer lead wires, because their low-frequency operation reduces the effects of stray capacitance. Other advantages include resistance to contamination by various chemical vapors.

Polymer sensors are immune to condensed water and therefore can have a wider range than metallic oxide ones. These units are available as transmitters with intelligent electronics and are capable of detecting low dew points while requiring reduced maintenance due to their stability.

Humidistat Design Features

As shown in Figure 7.9q, the pneumatic humidistats are similar in design to thermostats, except that the bimetallic measuring element is replaced by a humidity-sensitive element. A common humidity-sensitive element is cellulose acetate butyrate. This substance expands and contracts with changes in relative humidity, and the resulting movement can be used to operate the flapper of the pneumatic humidistat shown in Figure7.9q or it can open and close the contacts of electric humidistats.



This humidistat is a reverse-acting one, because an increase in ambient humidity causes the element to expand, which in turn increases the nozzle backpressure on the reverse-acting relay, resulting in a lowering of the humidistat output signal

This humidistat is the "adjustable" proportional band type, because the distance "B" and therefore the ratio A/B are adjustable

Remotely adjustable pneumatic set point sets the "Normal" value "Mo" in Figure 7.9c

High volume (10–30 SCFH or 0.3–0.85 m^3/hr) output signal to dampers and/or valves

Feedback bellows operates to reposition the flapper

0.01" (0.25 mm) diameter restriction

FIG. 7.9q
Reverse-acting humidistat with pneumatic set point and adjustable proportional band. The use of the repeater relay increases the humidistat output flow capacity, and therefore this design is also referred to as "high volume."

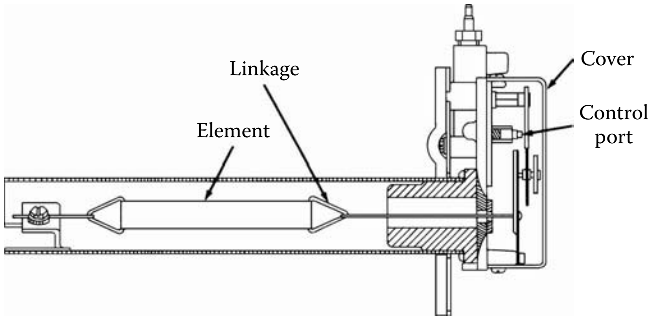


FIG. 7.9r
Duct-mounted humidistat. (Courtesy of Johnson Controls Inc.)

The choice of humidistat features and characteristics is similar to those of thermostats.

1. They can be direct or reverse acting.
2. They can be high or low volume (relay type or non-relay type).
3. The "normal" value can be set manually or by remotely adjustable pneumatic signal.
4. The proportional sensitivity determined by the A/B ratio can be fixed or adjustable.
5. Feedback bellows can be added to minimize the effects of variations in supply pressure or temperature, to reduce output leakage, and to increase the range of adjustability of the proportional sensitivity setting.

Humidistats are also installed in air ducts to control upper and lower limits of the relative humidity of the air. One such duct-mounted device is illustrated in Figure 7.9r. This unit is usually set for either 85% RH or for 35% RH.

Types of Drives:	A. Mechanical drives B. Hydraulic, hydroviscous, and fluid coupling drives C. Magnetic particle, fluid, and eddy current drives D. Variable voltage E. Variable-speed DC, thyristor DC F. Variable-frequency AC F1. Voltage source, pulse-width modulated (PWM) F2. Current source F3. Load commutated inverter (LCI) on synchronous motor F4. Power recovery versions of F1, F2, or F3
Abbreviations Used:	ASCI—Autosequentially commutated current-fed inverter GTO—Gate-turn-off thyristor IGBT—Insulated gate bipolar transistor LCI—Load commutated inverter PU—Per unit PWM—Pulse width modulated RMS—Root mean square SCR—Silicon-controlled rectifier VFD—Variable-frequency drive VVVF—Variable-voltage variable-frequency drive
Size Range:	A. 1 to 100 hp (0.75–75 kW) B. Up to 4000 (up to 3MW) C. Air-cooled up to 900 hp (670 kW); water-cooled up to 18,000 hp (13.5MW) D. 10 to 100 hp (7.5–75 kW) E. From under 1 to 500 hp (to 375 kW) F1. From under 1 to 500 hp (to 375 kW) F2. From under 100 to over 1000 hp (75 to 750 kW) F3. From 100 to 20,000 hp (75 kW to 15MW); generally above 1000 hp (750kW)
Speed Turndown:	A. 6:1 B. 3:1 to 40:1 C. 5:1 to 10:1 D. Low E. 10:1 with standard and 100:1 with tachometer feedback F. 3:1
Efficiency at 70% of Full Speed:	A. 50% B. 55% C. 58% D. 52% E. 80% F. 78%
Inaccuracy of Speed Control:	2 to 5% in standard (can do better with feedforward) and 0.1 to 1% with tachometer feedback designs

Variable Speed Drive Costs (Excluding the Motor):
E. For a 200 hp (150 kW) motor, a single converter, and thyristor DC drive: $13,000 F1 and F2. For a 200 hp (150 kW) induction motor: $20,000
F3. $200/hp ($270/kW) at around 1000 hp (750 kW) size and $100/hp ($130/kW) at around 5000 hp (3.75MW) size
(For the costs of other sizes and designs, see Tables 7.10r and 7.10u.)

INTRODUCTION

This section begins with a brief explanation of the role of variable-speed drives in improving the efficiency of transporting materials. After that, the different variable-speed drive designs are described, starting first with the older electromechanical designs and then proceeding to the more modern electrical and solid-state drives.

TRANSPORTATION EFFICIENCY

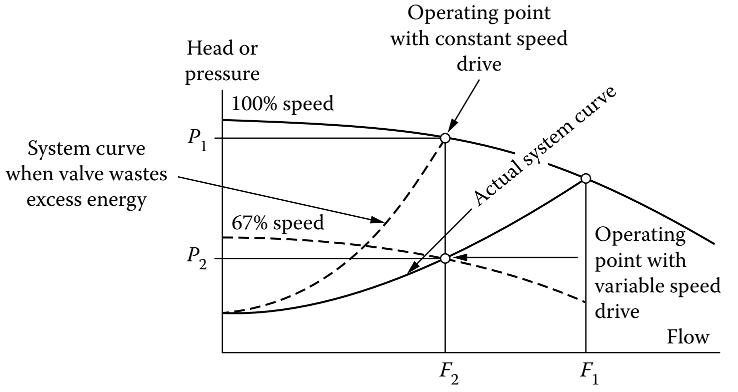
Constant or variable-speed drives can be applied to the transportation of liquids and gases. The amount of discharge pressure needed in these transportation systems is a function of the flow rate demanded by the process, the load. This relationship between the required flow and pressure is called the system curve. This curve rises with load (Figure 7.10a), while the pump curve drops with increasing flow. When constant speed drives are used, the pump, fan, or compressor curve is fixed, and therefore it cannot coincide with the system curve at more than one point.

As shown in Figure 7.10a, a control valve or damper needs to be introduced to burn up (waste) the excess energy, which should not have been introduced in the first place. Variable-speed drives eliminate this waste by shifting the pump or fan curve to cross the system curve, thereby eliminating waste by introducing only as much transportation energy as is needed to meet the load (Figure 7.10a). This subject is covered in Chapter 8, where the control of variable-speed pumps, compressors, fans, and turbines is covered in some detail.

CHARACTERISTICS OF VARIABLE-SPEED DRIVES

All drives for centrifugal pumps, regardless of type, must have certain characteristics to make them acceptable for operating centrifugal pumps. Some of these characteristics are as follows:

1. Broad speed turndown without damage to the motor or variable speed drive. The operating speed range for most variable speed pumps is from 50 to 100% of the synchronous speed. However, through misadjustment



Speed, %	*Flow, %*	*Horsepower required, %*
100	100	100
90	90	73
80	80	51
70	70	34
60	60	22
50	50	13
40	40	6
30	30	3

FIG. 7.10a

When pumping with a constant speed drive, energy is wasted, as the unnecessarily introduced pumping energy is burned up in a flow control valve. In contrast, when the flow rate is reduced by lowering the speed, such energy is not introduced in the first place.

or momentary system dynamics, the controls may cause the pump to run at zero speed. The drive must be able to function with zero pump speed without damage or actuation of circuit protection devices such as thermal overloads for a significant period of time.

2. Control repeatability, so that fluid system controls can achieve desired pump speeds at all loads.
3. Reliability. The variable-speed drive and motor must be designed to fit field operating conditions that vary appreciably in centrifugal pump applications. Ambient temperature in the field is often outside the "nominal" rating of the motor. Ambient temperature of the drive electronics may also be other than anticipated by the designer.
4. Serviceability. The personnel normally employed for maintenance of motors and pumping equipment must be capable of servicing the electronic, electrical, or mechanical equipment involved on each specific application.

ELECTROMECHANICAL DRIVES

Electromechanical drives include those that utilize an electrical motor to drive a mechanical, speed-changing device that is connected to the centrifugal pump. These include the following:

1. V-belt drives
2. Hydraulic couplings
3. Hydroviscous couplings
4. Eddy current couplings

There are a great number of methods for speed adjustment of rotating machines. These methods fall into two categories: speed adjustment of the prime mover and speed adjustment through a transmission connecting the driver to the driven machine.

Within each of these two groups several degrees of sophistication are possible, ranging from manually actuated stepwise speed changes to continuously variable automatic speed changers. Each method of speed control offers certain advantages and disadvantages (Table 7.10b) that must be weighed against the design criterion to permit a proper selection.

Mechanical Variable-Speed Drives

Stepped Speed Control Mechanical methods of speed adjustment offer a number of gear and pulley devices for both stepped and continuously variable-speed control. Stepped speed control methods provide setting a number of speeds very accurately. However, they are not readily adaptable to automatic process control.

The stepped pulley system shown in Figure 7.10c is one of the earliest methods of speed adjustment. Its advantages are low cost and simplicity, but belt slippage contributes to inefficiency, high maintenance, and reduced speed control. Two factors to be considered in the design of a stepped pulley system are the proper ratio of pulley diameters to obtain the desired speeds and proper pulley dimensions to maintain belt tension for all positions.

Pulley dimensions for a system such as in Figure 7.10c can be determined from the relationships in Equations 7.10(1) and 7.10(2).

$$\frac{\pi}{2}(R_1 + r_1) + \frac{(R_1 - r_1)^2}{4d} = \qquad \mathbf{7.10(1)}$$

$$\frac{\pi}{2}(R_2 + r_2) + \frac{(R_2 - r_2)^2}{4d}\frac{S_2}{S_1} = \frac{R_2}{r_2} \qquad \mathbf{7.10(2)}$$

The variables in the above equations are defined in Figure 7.10c.

TABLE 7.10b

Features and Applications of Various Rotary Drives

	Type of Drive				
Service and Feature	*Electric Motor*	*Eddy Current or Magnetic Couplings*	*Mechanical Stepped-Speed Transmissions*	*Continuously Variable Mechanical Drives*	*Hydraulic Drives*
Very wide range of speeds	✓				
Few speed steps with remote control	✓				
Few speed steps with local and manual output	✓		✓		
Very high output power at variable speed	✓	✓			
Vibration at load or driver		✓			
Small or moderate load with narrow speed range				✓	
Accurate speed control	✓	✓			✓
Shock loads, frequent overloads					✓
Speed reversal required	✓		✓		✓

Gear transmissions offer high efficiency of power transmission at precise stepped speed control. For speed changes of gear train drives, either clutches or brakes are required or the change must be made at rest. Epicyclic gears, such as planetary gears, offer the most compact unit, operating quality, and high efficiency. However, auxiliary clutches and brakes are required, and the cost is therefore higher than that of other gear drives. The complexity of control arrangements increases rapidly with the number of speeds required, making the planetary gear drive impractical above four or five speeds.

Continuously Variable-Speed Drives The cone pulley systems in Figure 7.10d is a natural evolution of the stepped pulley system shown in Figure 7.10c. Cone pulleys are designed similarly to stepped pulleys. A series of diameters is calculated equidistant on the pulley axis. The diameter end points are joined to form the pulley contour.

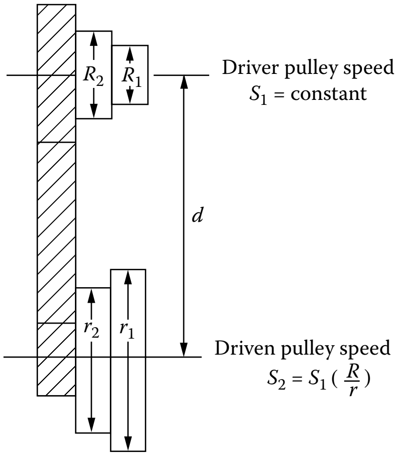


FIG. 7.10c
Early method of speed adjustment: the stepped pulley system.

The cone pulley is inherently inefficient, because contact surface speed varies across the belt, causing slippage. Belts must be kept narrow to reduce slippage and wear, and thus the capacity for power transmission is reduced. Belt guides at the pulleys are required to hold the belt in position. These guides must move simultaneously for speed changes.

Variable-Pitch Pulleys Cone pulleys were the forerunners of the more sophisticated variable-pitch pulley systems, which permit continuous, automatic speed adjustments over wide ranges. Speed adjustment in all of these systems is obtained by means of sliding cone face pulleys or sheaves, whose effective diameter can be changed.

A simple variable-pitch sheave is shown in Figure 7.10e. Two flanges are mounted on a threaded hub. The flanges are set to the desired spacing and locked in place with a set-screw. Speed adjustments are accomplished by changing the flange spacing, producing in effect a pulley of different diameter. This method is very economical, but it requires stationary

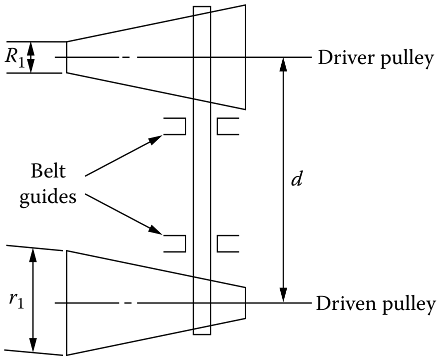

FIG. 7.10d
Continuous variation of speed can be provided by the cone pulley system.

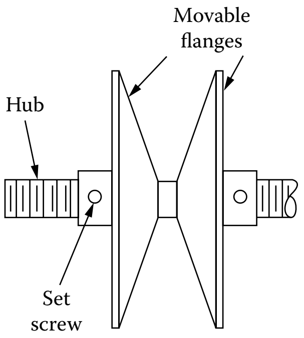

FIG. 7.10e
Automatic speed adjustments over wide ranges can be provided by the variable-pitch sheave.

speed adjustment and special adjustable motor bases to maintain belt tension.

In place of the adjustable motor base, a spring-loaded flat-face idler pulley can be used to maintain belt tension when center-to-center distance must be held constant. Alignment of driving and driven sheaves is also critical, because belt wear will be severe with poor alignment. Also, speed adjustment with this drive is limited because the set-screw must engage a flat surface.

A number of designs are available with in-motion speed adjustment. The designs vary from manual speed adjustment, through a crank or handwheel, to automatic actuators. Generally these drives use one sheave with adjustable pitch and one spring-loaded sheave that automatically adjusts itself to maintain belt tension (Figure 7.10f).

Speed adjustment is obtained by means of a mechanical linkage that moves one of the flanges of the driving sheave. The opposite flange on the driven sheave is spring loaded and moves to maintain belt tension and alignment. Radial motion of the belt along the flange faces in response to speed changes is facilitated by the rotary motion of the sheaves. When speed adjustments are made at rest, the belt cannot move radially and the adjusting linkage may be damaged. On automatic actuators, an interlock should be provided to vent air off the diaphragm whenever the drive is stopped and inhibit speed changes at rest.

Variable-pitch sheave drives are available as package units including motor. Speed adjustment ranges of 4:1 are common, but higher ranges to 10:1 are possible. Horsepower ranges to 100 hp (75 kW) are also possible. For very narrow speed ranges, drives to 300 hp (225 kW) are available.

Hydraulic Variable-Speed Drives

In hydraulic variable-speed drives, a pump with fixed or variable displacement drives a hydraulic motor, which itself can have fixed or variable displacement. The pump is driven by an electric motor at fixed speed. Output speed is controlled by changing pump or motor displacements.

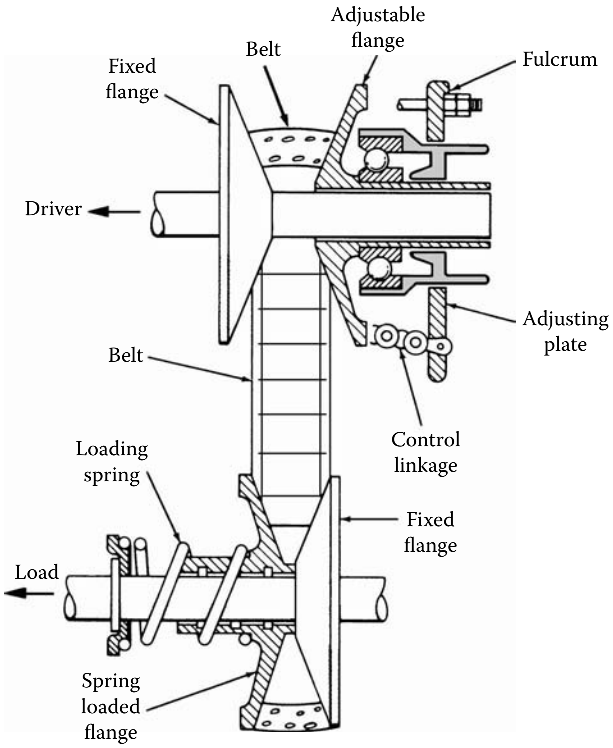

FIG. 7.10f
The main components of a continuously adjustable mechanical speed transmission system.

Pumps and motors are virtually identical, differing only in the location of the power input and output. Several designs of variable-displacement units are possible, including axial piston, radial piston, and vane types. An axial piston unit is shown in Figure 7.10g.

Of course, combinations of pumps and motors with variable or fixed displacement are possible for speed control. Pumps with variable displacement combined with motors with fixed displacement yield a variable-horsepower, fixed-torque drive. Motor speed reversal is possible by reversing the pump stroke.

Combinations of fixed-displacement pump with variable-displacement motors produce drives with fixed horsepower and variable torque. Speed reversal in this combination, however, requires the use of a valve to reverse the supply and return connections at the motor. A variable-displacement pump in conjunction with a variable-displacement motor has characteristics intermediate between the two previously discussed combinations. Range of speed control, however, is widest for this combination.

Pumps and motors with fixed displacement can be used for speed control by controlling the amount of fluid delivered to the motor. This can be accomplished by means of a pressure relief valve on the pump discharge and throttling valve in the oil line to the motor. Motor reversal can also be accomplished by means of a four-way valve, reversing the oil supply

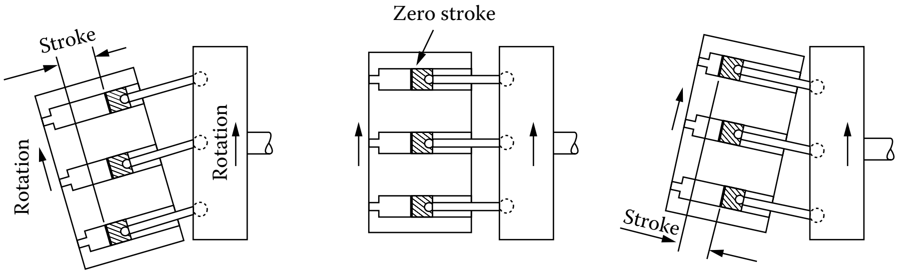

FIG. 7.10g
Axial piston pump provides the variable displacement in this hydraulic variable-speed drive.

and return lines at the motor. These methods, however, are comparatively inefficient and are not used with automatic control.

Hydraulic drives are available as pump-motor packages, or the motor can be mounted remotely and connected to the pump by hydraulic tubing. Displacement is adjustable through push-pull rods or handwheels, and both methods are adaptable for operation by hydraulic (usually integral) and pneumatic actuators or by electric motors for automatic speed control. Speed ranges are adjustable up to about 40:1 at power ratings up to 4000 hp (3 MW).

Several attributes of hydraulic variable-speed drives are clear advantages over the other types of drives discussed. Hydraulic drives offer the fastest response in acceleration, deceleration, and speed reversal. They are generally better suited than other types of drives for high shock loads, frequent speed-step changes, and reversals.

A disadvantage associated with hydraulic drives is frequent fluid leaks. Besides requiring maintenance, leakage of hydraulic fluid creates safety hazards that can preclude their use. Nonflammable hydraulic fluids are available, but the choice of compatible fluid and equipment may be limited. For offshore applications, once-through hydraulic systems are sometimes used. These are normally water-based fluids with low-marine-toxicity additives.

Hydraulic systems normally operate at pressures of 1500–3000 psi (10–20 MPa), but higher pressure equipment is available and can save weight. To avoid cavitation damage, it is usual to maintain the entire return system at a slight positive pressure in the order of 70 psi (500 kPa).

Fluid Couplings Fluid couplings consist of two coupling halves, one driven by a standard electrical motor and the other connected to the centrifugal pump. Oil is circulated in the coupling to regulate pump speed. A splitter or diverter assembly applies the oil to the coupling or bypasses it around the coupling. The pump shaft speed increases as the amount of oil supplied to the coupling is increased, thus producing a simple control system for varying pump speed.

The fluid coupling has historically been one of the most popular variable-speed devices for centrifugal pumps because of its relatively low first cost, high reliability, and ease of maintenance. It is a slip-type device, like the eddy current coupling, and has a lower efficiency curve than the variable frequency, direct current, and wound rotor regenerative types of variable speed drives.

Hydroviscous Drives Hydroviscous drives are similar to fluid couplings in configuration and operation. Instead of an oil-filled coupling, one or more disk assemblies are used, with driving and driven members pressed together by oil pressure. Increasing the oil pressure increases the pump speed; likewise, reducing the oil pressure reduces the pump speed.

The hydroviscous drive is, therefore, a slip-type device, like the eddy current coupling, and has a lower efficiency curve than most electrical-type drives. This drive often requires a more complex control system than other drives because of variations in oil pressure caused by oil viscosity or temperature.

Magnetic Variable-Speed Drives

Eddy Current Couplings The eddy current coupling was for many years the most acceptable drive for centrifugal pumps, particularly for large vertical turbine pump applications. It is rugged in design and available in both horizontal and vertical configurations. The eddy current coupling uses a standard, constant-speed motor that drives the eddy current coupling, which consists of a drum connected to the electric motor and electromagnetic pole-type rotor assembly, which is connected to the centrifugal pump, inside of and free from the drum.

The speed control system regulates the amount of flux that exists between the drum and rotor assemblies. The amount of slip or speed difference between motor and pump increases and decreases with the flux density in the coupling. Being a slip-type, variable-speed device, the eddy current coupling has a lower efficiency than the variable frequency, direct current, and wound rotor regenerative types of variable speed drives.

In most electrical machinery, eddy currents are detrimental to operating efficiency, and great pains are taken to eliminate them. In the eddy current coupling, however, these

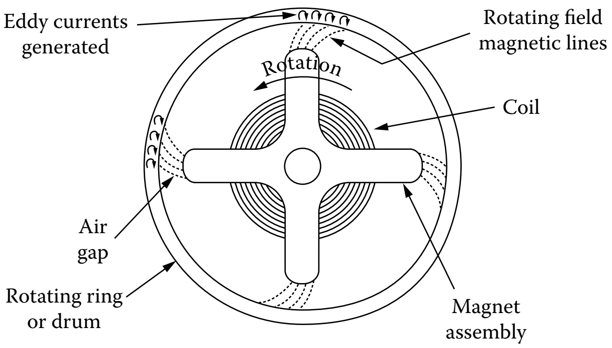

FIG. 7.10h
The main components of an eddy current coupling.

currents are harnessed and are the basis for the operation of the coupling. The eddy current coupling is a nonfriction device where input energy is transferred to the output through a magnetic field.

The eddy current coupling consists of a rotating magnet assembly separated from a rotating ring or drum by an air gap. In addition, a coil is wound onto the magnet assembly (Figure 7.10h), or, on larger units, the coil is stationary on the coupling frame.

There is no mechanical contact between the magnets and drum. When the magnet assembly is rotated, the drum remains stationary until a DC current is applied to the coil. Relative motion between magnet assembly and drum produces eddy currents in the drum, whose magnetic field attracts the magnet assembly. Attraction between the two magnetic fields causes the drum to follow the rotation of the magnet assembly. The attraction between the two rotating members is determined by the strength of the coil's magnetic field and by the difference in speed between the two members. Thus, by controlling the coil excitation, the amount of slip and, hence, the output speed can be controlled.

Slip and Slip Loss Being a slip device, the eddy current coupling must of necessity develop slip and reject the slip power in the form of heat. The amount of slip loss can be determined from Equation 7.10(3):

$$P_s = P_L \frac{S_s}{S_0} \qquad \textbf{7.10(3)}$$

where
P_s = slip loss power
P_L = load power
S_s = slip speed (rpm)
S_0 = output speed (rpm)

Slip devices always generate heat, so eddy current couplings are either air or water cooled. Small air-cooled units below 5 hp (4 kW) can be designed to dissipate all of the rated power. Air-cooled units above 300 hp (225 kW) in size can dissipate only about 25% of the rated power capacity. For this reason, air-cooled units are not recommended where cooling capacity would be greater than about 20% of rated power.

Water-cooled units are designed to dissipate the rated horsepower continuously. In addition, water-cooled units show a small efficiency advantage over air-cooled ones, particularly on "water-in-the-gap" types, where the water contributes slightly to the torque capability. Generally, water-cooled units are preferred to air-cooled types except when lack of coolant precludes their use or where very low slip losses are encountered.

Eddy current couplings require only a low percentage of transmitted power for excitation. Typically, a 3 hp (2.2 kW) unit will require 50 W of excitation, while a 12,000 hp (9 MW) unit will require 20 kW. Eddy current couplings are readily adaptable to silicon-controlled rectifier (SCR) (Section 7.2), providing speed control within 1% accuracy, over 10–100% load change.

Size and Efficiency Efficiency of the eddy current coupling is acceptable in the large sizes and at full speed torque, as will be shown later. At lower speeds, efficiency drops considerably, while efficiencies as high as 95% are possible at full excitation and torque. Because there is no contact between the input and output shafts of the coupling, the unit will not transmit vibrations. On prime movers that exhibit some torsional vibration, the use of an eddy current coupling can be of advantage because it will attenuate these vibrations.

Integral combinations of motor, coupling, and excitation are available in small sizes of 1 hp (0.75 kW) or less. Air-cooled couplings range in size up to 900 hp (670 kW), but the larger sizes are practical only where a relatively low cooling capacity is required. Liquid-cooled units can be as large as 18,000 hp (13.5 MW) capacity. Speed-control units range from simple open-loop control to precise, automatic closed-loop control with tachometer-generator speed feedback.

Magnetic Particle Coupling The magnetic particle coupling offers another solution to adjustable speed drives. Basically the coupling consists of two concentric cylinders separated by an air gap and a stationary excitation coil surrounding the cylinders. Ferromagnetic particles fill the gap between the concentric cylinders.

When a controlled amount of current is used to energize the coil, the particles form chains along the magnetic lines of flux connecting the cylinder surfaces. The shear resistance of the magnetic particles is proportional to the coil excitation and provides the basis for power transmission from input to output.

The output torque of this unit is always equal to input torque, regardless of speed. This fact allows the output torque to be set at standstill by controlling the coil excitation. Whenever the torque capacity of the coupling is exceeded, slip will

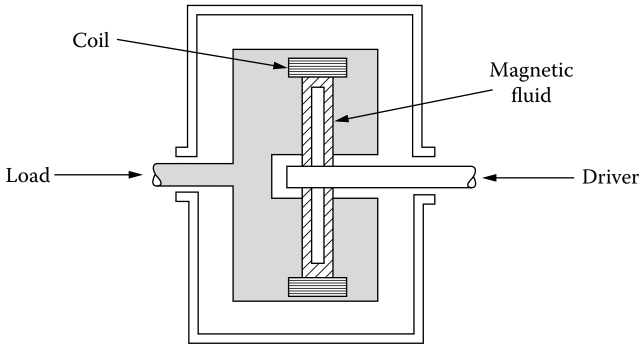

FIG. 7.10i
Disc-type magnetic fluid clutch.

result with accompanying heat liberation. Whenever the coupling is used for speed control, selection of a coupling with adequate cooling capacity is of great importance. Air-cooled units are available with large heat dissipation capacity; however, water cooling is more effective and therefore preferred.

Magnetic particle couplings can be used effectively for speed control, because they can provide a constant torque output independent of speed. However, a closed-looped control system is required for effective speed control in order to cancel the effect of changing torque on slip speed.

Magnetic Fluid Clutches The magnetic fluid clutch is similar in operating principle to the magnetic particle coupling, but either a magnetic dry powder or magnetic powder suspended in a lubricant is utilized. A typical disc-type magnetic fluid clutch is shown in Figure 7.10i.

While the operating principle is similar to that of magnetic particle coupling, the clutch can be used only for low-power applications in the order of a few horsepower. Recharging of the clutch due to fluid deterioration is a definite disadvantage; however, recharging can be fairly easily accomplished during routine maintenance.

VARIABLE VOLTAGE

One of the least desirable drives for centrifugal pumps is the variable voltage drive utilizing NEMA D, high-slip, induction motors. This is because of their poor efficiency, limited speed turndown, and need for special motors. This drive is no longer in common use.

POLE-CHANGING AC MOTORS

AC motors, while not readily usable for continuous speed control, can be made reversing or furnished with several fixed speeds. The squirrel cage induction motor is best suited from the standpoint of reliability, and it can be furnished with up to four fixed motor speeds.

Speed changes are accomplished through motor starter contacts that reconnect the windings to yield a different number of poles. In the resulting pole motor, the sections of the stator winding are interconnected through the motor starter to provide different motor speeds. On separate winding motors, a different winding with the required number of poles is energized for each motor speed. The starter contactors, however, must be interlocked to prevent two or more contactors from closing simultaneously. In current practice, more than two-speed designs are unusual, and variable-frequency drives have become common.

SOLID-STATE VARIABLE-SPEED DRIVES

In the past three decades, the use of solid-state variable-speed drives has increased dramatically. There are several reasons for this trend. The energy shortages of the 70s were a powerful incentive to find new ways to save energy. Because a third of all the electric power generated in the United States is consumed by AC motors, a major focus was on means of cutting the power consumed by those motors.

The main use of the AC motor is as a prime mover for pumps and fans. The traditional practice of flow control was to use a throttling valve or damper. These methods are notoriously wasteful (Figure 7.10a). Efficient flow control can be achieved by changing the speed of the pump or fan and thereby eliminating the valve entirely, but with an AC motor that could only be achieved (while maintaining efficiency) by two-speed motors, rotary frequency changers, or inverter motor drives.

The increase in the cost of electric power brought the payback period down to the point where the use of AC drives became cost-effective. During this same period, technological advances improved the performance, increased the reliability and efficiency, and lowered the cost of AC and DC solid-state motor drives. The main developments that caused this rapid advance were the improvements in semiconductor switching devices, large-scale integrated circuits, and the microprocessor.

The engineers designing the drives immediately adopted these advances and incorporated them into their products. As a result, the price of small AC variable-speed drives (below 20 hp/15 kW) has dropped by about a factor of three. The combined effect of better and cheaper drives and the need to save energy is responsible for rapid growth of the solid-state drive industry.

Underlying Semiconductor Technology

All solid-state variable-speed drives are based on semiconductor switching devices. The important ones are the rectifier diode, the power transistor, the thyristor, the gate-turn-off thyristor (GTO), and the insulated gate bipolar transistor (IGBT). All except the diode have the property of being

TABLE 7.10j
Comparison of Semiconductor Switches

Device Type	Blocking Voltage	Current Capability	Switching Time
Thyristor	6000 V	5000 A	50–300 μsec
GTO thyristor	4500 V	1000 A	10–50 μsec
Transistor	1400 V	500 A	3–10 μsec
IGBT	1400 V	400 A	100–300 nsec

controlled by a low power signal that changes their state from blocking to conduction.

Thyristors can be turned on by gate control but not turned off at the gate. The GTO, transistor, and IGBT have both turn-on and turn-off capability. The ability of these devices to handle higher currents and voltages has improved steadily, with the result that drives could be built for ever-larger power ratings.

Table 7.10j illustrates the primary switching properties of devices available in production quantities in 1992. Today, drives are available that operate directly at 7200 V, although the most common drive voltages in the United States are 230 and 460 V, three-phase.

Although the thyristor was the first semiconductor switch used in drives, it has been supplanted in the power range below 500 hp (370 kW) by power transistor- and IGBT-based drives. The GTO has been used at all drive power levels, but it too is being displaced by the transistor and IGBT. GTO-based drives are primarily limited to drives above 1 MW and those in which space and weight is at a premium, such as propulsion system drives. Due to the voltage limitations of the semiconductor switches, transistor drives are available at 600 V and below.

Drive Circuit Topologies

All drives have an input stage that converts the fixed voltage and constant-frequency AC mains to DC. If the input devices are controllable, like thyristors, then the DC output of this stage is adjustable. If the input devices are diodes, which conduct whenever forward biased, then the output DC is a fixed proportion of the input AC voltage. After the input stage, the details of the circuit depend on the type of motor being controlled.

The simplest power circuit applies to DC motors, because their speed may be controlled by adjusting the DC armature voltage. AC drives are more complex, because the output voltage must be adjustable-frequency and adjustable-voltage AC. This necessitates another stage of power conversion to invert the DC from the input stage into AC for the motor. In AC drives the DC power from the input stage is filtered by a bank of electrolytic capacitors or an inductor.

Variable-Speed DC Motors

Direct current motors lend themselves extremely well to speed control, as demonstrated by the variety of speed-load and load-voltage characteristics obtainable by means of parallel, series, or separate excitation. A typical set of speed-load characteristics for shunt, series, and compound motors is shown in Figure 7.10k.

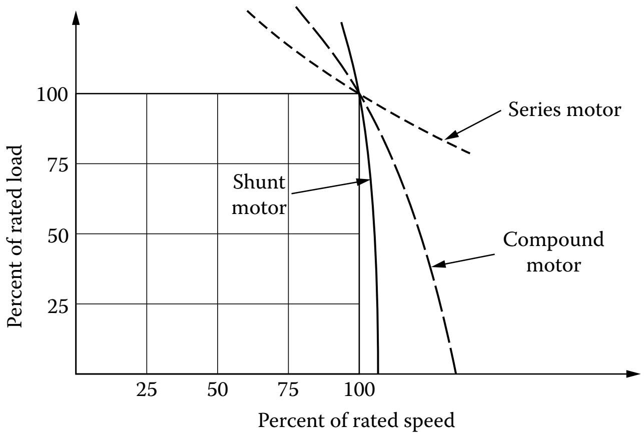

FIG. 7.10k
Speed-load characteristics of DC motors.

The inherent speed regulation, or constancy of speed under varying load conditions, of the shunt motor is shown graphically in the diagram. The speed change of the motor is only 5% for a load change from zero to full load. Although the methods of speed control are applicable to all types of DC motors, the superior speed regulation of the shunt motor accounts for its wider use on control applications.

The speed of a DC motor is a function of armature voltage, current, and resistance; the physical construction of the motor; and the magnetic flux produced by the field winding. The equation relating these variables to speed is:

$$S = \frac{V - IR}{K\Phi} \qquad \textbf{7.10(4)}$$

where
S = motor speed
V = armature terminal voltage
I = armature current
R = armature resistance
Φ = magnetic field flux
K = a constant for each motor depending on physical design

Three methods of speed control are suggested by Equation 7.10(4): adjustment of field flux Φ, adjustment of armature voltage V, and adjustment of armature resistance R.

Field Flux Adjustment The first of these, adjustment of field flux, involves varying the field current. This can be accomplished either by means of a field rheostat or by the current being controlled electronically by a set-point signal through an energy-throttling device such as an SCR. Open-loop control

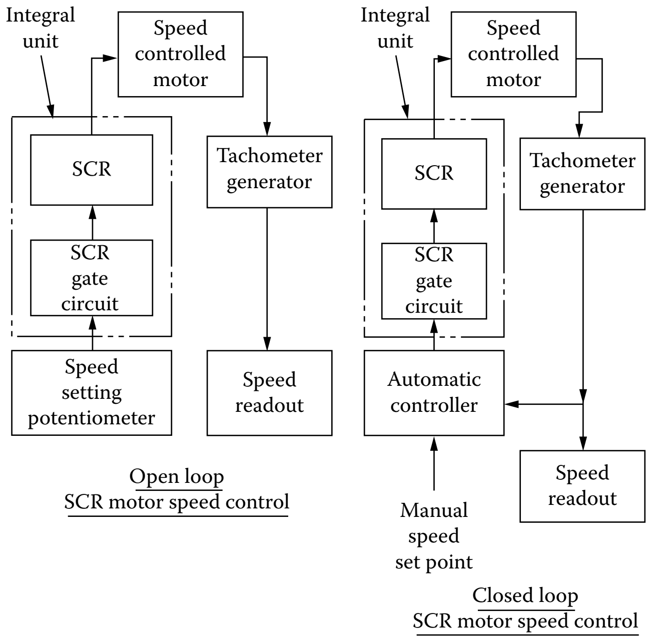

FIG. 7.10l
SCR-based motor speed controls can either be open or closed loop.

should be utilized only when the load is constant and precise speed control is not essential.

Closed-loop control is generally used in conjunction with electronic devices and offers better control than open loop, but at higher cost (Figure 7.10l). Either type of control requires a measurement of the controlled speed; in closed-loop control the measured speed is compared with the set point, and the field current is adjusted automatically to bring the difference to zero.

For a discussion of speed sensors refer to Section 7.19 of the *Process Measurement* volume of this handbook. In open-loop control a speed readout is required to permit set adjustments by the operator for the desired speed.

Adjustment of field flux yields a motor with constant horsepower. The allowable armature current is approximately limited to the motor rating in order to prevent overheating. The effects of changing flux and changing speed effectively cancel each other so that the allowable output horsepower—the product of armature current and induced armature voltage—is constant. Torque, however, varies directly with field flux, and therefore this type of speed control is suited for applications involving increased torque at reduced speeds. The speed range possible with field flux adjustment is approximately 4:1.

Armature Voltage Adjustment Armature voltage control can also be used to control motor speed. With armature voltage control, the change in speed from zero to full load is almost entirely due to the full-load armature resistance drop, and this speed change is independent of the no-load speed. Consider two motors with identical speed changes from zero to fully loaded, but one operating at 100 rpm and the other at 1000 rpm at zero load. In terms of percent speed change, a 10 rpm variation may be unacceptable for the lower-speed motor but may be insignificant for the higher-speed motor.

One method used for armature voltage control is the use of a motor-generator set to supply a controlled voltage to the motor whose speed is to be regulated. An AC motor drives a DC generator whose output voltage is variable and supplies the variable-speed motor armature. An obvious disadvantage of this method is the initial investment in three full-size machines; this method is so versatile, however, that it is often used.

Armature voltage, of course, can also be controlled electronically by one of the devices discussed in Section 7.2. These are more commonly used for speed control due to the lower investment and greater efficiency as compared to the motor-generator set. In the motor with controlled armature voltage, both the allowable armature current and field flux remain constant. The driver therefore has a constant torque output, as opposed to the constant horsepower output of the field-controlled motor.

The armature voltage method of speed control yields speed ranges in the order of 10:1. By combining field flux control and armature voltage control, speed ranges of 40:1 are obtainable. The base speed of the motor is set at full armature voltage and full field flux; speeds above base are obtained by field flux control, speeds below base by armature voltage control. Speed ranges greater than 40:1 are obtainable through the addition of special motor windings and SCR controls.

Armature Resistance Adjustment Adjustment of armature resistance is another method of speed control suggested by Equation 7.10(4), and it can be used to obtain reduced speeds. An external, variable resistance is inserted into the armature circuit (Figure 7.10m). Speed regulation with this method and its variants is very poor, however, and this type of speed control is not commonly used. An added disadvantage of the armature resistance method is the decrease in efficiency due to the power consumption in the resistor.

Starting Circuits DC motors must be protected from high in-rush currents during starting. In Figure 7.10n, the starting current through the armature is limited by resistors $R1$, $R2$,

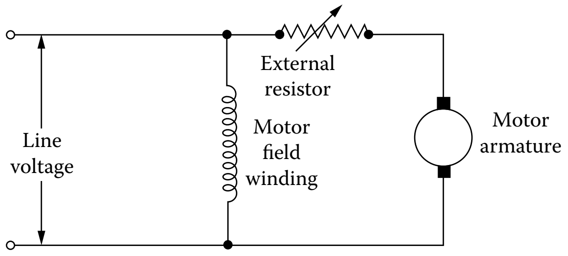

FIG. 7.10m
Shunt motor is controlled by varying the armature resistance.

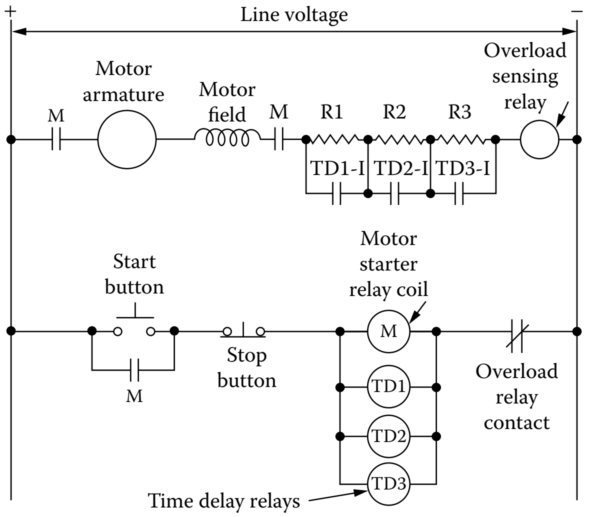

FIG. 7.10n
The starting circuit of a nonreversing DC motor.

and *R*3. When the start button is depressed momentarily, relay M and timer delay relays TD1, TD2, and TD3 are energized. The two M contacts close instantaneously, providing power to the motor. After a time delay, contact TD1-1 closes, shunting resistor *R*1. Contacts TD2-1 and TD3-1 close successively until the armature is directly on the line. The number of resistors is set by the torque and current limitations of the motor and the desired smoothness of startup.

Braking, Control, and Reversing The motor will also act as a generator, converting mechanical energy to electrical energy. This feature can be utilized to advantage where rapid stopping of the motor is required. In this configuration, when power is disconnected from the motor, a resistor is automatically connected across the armature and the mechanical energy of the rotating member is dissipated as heat in the resistor.

DC motors can be run in reverse rotation by changing the polarity of the armature voltage. This can be accomplished by means of two contactors—one forward, one reverse. These must be either mechanically or electrically interlocked to inhibit closing both contactors simultaneously and to prevent applying reverse line voltage to the motor prematurely.

Normally, DC power for operation of the motors is not readily available. Rectifier tubes and solid-state devices such as SCRs are used extensively to convert the incoming power to DC and simultaneously to throttle the current or voltage delivered to the motor in response to an external control signal. A discussion of these devices is given in Section 7.2.

Pump Drives Direct current motors have become more popular for pump drives because of the development of silicon-controlled rectifiers. The SCRs and direct current motor have resulted in a variable-speed drive of modest first cost and high efficiency. The significant objection to direct current motors has been maintenance of commutators and brushes. Direct current motors have been used on elevators in public buildings for many years.

Unlike centrifugal pumps, elevator loads are of the constant torque type. Brush life varies from 6 weeks to 18 months on elevator applications. At present, no extensive experience is available on brush and commutator wear and maintenance on centrifugal pump applications in the 1–100 hp (75 kW) range. If trained maintenance personnel are available at the point of application, the direct current drive can provide a highly efficient, variable-speed drive for centrifugal pumps. Cost of brushes and brush maintenance must be included in any economic evaluation. At the present, direct current motors are not as readily available as AC induction motors.

Thyristor DC Drives

The thyristor DC drive is the oldest form of solid-state drive and is still a viable choice, although the drawbacks of the DC motor, including high cost, size, and sparking, have not been overcome. These drives can be built over a wide power range, but due to difficulties in commutation in the machine they are usually limited to less than 700 VDC output. Thyristor DC drives are available off the shelf with or without the motor from fractional to 500 hp (375 kW). Fractional horsepower drives typically are powered from 240 VAC single phase, while the range above 5 hp (3.7 kW) is furnished for 240 or 480 VAC three-phase.

The behavior of the shunt DC motor makes it relatively easy to control. Torque is proportional to the product of current and flux, while voltage is proportional to the product of speed and flux. Figure 7.10o is a block diagram of a single converter thyristor DC drive suitable for two-quadrant operation. The thyristor converter is equipped with a fast current regulator, which effectively controls the motor torque. Enclosing the current loop is a speed regulator that amplifies the speed error and generates the current reference for the inner current loop. Speed feedback is provided by a tachometer for precision (0.1–1% accuracy and 100:1 turndown) or

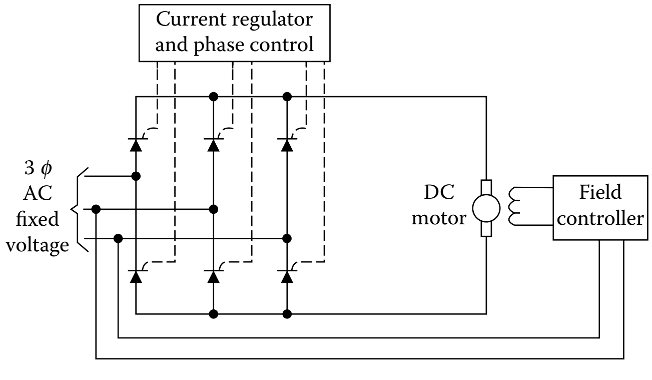

FIG. 7.10o
Single converter thyristor DC drive.

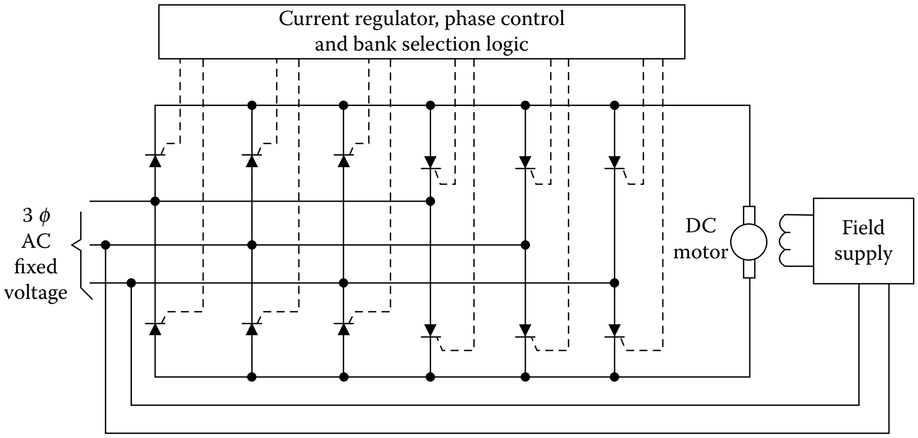

FIG. 7.10p
Dual converter thyristor DC drive.

by the motor terminal voltage for less demanding applications (2–5% accuracy and 10:1 turndown).

Because the converter can produce current in one direction only, a fast-reversing drive requires a second converter in inverse parallel to the first (see Figure 7.10p). Only one converter at a time is in conduction, depending on the desired direction of the motor torque. Although it is also possible to control direction with reversing contactors in the armature circuit, nowadays that feature is done with dual converters or field reversing.

Field-reversing drives use the property of the machine that the torque direction is controlled jointly by armature current direction and flux polarity. For applications in which the fastest reversing is not necessary, a small dual converter on the field is an economical approach to reversing drive applications (see Figure 7.10q).

Approximate costs of thyristor DC drives are listed in Table 7.10r. These costs include only the power conversion equipment, not the motor. Although the cost of the DC drive electronics is less than that of the AC variable-frequency drive, when the much lower cost of the AC motor is included, an AC drive and motor package usually costs less than the DC package of the same rating. This is almost always true if a weather-protected motor or explosionproof motor is required.

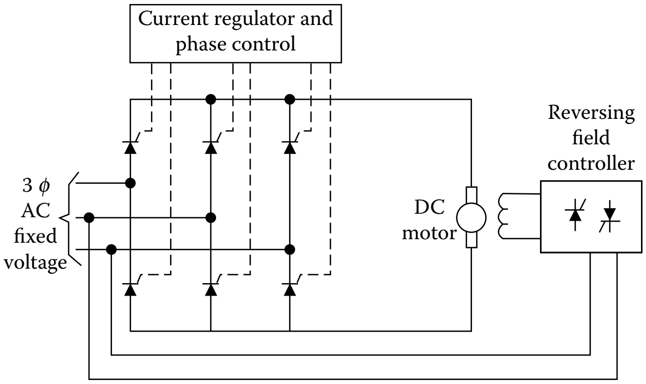

FIG. 7.10q
Three-phase field-reversing thyristor DC drive.

Variable-Frequency Drives

Often called *adjustable frequency,* these drives convert alternating current to direct current and back to alternating current at frequencies from 0 to 120 Hz. Of solid-state construction, these drives provide a highly reliable means of varying pump speed. They have wire-to-shaft efficiencies as high as 95% at full speed and 70–75% efficiencies at 40% speed when driving new, high-efficiency motors. The motors are standard induction types, found in stock in most major cities. (Load commutated inverter, or LCI, is applied to synchronous motors.)

The primary objections to these drives were their high first cost and complex designs. The development of power transistors and other electronic advances has reduced the cost of these drives, and the ongoing training of field personnel in electrical and electronic service has made variable frequency more acceptable in fields that have, traditionally, used mechanical, variable-speed drives. Variable-frequency drives are available up to 5000 hp with broad speed turndown ranges.

TABLE 7.10r
2004 Cost of Thyristor DC Drives

Power Rating	*Single Converter*	*Dual Converter*
100 hp (75 kW)	$5,000	$6,500
200 hp (150 kW)	$7,000	$8,000
500 hp (375 kW)	$15,000	$18,000
1000 hp (750 kW)	$20,000	$27,000

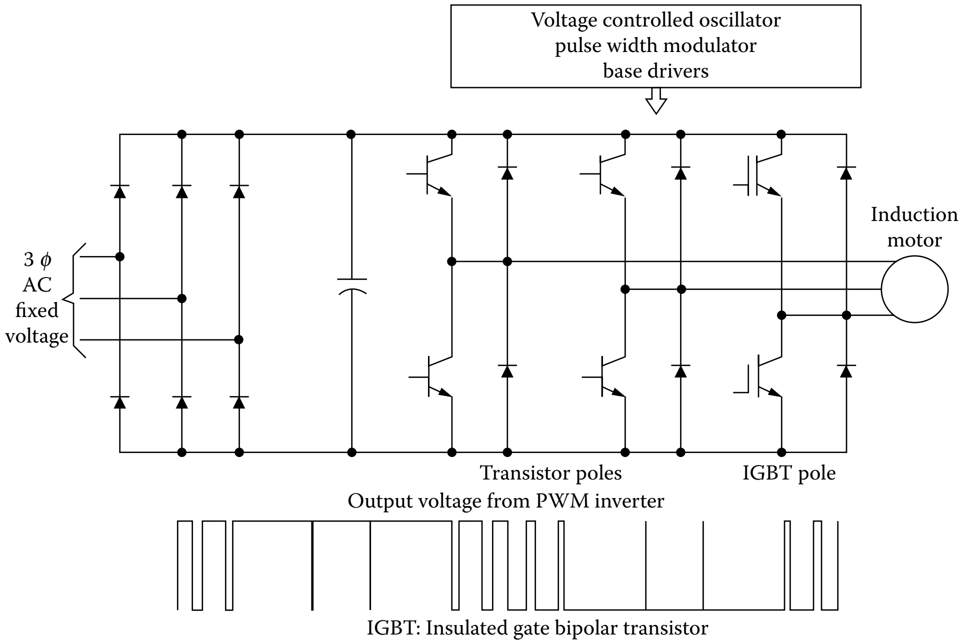

FIG. 7.10s
Pulse-width modulated inverter drive using transistors.

For the AC variable-frequency drive, the power electronics is more complex than for the DC drive, but the advantages of the AC motor over the DC are so pronounced that AC drives are now more economical in most applications and will ultimately supplant DC drives. More sophisticated approaches such as the use of field-oriented control have permitted AC drives to match the performance of DC drives.

There are two basic approaches to AC drives, which are distinguished on the basis of how the DC power from the input stage is handled. If the DC link filter is a capacitor and the inverter output consists of pulses of voltage from the link, then it is a voltage-fed drive. This category includes all drives with diode bridge inputs, such as pulse-width modulated (PWM) drives.

On the other hand, if the link filter is an inductor and the inverter output consists of pulses of current, then it is a current-fed drive. In this group we find the conventional autosequentially commutated current-fed inverter (ASCI), the load commutated inverter, and almost all other induction motor drives that operate at 2.3 kV and above. It is worth noting that different types of drives generally use different switching devices, as the different properties lend themselves to certain types of circuits.

Transistors and IGBTs are used in PWM drives; thyristors are used in DC drives, ASCIs, and LCIs. GTOs can be used in any of the drive circuits. These four types of drives (DC, PWM, ASCIs, and LCIs) dominate the solid-state variable-speed drive market. There is no one “best” drive; all of them have a different mix of features such that one needs to define the application requirements carefully in order to choose the best drive for the particular service.

Pulse-Width Modulated Drives Figure 7.10s illustrates the power circuit of a PWM drive using transistors. It is a very simple circuit, with an input diode bridge, fixed voltage DC link, and six output switches. Control of the output voltage and frequency is exercised entirely by the modulation strategy for the transistors. As the output voltage waveform indicates, the DC link voltage is applied to the motor in short pulses by turning the transistors on and off.

The duration of the pulses and their spacing controls the harmonic spectrum of the output. The objective is to have a large fundamental and as small an amount of harmonics as possible. The inverter determines the amplitude and frequency of the motor voltage, but the motor current is determined by the motor parameters and the load on the motor. Modern PWM drives switch rapidly (greater than 1 kHz for transistors; greater than 10 kHz for IGBTs), so that the low-order harmonics are essentially eliminated and a smooth sinusoidal motor current is obtained.

The best modulation strategies require very complex combinatorial logic or fast real-time computer processing, features that are now readily available in PWM drives but were not when they first appeared on the market. Transistor PWM drives are available in fractional through about 500 hp (400 kW) at rated input voltages of 120, 240, 480, and 600 VAC; GTO PWM drives are available in even higher voltage and power ratings.

Current Source Variable-Frequency Drives The basic power circuit of the current source inverter is shown in Figure 7.10t. The input conversion is performed by a thyristor bridge. This is controlled with a current regulator to function as an adjustable

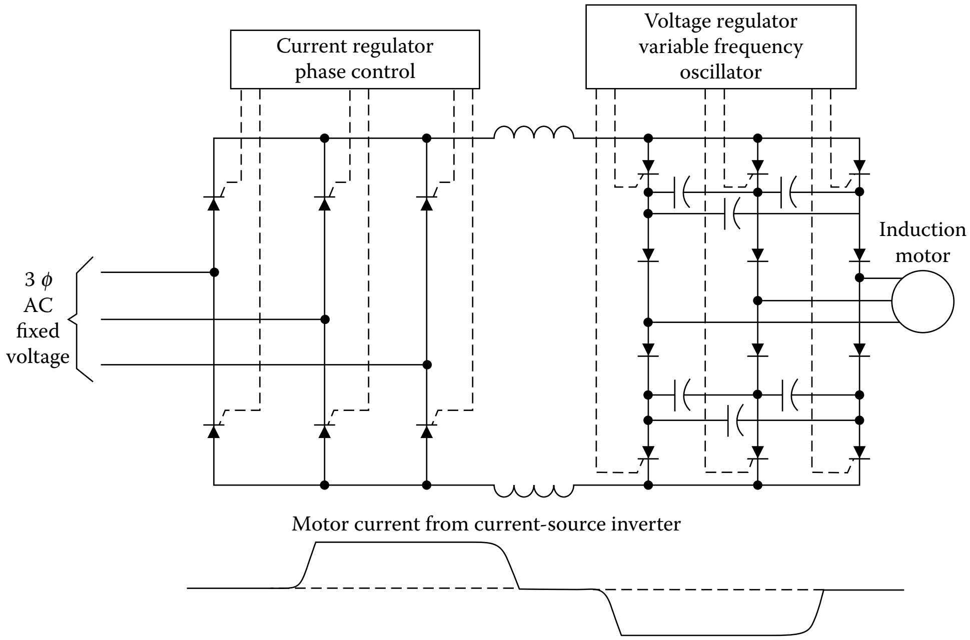

FIG. 7.10t
Autosequentially commutated current-fed inverter (ASCI).

current source. The voltage ripple of the converter is filtered by the choke in the DC link so that a smooth current flows into the output inverter stage. This current is steered in sequence into the motor windings by the thyristors so that the motor receives a trapezodial current waveform.

Because the thyristors cannot be turned off by gate control, commutation is forced by the energy stored in the capacitors. This energy is exchanged between the machine inductance and the capacitors. It is prevented from discharging into the machine by the diodes in series with the thyristors. In this case the inverter establishes the motor current, but the motor voltage is determined by its parameters and load.

Unlike the PWM inverter, the output amplitude is controlled by the current regulator on the input converter, and the output stage controls only the frequency. Because this type of drive is constructed from thyristors, it can be economically built in very large power ratings. A cost comparison of ASCI and PWM variable-frequency drives is shown in Table 7.10u. Once again, cost of the machine is not included.

Load Commutated Inverters Yet another common type of drive is the load commutated inverter, whose power circuit is shown in Figure 7.10v. This is also a current-fed topology, as evidenced by the similarity to Figure 7.10t. The input converter is a thyristor bridge equipped to function as a controlled current source. Smooth DC current flows through the choke into the thyristor inverter, where it is switched into the motor windings. But in this case commutation is performed by the machine.

By operating the machine at a leading power factor, the thyristors are naturally commutated because an off-going device experiences reverse voltage from the machine. However, a synchronous machine is required because an induction motor cannot be operated at a leading power factor. Although it is possible to build LCIs over a wide power range—100–20,000 hp (75 kW–15MW)—they are generally used in applications above 1000 hp (750 kW), where the cost differential between a synchronous and induction motor narrows. The cost of a medium voltage LCI (excluding motor and exciter) ranges from $150 per hp ($200 per kW) down to $75 per hp ($100 per kW), as the rating increases from 1000 to 5000 hp (750 kW to 3.7 MW).

Drives with Power Regeneration The ability to receive mechanical energy from the load and return it to the AC line is inherent in the ASCI and LCI, and the DC dual converter. The

TABLE 7.10u
2004 Cost of Variable-Frequency Induction Motor Drives

Power Rating	*PWM Including Reactor*	*Current-Fed ASCI*
10 hp (7.5 kW)	$1,700	
20 hp (15 kW)	$2,500	
50 hp (37 kW)	$5,300	
100 hp (75 kW)	$7,500	$8,000
200 hp (150 kW)	$11,000	$12,000
500 hp (375 kW)		$18,000
1000 hp (750 kW)		$32,000

Note: The reactor price adds 50–90% to the base price of the variable-frequency drive electronics.

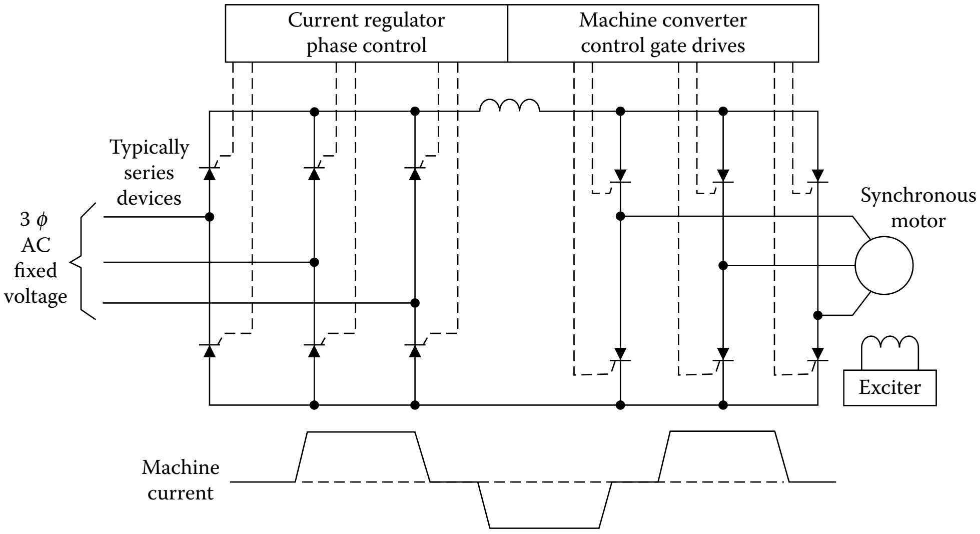

FIG. 7.10v
Load commutated inverter (LCI).

PWM drive requires an additional input stage to achieve this property. This capability is essential for a four-quadrant drive.

The wound rotor motor has been used for many years to vary the shaft speeds of cranes, machine tools, and similar heavy equipment. The energy loss due to heating of secondary resistance in these earlier applications has been recovered through the use of rectifiers and inverters and has resulted in efficient drives for centrifugal pumps. The higher cost of the wound rotor motor and drive makes this design cost-effective only for larger pumps in the range of 500–10,000 hp (375 kW–7.5MW).

Comparison of Solid-State Drives

The specific requirements of the application determine which type of drive is best; they all have somewhat different properties. It is difficult to make quantitative comparisons because drives of the same type may behave differently due to detail design differences such as size of suppressors and rating of devices. Some general comments follow.

Input Power Factor The diode bridge input configurations like PWM drives usually have near-unity displacement power factor, regardless of speed and load. However, the total power factor can be much lower due to input harmonic currents if there is inadequate inductance in the DC link or on the line side of the bridge. Drives with an input thyristor converter like DC drives, ASCIs, and LCIs have an input displacement power factor proportional to PU speed (for DC drives) or PU speed times motor power factor in the case of current-fed AC drives.

Physical Size and Weight The DC drive is the most compact design as it has fewest components; PWM drives are slightly larger; and the current-fed units are the largest and heaviest due to the magnetic components.

Immunity to Shorts and Ground Faults The current-fed designs (ASCI and LCI) have inherent immunity to load shorts and ground faults due to their current regulators and high-impedance link chokes. PWM drives rely on detecting such faults and quickly turning off the transistors. DC drives are frequently equipped with transformers to isolate the drive from a ground-referenced AC source.

Input Harmonic Currents All solid-state motor drives draw harmonic currents from the source. The harmonic spectrum of all the six-pulse drives that were mentioned results in at least 30% total harmonic current. The LCI, ASCI, and DC drives that have a highly inductive DC link draw odd harmonics excluding those divisible by three. The magnitude of the currents is approximately 1/h times fundamental where h is the harmonic number.

The same harmonics are present in the input currents of a diode bridge, but it is harder to quantify the current distortion because that depends on the values of the AC line reactance and link choke, if present. For low inductance PWM designs, the total harmonic current can easily exceed 50%.

Motor Effects All VFDs have a nonsinusoidal output. This results in a higher RMS motor current for the same motor output as compared to line (sinusoidal) operation. Consequently, more motor heating occurs, necessitating careful motor selection or de-rating.

The extra current varies from 3% for LCI and ASCI drives down to well under 1% for PWM drives. However, the extremely high amplitude and high frequency modulation of PWM drives raise eddy current losses and rotor losses in the machine. A rule of thumb is that the total motor losses increase by 5–15% (compared to line operation) when used with a drive. In the case of DC drives, the output voltage is not smooth but is rich in harmonics. However, the armature inductance in modern DC motors filters this so that the current is acceptably smooth and no motor de-rating is necessary.

Efficiency of Solid-State Drives

All the drives mentioned here have efficiencies at full speed and full load of 95% or more. Drives rated at higher power have slightly higher efficiencies than do lower power units because the fixed-power-consumption components, such as control circuits and cooling fans, constitute a larger proportion of the smaller power rating. This is also true for higher voltage ratings, because the conduction losses of the semiconductors arise from a nearly constant forward voltage drop.

The focus of efficiency should be on the energy savings due to the use of the drive (as compared to throttling devices) rather than small differences between types of drives. Furthermore, there are no industry standards on efficiency measurement or calculation for drives, which means that precision comparisons between manufacturers' claims are not very meaningful. To some extent there is a trade-off between efficiency and protective circuits, as components like suppressors and line reactors degrade efficiency but improve the reliability of the drive.

Recent VFD Developments

Over the past 40 years, since the VFD was first developed, the weight of the drive electronics has dropped rapidly. The first Danfoss VLT5 2 hp (1.5 kW) drive weighed 128 lb (58 kg). The current equivalent VLT5000 weighs just 17.6 lb (8 kg), a sevenfold reduction.

Current-generation equipment offers serial communication capability (ModbusPlus, LONWorks, Profibus, Device-Net, etc.) and is frequently provided with PID control capability with 4–20 mA I/O, providing access to a variety of internal parameters.

When the drive motors are fitted with an encoder, position feedback allows a whole series of individual drives to be synchronized, matched in angular position, or adjusted as though they had a mechanical gearbox between them.

For asynchronous motors, $T \sim \phi \times I_L$ normally applies, where (T) is the torque developed, I_L is the rotor current, and ϕ is the air gap flux of the machine. To optimize torque from the motor, the air gap flux of the machine ($\phi \sim V/f$) should be kept constant (Figure 7.10w). This means that if the line frequency (f) is changed, the line voltage (V) must be changed proportionally.

For heavy starts (screw conveyors) and to optimize the stalling torque, an extra (start) voltage (Vo) is required. When loaded and in the low speed range (f < 10 Hz), the voltage loss is clearly seen on the active resistance of the stator winding (particularly in small motors), leading to a specific weakening of the air gap flux (ϕ).

When operating above normal supply frequency (many small four-pole motors are capable of operation up to two-pole speeds), the torque available becomes inversely proportional to speed, and the motor is limited to design power, regardless of speed.

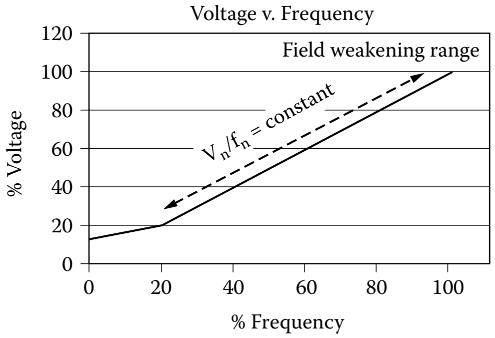

FIG. 7.10w
The motor torque is optimized by keeping the ratio of line voltage to line frequency constant.

EFFICIENCY OF VARIABLE-SPEED DRIVES AND PUMPS

The following three efficiencies should be evaluated for any application of variable-speed pumps:

1. Wire-to-shaft efficiency of the variable-speed drive and the motor. Obviously, this is the ratio of the useful energy applied to the pump shaft divided by the energy applied to the drive-motor combination.
2. Pump efficiency.
3. Wire-to-water efficiency of the drive, motor, and pump. This is the ratio of the useful energy applied to the water divided by the energy applied to the pump-motor-drive combination.

Following is a list of terms that will be used to describe the efficiencies of various pump-motor-drive combinations. All of the energy terms are in horsepower to simplify this discussion; they can be converted into watts (HP = 746 w).

Chp = Energy input to an electrical drive
Ce = Efficiency of an electrical drive
Ihp = Energy input to an electric motor
Me = Efficiency of an electric motor
Dhp = Energy input to a mechanical-type drive
De = Efficiency of a mechanical-type drive
Php = Energy input to a centrifugal pump
Pe = Efficiency of a centrifugal pump
Whp = Water horsepower or useful energy applied to the water
Ws = Wire-to-shaft efficiency (often called line-to-shaft efficiency)
Ww = Wire-to-water efficiency

Figure 7.10x describes the configuration of an electrical-type variable-speed drive and pump.

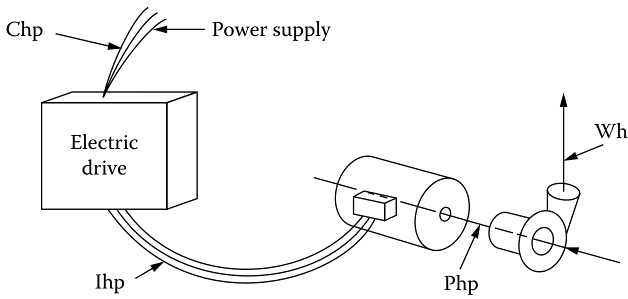

FIG. 7.10x
The configuration of a pump provided with an electrical variable-speed drive.

Following are the equations for this combination. The efficiencies are entered into these equations as fractions.

$$\text{Whp} = \text{water horsepower} = \frac{\text{GPM} \times \text{pump TDH (in ft of water)}}{3960} \quad \textbf{7.10(5)}$$

$$\text{Php} = \text{pump brake horsepower} = \frac{\text{Whp}}{\text{Pe}} \quad \textbf{7.10(6)}$$

$$\text{Ihp} = \text{motor input horsepower} = \frac{\text{Php}}{\text{Me}} \quad \textbf{7.10(7)}$$

$$\text{Chp} = \text{energy input to electrical drive} = \frac{\text{Ihp}}{\text{Ce}} \quad \textbf{7.10(8)}$$

$$\text{Ws} = \text{wire-to-shaft efficiency} = \frac{\text{Php} \times 100\%}{\text{Chp}} = \text{Ce} \times \text{Me} \times 100\% \quad \textbf{7.10(9)}$$

$$\text{WW} = \text{wire-to-water efficiency} = \frac{\text{Whp}}{\text{Chp}} = \text{Ce} \times \text{Me} \times \text{Pe} \times 100\% \quad \textbf{7.10(10)}$$

Figure 7.10y describes the configuration of the electromechanical drive and pump along with the various energy terms that are applicable to this combination.

The following equations are similar but not necessarily equal to those for electrical drives. Equations 7.10(5) and 7.10(6), for water horsepower and pump brake horsepower, are the same.

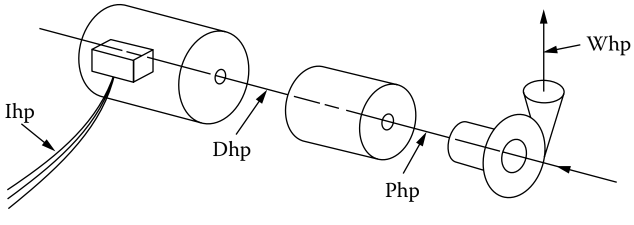

FIG. 7.10y
The configuration of a pump provided with an electomechanrical variable-speed drive.

$$\text{Dhp} = \text{mechanical drive input horsepower} = \frac{\text{Php}}{\text{De}} \text{(same as the electric motor shaft horsepower)} \quad \textbf{7.10(11)}$$

$$\text{Ihp} = \text{motor input horsepower} = \frac{\text{Dhp}}{\text{Me}} \quad \textbf{7.10(12)}$$

$$\text{Ws} = \text{wire-to-shaft efficiency} = \text{Me} \times \text{De} \times 100\% \quad \textbf{7.10(13)}$$

$$\text{Ww} = \text{wire-to-water efficiency} = \text{Me} \times \text{De} \times \text{Pe} \times 100\% \quad \textbf{7.10(14)}$$

Evaluation of VSD Efficiencies

The above equations demonstrate that the wire-to-shaft efficiency for any drive-motor combination is dependent upon the efficiency of the electric motor and the drive, whether the drive is electrical or mechanical. As shown in Equations 7.10(9) and 7.10(13), the efficiency of both the motor and the drive must be determined to achieve the true wire-to-shaft efficiency. These component efficiencies should be determined throughout the anticipated operating speed range, not just at full-speed condition.

The high-efficiency electric motor has created the opportunity for achieving higher wire-to-shaft efficiencies for variable-speed drives, but it is imperative that equivalent motors be used when comparing the efficiency of one type of drive with that of a different type. If high-efficiency motors are used, their efficiencies should have been secured from tests conducted in accordance with NEMA Standard MG1-12.53a, which is based on Institute of Electrical and Electronics Engineers (IEEE) Standard 112, Method B.

Figure 7.10z provides a general comparison of the efficiencies of various types of variable-speed drives for centrifugal pumps. The curves shown in this figure should not be used for energy calculations for a specific application. Rather, efficiencies for drives and motors under consideration should be certified by the manufacturers of that equipment.

As shown in Figure 7.10z, most electric drives are more efficient than electromechanical drives at reduced speeds. The exception is the variable-voltage electric-type drive, which is generally less efficient than mechanical drives. The mechanical drives are usually less efficient than the electric drives, because most of them utilize slip between the input and output shafts of the mechanical drive. This results in a slip loss that is directly in proportion to the amount of slip. The equation for slip loss is

$$\text{slip horsepower loss} = \frac{\text{slip rpm} \times \text{Php}}{\text{output rpm}} \quad \textbf{7.10(15)}$$

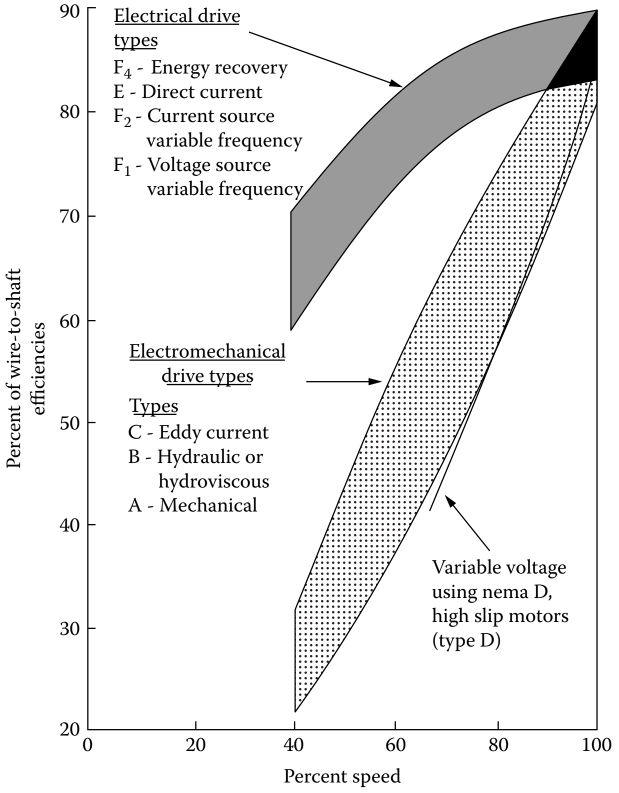

FIG. 7.10z

The wire-to-shaft efficiencies of various variable-speed centrifugal pump drives.

The wire-to-shaft efficiency of the electromechanical drive is

$$
\begin{aligned}
\mathrm{Ws} &= \frac{\mathrm{Php}}{\mathrm{Ihp}} \\
&= \frac{\mathrm{Php} \times \mathrm{Me} \times 100\%}{\mathrm{Php} \times \dfrac{\text{slip rpm}}{\text{output rpm}} + \mathrm{Php} + \text{circulation losses}} \\
&= \frac{\mathrm{Php} \times \mathrm{Me} \times 100\%}{\dfrac{\text{input rpm}}{\text{output rpm}} \times \mathrm{Php} + \text{circulation losses}} \qquad \mathbf{7.10(16)}
\end{aligned}
$$

Circulation losses are those losses incurred by the constant rotation of the input shaft, along with energy for specific uses such as the loss imparted by oil pumps to circulate oil in fluid couplings and hydroviscous drives. Circulation losses must always be stated by mechanical drive manufacturers.

The overall system efficiency index (SEI) of a variable-speed pump installation is determined as follows:

$$\mathrm{SEI} = (\mathrm{Ep} \times \mathrm{Em} \times \mathrm{Ev} \times \mathrm{Eu})10^{-6} \qquad \mathbf{7.10(17)}$$

where

Ep = Pump efficiency
Em = Motor efficiency
Ev = Variable-speed drive efficiency
Eu = Efficiency of utilization = (Qa)(Ha)/(Qd)(Hd)
Ha = Actual head
Hd = Design head
Qa = Actual flow
Qd = Design flow

CONCLUSIONS

The above brief descriptions provide general information on the various types of variable-speed drives. Actual selection of the drive for a specific application requires an evaluation of (1) wire-to-shaft efficiency, (2) first cost, (3) reliability, (4) serviceability, (5) maintenance costs, (6) need for special motor, (7) speed range, and (8) control repeatability.

No variable-speed drive should be selected for a centrifugal pump without careful evaluation of the process load itself to determine the feasibility of variable speed. This, along with consideration for the eight factors listed above, should result in the selection of the optimum drive. For more details on pump applications and pump controls, refer to Chapter 8.

8.1 Aeration and DO Controls

P. KESKAR (2005)

INTRODUCTION

Aeration is mostly used in wastewater treatment facilities to introduce oxygen into the wastewater. Oxygen is necessary for biological treatment of carbonaceous matter (secondary treatment) and for oxidation of ammonia into nitrite and nitrate (nitrification). The transfer of oxygen is accomplished using two basic aeration methods. One method is the use of mechanical aerators (mechanical mixing), and the other method is the delivery of air through a network of pipes and diffusers located at the bottom of treatment basins (diffused aeration).

Aeration control is a very important part of any wastewater plant control system design. The volume of air required depends upon the biomass oxygen demand of the wastewater, which is continuously changing. An inadequate supply of air (oxygen) can inhibit secondary treatment and nitrification processes, causing major process problems. Excessive air supply wastes energy and can dramatically increase plant-operating costs. It is estimated that aeration energy consumption can be 50–90% of the total energy demand of an activated sludge process.

A well-thought-out aeration control scheme could optimize the overall process and significantly reduce energy cost. Aeration control schemes include two basic building blocks, namely the measurement of the process variable, which in this case is dissolved oxygen (DO) concentration in the wastewater, and implementation of control adjustments using control algorithms and final control elements, like control valves on air lines or surface aerator speeds via variable-frequency drives (VFDs). The control strategies can be as simple as manual control of final control elements based on DO concentrations or advanced control algorithms utilizing feedback/feedforward and cascade control.

Success of any control strategy depends upon careful evaluation of all elements of the control loop, including the field instrument measuring the process variable (DO), the algorithm, the final control element, and other related mechanical process equipment utilized in the process (e.g., blowers, diffusers, and surface aerators).

The following paragraphs in this section will discuss the process equipment, field instrumentation, control strategies, and current trends in implementation of aeration and DO control.

MECHANICAL AERATION

Mechanical aeration is accomplished by transferring atmospheric oxygen to the liquid by surface agitation. Mechanical aerators are classified as plate, updraft, downdraft, and brush types.

The plate-type aerator employs a circular plate equipped with radial blades and creates a large amount of turbulence by causing a peripheral hydraulic jump.

The updraft-type aerator employs a surface impeller, which draws liquid upward and violently outward at the surface. The surface turbulence causes oxygen transfer. The updraft-type aerators are popular because of their low cost, high oxygen transfer efficiency, and good mixing. The disadvantages include high maintenance and operational costs due to large number of units, frequent icing in cold weather, uneven DO distribution, and not enough oxygenation for nitrification. The updraft-type aerators are particularly suitable for smaller plants in warmer climates that do not require nitrification.

The downdraft-type aerator employs an impeller in a vertical tube to force liquid from the surface, down through the tube to the bottom of the tank. Air is entrained in the liquid as it is forced down into the tube.

The brush-type aerator rotates around a horizontal shaft equipped with a series of projections. Oxygen transfer is accomplished by surface turbulence. The brush-type aerator is used extensively in oxidation ditch application. Typical advantages are high oxygen transfer efficiency, low capital cost, and low operational cost. However, this type of aerator is not suitable for cold climates (due to icing problems), requires critical level controls, and does not provide enough oxygenation capacity for nitrification.

Process Configurations

Two basic types of process configurations are used for mechanical aeration systems.

Plug Flow Configuration Figure 8.1a shows the plug flow configuration. Rectangular tanks with large length-to-width ratios and containing several aerators approach plug flow conditions. In this configuration the tank essentially operates like several smaller tanks connected in series, and the result is more like plug flow rather than complete mixing.

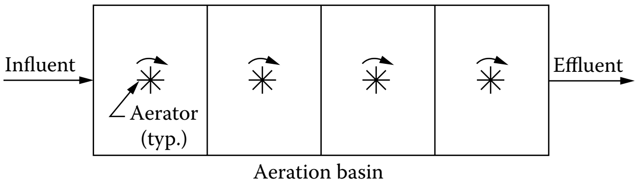

FIG. 8.1a
Plug flow configuration of a mechanical aeration system.

In this configuration control of aeration capacity is accomplished in two ways:

Speed Control of Aerators Simultaneous speed control of all aerators based on DO concentration may not be the best way to control oxygen transfer. Aerators can be classified in several groups, e.g., those near the influent end, those in the middle, and those at the effluent end. Speed of each group of aerators is controlled using a dedicated DO probe to maintain the DO concentration within an acceptable band.

Level-Based Control Adjustment of oxygen transfer capacity can be applied to the entire tank by raising or lowering of the effluent weir to change submergence of the aerators. The weir position is changed to keep the DO levels within acceptable band. The location of the DO probe for weir control is best left up to the operator. DO probe receptacles should be provided at several locations to allow placement of DO probe at the most optimum location following a period of trial and error.

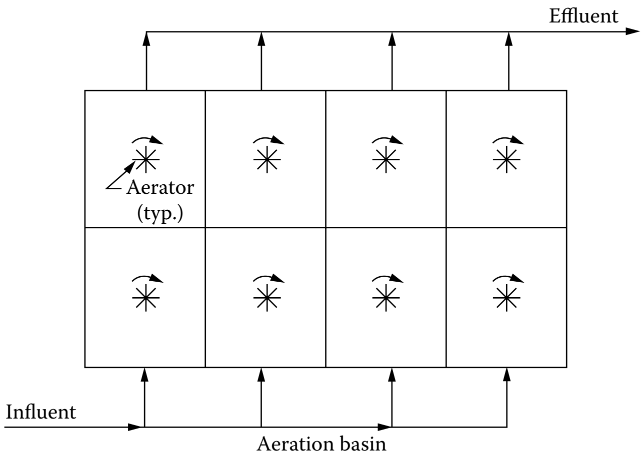

FIG. 8.1b
Completely mixed configuration of a mechanical aeration system.

Completely Mixed Configuration Figure 8.1b shows a completely mixed configuration of aerators. For control purposes, the four aerators near the influent end can be grouped in one group for simultaneous speed control, and the four aerators near the effluent end can be gathered in another group for collective speed control. Other groupings may be considered for achieving better control; i.e., the four aerators at each end can be divided into two groups, making a total of four groups for collective speed control. Dedicated DO probe can be provided for each group for speed control.

Aerator Control Strategies

On/Off Control Figure 8.1c shows a typical on/off aerator control strategy. In this control scheme, multiple single-speed aerators in a zone are controlled based on DO measurement in that zone. The sequence in which the aerators are to be

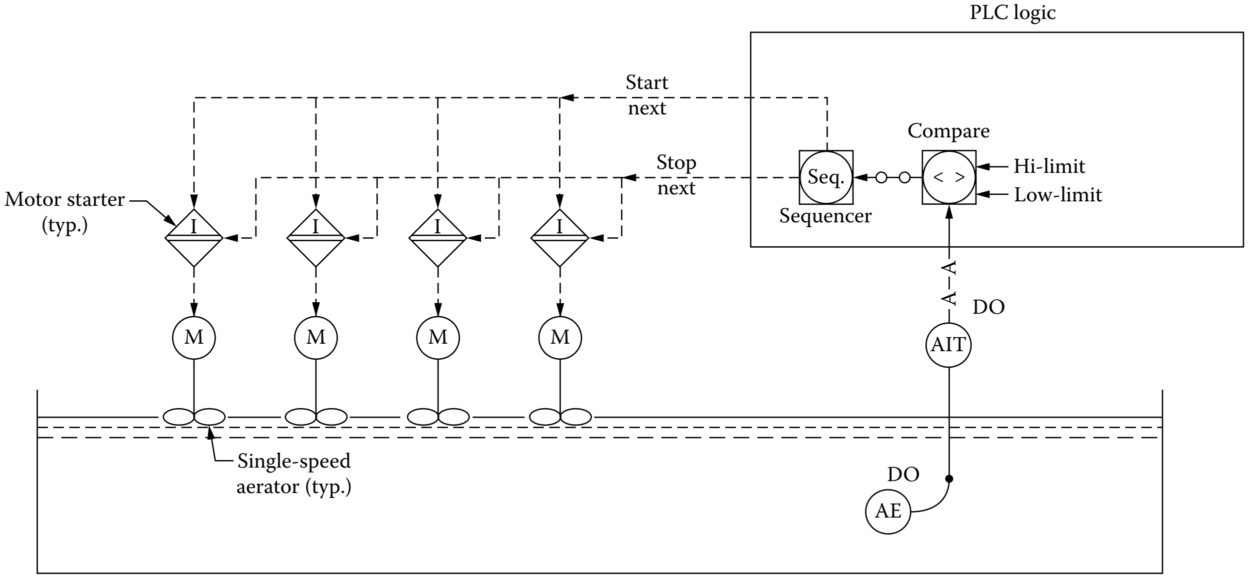

FIG. 8.1c
On/Off aerator control system.

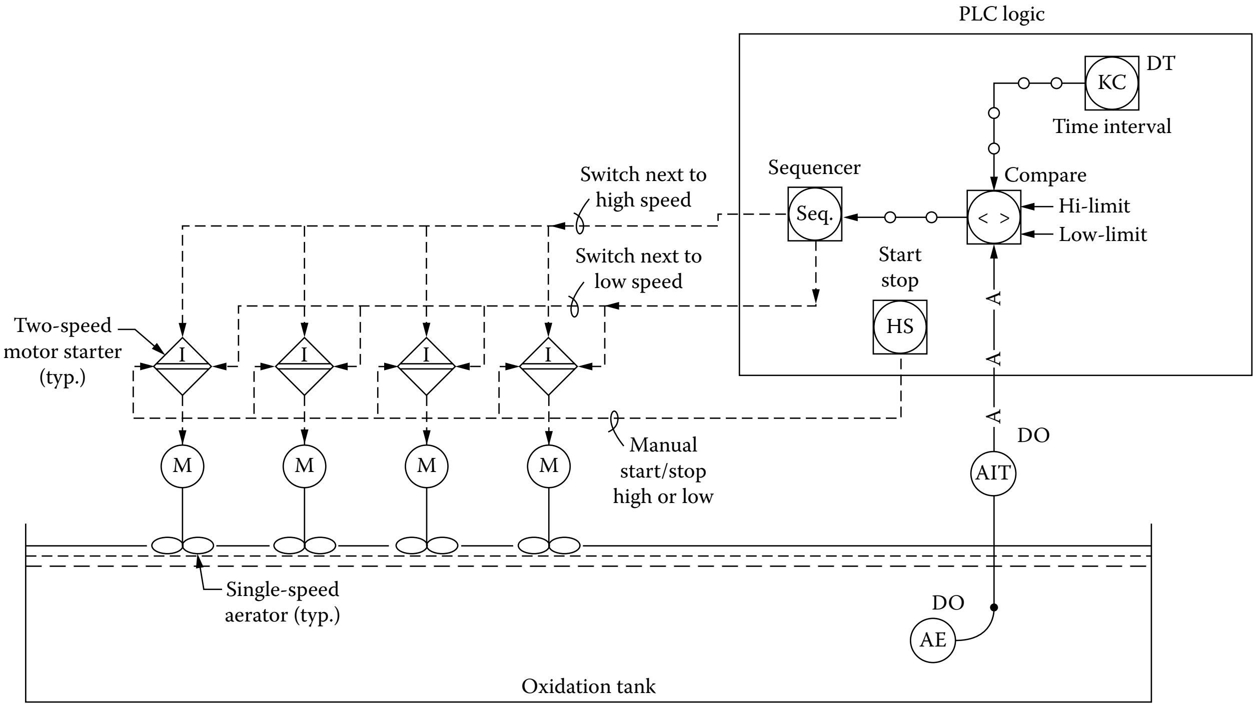

FIG. 8.1d
Dual-speed aerator control system.

started or stopped based on DO level is loaded in a sequence table part of the PLC logic. The operator can change the sequence via operator interface.

A DO sensor/analyzer sends a 4–20 mA signal to the PLC. The DO signal is linearized and is compared against the high and low DO set points. If the DO is below the low limit set point for an adjustable time period, the sequence logic sends a start command to the "next" aerator to start. As long as the DO level is below the set point, the sequencer will start the next aerator until either all aerators have been started or the DO level is within the high and low DO set points.

If the DO signal is above the high set point for an adjustable time period, the sequencer issues a stop command to the next aerator. No aerator is stopped or started by the sequencer as long as the DO level is within the band set by the high and low DO set points. Excessive cycling of the aerators can be avoided by increasing the DO control band or by adjusting the time delay before a start or stop command is issued to the aerators.

Dual-Speed Control Dual-speed aerators are used to achieve a better control on aeration and save energy. Figure 8.1d shows a typical dual-speed aerator control system. Dual-speed motor starters are used to run the motors at two different speeds. As discussed before, a DO sensor/analyzer is used to measure DO in the wastewater and transmit a 4–20 mA signal to PLC.

PLC logic performs the following functions:

At the end of each adjustable preset time interval of DT, as determined by an interval timer logic, check the measured DO signal against the preset high and low DO limits. If at the end of each time interval the measured DO level is less than preset, start the next aerator at low speed in accordance with the sequence loaded in the sequencer.

When all aerators in the zone are running at low speed and the DO level is still below preset, switch the first aerator to high speed.

On subsequent time intervals, if the DO level remains below the low limit, continue switching the next aerator to high speed as determined by the sequencer. If the DO level continues to be below the low limit, eventually all aerators will be running at high speed and the DO level will be at the maximum achievable limit. On the other hand, during any time interval, if the DO level is above the preset high limits during subsequent time intervals, the sequencer will switch the next aerator to low speed one at a time. The aerators can be manually started at high or low speeds or stopped via commands from the operator interface.

Figure 8.1e shows a hypothetical graph of typical aeration capacity variation vs. time that can be expected using dual-speed control. The aeration capacity is at minimum when all aerators are running at low speed. The aeration capacity is increased by a step of DA during a time interval DT when an aerator is switched from low to high speed. Maximum aeration capacity is reached when all aerators are running at high speed.

Variable-Speed Control Variable-speed drives can be used to continuously vary the speed of the aerator based on DO

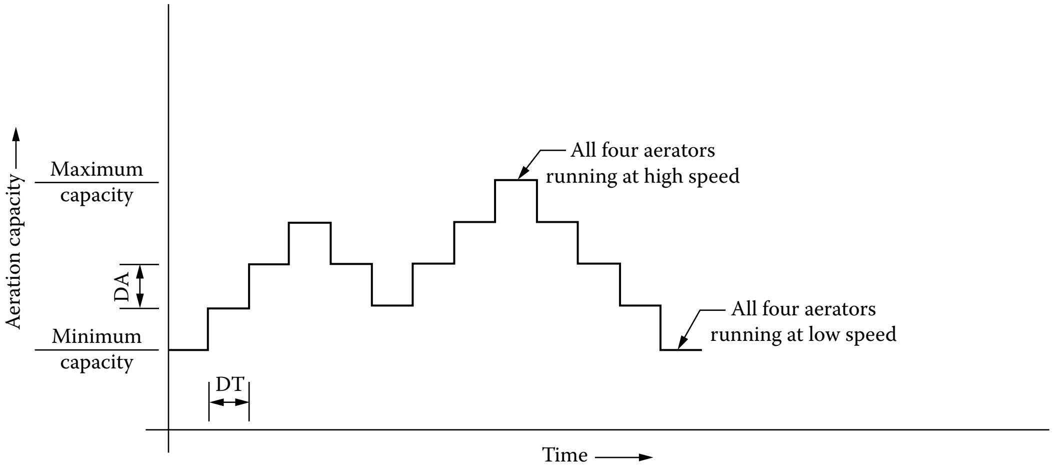

FIG. 8.1e
The above relationship can be expected between aeration capacity and time, when using dual-speed aeration controls.

measurement. The speed can be either manually adjusted from the operator interface based on the DO readings or controlled automatically using a PID algorithm part of the PLC logic. The DO measured variable is compared against the desired set point to generate an error signal, and the controller output and speed of the aerator is modulated to minimize the error. Manual speed control is accomplished by putting the controller in manual and adjusting controller output to desired value.

Figure 8.1f shows a typical variable-speed aerator control loop. It should be noted that the aerators are constant torque machines, and the kW power requirement varies linearly with the speed; therefore, energy savings at reduced speeds are not as dramatic as in case of centrifugal blowers.

Variable-Impeller Depth Control Aeration transfer capacity of a turbine-type aerator can be controlled by varying the submergence depth of the impeller. Figure 8.1g shows a typical variable-impeller depth control system. Two cascaded control loops are used for this control system. A faster internal control loop is used to adjust the vertical position of the impeller to maintain the position set point.

Position transmitter ZT provides the measured variable and PID controller ZIC compares the actual position with the position set point and adjusts the vertical position to minimize the error. The position set point is modulated proportional to the output of PID controller AIC (external slower control loop), whose output is based on error between the measured DO and the desired DO set point.

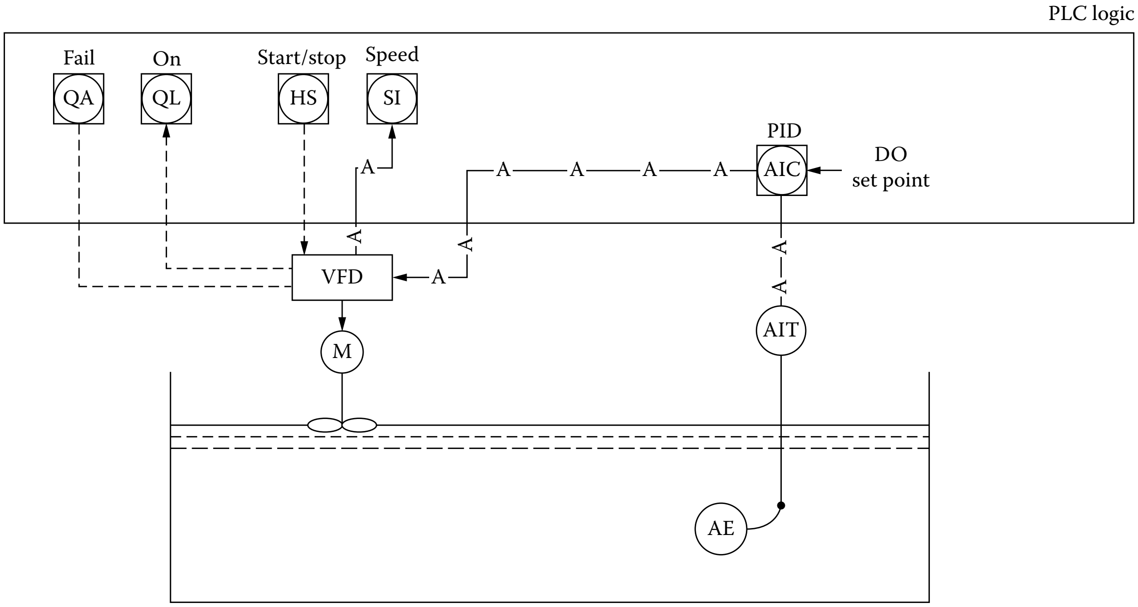

FIG. 8.1f
Variable-speed aerator control system.

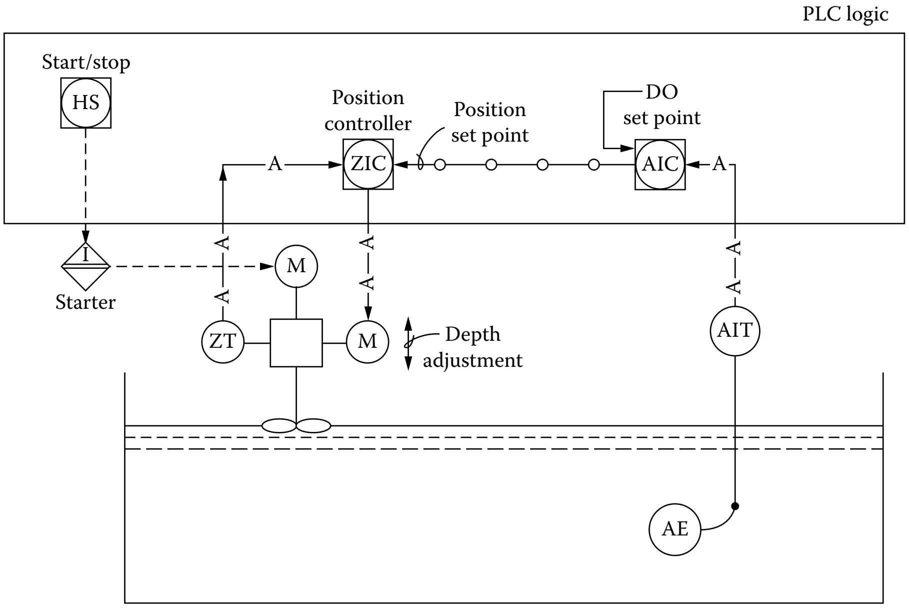

FIG. 8.1g
Variable-impeller depth control system.

Variable-Level Control Another method to control the oxygen transfer rate of a turbine-type aerator is by controlling the level of wastewater in the oxidation tank, thereby controlling the submergence of the turbine impeller. The liquid level is controlled by raising or lowering a weir. The cascaded control loops, similar to the variable impeller depth control loop described above, are used.

The faster inner loop (ZIC) controls the position of the weir, and the position set point is modulated by the external slow DO control loop (AIC). Adjusting the weir position adjusts the liquid level, thus adjusting the submerged impeller depth.

Diffused Aeration Diffused aeration is accomplished by injecting air from an external source into the aeration basin through a diffuser. A diffuser can be as simple as a perforated pipe or a complex device. Air is pushed through the diffuser using air blowers.

Several types of configurations and aeration control strategies are used for diffused aeration of wastewater. Proper application of blowers, blower capacity control, and control valve selection can lead to an energy-efficient aeration system. This subsection provides general background on types of diffusers and blowers used, methods of blower capacity control, blower surge control, and the types of control valves used for air distribution. Measurement of DO and typical control strategies are discussed in later subsections of this section.

Aeration Diffusers

There are two basic types of diffusers used in diffused aeration, namely the coarse bubble diffusers and the fine bubble diffusers. Three factors are important in selection and application of diffusers, namely the head loss through the diffusers, the oxygen transfer efficiency, and the layout and arrangement of diffusers. Excellent discussion of diffusers and their application is available in the literature referenced at the end of this section. A brief discussion is provided here as an overview.

Coarse Bubble Diffusers These diffusers release large air bubbles into the wastewater. These diffusers are further divided into four general categories: orifice, valve, shear, and shallow submergence diffusers. The selection of the type of diffuser depends upon application, head loss characteristics, and oxygen transfer efficiency of the diffuser. The main advantage of the valve-type orifice diffuser is that it prevents backflow of liquid in the air header on loss of air pressure.

Shear-type diffusers are difficult to attach to removable pipe headers, and therefore these types of diffusers are used only in applications where they can be attached to the bottom of the tank. The shallow submergence diffusers are installed at shallow depths of about 3 ft below the liquid surface. The main advantage of shallow submergence-type diffusers is the low air pressure required, which allows the use of low-pressure blowers, reducing blower capital cost. In general, the coarse bubble diffusers are less efficient compared to fine bubble diffusers.

Fine Bubble Diffusers The fine bubble diffusers produce fine air bubbles, which produce less turbulence in the wastewater, as compared to the coarse bubble diffusers. Diffuser devices are generally made from porous ceramic materials or elastometric membranes. Fine bubble diffusers are available in flat tubes, hollow plates, or dome-type construction. The head loss characteristics for different types of fine bubble diffusers are not much different but their oxygen transfer efficiencies may differ significantly.

The fine bubbles created by porous ceramic and elastometric membrane-type diffusers mounted on a piping grid at the bottom of the aeration basin provide the best oxygen transfer efficiency.

Aeration Blowers

There are two types of blowers commonly used in aeration applications, namely the positive displacement (PD) blowers and the centrifugal blowers. There is plenty of literature available on the subjects of blowers and their applications in the references listed at the end of this section. Only a brief overview is included in this paragraph. Selection of an appropriate blower type should be based on capital cost, operating cost, efficiency, and the flow/capacity turndown capability. Complete life-cycle costs should be analyzed for various blower types/configuration before a final selection is made.

Positive Displacement Blower The rotary, two-impeller, PD blower is a constant volume, variable-pressure machine. At the rated speed, this type of blower provides constant flow at widely varying discharge pressures. Figure 8.1h shows the typical operating characteristics of a PD blower. Low capital costs and its ability to operate at widely varying pressures are the advantages of a PD blower. The disadvantages include the difficulty of throttling the air flow rates to meet the varying demands, high maintenance cost, and noisy operation.

The capacity control of a PD blower can be achieved either by blowing off excess air through a blow-off valve or by varying the speed of the blower using a variable-frequency drive. The first method of blowing off the excess air during low air demand period wastes energy and is not recommended.

Reducing air flow by reducing the blower speed is a better way of controlling air flow of a PD blower, because it conserves energy by reducing blower horsepower requirement. However, it should be noted that the blower efficiency drops significantly at lower speed and the energy savings are not as dramatic, as in the case of the centrifugal blower, because the horsepower vs. speed relationship is linear. A turndown of 100–50% capacity is possible by using variable-frequency drives to vary the speed of a PD blower.

The PD blower is used typically in small aeration systems requiring aeration flows of 1000 SCFM or less. PD blowers were used extensively before 1960; however, the development of high-efficiency centrifugal machines with single- and dual-vane capacity control has limited the use of PD blowers to smaller systems with variable head requirements.

Centrifugal Blowers Figure 8.1i shows a typical operating characteristic of a centrifugal blower. The curve *B*1-*B*2 is the blower-operating curve. Curve *S*1-*S*2 represents the system curve that includes the static head and the frictional resistance. The intersection of the two curves (point "*O*") is the operating point of the blower. At the operating point, the blower is running at rated speed to deliver the flow at the pressure dictated by the system curve, without any speed control or valve throttling.

It should be noted that the blower curve is almost horizontal at point *B*1 and shown as a dotted line to the left of point *B*1. "*B*1" is the "surge condition" point of the blower, which indicates unstable blower operating point; the blower should not be operated at or to the left of the point *B*1. In all practical applications, blower capacity control is required to meet the varying demands of the aeration process. The blower discharge flow can be controlled by using one of the three methods: (1) discharge throttling by using a control valve in the discharge line, (2) changing the speed of the blower, and

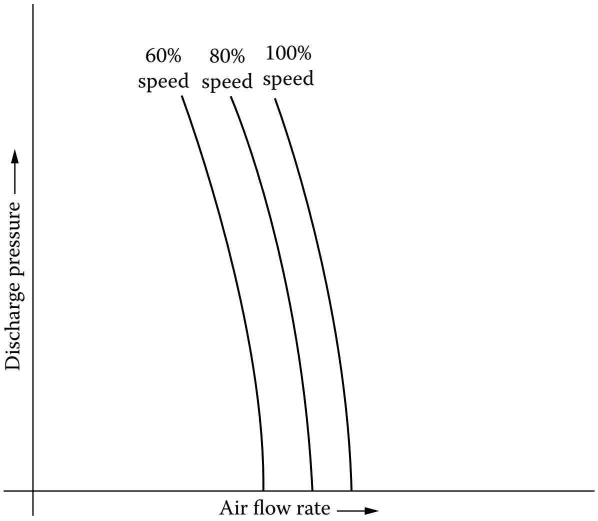

FIG. 8.1h
Characteristic curves of a typical rotary positive displacement blower.

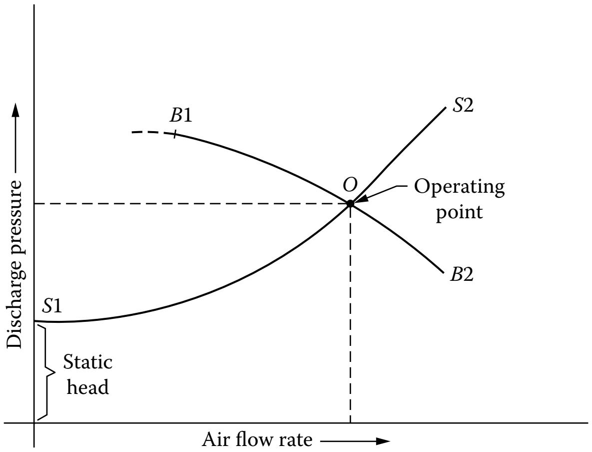

FIG. 8.1i
Characteristic curves of a typical centrifugal blower.

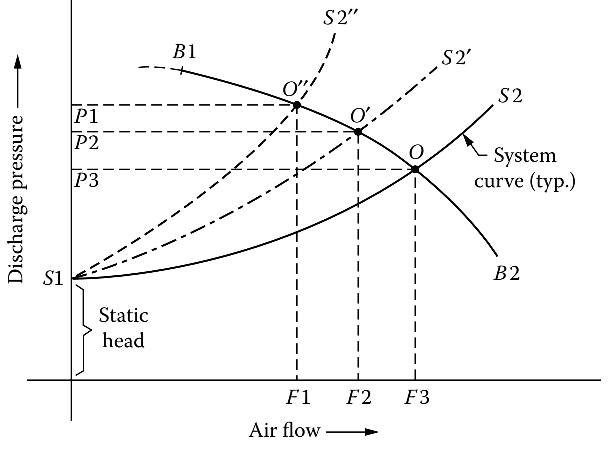

FIG. 8.1j
The effect of discharge valve throttling on the outlet pressure and flow of a centrifugal blower.

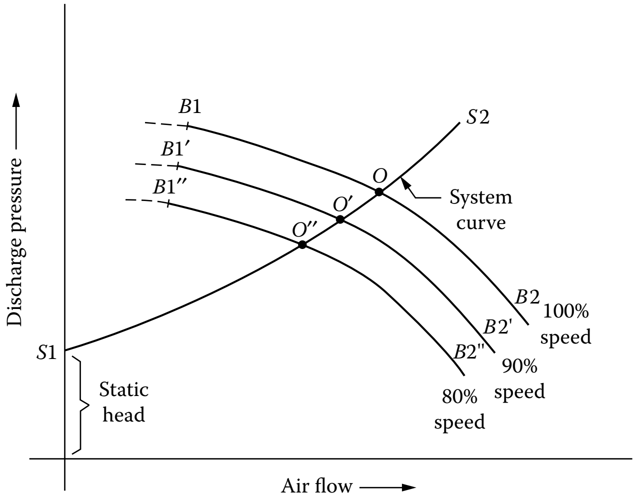

FIG. 8.1k
The effect of suction valve throttling on the outlet pressure and flow of a centrifugal blower.

(3) throttling the inlet using a throttling valve or inlet guide vanes.

Discharge Throttling The effect of discharge throttling on the blower-operating characteristic is shown in Figure 8.1j. Curve $B1$-$B2$ is the blower-operating curve. $S1$-$S2$ is the system curve representing system static head and resistance without any throttling. Point "O" is the operating point without any throttling. System curves $S1$-$S2'$ and $S1$-$S2''$ represent increased resistance for two separate throttled positions of the discharge valve. Note that as the valve is throttled to reduce flow, the operating point "O" moves to the left on the operating curve to point O' and O'', respectively, increasing the header pressure.

As the valve is throttled and the operating point starts moving toward the surge point $B1$, care must be taken so that the operating point never reaches the surge point $B1$. Several methods of surge control are discussed later in this section. Although discharge valve throttling is an effective method of blower capacity control over a limited range, it suffers from two problems.

First, the throttling of valve adds artificial resistance in the system, wasting valuable pressure and energy across the discharge valve, and second, the method is susceptible to reach surge conditions if the pressure and flow are not carefully controlled. To avoid surge conditions, blower output should be kept above 60% of rated output. Because throttling of discharge valve wastes energy, other methods of controlling blower output are more attractive.

Blower Speed Control Blower output can also be regulated by changing the blower speed. Figure 8.1k shows the effect of blower speed control on the blower operating curves. The operating points O, O', and O'' are for 100, 90, and 80% blower speeds, respectively. It should be noted that lower speeds will cause lower system pressure, and any fluctuation in speed will cause fluctuation of flow and pressure conditions.

There is potential for significant energy savings due to the cubic relationship between speed and horsepower requirements for a centrifugal blower. Variable-speed control of blowers is most commonly used with the multistage centrifugal blower applications. Multistage blowers tend to lose efficiency at lower speeds.

Blower Inlet Throttling Blower inlet throttling can be accomplished by using either a throttling control valve or inlet guide vanes (IGVs) at the inlet of the centrifugal blower. The inlet-throttling valve to modulate the blower capacity is used with the multistage centrifugal blowers. However, in this method of capacity control, the blowers tend to lose efficiency at lower capacities due to the pressure drop generated by the inlet-throttling valve.

The IGV are used for capacity control of single-stage centrifugal blowers. The design of the single-stage blowers incorporates IGVs used for controlling the flow and head conditions without a need for speed adjustment of the impeller. In the past, single-stage blowers were controlled utilizing a single set of vanes positioned in the front of the impeller (IGV). Most of today's single-stage blowers utilize a dual vane control system. The two types of controls are briefly described below.

Single vane control utilizes a series of guide vanes positioned in front of the impeller for air flow control. These vanes are utilized to throttle the amount of air allowed into the blower's impeller. By throttling (restricting) the incoming inlet air, an increased pressure differential is built across the blower, resulting in a decrease of discharge air volume. This, in turn, reduces the amount of work required by the mechanical process and reduces the loading on the electric motor.

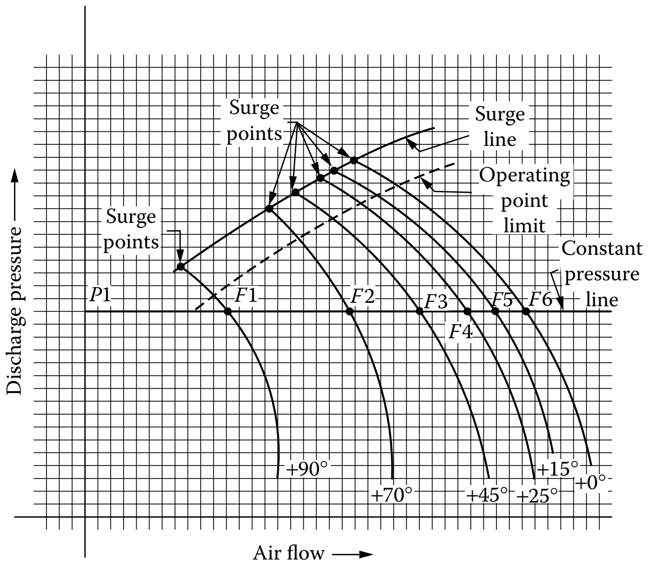

FIG. 8.1l
The characteristic operating lines and surge points when a constant discharge pressure is maintained by setting the inlet guide vane of a centrifugal blower at various angles.

This load reduction translates into a reduction in amp draw, which is directly related to operational expense through the consumption of electric power.

Although less than in the throttling valve of a multistage, the single vane control causes the single-stage blowers to lose efficiency at partial capacity due to the pressure drop generated by the inlet vanes. Figure 8.1l shows how blower capacity control is accomplished by modulating inlet guide vane angles. Again, the surge points are noted for each vane angle position. Care must be taken to avoid flows and pressure conditions corresponding to the surge points. Surge control methods are discussed later in this section.

Dual vane control utilizes two sets of control vanes, one fore and one aft of the blower's impeller. In this control design, the aft or discharge guide vanes are used to control the aerodynamic shape or flow pattern of the air, as it is released from the tip of the impeller blade. By increasing or restricting this airflow path, the amount of flow coming off the impeller wheel is controlled. In concert with this series of flow control vanes, the blower also utilizes onboard instrumentation (differential pressure transmitter and inlet air temperature transmitter), a PLC processor, and an additional set of inlet efficiency optimizing control vanes to achieve optimal airflow efficiency through the blower.

The three variables of machine flow (position of discharge guide vanes), inlet air temperature (this is related to air density of mass), and the differential pressure measured across the machine are utilized to compute the optimal position of the inlet guide vanes in relationship to these three input variables. This process thereby keeps a balanced impeller condition by putting no more air into the impeller than is required by the discharge flow demand.

This dual vane control technology dramatically increases the efficiency of the mechanical blower process. Because of the dual vane control system, the single-stage unit can modulate capacity from 100% to approximately 40%, maintaining the high efficiency practically constant throughout the entire turndown. Today, single-stage blowers with dual vane control systems are the most efficient units on the market. For installation greater than 100–150 hp and higher, with cost of power of $0.035 per kWh and higher, single-stage dual vane blowers have the lowest life cycle cost. The surge points and related control strategies are discussed in the following paragraphs of this section.

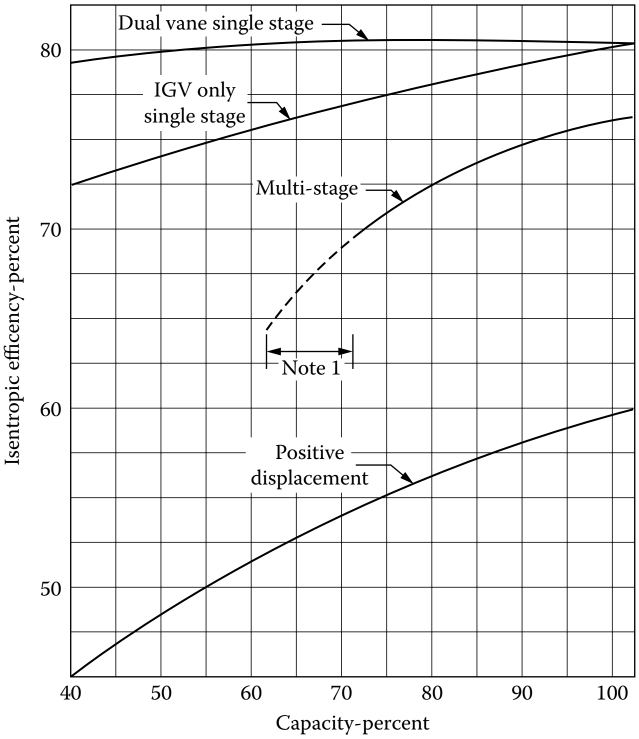
Comparison of Blowers Over the last 75 years, blower design has shown a continuous improvement in optimizing efficiency and operating costs. This improvement in efficiency and lower operation and maintenance cost translates into higher capital cost. Table 8.1m shows an approximate comparison of relative cost and efficiency for various types of blowers used in the aeration process.

Before 1960, positive displacement blowers were widely used in aeration applications. Between 1960 and 1980, multistage blowers became popular due to their higher efficiencies. During the 1980s and 1990s, the single-stage blower with a single inlet vane (IGV) was used extensively because of its higher efficiency, better turndown capability, and the fact that these blowers did not require variable-speed drives.

The present state of the art is the use of single-stage dual vane blowers. Although higher in capital cost, it has the advantage of maintaining high efficiency throughout the entire turndown range of 100–45% of capacity. Figure 8.1n shows isentropic efficiency curves for different types of blowers. It can be seen why single-stage single vane and dual vane blowers are preferred for high-volume aeration applications. The multistage blowers are not only less efficient at 100% capacity but rapidly lose efficiency as the inlet butterfly valve is closed to reduce capacity. Turndown is often limited to 70–80% of capacity. Although low in capital cost, their lower efficiency and high operational cost limit their use in high-volume applications. The positive

TABLE 8.1m
Comparison of Relative Cost and Efficiency for Various Types of Blowers

Type of Blower	*Relative Cost*	*Isentropic Efficiency (%)*
1. Positive displacement blower	1.0	50–60
2. Multistage centrifugal blower with inlet throttling or variable-speed drive	1.5	65–75
3. Single-stage single inlet vane (IGV) centrifugal blower	2.0	72–80
4. Single-stage dual vane centrifugal blower	2.5	80–85



Note:

1. Dashed multistage curve indicates limited turndown

FIG. 8.1n

The isentropic efficiencies of four blower designs.

displacement blowers are used in smaller applications of up to 3000 SCFM (100 hp). As seen in Figure 8.1n, PD blowers have very poor efficiency at 100% capacity, and the efficiency drops rapidly as speed control is used to reduce capacity. Although lowest in efficiency, PD blowers remain popular in small applications due to their low cost.

It is important to note that both capital cost and operational cost must be considered during the blower selection process. A present-worth analysis based on life-cycle costs should be performed to select the best type of blower for a given application.

Surge Control of Blowers Centrifugal blowers have a minimum flow point below which the blower performance becomes unstable. This unstable operating point is called surge condition, and when this condition is reached, wide oscillations in pressure and flow conditions can occur, causing damage to the blower. The surge condition is prevented by always maintaining flow greater than the safe minimum required. This is accomplished by providing a blow-off valve on the discharge line and blowing off excess flow through this valve during low-flow conditions. Figure 8.1o shows typical characteristic curves for a variable-speed centrifugal blower and the function of a surge control algorithm.

The graph of minimum flow surge points for various pressure and speed conditions is called the surge line. The surge line represents a parabolic pressure flow relationship. The purpose of a surge control algorithm is to keep the blower operating to the right of the surge line at all times. The dotted line in Figure 8.1o shows the minimum flow blower operating points maintained by the surge control algorithm. Figure 8.1.1 also shows the surge points and the operating point limit set by the surge control algorithm for a single-stage blower using inlet guide vanes. Blower manufacturers generally provide the data for the surge line as part of their package to ensure that the blower will never be allowed to go into surge.

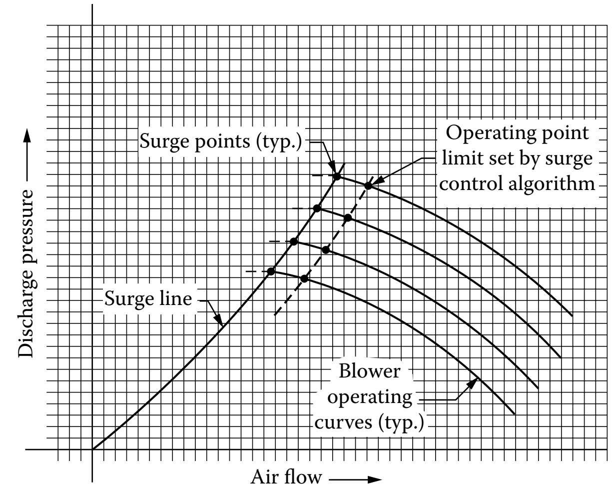


FIG. 8.1o

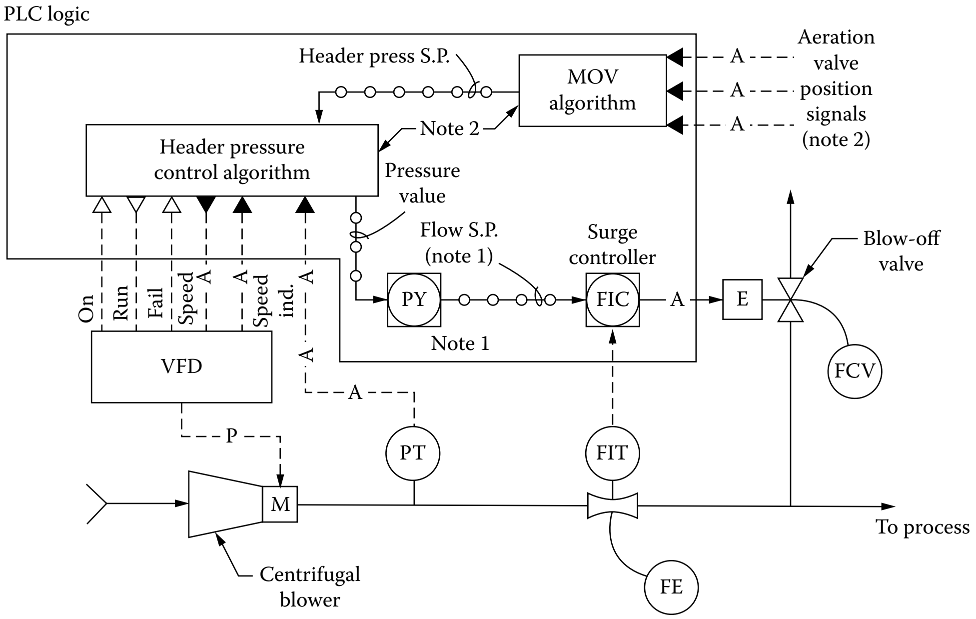
The characteristic curves and surge points of a variable-speed blower at various speed settings.

Several different control strategies are used to prevent surge. Figure 8.1p shows a typical surge control strategy for a variable-speed centrifugal blower. Blower discharge pressure, flow, and aeration cell valve positions are measured and transmitted to the PLC as analog inputs. Based on aeration valve position signals, the most-open valve (MOV) algorithm computes the header pressure set point.

The header pressure algorithm maintains the pressure set point by controlling the blower speeds. Both the MOV and header pressure algorithms will be discussed in the Aeration System Control subsection. The "PY" block in Figure 8.1p receives the pressure value from the header pressure algorithm and computes the minimum permissible flow set point using either a look-up table or an equation (dotted line in Figure 8.1o). The flow set point computed by the "PY" block is used by the surge controller (FIC) to control the blow-off valve to maintain the flow set point that avoids surge conditions.

Figure 8.1q shows another control strategy that can be used for surge control of the centrifugal blower that uses inlet guide vane throttling for control of blower capacity. In this example, the blower motor current and the inlet vane position are continuously measured and transmitted to the PLC.



Notes:

1. Minimum permissible flow S.P. corresponding to a pressure value to prevent surge is computed using either a look-up table or an equation, part of "PY" block.
2. Detailed strategies for most-open valve (MOV) algorithm and header pressure control are described in Figure 8.1w and the subsection Aeration System Control.

FIG. 8.1p
Surge protection control strategy for a variable-speed centrifugal blower, which prevents the blower flow from dropping below an allowable limit.

When inlet vanes are modulated by the header pressure algorithm, to reduce blower output, the motor current draw corresponding to surge point also reduces. The relationship between the inlet vane position and the surge point current draw is nonlinear. This nonlinear relationship can be programmed in the PLC either as a look-up table or an equation. For a measured inlet vane position, the desirable minimum motor current draw is computed ("ZY" block) and used as a set point for the current control algorithm, part of the surge controller (IIC).

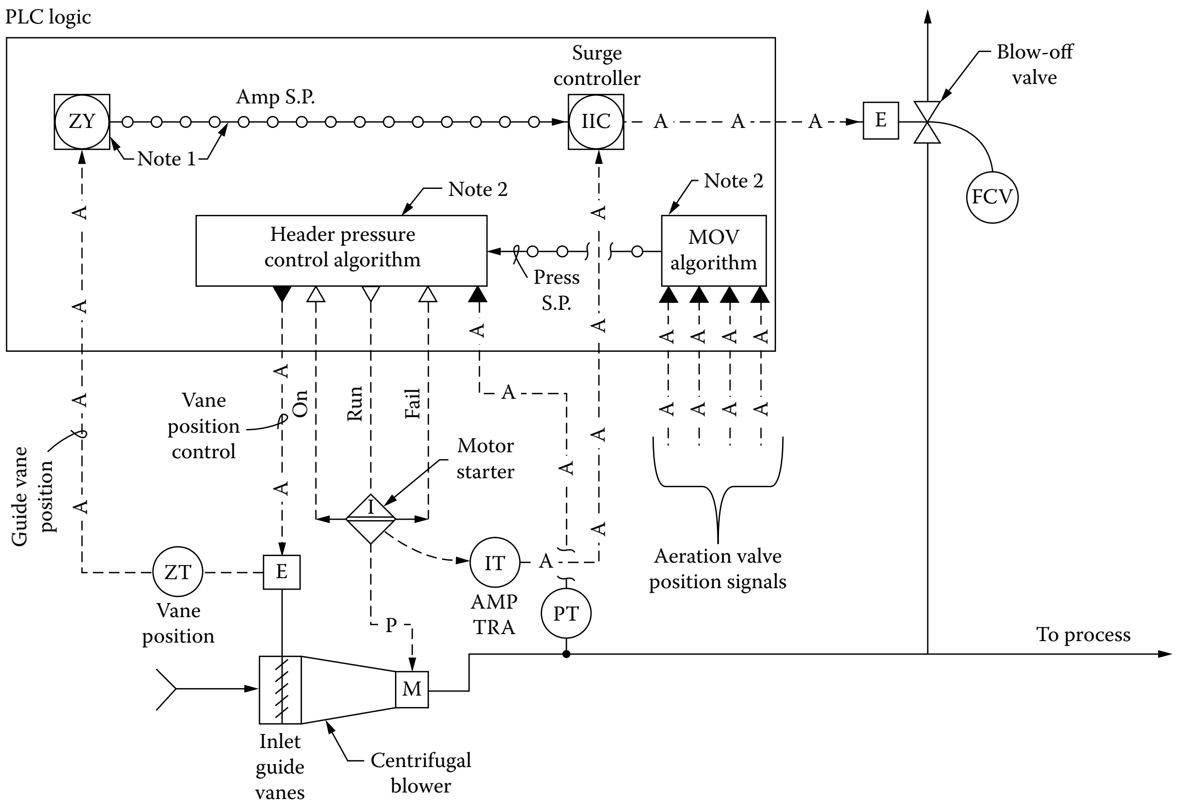
The error between the set point and the actual motor current measurement is used by the PID algorithm (IIC) to open the air blow-off valve to increase the motor ampere draw to avoid the surge point. As was noted earlier, the header pressure and MOV control algorithms will be described in the Aeration System Control subsection. In both Figures 8.1p and 8.1q, the blow-off valve is a modulating-type control valve.

Air Distribution Control Valves

Air distribution control valves are important building blocks of any aeration control system. Selection, sizing, and application of the correct type of control valves for air distribution are very important for a properly operating aeration control system. An oversized control valve can reduce the effective air flow turndown capability, create flow oscillations and difficulty in maintaining flow or pressure set points. However, an undersized control valve can cause excessive pressure drops, energy losses, and increased noise levels. The subject of control valves, their selection, and sizing is discussed in detail in Chapter 6 of this handbook; however, a brief discussion is included here for the sake of continuity.

Typical valve-sizing calculations should include checking for choked flow, determination of the expansion and compressibility factors, and the calculation of valve capacity coefficient C_v. The valve-size selection should also include air velocity and noise considerations.

Selection of valve flow characteristics is an important consideration in designing a stable control system. The most common flow characteristics are linear, equal percentage, and quick opening. For aeration flow application, the equal-percentage characteristics are the most suitable. As the name suggests, the equal-percentage characteristic increases the valve flow capacity by the same percentage for each equal increment of travel. Equal-percentage butterfly valves are commonly used in the aeration flow and pressure control applications.



Notes:

1. Minimum permissible blower amp set point corresponding to a guide vane position to prevent surge is computed either using a look-up table or an equation, part of ZY block.
2. Detailed strategies for most-open valve (MOV) algorithm and header pressure control are described in Figure 8.1w and the subsection Aeration System Control.

FIG. 8.1q
Surge protection control strategy for an inlet vane controlled centrifugal blower, using the inlet guide vane position and the motor current drawn to detect the approach of a surge condition.

Automatic valve actuators serve to position the valve in accordance with the control signal received. The commonly used actuators in aeration applications include the pneumatic spring and diaphragm and the electric motor-driven designs.

Pneumatic Actuators A pneumatic actuator in conjunction with a three-way solenoid valve is used in an on/off application, whereas an actuator with a positioner allows modulation of the valve in response to a control signal. The electronic 4–20 mA control signal is converted to 3–15 psi pneumatic signal applied as input to the positioner.

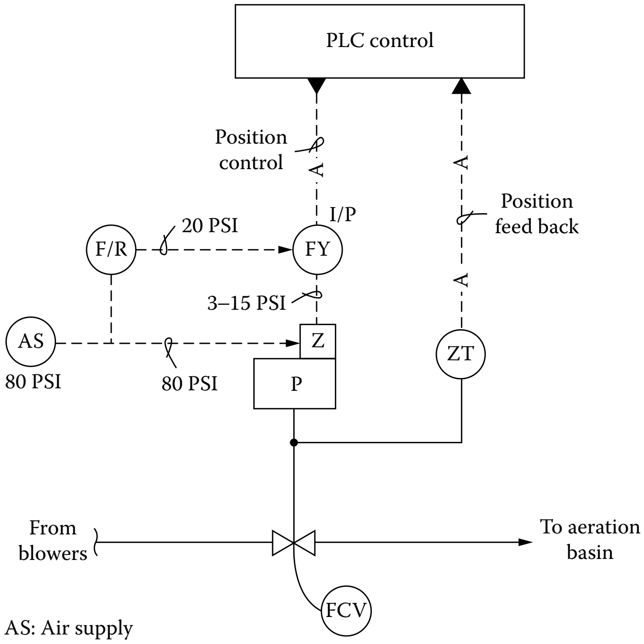
Figure 8.1r shows typical control and instrumentation devices associated with pneumatic diaphragm-type valve, actuator, and positioner. For applications where fail open- or fail close-type operation is desired, the pneumatic spring-and-diaphragm-type actuator has a distinct advantage because the failure modes are easily implemented.

Electric Actuators The electric motor-driven actuators can be on/off or modulating. The actuator consists of an electric motor and a reversing starter/contactor that allows the motor to run in forward or reverse direction, thus opening or closing the valve. Modulating valves can be throttled by a 4–20 mA electronic signal.

The actuators for smaller valves operate on 120 V, single-phase AC power, utilizing single-phase "capacitor start" motors, and for the larger valves, the actuators operate on 480 V, three-phase, AC power supply using three-phase motors. The valve operational torque requirements determine the type of motor and power supply.

Typically a modulating valve with electric actuator consists of the following devices:

A local-off-remote switch. When this switch is in local position, the valve can be manually controlled using either actuator-mounted open–close pushbuttons or a local potentiometer to



AS: Air supply
F/R: Air filter/pressure regulator
FY: Current to pressure converter
ZT: Position transmitter
Z: Pneumatic positioner
P: Pneumatic actuator
FCV: Flow control valve

FIG. 8.1r

adjust the valve position. When the switch is in remote position, the valve is controlled by a remote 4–20 mA signal generated from the PLC-based control system.

Limit switches indicate fully open or closed position of the valve; they are often wired to the PLC for status indication.

A position transducer transmits an analog 4–20 mA signal proportional to the valve position to be wired to the PLC-based control system.

Figure 8.1s shows the components of a loop consisting of an electrically operated throttling valve, which is controlled by a PLC.

Materials of construction for the valve body, trim, and liner must be specified to suit the application. The best way to specify a control valve is to use a standard ISA data sheet with all the blanks filled appropriately.

MEASUREMENT OF DO CONCENTRATION

Section 8.43 in the first volume of this handbook provides an in-depth discussion of the features and capabilities of all the oxygen detector designs that can be used with liquid samples. Accurate measurement of DO concentration is very important to the success of any aeration control strategy.

FIG. 8.1s
The components of a control loop consisting of a PLC that is controlling an electrically actuated control valve, which is provided with stem position feedback.

Typically, a DO sensor generates an electronic low-level signal proportional to the DO level in the process fluid, which is converted to a 4–20 mA analog signal by the transmitter/analyzer for connection to the control system.

Galvanic Cell

In a galvanic-type DO sensor, the reduction of oxygen at the cathode and production of electrons at the anode generates a current. The magnitude of the current flowing between the cathode and anode is proportional to the amount of DO present in the process fluid. The electrodes are either made of silver alloy and zinc or platinum and lead. There are two types of designs available in the galvanic-type sensors.

In the first type of design, the electrodes are enclosed in a thin membrane to isolate and protect them from the process fluid. The membrane-type sensors have to be periodically cleaned to keep them operational, and they require electrolyte solution. Some manufacturers supply integral automatic cleaning systems with the electrodes for ease in maintenance. The periodic automatic cleaning is accomplished using a high-pressure air jet to scour the membrane of the accumulated deposits. The sensor is electrically connected to the analyzer/transmitter for generating 4–20 mA analog output proportional to DO. The high-pressure air supply and associated control is incorporated in the analyzer/transmitter enclosure. The control logic, part of the analyzer, holds the analog output during the cleaning cycle to avoid interruption of the signal to the control system.

In the second type of design, the galvanic electrodes are directly immersed in the process fluid without any membrane. The cleaning of electrodes is accomplished by a motor-driven diamond grindstone to provide a continuous cleaning action on the metal electrodes. This self-cleaning action on the electrodes addresses the maintenance problem. The electrodes are protected from large suspended solids using a sample chamber. The sample chamber continuously oscillates to pump fresh sample to the measuring electrodes.

Polarographic Cell

These types of sensors use oxygen current measurement technique, wherein a "polarizing voltage" is applied across a selected electrode, where the oxygen reduction occurs via an electrical reaction called *polarographic*. The polarographic current is proportional to the oxygen concentration in the process fluid.

The sensor is a three-electrode polarographic sensor consisting of a silver reference, silver anode, and a gold cathode. The electrodes are covered by a 50μ hydrophobic membrane, which is preinstalled in a membrane head assembly. The membrane and membrane head assembly are constructed of fluorinated ethylene propylene and polyoxymethylene, respectively. The sensor body is constructed of stainless steel and polyoxymethylene. The sensor includes automatic temperature compensation to compensate for changes in process temperature.

Again, the presence of membrane requires extra care in maintenance and the need for electrolyte solutions.

Galvanic and Polarographic Cell Limitations

The galvanic and polarographic DO sensing techniques have been used for the last 50 years. As discussed before, the key components used in these types of sensors are anodes, cathodes, membranes, membrane cleaning devices, and electrolyte solutions. Although these types of sensors have a long track record of successful applications, they pose the following challenges related to operation and maintenance.

Some of the limitations and concerns include:

1. Anodes are eventually consumed and require periodic replacement and calibration.
2. Calibration kits consisting of disposable calibration bags are required to perform "saturation method" air calibrations.
3. Electrolyte solutions require periodic replacement and are subject to contamination.
4. Gases like hydrogen sulfide can contaminate electrodes and electrolytes, requiring replacement.
5. Sensor membranes become coated with grease and dirt and require regular cleaning. Although some manufacturers provide mechanisms like air-blast cleaning for periodic automatic cleaning, these mechanisms also need additional maintenance.
6. The sensors are subject to interference from anything that produces small voltages.

Luminescent DO Sensors

Luminescent DO sensors are relatively new in the DO sensor technology. These types of sensors have been developed to minimize the maintenance problems associated with the galvanic- or polarographic-type sensors. Figure 8.1t shows the basic operating principle of a luminescent-type DO sensor.

The luminescent sensor is coated with a luminescent material. Blue light from a light-emitting diode (LED) is transmitted to the sensor surface. The blue light excites the luminescent material. As the material relaxes, it emits red light. The time from when the blue light was sent and the red light is emitted is measured by the photo diode. The more oxygen that is present, the shorter the time it takes for the red light to be emitted. This time is measured and correlated to the oxygen concentration. Between the flashes of blue light, a red LED is flashed on the sensor and used as a reference.

Although not enough actual operational data is available at the time of this writing, the limited experience indicates that this type of sensor has a good potential for success. The luminescent-type DO sensor has the following advantages over the traditional sensors:

1. Membrane cleaning and replacement is eliminated because the technique does not use membranes. Because membranes are not used, there is no need for electrolytes.
2. There are no anodes or cathodes, and this eliminates the need for their replacement.

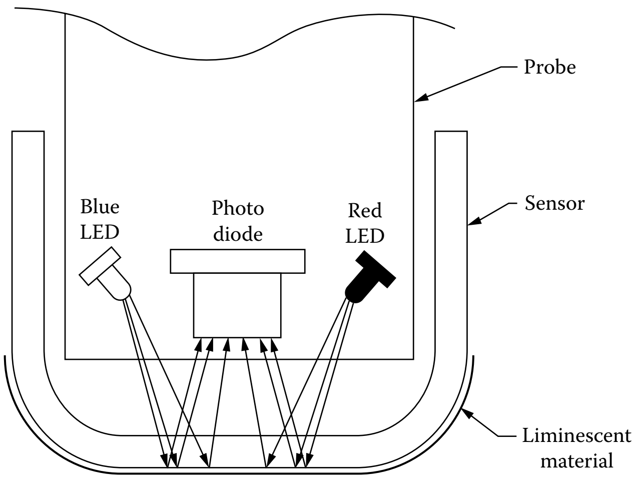

FIG. 8.1t
The main components of a luminescent dissolved oxygen sensor.

3. Sensing technique is less susceptible to interference from spurious signals.
4. The sensor can be mounted at any desired submersion depth.

MISCELLANEOUS FIELD INSTRUMENTS

Other important measurements required in any aeration control system are air flow, header pressure, and air temperature measurements. Air flow to each aeration cell, part of the aeration basin, is measured to be used as a process variable in the air flow control algorithm discussed later in this section. The newer thermal dispersion-type flow meter is successfully used in air flow measurement applications.

A pitot tube or a venturi tube can also be used for air flow measurements, but the pitot tube is less accurate than the thermal dispersion-type flow meter. The venturi tube gives satisfactory results, but is expensive and requires long straight pipe runs upstream and downstream of the meter. Orifice plates are not suitable for flow measurement on low-pressure systems. Pressure transmitters are required for measurement of header air pressure to be used for control of blower capacity.

Both air temperature measurement and differential pressure measurement across the blower are used by blower manufacturers to develop algorithms for precise control of dual vane single-stage centrifugal blowers.

CONTROL OF DIFFUSED AERATION

Parallel and Cascade Control of Blowers

All major aeration applications require multiple blower units connected to a common header. Blowers are turned ON or OFF and the capacities controlled to suit the aeration cells. Today, many of the high-volume aeration processes use single-stage blowers because of their efficiency and ease of control by modulating inlet guide vanes. Two types of single-stage blowers are generally used, namely single stage with IGV only and single stage with dual vanes (IGVs and variable diffuser vanes). Depending on the type of blower used, two types of capacity control strategies are used:

In *Parallel capacity control*, multiple blower capacities are simultaneously modulated to suit the air demand. As explained in the next paragraphs, due to the drooping "surge line," the single IGV blowers are restricted to use only parallel capacity control, which allows capacity control without the possibility of approaching surge conditions.

Cascade capacity control is defined as varying the capacity of one on-line blower while capacities of other blowers are held at either maximum or minimum. Because of the flat "surge line" of the dual vane blowers, the cascade control can be used for these blowers without the possibility of reaching surge conditions.

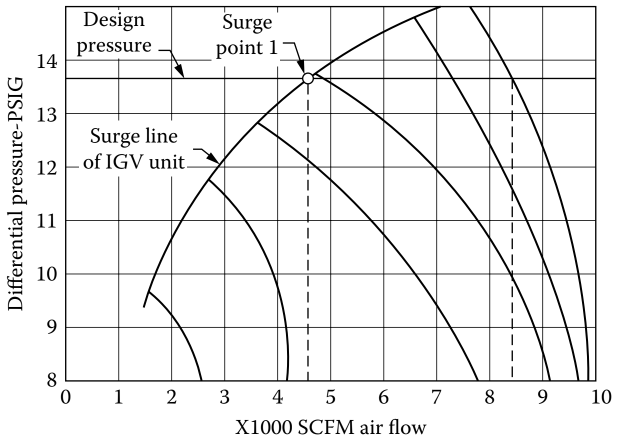

FIG. 8.1u
The surge and operating lines of blowers whose capacity is controlled by inlet guide vanes.

Single-Stage IGV Blowers in Parallel Capacity control of single IGV blowers is accomplished by modulating the inlet guide vanes to throttle the inlet airflow. Closing the IGVs to reduce the capacity increases pressure drop across the IGVs and thus reduces both the discharge pressure and the surge pressure point of the unit.

Figure 8.1u shows the air flow vs. differential pressure curves for the IGV blower with the characteristic curves corresponding to the various positions of the inlet guide vanes. As shown in the figure, as the capacity is reduced by the closure of the vanes, the surge pressure is also reduced. This results in a drooping surge line, which is the reason why these blowers must operate in parallel.

To explain the limitations of parallel operation, assume as shown in Figure 8.1u that the design pressure is 13.7 PSIG, and the maximum flow is 8700 SCFM. Let us further assume the unit is designed to turndown to a minimum of 45% capacity or 3400 SCFM, which is below the surge limit. Hence, at high ambient temperature conditions (100°F), the unit may go into surge before maximum turndown is reached.

This is illustrated in Figure 8.1u, where the surge point 1 is at 4400 SCFM or at 51% of maximum capacity. Thus, in case of an operation where a single blower was meeting the process load until its full capacity (100%) is reached and at that point a parallel blower is started, the resulting total loading would be 50%, while the surge limit is 51%, hence the system would go into surge. On the other hand, if the on-line unit(s) were reduced in capacity and the off-line unit brought on-line at this same reduced capacity, all units would thereby have equal surge pressures, and one unit would not go into surge before the others.

The parallel capacity control has the following limitations:

All on-line units vary capacity at the same time, which means small changes in vane setting creates large flow changes and finer airflow variation cannot be accomplished.

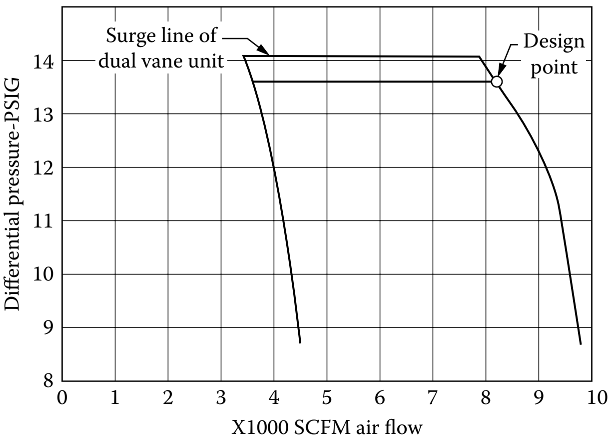

FIG. 8.1v
The surge and operating lines of blowers whose capacity is controlled by dual vanes.

Parallel control requires more elaborate instrumentation to keep all units at the same vane position over long operating periods. Vane position feedback signals or motor current draw are used for keeping the units from "floating" away from each other over long periods of continuous operation.

Single-Stage Dual Vane Blowers in Cascade Single-stage dual vane blowers were developed in the mid 1980s. These designs utilize inlet guide vanes with variable-diffuser vanes. These types of blowers not only have the highest efficiency, but also change the surge curves of single-stage blowers.

As shown in Figure 8.1v, the surge curve is flat (as opposed to drooping in the case of IGV blowers) over the entire turndown range. The surge pressure is the same, regardless of the vane position. This flat surge curve allows cascade control where only one blower capacity is modulated, while others are held constant at maximum or minimum capacity. A typical example of cascade control sequence to maintain discharge header pressure (to meet flow demand) for a three-blower system is described below. In this description, 100% capacity refers to full capacity of single unit.

First Blower The following is the sequence of system response as the process load (demand for air) rises:

On-line at 45% capacity
If, in order to maintain the header pressure set point (S.P.), more air is required:
Increase first compressor to 100% as required to maintain header pressure S.P.
If, in order to maintain the header pressure set point, more air is required:

Start Second Blower

During 2-min prelube cycle, first unit reduces to 45% capacity.
Second unit comes on-line at 45% capacity, resulting in a total capacity of 90%.
Hold second unit at 45%, increase first unit up to 100% as required to maintain header pressure S.P. When first unit reaches 100%, this results in a total of 145% capacity.
If, in order to maintain the header pressure set point, more air is required:
Hold first unit at 100% capacity, increase second unit to 100% as required to maintain header pressure S.P. When second unit reaches 100%, this results in a total of 200% capacity.
If, in order to maintain the header pressure set point, more air is required:

Start Third Blower

During 2-min prelube cycle, the first unit remains at 100%, the second unit reduces to 45% capacity, and the third unit comes on-line at 45% capacity, resulting in a total capacity of 190%.
If, in order to maintain the header pressure set point, more air is required:
Hold first unit at 100% capacity, hold third unit at 45%, increase second unit to 100% as required to maintain header pressure S.P. When second unit reaches 100%, this results in 100% + 100% + 45% = 245%.
If, in order to maintain the header pressure set point, more air is required:
Hold first and second units at 100%, increase third unit to 100% as required to maintain header pressure S.P.
On decreasing air demand or increasing header pressure, a sequence similar to above but in reverse order can be followed to reduce speed to 45% and shut down blowers one at a time.

In this example, cascade control allows precise control of air flow from 45% of the single unit's capacity to the maximum of 300% of the single unit capacity. The control is simplified because exact vane position of the modulating unit is not as important as in parallel control. Because of their higher efficiency and more precise capacity control, the dual vane single-stage blowers are becoming popular.

Aeration System Control

Figure 8.1w shows major control loops for a typical aeration process. This example shows three single-stage blowers (*B*-1, *B*-2, and *B*-3) that are discharging into a common air header. Three separate air lines branch off from the common header and connect to the diffusers in three separate aeration cells. Each aeration cell includes DO sensors and transmitters (AE/AT-1, -2, -3) for the measurement and transmission of DO concentration data. Each of the air lines includes a flow

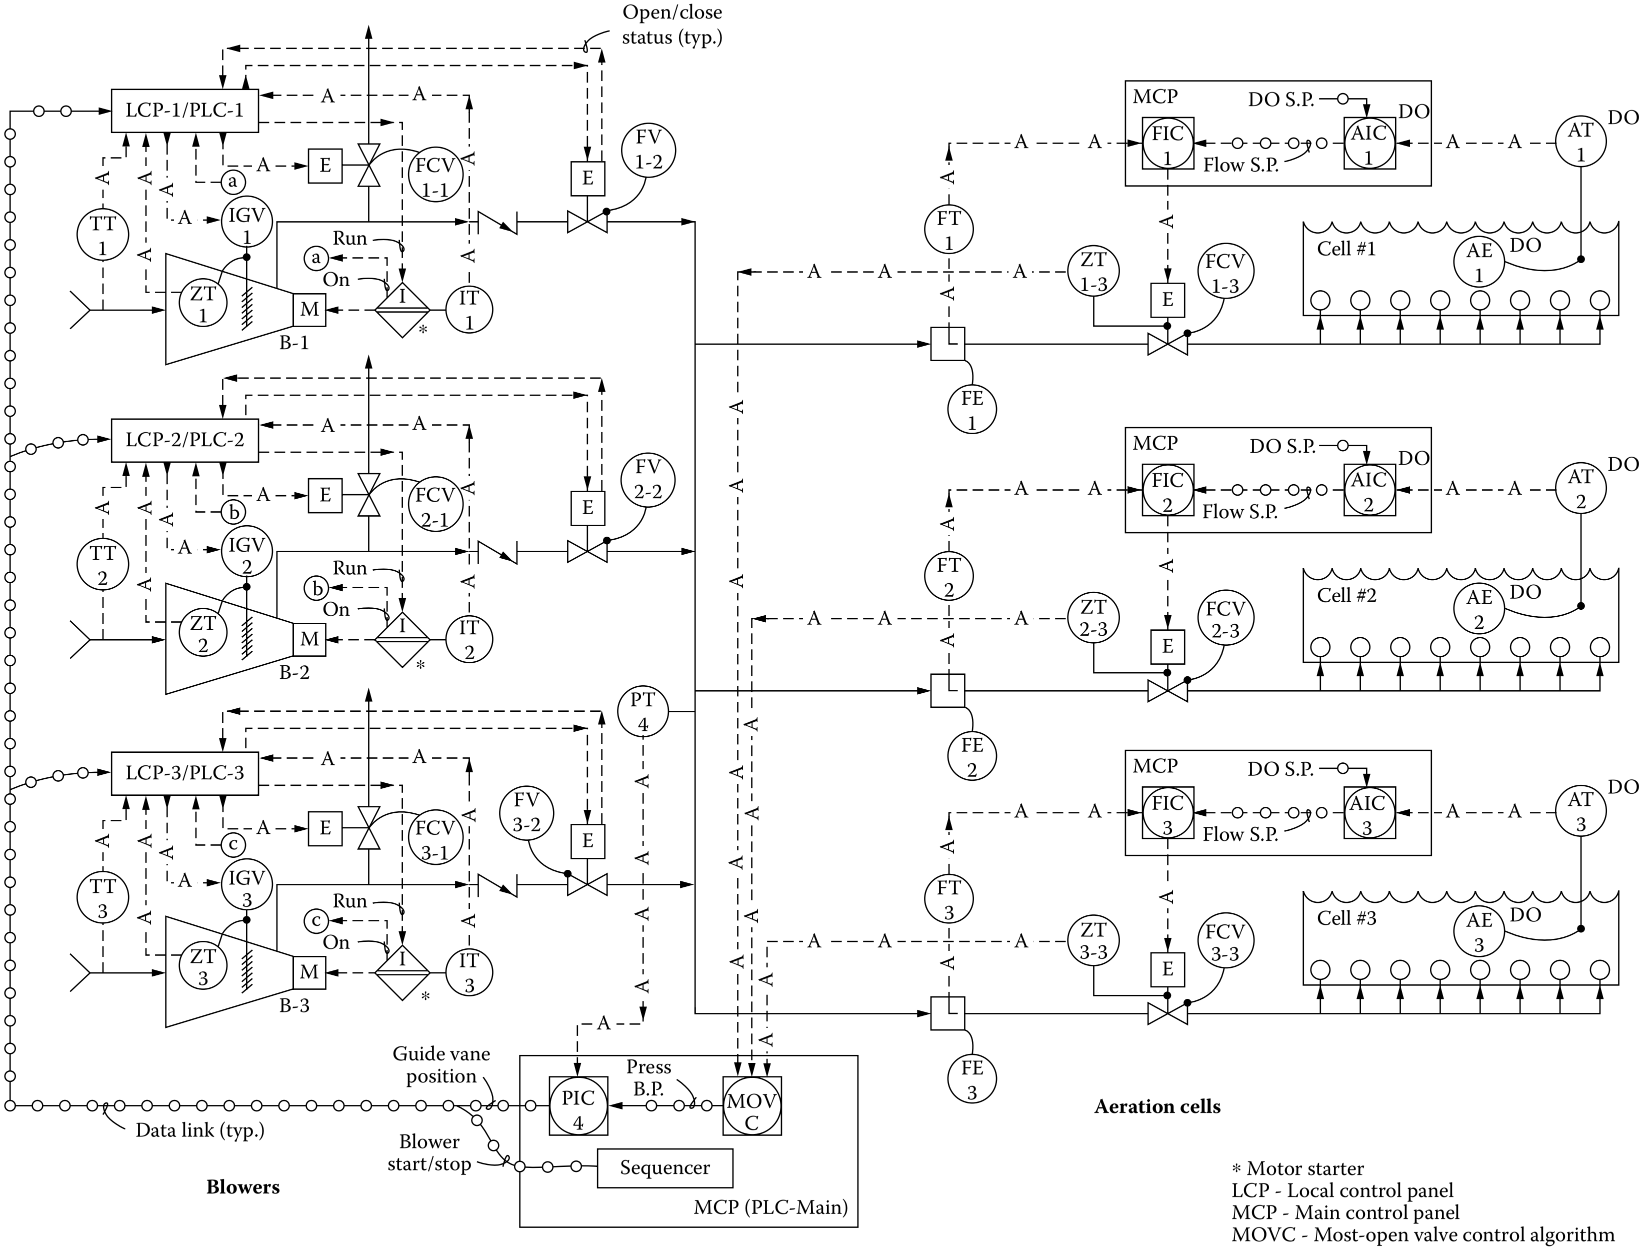

FIG. 8.1w
The overall control system of an aeration process.

meter (FE/FT-1, -2, -3) and a control valve (FCV-1-3, -2-3, -3-3) for measurement and control of air flow into each cell.

The common air header includes a pressure transmitter (PT-4). The discharge air header pressure controller (PIC-4) controls the blower capacities. Each blower discharge line includes a blow-off valve (FCV-1-1, -2-1, -3-1) and a discharge valve (FV-1-2, -2-2, -3-2). The blower can be multistage with inlet throttling valve or single stage with single IGV type or dual vane, but an IGV type is shown.

The position of IGV is transmitted to the local control panel using position transducers (ZT-1, -2, -3). Blower motor current for each blower is also transmitted to the local control panel using current transducers (IT-1, -2, -3). Each blower is equipped with a local PLC-based control panel for control and monitoring of the blower (LCP-1, -2, -3).

A PLC-based main control panel (MCP) is provided for overall control of the aeration process, including DO control, air flow control, air header pressure control, and blower control. A data link allows communication between the main PLC and the local PLC panels.

Major Control Loops Referring to Figure 8.1w, the overall aeration control system can be divided into three basic subsystems:

- Aeration cell control loops
- Header pressure and "most-open valve" control
- Control of blowers to maintain header pressure

Aeration Cell Control Loops (Loops 1, 2, 3) Control of air flow to each aeration cell is accomplished using a dedicated cascade flow/DO control loop as shown in Figure 8.1w. For cell #1, the inner loop or faster loop is a flow control loop, which modulates the flow control valve (FCV-1-3) to maintain the flow set point. Flow transmitter FT-1 provides the measured variable signal to PID flow controller FIC-1, which generates an output to modulate FCV-1-3 to maintain the air flow set point. However, the flow set point must be continuously adjusted to suit the oxygen demand of the aeration cell.

This continuous flow set point adjustment is provided by the slower outer DO control loop. DO transmitter AT-1 provides the DO signal proportional to DO concentration in the aeration cell #1. The DO controller AIC-1 compares the DO signal with the desired DO set point and generates an output that is linearized to provide a flow set point to the inner flow control loop, which maintains the desired air flow to the aeration cell. Thus, the aeration cell control loop consists of two subcontrol loops; the outer DO loop is cascaded with the inner flow control loop for air flow control.

The DO loop is a much slower loop and the response of the DO probe must be averaged over relatively long periods of time. A dead band can be provided on the flow set point such that the set point is not changed unless the change is greater than the preset dead band. This will minimize excessive change in the flow set point. Control loops for other cells (#2 and #3) are similar.

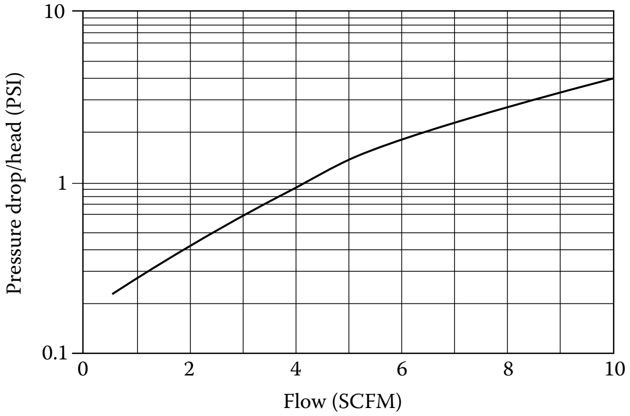

FIG. 8.1x
The relationship between flow and pressure drop in a fine bubble diffuser.

Minimum and maximum flow limits are usually set to maintain minimum mixing requirements and to maintain air flow within efficient operating ranges of the aeration cell diffusers and piping. In general, the speed of the aeration flow control loops should be approximately one tenth of the speed of the blower control loops in order to maintain system stability.

All flow and DO controllers are PID algorithms programmed in the PLC, part of the main control panel.

Header Pressure and Most-Open Valve Control Air header pressure is used as the process variable to control blower capacity. The air header pressure set point must be defined to provide enough pressure at maximum flow to overcome all frictional losses through piping and head loss through the diffusers. Figure 8.1x shows the head loss characteristics of a typical fine bubble diffuser.

Doubling the air flow through the diffuser can more than double the head loss, depending upon where the air flow is located on the pressure drop curve. Thus, for controlling an aeration system, it is very important to vary the air header pressure as a function of flow. Using Bernoulli's equation, the following relationship can be used to define the header pressure set point as a function of aeration flow.

$$SP = K_1 + K_2 \ (Q_T/K_3)^2 \qquad \mathbf{8.1(1)}$$

where

SP = header pressure set point
Q_T = total flow set point (sum of flow set points of all cells)
K_1, K_2, K_3 = constants

The problem in using this equation is that it does not account for the actual system pressure losses. Equation 8.1(1) is generally characterized and constants are evaluated during start-up by conducting tests. No correction is applied for gradual increase in differential pressure across the diffusers as the system gets dirty, diffusers clog, or an abnormal obstruction occurs in the piping to one of the cells.

Another method to relate the header pressure set point to the aeration flow is to define a relationship between the header pressure set point and the most-open air flow control valve position for the aeration cells. Equation 8.1(2) shows a typical relationship:

$$SP = K_1 + K_2\,(VP) \qquad \mathbf{8.1(2)}$$

where

SP = header pressure set point
VP = most-open valve position
K_1, K_2 = constants

Equation 8.1(2) is a linear equation that is a reasonable approximation to the actual relationship, which should follow Bernoulli's equation.

The constants K_1 and K_2 can be determined theoretically during aeration system design and further refined during start-up by conducting tests. During the design phase, the pressure drop to each aeration cell is characterized for minimum and maximum design flows. The flow control valve to each aeration cell (FCV-1-3, -2-3, and -3-3) should be chosen to provide pressure control between 30 and 80% open.

During process start-up, a test is conducted to determine header pressure at minimum and maximum flows. The values of header pressure and most-open valve position (VP) for minimum and maximum flow are substituted in Equation 8.1(2), resulting in two equations (one corresponding to minimum flow and the other corresponding to maximum flow) and two unknowns (constants K_1 and K_2). These equations are solved to determine the values of the two constants K_1 and K_2.

During operation, when the position of the most-open valve is changed either to adjust the air flow to maintain the DO set point or to maintain the flow under increased frictional or diffuser head loss, the header pressure set point is adjusted using Equation 8.1(2). In other words, the header pressure set point is continuously adjusted based on the position of the most-open valve.

For a review of the operation of the most-open valve algorithm refer to Figure 8.1w. Let us assume that cell #1 diffuser is clogged, restricting flow. Controller FIC-1 will cause the valve FCV-1-3 to fully open, trying to maintain the required flow set point. Equation 8.1(2) will increase the header pressure set point due to increased most-open valve (FCV-1-3) position VP. The increased header pressure will clear out the obstruction in the cell #1 diffuser and as soon as the diffuser is unclogged, FIC-1 will bring FCV-1-3 to its normal position, bringing the header pressure set point back to normal value.

The most-open valve algorithm is allowed to quickly and automatically fix the clogged diffuser situation, which otherwise would have remained unnoticed for a long period leading to process upset. A properly designed and tuned most-open valve algorithm allows all air flow control valves to find a natural equilibrium. Generally slight changes in the most-open valve position will cause all other valves to slightly open or close as a result of the algorithm using Equation 8.1(2).

Referring to Figure 8.1w, the most-open valve algorithm (MOV-C) is resident in the main PLC. It receives the valve position signals from all the valves, determines the most-open valve position, and generates a header pressure set point value using Equation 8.1(2). A dead band can be provided on the pressure set point that will not allow change in pressure set point unless the required change exceeds the dead band.

The header pressure PID control algorithm is also resident in the main PLC and generates output to control the blower capacities to maintain the pressure set point. The blower control is described in the next paragraph.

Control of Blowers to Maintain the Header Pressure Figure 8.1w shows three blowers (*B*-1, *B*-2, and *B*-3) connected to the common header part of the aeration system. The blowers shown in this example are single-stage centrifugal blowers. These blowers can be either multistage with inlet throttling valve or single-stage single vane (IGV) or dual vane blowers. Each blower has a PLC-based local control panel (LCP-1, -2, or -3) that controls the blower operation.

The local control panel receives air temperature and inlet vane position analog signals and generates analog outputs for controlling the inlet guide vanes and the blow-off valve. The local panel also generates digital outputs (dry contacts) to start/stop the blower, interfaced with motor starter and open/close outputs for control of blower discharge valve (FV-1-2, -2-2, -3-2). Each panel receives digital inputs (contact closure) from the motor starter for ON status and the open/close status from discharge valve. All safety control logic including surge control is part of the local panel controls.

As discussed in the previous paragraph the algorithm for header pressure control using the most-open valve algorithm is programmed in the main control panel PLC. The blower sequencer is also programmed in the main PLC. The local panel PLCs (PLC-1, PLC-2, or PLC-3) receive blower start/stop commands, IGV position commands, and header pressure values from the main PLC via data link.

The sequencer logic decides when to start or stop the next blower, and the start/stop commands are relayed to the local panels via the data link. As described in the earlier section Parallel and Cascade Control of Blowers, either parallel or cascade control strategy is programmed in the main PLC, depending on whether the blowers are multistage or single or dual vane single-stage blowers.

Using the parallel or cascade control strategy, the sequencer issues commands for starting or stopping the next blower, and the header pressure control algorithm either modulates multiple blower IGVs (parallel control) simultaneously or single blower IGV one at a time (cascade control), depending upon the type of blower system selected. Both parallel and cascade control strategies have been described in the earlier section Parallel and Cascade Control of Blowers.

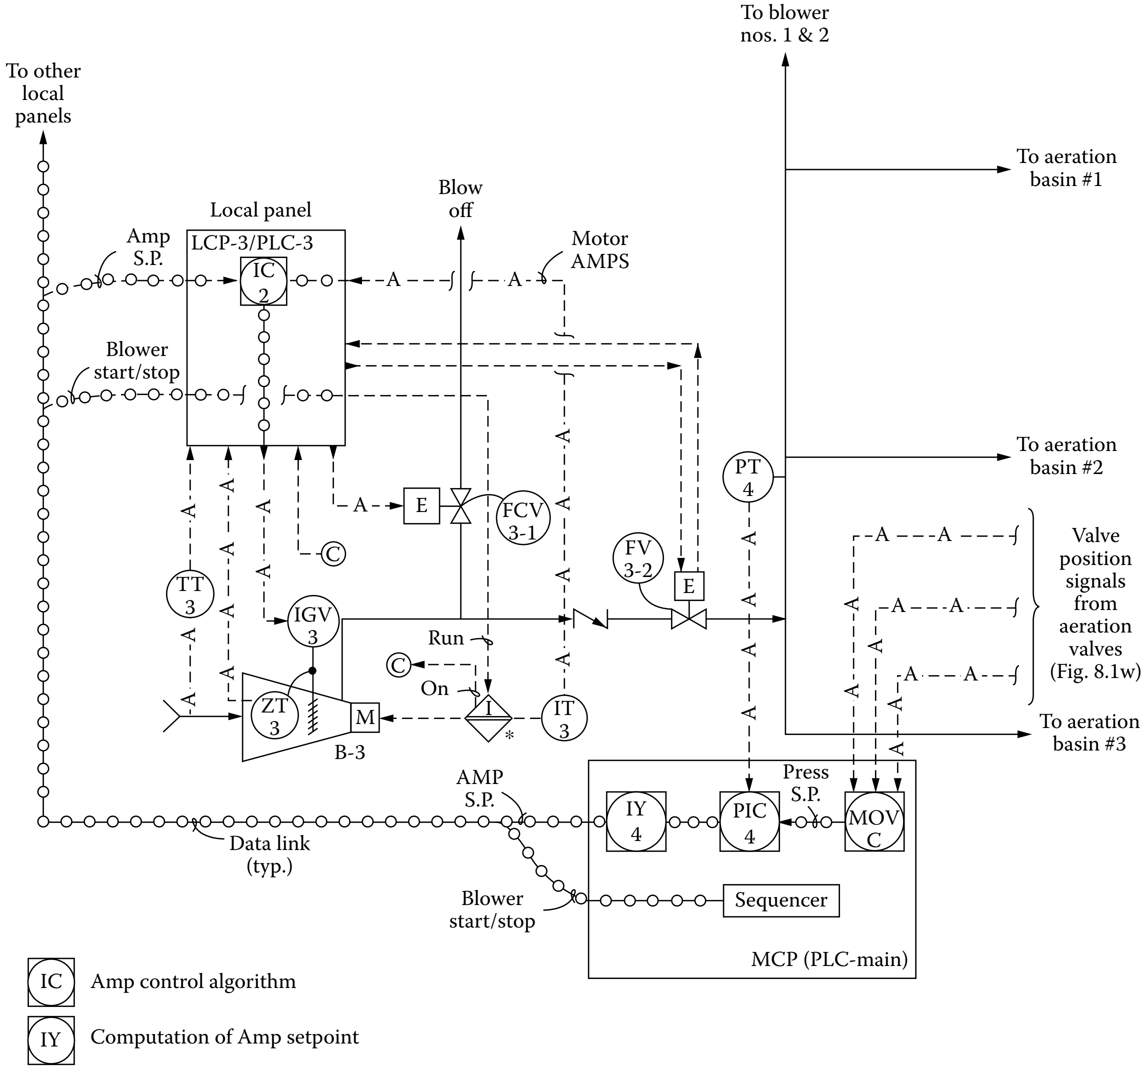

FIG. 8.1y
Controlling the header pressure by throttling the current to the blower motor.

The surge control strategy for each blower is programmed in the local PLC, part of the dedicated local control panel for each blower. The control strategies for surge control for different types of blowers were discussed in the earlier subsection Surge Control of Blowers. The local PLC logic includes a look-up table that provides the desired blower ampere draw set point that is required to avoid surge conditions for a given inlet guide vane position. The ampere controller algorithm looks at the measured blower current and compares this value with the desirable set point.

If the measured current is less than the desired set point, the algorithm generates an output to open the blow-off valve to bring the motor current draw to the desired value that is within the safe operating region. Thus, in this example, blower ampere draw is controlled to prevent the blower from going into surge condition.

Throttling Motor Current to Maintain Header Pressure In some applications, the inlet guide vanes for the single-stage blowers, or the inlet valve in the case of multistage blowers, is modulated to maintain a blower motor current set point. Referring to Figure 8.1y, the output of the pressure controller PIC-4 is converted into a blower current (amperes) set point using a linear equation, using the computation block IY-4. The computed ampere set point is transmitted to the local PLC panel (LCP-3), via the data link. The amp controller (IC-3) is programmed in the local individual blower panel PLC.

The current (amp) controller receives the measured value of motor current, compares it to the desired amp set point, and generates an output to modulate the inlet guide vane or valve to bring the motor current to the set point. The other control loops for aeration basin flow control, DO control, and most-open valve control strategies remain the same as shown in Figure 8.1w.

NITROGEN PROFILE ANALYZERS FOR WASTEWATER

The classical method of aeration control has been to maintain a desired DO concentration set point using DO measurement and control algorithms discussed before in this section. One problem with this approach is that the DO set point is usually set very conservatively to ensure excess of DO in the wastewater. Maintaining surplus DO in the aeration basin effluent to an arbitrary high set point is a convenient way to ensure that all ammonia has been converted to oxidized nitrogen, i.e., the wastewater has been fully "nitrified."

The difference between the oxygen required to achieve process objectives (full nitrification) and the actual oxygen delivered to meet a DO set point represents the potential energy savings that can be realized by measuring ammonia, nitrate, and nitrite concentrations on-line and using these values to control the aeration process. The nitrification process is a two-step process involving two types of microorganisms. The first type converts ammonia into nitrite (NO_2), and the second type converts the nitrites into nitrates (NO_3). Complete nitrification is achieved when all ammonia is converted into nitrates.

If the objective of the aeration process is full nitrification, the aeration energy costs can be optimized by direct measurement of ammonia and nitrates at several points and using this data to control the aeration process. Higher ammonia and lower nitrate concentrations indicate greater oxygen demand, and lower ammonia and higher nitrate concentrations indicate lower aeration demand.

The aeration process can be either manually or automatically controlled using on-line ammonia/nitrate concentration monitoring to achieve complete nitrification. This approach, in some cases, can lead to optimum aeration and reduced energy costs as compared to classical strategies based on DO measurement and control. DO measurement can still be used as a check on the overall success of the aeration process. The technique of measurement of ammonia, nitrite, and nitrate concentrations at various sample points is called "nitrogen profiling."

Nitrogen Profile Analyzers

The nitrogen profile analyzers receive filtered wastewater samples from multiple sampling points in a sequential manner and perform UV spectrum analysis to determine ammonia, nitrite, and nitrate concentrations in each sample. Typically, a single high-capacity pump is used to draw samples from multiple sampling points. Each sample point is controlled by a motor-operated ball valve on the suction side of the pump, controlled via signals from the sequencer, part of the analyzer. Sample obtained from each sampling point is filtered and placed in an accumulator.

Sample from the accumulator is transferred to a flow cell using a small pump part of the analyzer. The analyzer uses reagents and UV spectrum analysis to determine the ammonia, nitrite, and nitrate concentrations. The sequencer automatically controls the sample collection and analysis of each sample. Either analog 4–20 mA signals or digital data via Modbus communication link are available, corresponding to each parameter. Figure 8.1z shows a simplified block diagram of a typical nitrogen profile analyzer.

Mechanical Aerator Control Application

Figure 8.1aa shows a typical installation of mechanical aerators in the aeration basin. The influent flow is split into the East and West basins. Each basin is divided into four cells. Cell #1, #3, #5, and #7 include dual-speed 125/81 hp aerators. Cell #2 and #6 include 200 hp adjustable-speed aerators, and cell #4 and #8 have 75 hp adjustable-speed aerators.

A single nitrogen profile analyzer is used for on-line measurement/display of ammonia, nitrite, and nitrate concentrations at two locations in each basin (East and West). The nitrogen profile data is transmitted to the plant SCADA system and displayed on the graphic screens. Plant operators look at the nitrogen profiles to make adjustments to the aerator operation. For example, at minimum ammonia and maximum nitrate levels, all aerators are running at low speeds. As the ammonia levels rise and nitrate levels fall, the two dual-speed aerators #1 and #5 are switched to 100% speed.

If the ammonia levels still keep rising, the speeds of 200 hp aerators #2 and #6 are gradually increased to meet the oxygen demand. The last two aerators #4 and #8 are ramped up if, in a highly unlikely event, the South sampling point (located close to aerators #4 and #8) shows higher ammonia concentrations. Most of the time the North sampling point is used to validate the results of the control actions. The aerators are ramped down in reverse sequence on falling ammonia levels.

As an additional check, DO levels are measured in aeration cells #4 and #8 to ensure adequate DO level. The plant operators indicate that before installation of the nitrogen profile analyzer, their target DO levels in the basin effluent were 1.0 mg/l. However, following the installation of nitrogen profile analyzer and using the nitrogen profile for aeration control, the DO levels dropped to 0.3 mg/l, translating in energy savings while ensuring complete nitrification.

Diffused Aeration Control Application

A nitrogen profile analyzer can also be used for diffused aeration control. Referring to Figure 8.1w, the DO control loop can be replaced with an ammonia or nitrate control loop. Operator could select either ammonia or nitrate control mode. The DO controllers (AIC-1, -2, -3) are replaced with ammonia or nitrate controllers. The output of ammonia/nitrate controller is used to adjust the set point of the flow control loop that modulates the air control valve to each aeration cell. A single analyzer can be used to analyze samples from different aeration cells.

When ammonia concentration is chosen for control, the controller compares ammonia concentration in the sample with the set point and increases the air flow controller

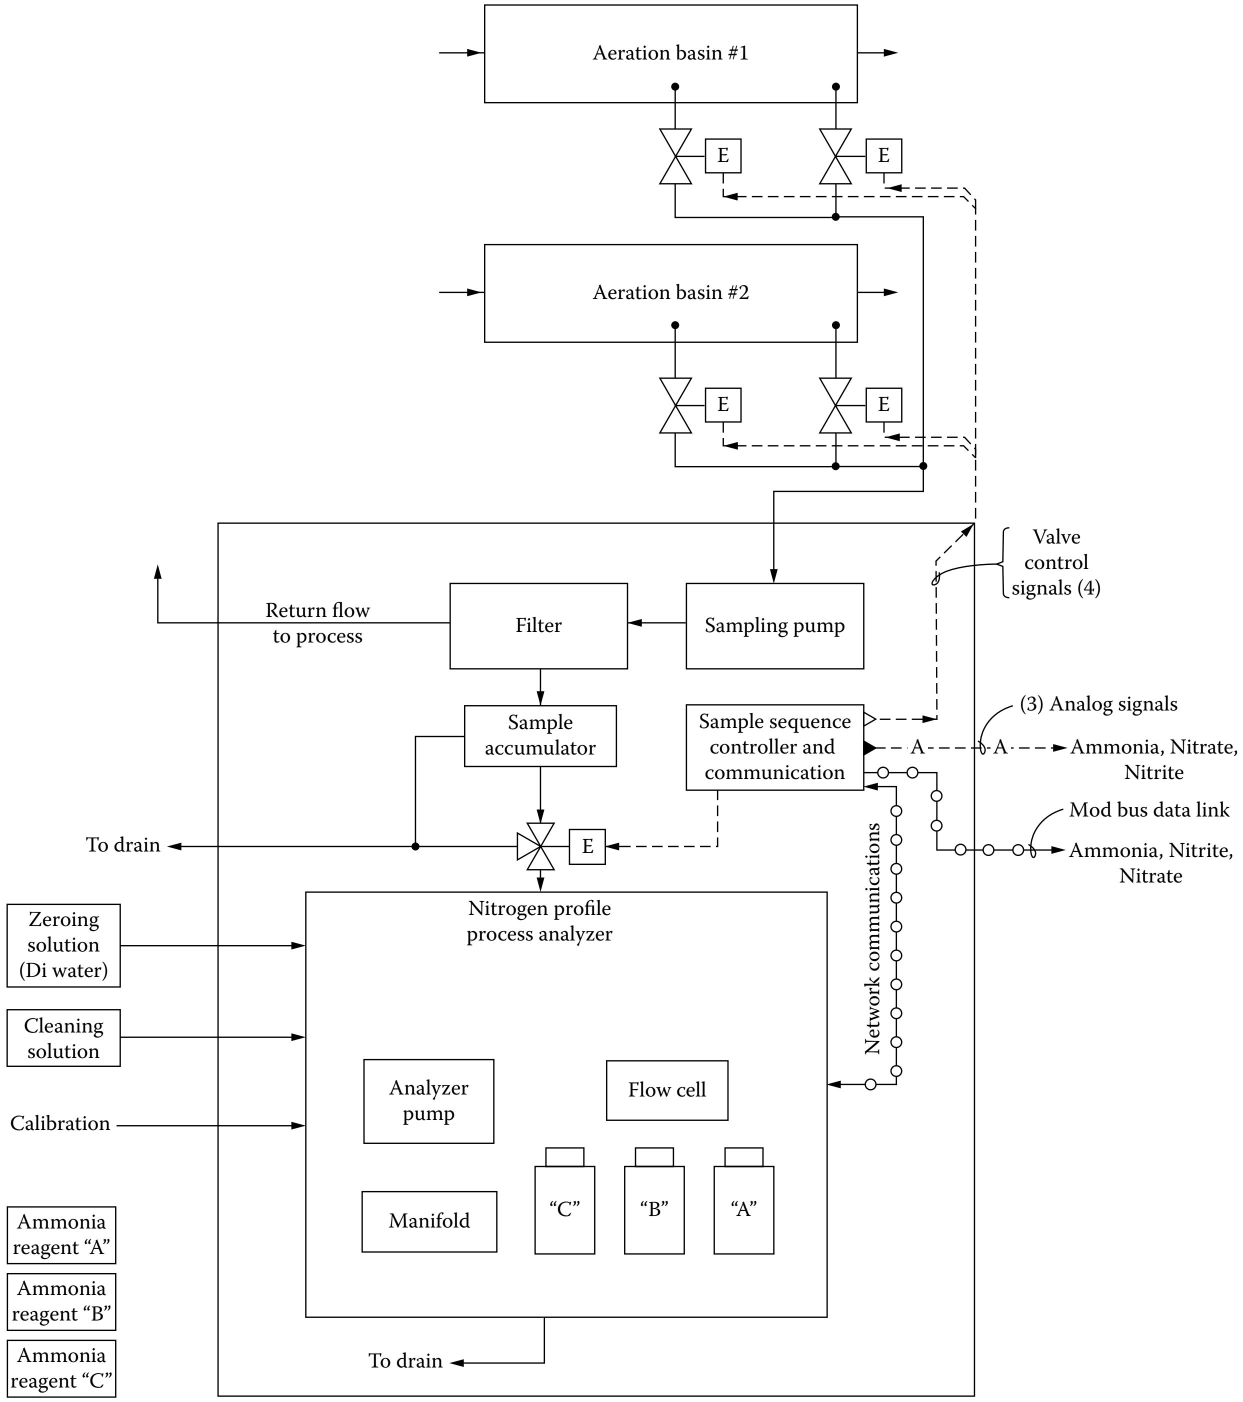

FIG. 8.1z
A simplified block diagram of a nitrogen profile analyzer.

(FIC-1, -2,- 3) set point as the ammonia concentration increases above set point, and reduces the air flow set point as the ammonia concentration starts dropping below the set point.

If nitrate concentration is chosen for control then the action of the nitrogen controller is opposite to that of ammonia control, i.e., the set point of air flow controller is reduced when the nitrogen concentration is above the set point and the set point of the air flow controller is increased when the nitrate concentration is below the desired set point. It is possible that ammonia control mode may work better in one cell while nitrate control mode may work better in another cell (Figure 8.1aa).

The most-open valve control strategy for header pressure control and the individual blower control is similar to that described in the earlier subsection Aeration System Control and shown in Figures 8.1w and 8.1y. Although nitrogen profile

technology is gaining support among plant operators, its cost and additional maintenance should be analyzed before making a final decision.

Ultimately, the decision of using nitrogen profiling or DO control will largely depend upon the size of the plant, cost analysis, process objectives, and the comfort level of the operators.

8.2 Airhandler and Building Conditioning Controls

B. G. LIPTÁK (1985, 1995, 2005)

INTRODUCTION

The main components of HVAC control systems include 1) the various comfort sensors, such as thermostats and humidistats (Section 7.9 in Chapter 7) and pressure sensors (Chapter 5 in Volume 1), 2) the control systems for heat and coolant supply systems, the boilers (Section 8.6), chillers (Sections 8.12 and 8.13), and the cooling towers (8.16 and 8.17), 3) the air and water transportation controls, including the fans and blowers (Section 8.25) and pumping stations (Section 8.34), and 4) the final control elements, including the dampers (Section 7.1), control valves (Chapter 6), and variable-speed drives (Sections 7.10). For more information on the above topics the reader is referred to the noted sections.

This section will concentrate on the control and optimization of the total space conditioning system. This will be approached by first discussing the process being controlled and its various operating modes as the seasons change. Once the "personality" of the process has been described, the control of the various comfort-related variables (temperature, humidity, and air quality) will be discussed. The emphasis will be placed on systems in which air is the final carrier of heat or cooling into the conditioned spaces, although brief mention will also be made of the more traditional, but still used, water-based systems.

In the second half of this section, the emphasis will be on the optimization of the total process by such methods as making the buildings self-heating and by eliminating the chimney effects.

THE AIRHANDLER

The airhandler is the basic unit operation of space conditioning. It is used to keep occupied spaces comfortable (Figure 8.2a) or unoccupied spaces at desired levels of temperature and humidity. In addition to supplying or removing heat or humidity from the conditioned space, the airhandler also provides ventilation and fresh air makeup. Depending on the type of space involved, from 75,000–300,000 BTU/year (19,000–76,000 cal/year) are required to condition 1 ft^2 (0.092 m^2) of office space. Depending on the energy sources used, this corresponds to a yearly operating cost of a few dollars per square foot of floor space.

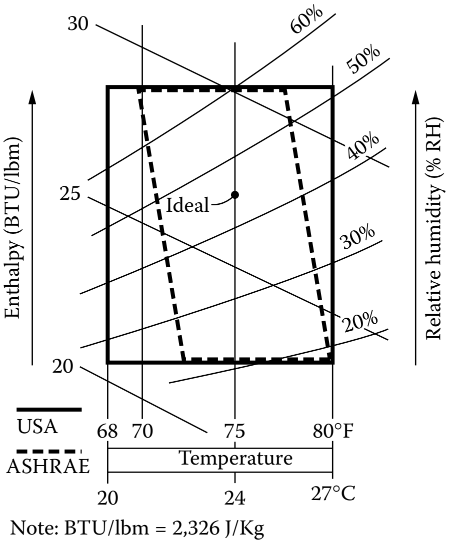

FIG. 8.2a
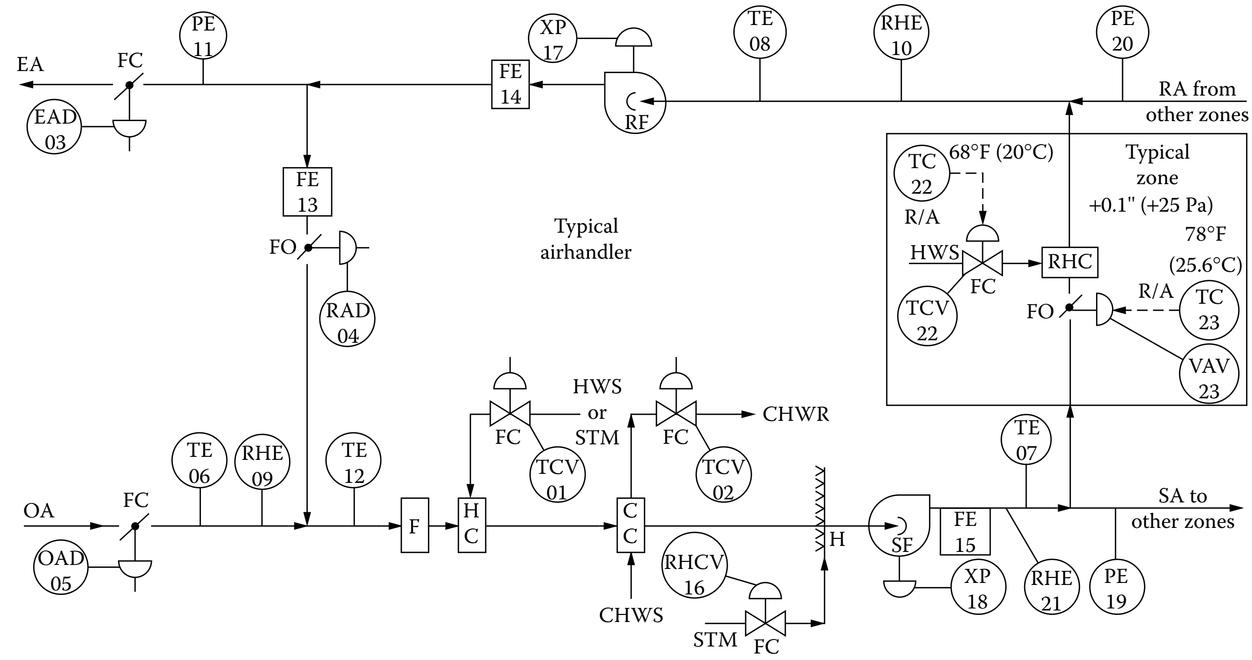
"Comfort zones" are defined in terms of temperature and humidity.[1]

Whereas other unit operations have benefited substantially from the advances in process control, airhandlers have not. Airhandlers today are frequently controlled the same way as they were 20 or 30 years ago. For this reason, airhandler optimization can result in much greater percentages of savings than can the optimization of almost any other unit operation. Optimization can sometimes cut the cost of airhandler operation in half — a savings that can seldom be achieved in any other type of unit operation.

Some of the optimization goals and strategies include the following:

- Let the building heat itself
- Use free cooling or free dying
- Benefit from gap control or zero energy band (ZEB)
- Eliminate chimney effect
- Optimize start-up timing
- Optimize air makeup (CO$_2$)
- Optimize supply air temperature
- Minimize fan energy use
- Automate the selection of operating modes
- Minimize reheat
- Automate balancing of air distribution



CC = Cooling coil
CHWR = Chilled water return
EA = Exhaust air
EAD = Exhaust air damper
F = Filter
FC = Fail closed
FE = Flow element

FO = Fail open
H = Humidifier
HC = Heating coil
HWS = Hot water supply
OA = Outside air
OAD = Outside air damper
PE = Pressure element

RA = Return air
RAD = Return air damper
RF = Return fan
RHC = Reheat coil
RHCV = Relative humidity control valve
RHE = Relative humidity element
SA = Supply air

SF = Supply fan
STM = Steam
TCV = Temperature control valve
TE = Temperature element
VAV = Variable air volume damper
XP = Positioner for fan volume control, such as a blade pitch positioner

FIG. 8.2b
A typical major airhandler has these components and controls.

Airhandler Components

The purpose of heating, ventilation, and air conditioning (HVAC) controls is to provide comfort in laboratories, cleanrooms, warehouses, offices, and manufacturing spaces. Supply air is the means of providing comfort in the conditioned zone. The air supplied to each zone must provide heating or cooling, raise or lower humidity, and provide air refreshment. To satisfy these requirements, it is necessary to control the temperature, humidity, and fresh-air ratio in the supply air.

Figure 8.2b illustrates the main components of an airhandler. The term *airhandler* refers to the total system, including fans, heat-exchanger coils, dampers, ducts, and instruments. The system operates as follows: Outside air is admitted by the outside air damper (OAD-05) and is then mixed with the return air from the return air damper (RAD-04). The resulting mixed air is filtered (F), heated (HC) or cooled (CC), and humidified (H) or dehumidified (CC) as required. The resulting supply air is then transported to the conditioned zones (groups of offices) by the variable-volume supply fan station. Variable volume means that the air flow rate generated by the fan(s) is variable.

In each zone, the variable air volume damper (VAV-23) determines the amount of air required, and the reheat coil (RHC) adjusts the air temperature as needed. The return air from the zones is transported by the variable-volume return-air fan station. If the amount of available return air exceeds the demand for it, the excess air is exhausted by the exhaust air damper (EAD-03). The conditioned spaces are typically pressurized to about 0.1 in. H_2O (25 Pa), relative to the barometric pressure on the outside. This pressurization results in some air leakage through the walls and windows, which varies with the quality of construction. Therefore, the air balance around the system is:

$$\text{OA} = \text{EA} + \text{pressurization loss} \qquad \textbf{8.2(1)}$$

Under "normal" operation, the airhandler operates with about 10% outside air. In the "purge" or "free cooling" modes, RAD is closed, OAD is fully open, and the airhandler operates with 100% outside air.

As can be seen, the HVAC process is rather simple. Its process material is clean air, its utility is water or steam, and its overall system behavior is slow, stable, and forgiving. For precisely these reasons, it is possible to obtain acceptable HVAC performance using inferior-quality instruments that are configured into poorly designed loops. Yet, there is an advantage in applying state-of-the-art process control to the HVAC process, because it can provide a drastic reduction in operating costs, attributable to increased efficiency of operation. Some of the more efficient control concepts are described in the paragraphs below.

Operating Mode Selection

The correct identification and timing of the various operating modes can contribute to the optimization of the building. The *normal* operating modes include start-up, occupied, night, and purge.

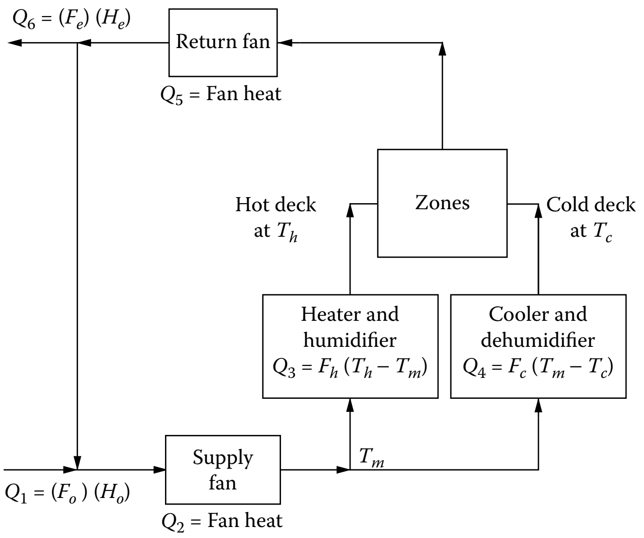
Optimizing the time of *start-up* will guarantee that the minimum required cost is invested in getting the building ready for occupancy. This is done by automatically calculating the amount of heat that needs to be transferred and dividing it according to the capacity of the start-up equipment. A computer-optimized control system will serve to initiate the unoccupied (night) mode of operation; it will also recognize weekends and holidays and, in general, provide a flexible means of time-of-day controls.

The *purge* mode is another convenient tool of optimization. Whenever the outside air is preferred to the return air, the building is automatically purged. In this way, "free cooling" can be obtained on dry summer mornings, or "free heating" can be provided on warm winter afternoons. Purging is the equivalent of opening the windows in a home. In computer-optimized buildings, an added potential is to use the building structure as a means of heat (or coolant) storage. In this case, the purge mode can be automatically initiated during cold nights prior to hot summer days, thereby bringing the building temperature down and storing some free cooling in the building structure.

Summer/Winter Mode Reevaluation Another important mode selection involves switching from summer to winter mode and vice versa. Conventional systems are switched according to the calendar, whereas optimized ones recognize that there are summer-like days in the winter and winter-like hours during summer days. Seasonal mode switching is therefore totally inadequate.

Optimized building operation can be provided only by making the summer/winter selection on an enthalpy basis: If heat needs to be added, it is "winter"; if heat needs to be removed, it is "summer," regardless of the calendar. In those airhandlers that serve a variety of zones, it is essential to first determine if the unit is in a "net" cooling (summer) or "net" heating (winter) mode before the control system can decide if free cooling (or free heating) by outside air can be used to advantage.

Figure 8.2c illustrates the heat balance evaluation that is required to determine the prevailing overall mode of operation. This type of heat balance calculation, which must be reevaluated every 15 to 30 minutes, can be implemented only through the use of computers.



F_c = Cold deck flow
H_o = Outside air enthalpy
F_e = Exhaust air flow
T_c = Cold deck temperature
F_h = Hot deck flow
T_h = Hot deck temperature
H_e = Exhaust air enthalpy
T_m = Mixed air temperature
Net airhandler load = $Q_0 = Q_1 + Q_2 + Q_3 - Q_4 + Q_5 - Q_6$

FIG. 8.2c
When the net airhandler load is negative, summer mode is required; when it is positive, winter mode is required.

Emergency Mode In addition to the above operating modes, the airhandler can also be placed in an *emergency* mode, if fire, smoke, freezing temperature, or pressure conditions require it. Table 8.2d lists the status of each fan, damper, and valve in each of the operating modes. In a computer-optimized control system, both the mode selection and the setting of the actuated devices is done automatically.

When a smoke or fire condition is detected by sensors S/F-4 or S/F-8 in Figure 8.2e, the fans stop, the OADs and RADs close, the EAD opens, and an alarm is actuated. The operator can switch the airhandler into its purge mode, so that the fans are started, OAD and EAD are opened, and RAD is closed. If the smoke/fire emergency requires, the fire command panel (FC in Figure 8.2e) can be used by firefighters. From this panel, the fire chief can operate all fans and dampers as needed for safe and orderly evacuation and protection of the building.

In another emergency condition, a freezestat switch on one of the water coils is actuated. These switches are usually set at approximately 35°F (1.5°C) and serve to protect from coil damage resulting from freeze-ups. Multistage freezestat units might operate as follows:

- At 38°F (3°C): close OAD
- At 36°F (2°C): fully open water valve
- At 35°F (1.5°C): stop fan

If single-stage freezestats are used, they will stop the fan, close the OAD, and activate an alarm.

Yet another type of emergency is signaled by excessive pressures in the ductwork on the suction or discharge sides of the fans, resulting from operation against closed dampers

TABLE 8.2d
The Status of Various Actuated Devices during Various Operating Modes

or from other equipment failures. When this happens, the associated fan is stopped and an alarm is actuated.

Fan Controls

The standard fan controls are shown in Figure 8.2f. Each zone shown in Figure 8.2b is supplied with air through a thermostat-modulated damper, also called a variable air volume box (VAV-23).

The VAV box openings in the various zones determine the total demand for supply air. The pressure in the supply air (SA) distribution header is controlled by PIC-19, which modulates the supply air fan station to match the demand (Figure 8.2f). When the PIC-19 output has increased the fan capacity to its maximum, PSH-19 actuates and starts an additional fan. Inversely, as the demand for supply air drops, FSL-15 will stop one fan unit whenever the load can be met by fewer fans than the number in operation. The important point to remember is that in cycling fan stations, fan units are started on pressure and are stopped on flow control. The operating cost of such a fan station is 20–40% lower than if constant-volume fans with conventional controls were used (Figure 8.2g).

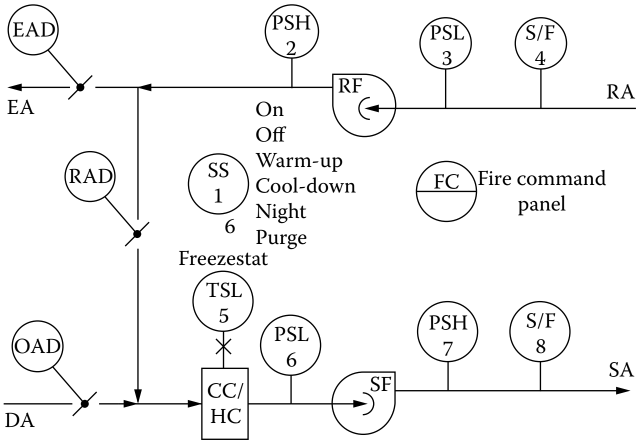

FIG. 8.2e
The safety and operating mode selection instruments used on an airhandler. Most abbreviations used on this figure have already been defined in connection with Figure 8.2b; S/F = smoke and fire detector, SS = selector switch, FC = fire command panel.

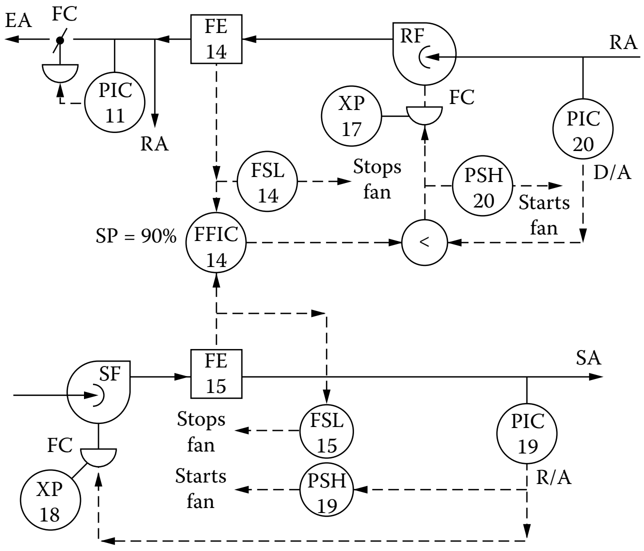

FIG. 8.2f
Variable-volume fan controls operate as shown here.

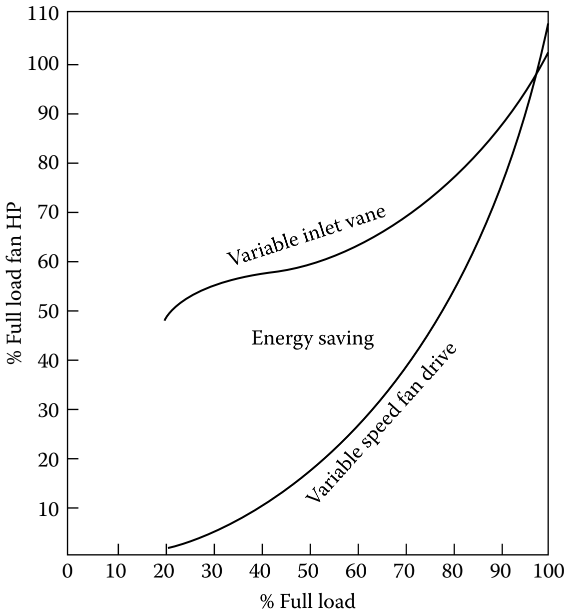

FIG. 8.2g
Using variable-speed fans can save significant amounts of energy. (Courtesy of Dana Corp.)

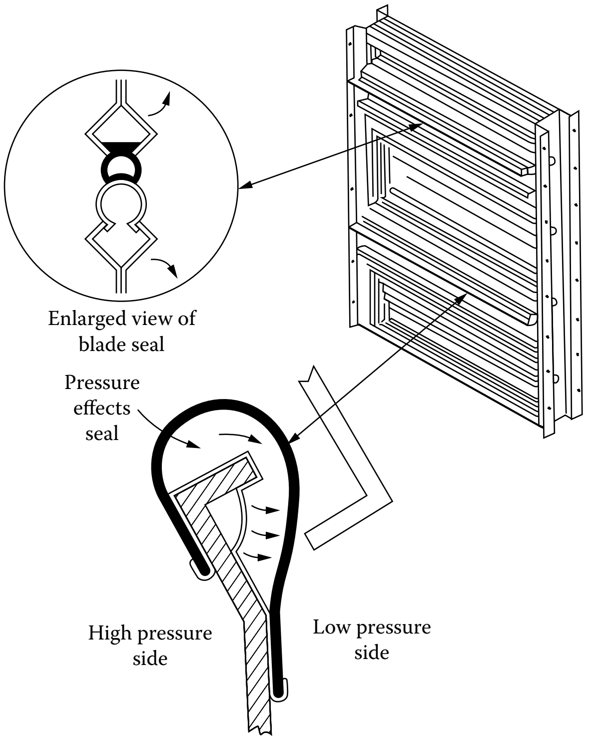

FIG. 8.2h
Low-leakage damper designs increase the efficiency of HVAC systems.

Because the conditioned zones are pressurized slightly, some of the conditioned air will leak into the atmosphere, creating pressurization loss. Being able to control the pressurization loss is one of the advantages of the control system described in Figure 8.2f. The flow ratio controller FFIC-14 is set at 90%, meaning that the return-air fan station is modulated to return 90% of the air supplied to the zones. Therefore, pressurization loss is controlled at 10%, which corresponds to the minimum fresh-air makeup requirement, resulting in a minimum-cost operation.

Because the conditioned zones represent a fairly large capacity, a change in supply air flow will not immediately result in a need for a corresponding change in the return air flow. Thus, PIC-20 (Figure 8.2f) is included in the system to prevent the flow-ratio controller from increasing the return air flow rate faster than required. This dynamic balancing eliminates cycling and protects against collapsing the ductwork under excessive vacuum. Closure of the exhaust-air damper by PIC-11 indicates that the control system is properly tuned and balanced and is operating at maximum efficiency. Under such conditions, the outside air admitted into the airhandler exactly matches the pressurization loss, and no return air is exhausted.

To maximize the benefits of such an efficient configuration, the dampers must be of tight shut-off design. When exposed to a pressure difference of 4 in. H_2O (996 Pa), a closed conventional damper will leak at a rate of approximately 50 cfm/ft^2 [15.2 (m^3/min)/m^2]. In the HVAC industry, a 5 cfm/ft^2 [1.52 (m^3/min)/m^2] leakage rate is considered to represent a tight shut-off design. Actually, it is cost-effective to install tight shut-off dampers with leakage rates of less than 0.5 cfm/ft^2 [0.15 (m^3/min)/m^2], because the resulting savings over the life of the buildings will be much greater than the increase in initial investment for better dampers (Figure 8.2h).

Dampers and Pressure Distribution In order for dampers to give good control, a fair amount of pressure drop should be assigned to them. They should be sized for a ΔP of about 10% of the total system drop. On the other hand, excessive damper drops should also be avoided, because they will increase the operating costs of the fans. A good sizing basis for outside and return air fans is to size them for 1500 fpm (457 m/min) velocity at maximum flow.

In locations where two air streams are mixed, such as when outside and return airs are ratioed (RAD-04 and OAD-05 in Figure 8.2b), it is important that the damper ΔP be relatively constant as the ratio is varied. Figure 8.2i shows that parallel blade dampers give a superior performance in this service.

Figure 8.2j illustrates the pressure levels in the various portions of typical airhandlers. It can be seen that the kind of pressure drops that would be required by opposed blade dampers (Figure 8.2i) are simply not available. Therefore, if such dampers were installed, the airhandler would be starved for air (the dampers could not pass the design flow) whenever the ratio was near 50:50 (percent).

Figure 8.2j also shows that in traditional airhandlers more fan energy is used than necessary. This is because the return air fan is sized to generate the pressure needed to exhaust the

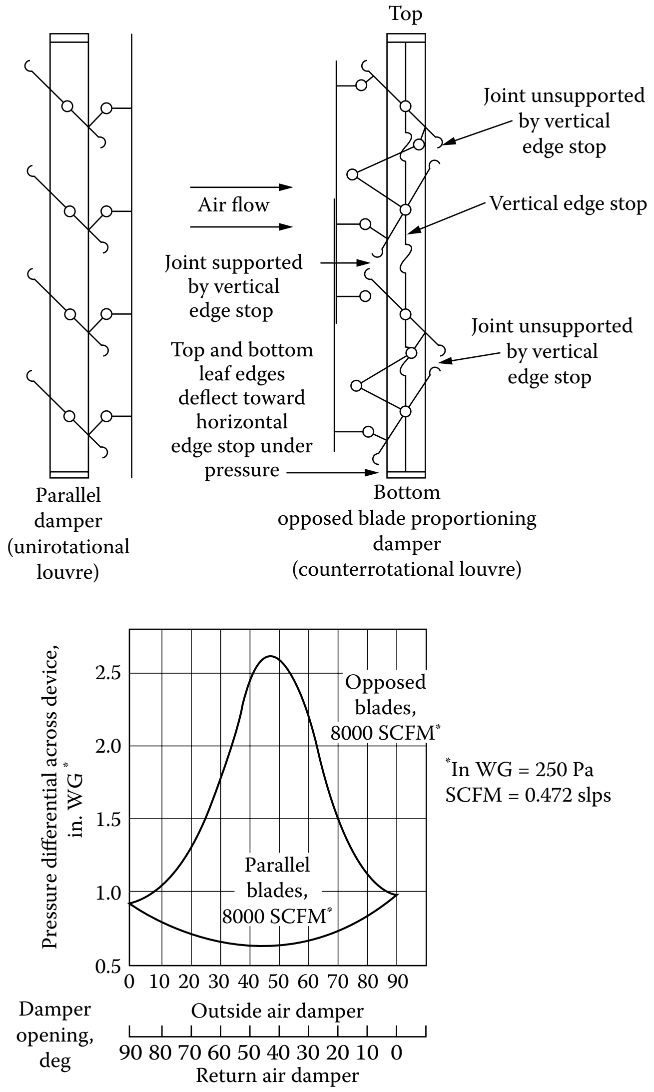

FIG. 8.2i
When outside and return air dampers are throttled to vary their ratio at constant total flow, the required pressure drop varies with damper design (see upper portion of figure). The lower portion of this figure shows the results of American Warming and Ventilating Co. tests (per AMCA Standard 500) of pressure drops across parallel-blade and opposed-blade outside and return air damper sets.[2]

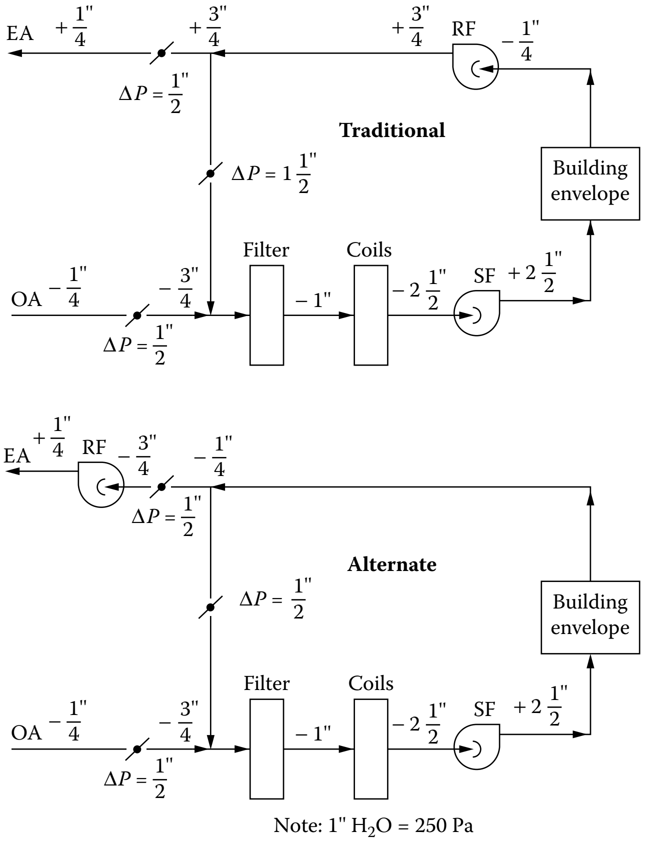

FIG. 8.2j
Damper pressure drops and the typical pressure levels in the various segments of airhandlers.

air from the building. A consequence of this is that the pressure drop of 1$^1/_2$ in. H_2O (375 Pa) across the return air damper is three times greater than what is necessary ($^1/_2$ in. H_2O, or 125 Pa).

The alternate system shown in the lower portion of Figure 8.2j eliminates this waste of fan energy. Here, only the supply fan (SF) operates continuously, which reduces the pressure drop across the return air damper to $^1/_2$ in. H_2O (125 Pa). The return fan (RF) is started only when air needs to be relieved, and its speed is varied to adjust the amount of air to be exhausted. Relocating RF also removes its heat input, which, in the traditional system, represents an added load on the cooling coil.

Temperature Controls

Space temperatures are controlled by thermostats. The traditional thermostat is a proportional-only controller (see also Section 2.2). The pressure of the output signal from a pneumatic "stat" is a near straight-line function of the measurement, described by the following relationship:

$$O = K_c(M - M_o) + O_o \qquad \textbf{8.2(2)}$$

where

O = output signal
K_c = proportional sensitivity (K_c can be fixed or adjustable, depending on the design)
M = measurement (temperature)
M_o = "normal" value of measurement, corresponding to the center of the throttling range
O_o = "normal" value of the output signal, corresponding to the center of the throttling range of the control valve (or damper)

Another term used to describe the sensitivity of thermostats is *throttling range*. As shown in Figure 8.2k, this term refers to the amount of temperature change that is required to change the thermostat output from its minimum to its

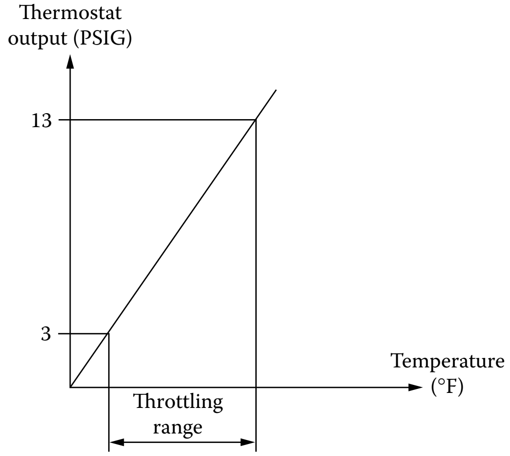

FIG. 8.2k
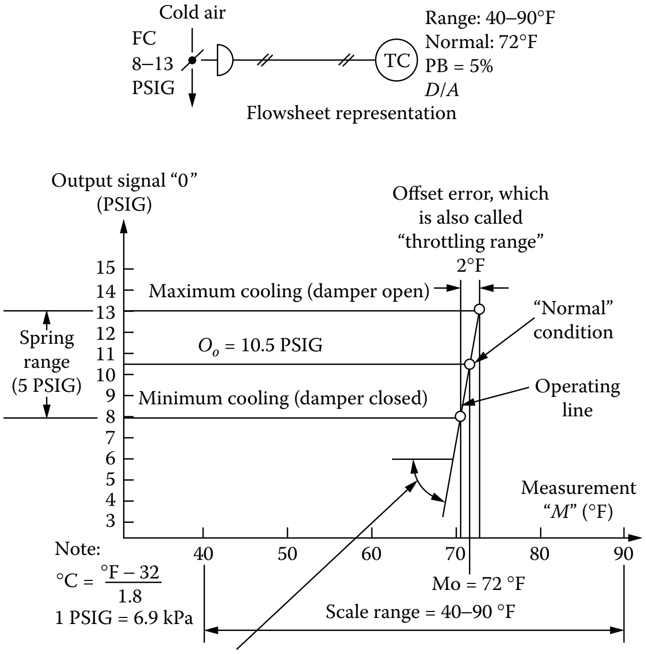
Throttling range can be defined as the temperature change required to change the thermostat output from its minimum to its maximum value.

maximum value, such as from 3 to 13 PSIG (21 to 90 kPa). The throttling range is usually adjustable from 2 to 10°F (1 to 5°C).

One important point to remember is that thermostats do not have set points, in the sense of having a predetermined temperature to which they would seek to return the controlled space. (Integral action must be added in order for a controller to be able to return the measured variable to a set point after a load change.) M_o does not represent a set point; it only identifies the space temperature that will cause the cooling damper in Figure 8.2l to be 50% open. This can be called a "normal" condition, because relative to this point the thermostat can both increase and decrease the cooling air flow rate as space temperature changes.

If the cooling load doubles, the damper will need to be fully open, which cannot take place until the controlled space temperature has risen to 73°F (23°C). As long as the cooling load remains that high, the space temperature must also stay up at the 73°F (23°C) value. Similarly, the only way this thermostat can reduce the opening of the cooling damper below 50% is to first allow the space temperature to drop below 72°F (23°C). Thus, thermostats have throttling ranges, not set points. If a throttling range is narrow enough, this gives the appearance that the controller is keeping the variable near the set point, when in fact the narrow range only allows the variable to drift within limits.

Special-Purpose Thermostats *Day-night, set-back,* or *dual room thermostats* will operate at different "normal" temperature values for day and night. They are provided with both a "day" and a "night" setting dial, and the change from day to night operation can be made automatic for a group of thermostats. The pneumatic day-night thermostat uses a two-pressure air supply system, the two pressures often being 13 and 17 PSIG (89.6 and 177 kPa) or 15 and 20 PSIG (103.35 and 137.8 kPa). Changing the pressure at a central point from one value to the other actuates switching devices in the thermostat and indexes them from day to night or vice versa.



Slope of operating line = Proportional sensitivity = 2.5 PSIG/°F = Proportional band = 5% = Gain = 20

FIG. 8.2l
A fixed proportional band thermostat has a fixed throttling range and no setpoint.

Supply air mains are often divided into two or more circuits so that switching can be accomplished in various areas of the building at different times. For example, a school building may have separate circuits for classrooms, offices and administrative areas, the auditorium, and the gymnasium and locker rooms. In some of the electric designs, dedicated clocks and switches are built into each thermostat.

The *heating–cooling* or *summer–winter thermostat* can have its action reversed and, if desired, can have its set point changed by means of indexing. This thermostat is used to actuate controlled devices, such as valves or dampers, that regulate a heating source at one time and a cooling source at another. It is often manually indexed in groups by a switch, or automatically by a thermostat that senses the temperature of the water supply, the outdoor temperature, or another suitable variable.

In the heating–cooling design, there are frequently two bimetallic elements, one being direct acting for the heating mode, the other being reverse acting for the cooling mode. The mode is switched automatically in response to a change in the air supply pressure, much as the day–night thermostats operate.

The *limited control range thermostat* usually limits the room temperature in the heating season to a maximum of 75°F (24°C), even if the occupant of the room has set the thermostat beyond these limits. This is done internally, without placing a physical stop on the setting knob.

A *slave or submaster thermostat* has its set point raised or lowered over a predetermined range, in accordance with variations in the output from a master controller. The master controller can be a thermostat, manual switch, pressure controller, or similar device. For example, a master thermostat measuring outdoor air temperature can be used to adjust a submaster thermostat controlling the water temperature in a heating system. Master–submaster combinations are sometimes designated as single-cascade action. When action is accomplished by a single thermostat having more than one measuring element, it is referred to as *compensated control.*

Multistage thermostats are designed to operate two or more final control elements in sequence.

A *wet-bulb thermostat* is often used for humidity control, as the difference between wet- and dry-bulb temperature is an indication of moisture content. A wick or other means for keeping the bulb wet and rapid air motion to ensure a true wet-bulb measurement are essential.

A *dew-point thermostat* is a device designed to control humidity on the basis of dew point temperatures.

A *smart thermostat* is usually a microprocessor-based unit with RTD-type or transistorized solid-state sensor. It is usually provided with its own dedicated memory and intelligence, and it can also be equipped with a communication link (over a shared data bus) to a central computer. Such units can minimize building operating costs by combining time-of-day controls with intelligent comfort gap selection and maximized self-heating.

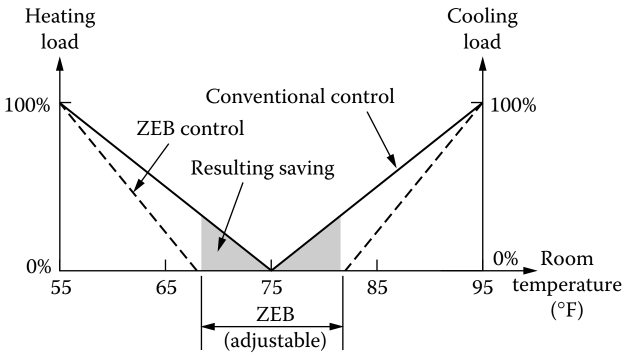


FIG. 8.2m
Zero energy band (ZEB) control is designed to save energy by not using any when the room is comfortable.

Zero Energy Band Control A recent addition to the available thermostat choices is the zero energy band design. The idea behind ZEB control is to conserve energy by not using any when the room is comfortable. As illustrated by Figure 8.2m, the conventional thermostat wastes energy by continuing to use it when the area's temperature is already comfortable. The "comfort gap" or "ZEB" on the thermostat is adjustable and can be varied to match the nature of the particular space.

ZEB control can be accomplished in one of two ways. The single set point and single output approach is illustrated on the left side of Figure 8.2n. Here the cooling valve fails closed and is shown to have an 8–11 PSIG (55–76 kPa) spring range, while the heating valve is selected to fail open and

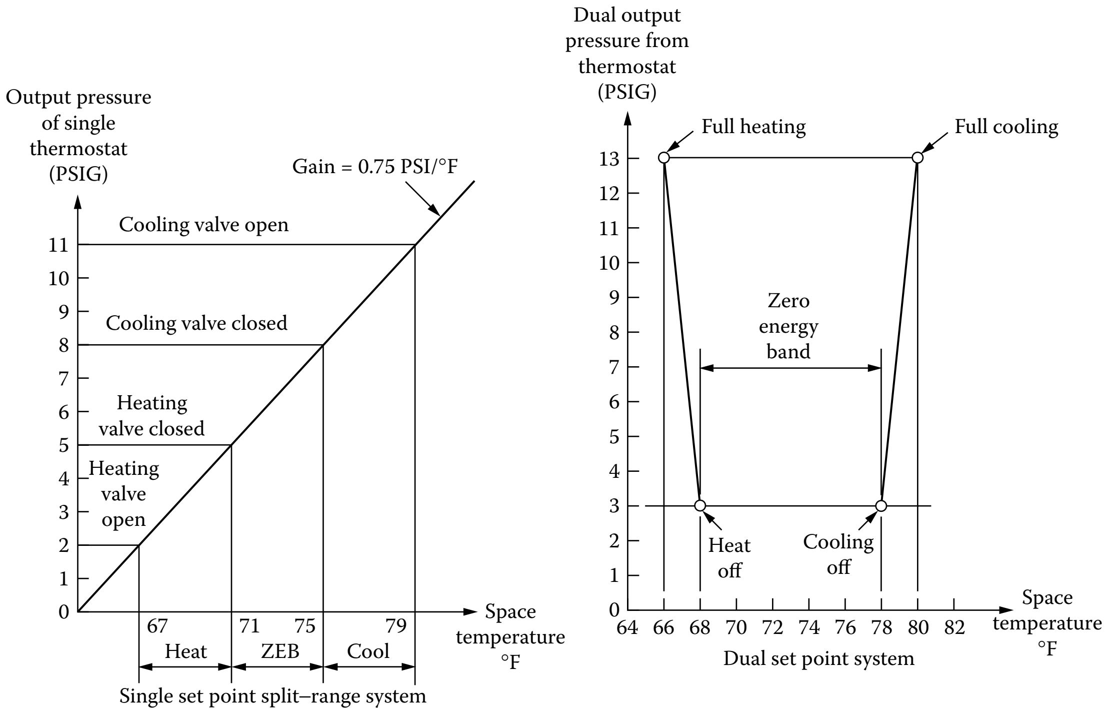

FIG. 8.2n
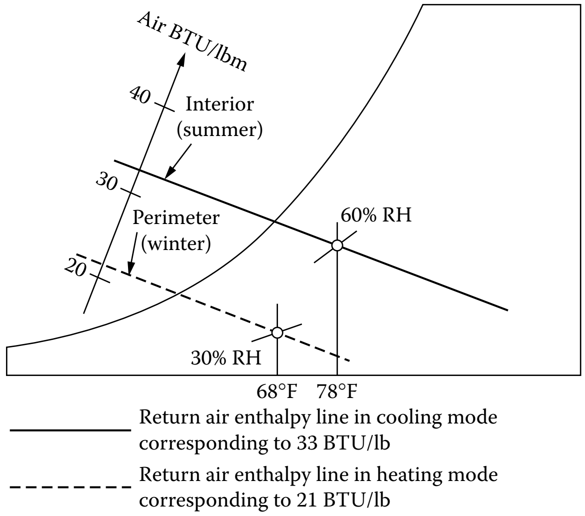
ZEB control schemes include the single setpoint split range approach (shown on left) and the dual set point approach (shown on right).

has a 2–5 PSIG (14–34 kPa) range. Therefore, between 5 and 8 PSIG (34 and 55 kPa), both valves are closed; no pay energy is expended while the thermostat output is within this range. The throttling range is usually adjustable from 5 to 25°F (3 to 13°C). Thus, if the ZEB is 30% of the throttling range, it can be varied from a gap size of 1.5°F (0.85°C) to 7.5°F (4.2°C) by changing the throttling range (or gain).

Although the split-range approach is a little less expensive than the dual set-point scheme (shown on the right of Figure 8.2n), it is also less flexible and more restrictive. The two basic limitations of the split-range approach are: 1) The gap width can be adjusted only by also changing the thermostat gain; maximum gap width is limited by the minimum gain setting of the unit. 2) The heating valve must fail open, which is undesirable in terms of energy conservation.

These limitations are removed when a dual set point, dual output thermostat is used. Here both valves can fail closed, and the bandwidth and the thermostat gain are independently adjustable. The gains of the heating and cooling thermostats are also independently adjustable. In Figure 8.2n, the heating thermostat is reverse-acting and the cooling thermostat is direct-acting.

The most recent advances in thermostat technology are the microprocessor-based units. These are programmable devices with memory capability. They can be monitored and reset by central computers, using telephone wires or other communication links. Microprocessor-based units can be supplied by continuously recharged backup batteries and accurate room temperature sensors. They can also operate without a host computer (in stand-alone mode). In this case, the user manually programs the thermostat to maintain various room temperatures as a function of the time of day and other considerations.



Note: BTU/lbm = 0.555 Kcal/Kg

FIG. 8.2o
The building can be made self-heating, because the return air can transport about 10 BTU/lbm to the perimeter spaces, which in the winter, because of the windows, do require heat.

Gap Control and the Self-Heating Building The winter and summer enthalpy settings of a building are illustrated in Figure 8.2o. The concept of gap control is simple: When comfort level in a zone is somewhere between acceptable limits, the use of “pay energy” is no longer justified. Allowing the zones to float between limits instead of maintaining them at arbitrarily fixed conditions can substantially reduce the operating cost of the building.

The savings come from two sources. First, there is a direct trade-off between the selected acceptable limits of discomfort and the yearly total of required degree days of heating and cooling. Second, there is the added side benefit that the building becomes self-heating during winter conditions. This occurs because during winter conditions, gap control automatically transfers the heat generated in the inside of the building to the perimeter areas, where heating is needed. This can result in long periods of building operation without the use of any pay energy.

Gap control can be looked upon as an override mode of control that is superimposed on the operation of the individual zone thermostats. As such, it can be implemented by all levels of automation, but the flexibility and ease of adjustment of the computerized systems make them superior in those applications in which the gap limits of the various zones are likely to change frequently.

Figure 8.2a illustrates the concept of comfort envelopes. Any combination of temperature and humidity conditions within such envelopes is considered to be comfortable. Therefore, as long as the space conditions fall within this envelope, there is no need to spend money or energy to change those conditions. This comfort gap is also referred to as zero energy band, meaning that if the space is within this band, no pay energy of any type will be used. This concept is very cost-effective.

When a zone of the airhandler in Figure 8.1b is within the comfort gap, its reheat coil is turned off and its VAV box is closed to the minimum flow required for air refreshment. When all the zones are inside the ZEB, the HW, CHW, and STM supplies to the airhandler are all closed and the fan is operated at minimum flow. When all other airhandlers are also within the ZEB, the pumping stations, chillers, cooling towers, and HW generators are also turned off.

With larger buildings that have interior spaces that are heat-generating even in the winter, ZEB control can make the building self-heating. Optimized control systems in operation today are transferring the interior heat to the perimeter without requiring any pay heat until the outside temperature drops below 10 to 20°F (2.3 to 6.8°C). In regions in which winter temperature does not drop below 10°F (–2.3°C), ZEB control can eliminate the need for pay heat altogether. In regions farther north, ZEB control can lower the yearly heating fuel bill by 30–50%.

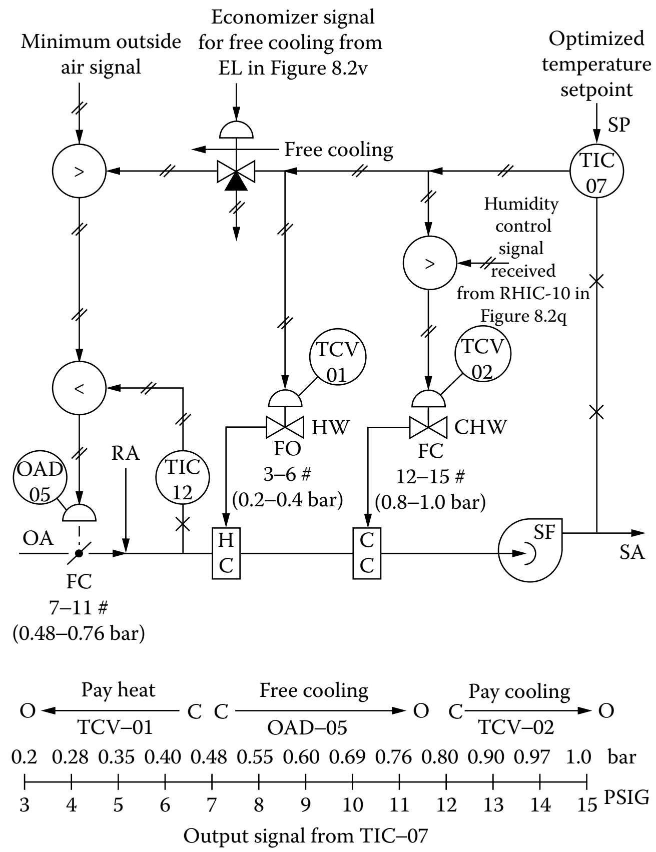


FIG. 8.2p
Illustration of a fully coordinated, pneumatic, split-range temperature control system. Such controls can reduce the yearly operating costs by more than 10%.[8]

Supply Air Temperature Control A substantial source of inefficiency in conventional HVAC control systems is the uncoordinated arrangement of temperature controllers. Two or three separate temperature control loops in series are not uncommon. For example, one of these uncoordinated controllers may be used to control the mixed air temperature, another to maintain supply (SA) temperature, and a third to control the zone-reheat coil. Such practice can result in simultaneous heating and cooling and, therefore, in unnecessary waste. Using a fully coordinated split-range temperature control system, such as that shown in Figure 8.2p, will reduce yearly operating costs by more than 10%.

In this control system, the SA temperature set point (set by the temperature controller, TIC-07) is continuously modulated to follow the load. The methods of finding the correct set point will be discussed under Optimizing Strategies. The loop automatically controls all heating or cooling modes. When the TIC-07 output signal is low — 3–6 PSIG (20.7–41.3 kPa) — heating is done by TCV-01. As the output signal reaches 6 PSIG (41.3 kPa), heating is terminated; if free cooling is available, it is initiated at 7 PSIG (48.2 kPa). When the output signal reaches 11 PSIG (75.8 kPa) — the point at which OAD-05 is fully open — the cooling potential represented by free cooling is exhausted, and at 12 PISG (82.7 kPa), "pay cooling" is started by opening TCV-02. In such split-range systems, the possibility of simultaneous heating and cooling is eliminated. Also eliminated are interactions and cycling.

Figure 8.2p also shows some important overrides. TIC-12, for example, limits the allowable opening of OAD-05, so that the mixed-air temperature will never be allowed to drop to the freezing point and permit freeze-up of the water coils.

The minimum outdoor air requirement signal guarantees that the outside air flow will not be allowed to drop below this limit.

The economizer signal allows the output signal of TIC-07 to open OAD-05 only when "free cooling" is available. (A potential for free cooling exists when the enthalpy of the outdoor air is below that of the return air.)

Finally, the humidity controls will override the TIC-07 signal to TCV-02 when the need for dehumidification requires that the supply air temperature be lowered below the set point of TIC-07.

Humidity Controls

Humidity in the zones is controlled according to the moisture content of the combined return air (see Figure 8.2q). The

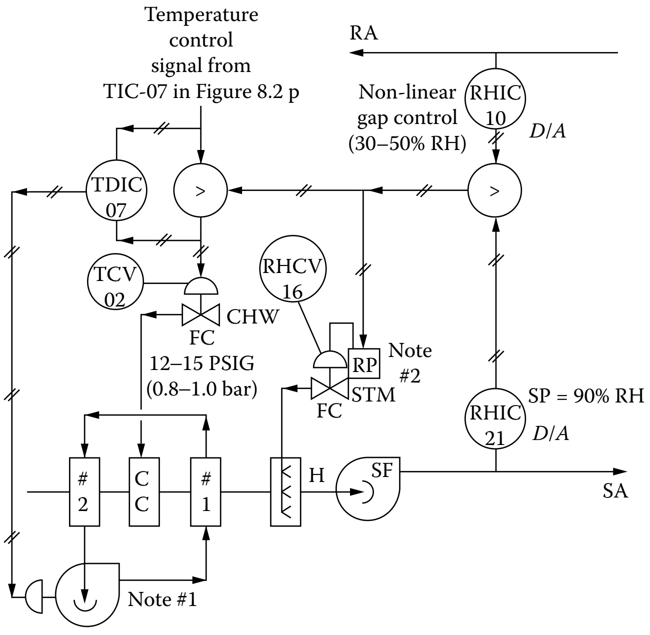

FIG. 8.2q
Humidity is controlled in the combined return air. Note 1: *When the need for dehumidification (in the summer) overcools the supply air and therefore increases the need for reheat at the zones, this pump-around economizer loop is started. TDIC-07 will control the pump to "pump around" only as much heat as is needed.* Note 2: *This reversing positioner functions as follows:*

Input from RHIC-10	*Output to RHCV-16*
3 PSIG = 0%	100% (open)
9 PSIG = 50%	0% (closed)

process controlled by RHIC-10 is slow and contains large dead-time and transport-lag elements. In other words, a change in the SA humidity will not be detected by RHIC-10 until some minutes later. During the winter, it is possible for RHIC-10 to demand more and more humidification. To prevent possible saturation of the supply air, the RHIC-10 output signal is limited by RHIC-21. In this way, the moisture content of the supply air is never allowed to exceed 90% RH.

For best operating efficiency, a nonlinear controller with a neutral band is used at RHIC-10. This neutral band can be set to a range of humidity levels — say, between 30% and 50% RH. If the RA is within these limits, the output of RHIC-10 is at 50%, and neither humidification nor dehumidification is demanded. This arrangement can lower the cost of humidity control during the spring and fall by approximately 20%.

The same controller (RHIC-10) controls both humidification (through the relative humidity control valve, RHCV-16) and dehumidification (through the temperature control valve, TCV-02) on a split-range basis. As the output signal increases, the humidifier valve closes, between 3 and 9 PSIG (20.7 and 62 kPa). At 9 PSIG (62 kPa), RHCV-16 closes and remains so, as the output signal increases to 12 PSIG (82.7 kPa). At this condition, TCV-02 starts to open.

Dehumidification is accomplished by cooling through TCV-02. This chilled water valve is controlled by humidity (RHIC-10) or temperature (TIC-07). The controller that requires more cooling will be the one allowed to throttle TCV-02.

Subcooling the air to remove moisture can substantially increase operating costs if this energy is not recovered. The dual penalty incurred for overcooling for dehumidification purposes is the high chilled water cost and the possible need for reheat at the zone level. The savings from a pump-around economizer can eliminate 80% of this waste. In this loop, whenever TDIC-07 detects that the chilled water valve (TCV-02) is open more than would be necessary to satisfy TIC-07, the pump-around economizer is started. This loop in coil #1 reheats the dehumidified supply air, using the heat that the pump-around loop removed from the outside air in coil #2 before it entered the main cooling coil.

In this way, the chilled-water demand is reduced in the cooling coil (TCV-02), and the need for reheating at the zones is eliminated. Although Figure 8.2q shows a modulating controller setting the speed of a circulating pump, it is also possible to use a constant-speed pump operated by a gap switch.

Outdoor Air Controls

Outdoor air is admitted to satisfy the requirements for fresh air or to provide free cooling. Both control loops are shown in Figure 8.2r.

The minimum requirement for fresh outdoor air while the building is occupied is usually 10% of the airhandler's capacity. In most advanced control systems, this value is not controlled as a fixed percentage but as a function of the number of people in the building or of the air's carbon dioxide content. In most conventional systems, the minimum outdoor air is provided by keeping 10% of the area of the outdoor air damper always open when the building is occupied.

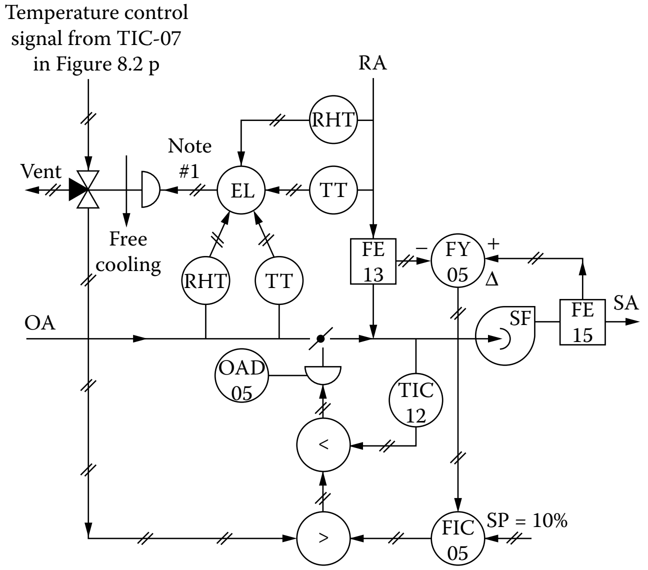

FIG. 8.2r
Outside air control loops provide fresh air or free cooling. Note: *The enthalpy logic unit (EL) compares the enthalpies of the outside and return airs and vents its output signal if free cooling is available. Therefore, the economizer cycle is initiated whenever Hoa < Hra.*

This method is inaccurate, because a constant damper opening does not result in a constant air flow. This flow varies with fan load, because changes in load will change the fan's suction pressure and will therefore alter the ΔP across the damper. This conventional design results in waste of air-conditioning energy at high loads and insufficient air refreshment at low loads.

The control system depicted in Figure 8.2r reduces operating costs while maintaining a constant minimum rate of air refreshment, which is unaffected by fan loading. Direct measurement of outdoor airflow is usually not possible because of space limitations. For this reason, Figure 8.2r shows the outdoor air flow as being determined as the difference between FE-15 and FE-13. FIC-05 controls the required minimum outdoor airflow by throttling OAD-05.

CO_2-Based Ventilation In conventional installations the amount of outdoor air admitted is usually based on one of the following criteria:

- 0.1–0.25 cfm/ft^2 (30–76 lpm/m^2) of floor area
- 10–25% of total air supply rates
- About 5 cfm (25 lps) volumetric rate per person

These criteria all originated at a time when energy conservation was no serious consideration; therefore, their aim was to provide simple, easily enforceable rules that will guarantee that the outdoor air intake always exceeds the required minimum. Today the goal of such systems is just the opposite: It is to make sure that air quality is guaranteed at minimum cost. As the floor does not need oxygen—only people do—some of the above rules make little sense.

There is a direct relationship between savings in building operating costs and reduction in outdoor air admitted into the building. According to one study in the United States,[4] infiltration of outdoor air accounted for 55% of the total heating load and 42% of the total cooling load. Another survey[5] showed that 75% of fuel oil consumed in New York City schools was devoted to heating ventilated air. Because building conditioning accounts for nearly 20% of all the energy consumed in the U.S.,[6] optimized admission of outdoor air can make a major contribution to reducing our national energy budget. This goal can be well served by CO_2-based ventilation controls.

The purpose of ventilation is not to meet some arbitrary criteria, but to maintain a certain air quality in the conditioned space. Smoke, odors, and other air contaminant parameters can all be correlated to the CO_2 content of the return air.[7] This then becomes a powerful tool of optimization, because the amount of outdoor air required for ventilation purposes can be determined on the basis of CO_2 measurement, and the time of admitting this air can be selected so that the air addition will also be energy efficient. With this technique, health and energy considerations will no longer be in conflict, but will complement each other.

CO_2-based ventilation controls can easily be integrated with the economizer cycle and can be implemented by use of conventional or computerized control systems. Because the rate of CO_2 generation by a sedentary adult is 0.75 cfh (27 lph), control by CO_2 concentration will automatically reflect the level of building occupancy.[8] Energy savings of 40% have been reported[9] by converting conventional ventilation systems to intermittent CO_2-based operation.

Economizer Cycles The full use of free cooling can reduce the yearly air-conditioning load by more than 10%. The enthalpy logic unit (EL) in Figure 8.2r will allow the temperature-controller signal (TIC-07 in Figure 8.2p) to operate the outdoor air damper whenever free cooling is available. This economizer cycle is therefore activated whenever the enthalpy of the outdoor air is below that of the return air.

Free cooling can also be used to advantage while the building is unoccupied. Purging the building with cool outdoor air during the early morning results in cooling capacity being stored in the building structure, reducing the daytime cooling load.

The conventional economizers—such as the one shown in Figure 8.2r—are rather limited devices for two reasons. First, they determine the enthalpy of the outdoor and return air streams, using somewhat inaccurate sensors. Secondly, although they consider the free cooling potential of the outside air, they disregard all the other possibilities of using the outdoor air to advantage.

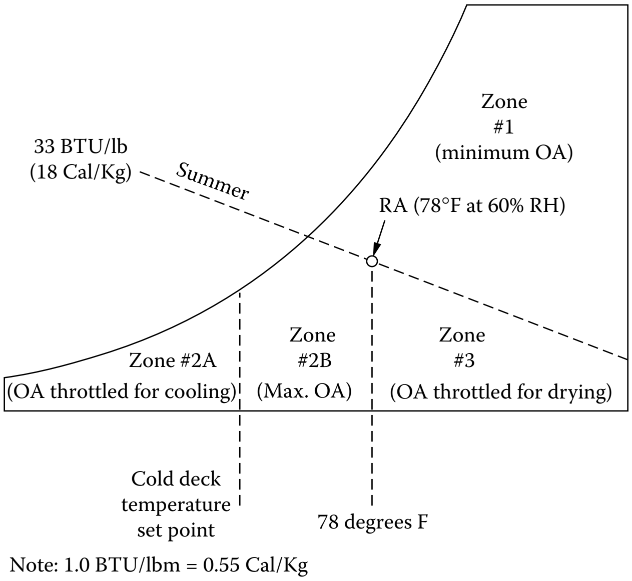

FIG. 8.2s
Free cooling and drying can often be obtained in the summer, depending on the zone where the outside air falls relative to the return air.

Advanced, microprocessor-based economizers overcome both of these limitations. They use accurate sensors and the psychrometric chart to evaluate all potential uses of outside air, not only free cooling. Figure 8.2s illustrates the various zones of operation, based on the relative conditions of the outside and return airs.

If the enthalpy of the outside air falls in zone 1 (that is, if its BTU content exceeds 33), no free cooling is available; therefore, the use of outside air should be minimized in the summer. In the winter or fall, it is possible that the enthalpy of the outside air on sunny afternoons will exceed the return air enthalpy, which in the winter is about 21 BTU/lbm (11.6 cal/kg). Under such conditions, "free heating" can be obtained by admitting the outside air in zone 1.

If the condition of OA corresponds to zone 2 (BTU < 33 and temperature < 78°F), free cooling is available. If the condition of OA corresponds to zone 3 (BTU < 33 and temperature > 78°F), free dehumidifying (latent cooling) is available.

When there are both cold and hot air ducts in the building (dual duct system), the control system in zone 2 will function differently depending on whether the outside air temperature is above or below the cold deck temperature. If it is above that temperature (zone 2B), maximum (100%) outside air can be used; if it is below that temperature (zone 2A), the use of outside air needs to be modulated or time-proportioned.

Therefore, in zone 2A, where the outside air is cooler than the cold deck temperature, free cooling is available, but only some of the total potential can be used. The OA damper

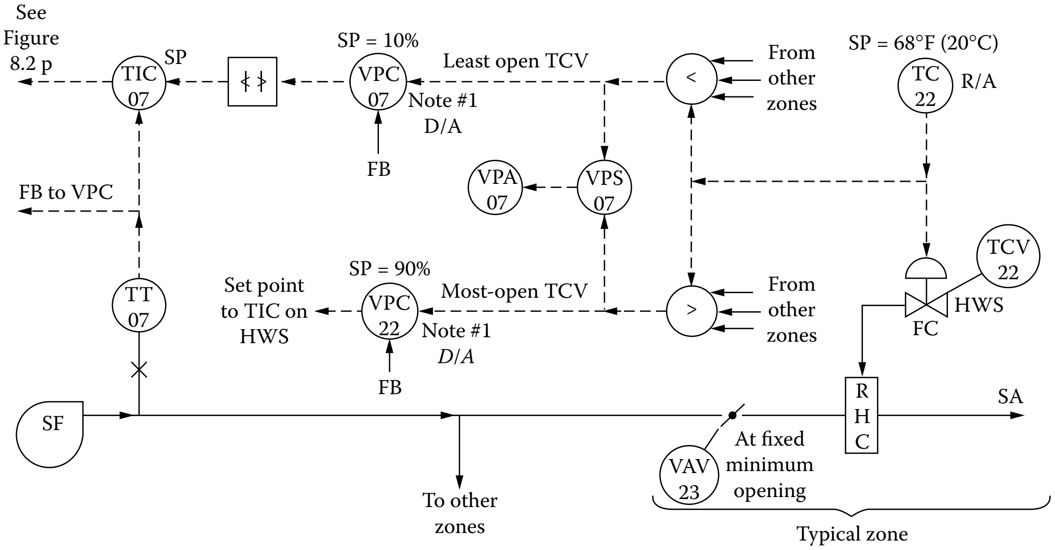

FIG. 8.2t

Optimization of air and water temperatures during heating (winter) mode of airhandler operation is designed to distribute the heat load efficiently between the main heating coil and the zone reheat coils. Note: *Valve position controllers (VPCs) are provided with integral action only for stable floating control. The integral time is set to be 10 times the integral time of the associated TIC. External feedback is provided to eliminate reset wind-up when VPC output is overruled by the setpoint limit on TIC-07.*

therefore must be either positioned or cycled to admit enough cold outside air to lower the mixed air temperature to equal the cold deck temperature set point. This way the need for "pay cooling" is eliminated.

When the outside air is in zone 3 (hot but dry), the control system should admit some of it to reduce the overall need for latent cooling. The amount of outside air admitted under these conditions should be controlled so that the resulting mixed-air dew point temperature will equal the desired cold deck dew point. This method takes full advantage of the free drying potential of the outside air.

As can be seen from the above, the use of the economizer cycles is similar to opening the windows in a room to achieve maximum comfort with minimum use of "pay energy."

OPTIMIZING STRATEGIES

The main goal of airhandler optimization is to match the demand for conditioned air with a continuous, flexible, and efficient supply. This requires the floating of both air pressures and temperatures to minimize operating costs while following the changing load.

In traditional HVAC control systems, the set point of TIC-07 in Figure 8.2p is set manually and is held as a constant. This practice is undesirable, because for each particular load distribution, the optimum SA temperature is different. If the manual setting is less than that temperature, some zones will become uncontrollable. If it is more than optimum, operating energy will be wasted.

Temperature Optimization in the Winter

In the winter, the goal of optimization is to distribute the heat load between the main heating coil (HC in Figure 8.2p) and the zone reheat coils (RHC in Figure 8.2t) most efficiently. The highest efficiency is obtained if the SA temperature is high enough to meet the load of the zone when the zone load is minimum. In this way, the zone reheat coils are used only to provide the difference between the loads of the various zones, whereas the base load is continuously followed by TIC-07.

In Figure 8.2t the set point of TIC-07 is adjusted to keep the least-open TCV-22 only about 10% open. First, the least-open TCV-22 is identified and its opening (in the valve position controller, VCP-07) is compared with the desired goal of 10%. If the valve opening is more than 10%, the TIC-07 set point is increased; if less, the set point is lowered. Stable operation is obtained by making VPC-07 an integral-only controller with an external feedback to prevent reset wind-up.

In Figure 8.2t it is assumed that the hot water supply (HWS) temperature is independently adjustable and will be modulated by VPC-22 so that the most-open TCV-22 will always be 90% open. The advantages of optimizing the HWS temperature include:

- Minimizing heat-pump operating costs by minimizing HWS temperature
- Reducing pumping costs by opening all TCV-22 valves in the system
- Eliminating unstable (cycling) valve operation, which occurs in the nearly closed position, by opening all TCV-22 valves

In Figure 8.2t, a valve position alarm (VPA-07) is also provided to alert the operator if this "heating" control system is incapable of keeping the openings of all TCV-22 valves between the limits of 10% and 90%. Such alarms will occur if the VPCs can no longer change the TIC set point(s), because their maximum (or minimum) limits have been reached. This condition will occur only if the load distribution was not correctly estimated during design or if the mechanical equipment was not correctly sized.

If the HWS temperature cannot be modulated to keep the most-open TCV-22 from opening to more than 90%, then the control loop depicted in Figure 8.2u should be used. In this loop, as long as the most-open valve is less than 90% open, the SA temperature is set to keep the least open TCV-22 at 10% open (zone A). When the most-open valve reaches 90% open, control of the least-open valve is abandoned and the loop is dedicated to keeping the most-open TCV-22 from becoming fully open (zone B). This, therefore, is a classic case of herding control, in which a single constraint envelope "herds" all TCV openings to within an acceptable band and, thereby, accomplishes efficient load following.

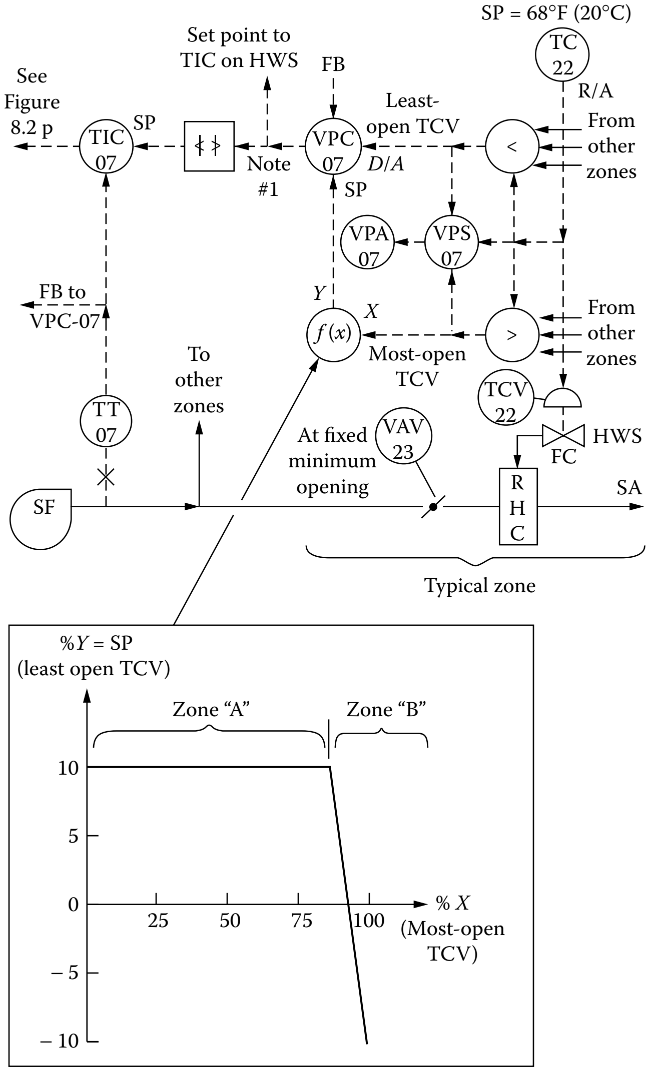

FIG. 8.2u

This alternative method of air supply temperature optimization in the winter should be used when the HWS temperature cannot be modulated. Note: *Valve position controllers (VPCs) are provided with integral action only for stable floating control. The integral time is set to be 10 times the integral time of the associated TIC-07. External feedback is provided to eliminate reset wind-up when TICVPC-07 output is overruled by the set-point limit on TIC-07.*

Temperature Optimization in the Summer

In the cooling mode during the summer, the SA temperature is modulated to keep the most-open variable volume box (VAV-23) from fully opening. Once a control element is fully open, it can no longer control; therefore, the occurrence of such a state must be prevented. On the other hand, it is generally desirable to open throttling devices such as VAV boxes to accomplish the following goals:

1. Reduce the total friction drop in the system
2. Eliminate cycling and unstable operation (which is more likely to occur when the VAV box is nearly closed)
3. Allow the airhandler to meet the load at the highest possible supply air temperature

This statement does not apply if air transportation costs exceed cooling costs (for example, undersized ducts, inefficient fans). In this case, the goal of optimization is to transport the minimum quantity of air. The amount of air required to meet a cooling load will be minimized if the cooling capacity of each unit of air is maximized. Therefore, if fan operating cost is the optimization criterion, the SA temperature is to be kept at its achievable minimum, instead of being controlled as in Figure 8.2v.

If the added feature of automatic switchover between winter and summer modes is desired, the control system depicted in Figure 8.2w should be used.

When all zones require heating, this control loop will behave exactly as does the one shown in Figure 8.2u; when all zones require cooling, it will operate as does the system shown in Figure 8.2v. In addition, this control system will operate automatically with maximum energy efficiency during the transitional periods of fall and spring. This high efficiency is a result of the exploitation of the self-heating effect.

If some zones require heating (perimeter offices) and others require cooling (interior spaces), the airhandler will automatically transfer this free heat from the interior to the perimeter zones by intermixing the return air from the various zones and moving it through the 10° zero energy band (between the settings of TC-22 and TC-23. When the zone temperatures are within this comfort gap of 68°F (20°C) to 78°F (26°C), no pay energy is used and the airhandler is in its self-heating, or free-heating, mode. This is an effective

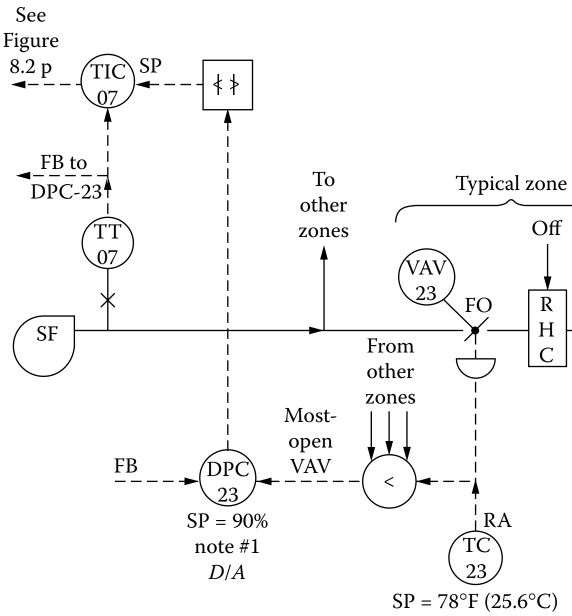

FIG. 8.2v
This method of air supply temperature optimization in summer (cooling mode) should be used if fan operating costs are less than cooling costs. Note: *The damper position controller (DPC) has integral action only, with its setting being 10 times the integral time of TIC-07. External feedback is provided to eliminate reset wind-up.*

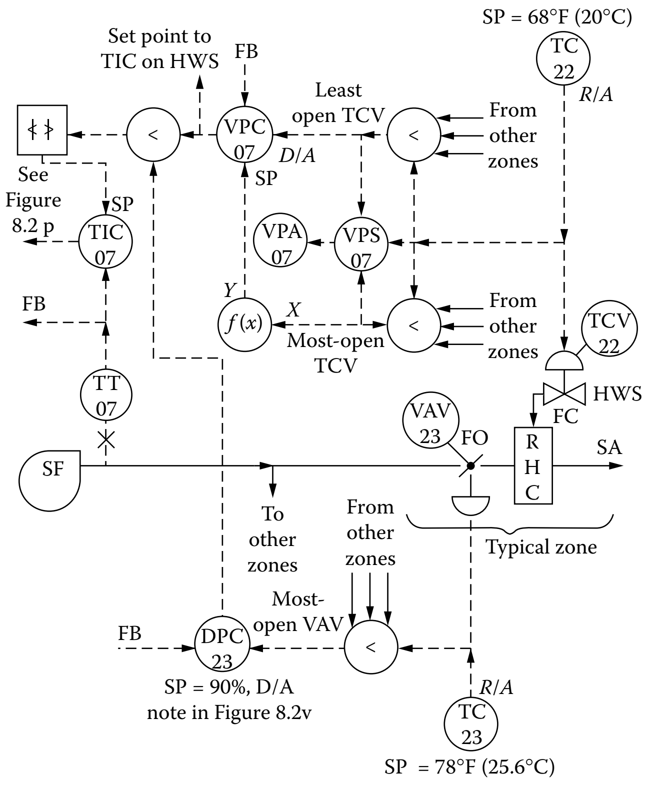

FIG. 8.2w
This control system optimizes the water and air temperatures in both summer and winter. See also Figures 8.2u and 8.2v.

means of reducing operating costs in buildings. The savings can amount to more than 30% during the transitional seasons.

When the temperature in one of the zones reaches 78°F (26°C), the air supply temperature set point will be lowered by DPC-23 and the air-side controls will be automatically switched to cooling (as depicted in Figure 8.2v). If, at the same time, some other zone temperatures drop below 68°F (20°C), requiring heating, their heat demand will have to be met by the heat input of the zone-reheat coils only. This mode of operation is highly inefficient because of the simultaneous cooling and reheating of the air.

Fortunately, this combination of conditions is highly unlikely, because under proper design practices, the zones served by the same airhandler should display similar load characteristics. The advantage of the control loop in Figure 8.2w is that it can automatically handle any load or load combination, including this unlikely, extreme case.

AutoBalancing of Buildings

In computerized building control systems, the optimization potentials are greater than those that have been discussed up to this point. When all zone conditions are detected and controlled by the computer, it can optimize not only the normal operation but also the start-up of the building.

The optimization of airhandler fans is directed at two goals simultaneously. The first goal is to find the optimum value for the set point of the supply air pressure controller (PIC-19 in Figure 8.2f). Generally, the supply air pressure is at an optimum value when it is at the lowest possible value, while all loads are satisfied. As the supply pressure is lowered, the fan operating cost is reduced, but with lowered supply pressures the VAV boxes serving the individual zones (VAV-23 in Figure 8.2b) will have to open up so that the airflow to the zones will not be reduced. Therefore, the optimum setting for PIC-19 is that pressure at which the most open VAV box is nearly 100% open, while all other VAV boxes are less than 100% open.

The second goal of optimization is to automatically rebalance the air distribution in the building as the load changes. If the VAV boxes (VAV-23 in Figure 8.2b) are not pressure independent (are not able to maintain constant air flow when the supply pressure changes), manual rebalancing is required every time the load distribution changes. Naturally this is a very labor-demanding and inefficient operation. The optimization strategy described below serves the multiple purposes of automatic rebalancing and finding the optimum set points for the supply air pressure and temperature.

Figure 8.2x illustrates an airhandler that is serving several zones. The abbreviations used in that figure and in the algorithm tables that follow are listed below:

AI-1 to AI-N: Analog inputs (zone temperatures)
AI-AT: Analog input (air supply temperatures)
AI-RT: Analog input (return air temperature)
AO-1 to AO-N: Analog output (zone VAV opening)

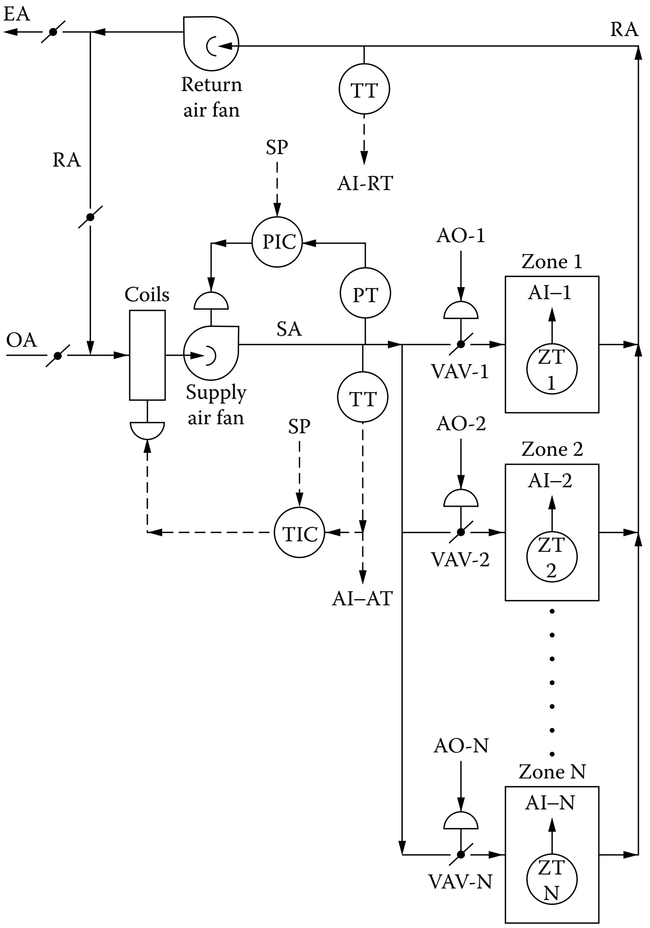

FIG. 8.2x

Airhandler optimization and auto-balancing can be handled efficiently by computer.

AT: Supply air temperature
EA: Exhaust air
OA: Outside air
PIC: Pressure controller (supply air)
PT: Pressure transmitter
RA: Return air
RT: Return air temperature
SA: Supply air
SP: Set point
TH: Upper limit of comfort zone (Figure 8.2a) (maximum allowable zone temperature)
TIC: Temperature controller (air supply)
TL: Lower limit of comfort zone (Figure 8.2a) (minimum allowable zone temperature)
VAV-1 to VAV-N: Variable air volume boxes
ZT-1 to ZT-N: Zone temperatures
ZT5-1 to ZT5-N: ZT 5 min after start-up
ZT10-1 to ZT10-N: ZT 10 minutes after start-up
XMIN: Minimum VAV opening required for ventilation
XSET-1 to XSET-N: Initial VAV opening after “start-up”
XMAX-1 to XMAX-N: Maximum limit on VAV opening during normal operation

Start-Up Algorithm

All VAV boxes are set to their minimum openings required for ventilation purposes (XMIN), such as 25%. Therefore, at the time of start-up, AO-1 through AO-N are all set for 25%. PIC is set to mid-scale; therefore, the start-up value of its SP = 50%. TIC is set for (TL+25)°F in the heating mode and for (TH-25)°F in the cooling mode.

After 5 min of operation, the zone temperatures are detected (ZT5-1, ZT5-2, and so on), and after 10 min of operation they are detected again (ZT10-1, ZT10-2, and so on). At the end of the first 10 min of operation, the supply air temperature is also measured as AT10 and the return air temperature as RT10.

Once the above readings are obtained, they are entered into a table such as Table 8.2y, which serves as the basis for determining the required start-up openings of each of the VAV boxes (XSET-1, XSET-2, and so on). The purpose of this table is to select the initial opening for each VAV box in a logical manner. Therefore, if the zone temperature after 10 minutes of operation is already within 5°F of reaching the comfort zone, the VAV box can be left at its minimum opening.

If comfort is not yet within 5°F, a higher opening is needed. The initial VAV opening is increased on the basis of the zone’s performance during the previous 5 minutes. The larger the temperature change experienced by the zone during the previous 5 minutes, the sooner it will reach the comfort zone and therefore the smaller the opening that is required. By this logic, the VAV boxes on those zones that are furthest from comfort and that are moving most slowly toward comfort will be given the highest openings.

Normal Algorithm for VAV Throttling

The initial VAV opening for each zone (XSET), which is determined by the methods above, is then used as the maximum limit on the VAV opening (XMAX) during the first 5 minutes of normal operation. The value of XMAX is reevaluated every 5 minutes, as shown in Table 8.2z. The logic here is to increase the maximum limit on VAV opening (XMAX) to any zone in which the VAV has been open on its maximum limit for 5 minutes. Similarly, this logic will lower the XMAX limit if the VAV damper was at its XMIN during the previous 5 minutes. If a VAV damper has been throttled somewhere in between these two limits (XMAX and XMIN), its limit will not be altered. The change increment of 10% shown in Table 8.2z is adjustable for maximum flexibility.

The algorithm described above and illustrated in Table 8.2z guarantees that changes in load distribution will not result in starving some zones; the building will be automatically rebalanced in an orderly manner. The value of XMAX from Table 8.2z and the permanent values of XMIN, determined by ventilation requirements, are used to reevaluate the individual VAV openings every 2 minutes, as described by the algorithm in Table 8.2aa.

TABLE 8.2y
Algorithm to Determine Start-Up Openings of Individual VAV Boxes (XSET)

Input Conditions			*Output*
Operating Mode	*Approach between Zone and Supply Temperatures*	*Amount of Temperature Change During Last 5 Minutes of Start-Up*	*Initial Value of XSET to be Used for AO-1 to AO-N (%)*
Heating (AT > RT)	(TL − ZT10) > 5°F	(ZT10 − ZT5) < 0.5°F	100
		(ZT10 − ZT5) 0.5–1°F	90
		(ZT10 − ZT5) 1–1.5°F	80
		(ZT10 − ZT5) 1.5–2°F	70

		(ZT5 − ZT10) 2–3°F	60
		(ZT5 − ZT10) 3–4°F	50
		(ZT5 − ZT10) 4–5°F	40
		(ZT5 − ZT10) > 5°F	30
	(ZT10 - TH) < 5°F	Disregard	25

Note: °C = (F − 32)/1.8.

The main optimizing and auto-balancing feature of this algorithm is that whenever a zone is inside the comfort gap, its VAV opening is reduced to XMIN. This reduces the load on the fans and also provides more air to the zones experiencing the highest loads.

Optimization of Air Supply Pressure and Temperature

Optimization means that the load is met at minimum cost. The cost of operating an airhandler is the sum of the cost of air transportation and conditioning. These two cost factors tend to change in opposite directions; minimizing the cost of one will increase the cost of the other. Therefore, it is important to monitor both the transportation and the conditioning costs continuously and to minimize the larger one when optimizing the system. Computerized control systems allow these costs to be readily calculated on the basis of utility costs and quantities.

TABLE 8.2z
Reevaluation of Value of XMAX

Input Conditions		*Output*
Has VAV been Continuously Open to its XMAX During Last 5 Minutes?	*Has VAV been Continuously Throttled to its XMIN During the Last 5 Minutes?*	*Incremental Change in Value of XMAX at the End of 5-Minute Period*
Yes	Yes	Leave XMAX = XMIN
	No	Increase by 10%
No	Yes	Decrease by 10%
	No	Leave as is

		No	N.C.	N.C.
More than one at 100% for more than 30 minutes continuously	Heating (AT > RT)	Yes, at max.	(at max.)	+0.25 in. H_2O
		No	+1°F	N.C.
	Cooling (AT < RT)	Yes, at min.	(at min.)	+0.25 in. H_2O
		No	−1°F	N.C.
More than one at 100% for more than 60 minutes continuously	Heating (AT > RT)	Yes, at max.	(at max.)	+0.5 in. H_2O
		No	+2°F	N.C.
	Cooling (AT < RT)	Yes, at min.	(at min.)	+0.5 in. H_2O
		No	−2°F	N.C.

*N.C. = No change is made at the end of that 5-minute period.

For example, if the transportation cost exceeds the conditioning cost, the optimization goal is to minimize fan operation. This is achieved by conditioning the space with as little air as possible. The quantity of air transported can be minimized if each pound of air is made to transport more conditioning energy; that is, if each pound of air carries more cooling or heating BTUs. Therefore, when the goal is to minimize fan costs, the air supply pressure is held as low as possible, and the air supply temperature is maximized in the winter and minimized in the summer. Fan costs tend to exceed conditioning costs when the loads are low, such as in the spring or fall, or when the economizer cycle is used to provide free cooling.

Table 8.2bb describes the algorithm used to achieve this goal. When none of the VAV boxes (Figure 8.2x) are fully open, indicating that all loads are well satisfied, the air pressure (PIC set point) is kept at a minimum, and the air temperature (TIC set point) is lowered in the winter and raised in the summer. When more than one VAV boxes are fully open, the air supply temperature is increased in the winter (lowered in the summer). When its limit is reached, the algorithm will start raising the PIC set point.

Table 8.2cc describes the algorithm used when the conditioning costs are higher than the fan operating costs. This is likely to be the case when the loads are high, such as in the summer or the winter. Under such conditions, the supply pressure is maximized before the supply air temperature is increased in the winter or lowered in the summer. When none of the VAV boxes in Figure 8.2x are fully open, the PIC set point is lowered, while the TIC set point is at or near minimum in the winter (maximum in summer). When more than one VAV box is fully open, the PIC set point is increased to its maximum setting. When that is reached, the supply temperature starts to be increased in the winter (decreased in the summer).

The algorithms described above provide the dual advantages of automatic balancing and minimum operating cost. They eliminate the need for manual labor or for the use of pressure-independent VAV boxes, while reducing operating cost by about 30%. They also provide the flexibility of assigning different comfort envelopes (different TL and TH values) to each zone. Thereby, as occupancy or use changes, the comfort zone assigned to the particular space can be changed automatically.

ELIMINATION OF CHIMNEY EFFECTS

In high-rise buildings, the natural draft resulting from the chimney effect tends to pull in ambient air at near ground elevation and to discharge it at the top of the building.

TABLE 8.2cc
Optimization of Supply Air Pressure and Temperature, When Conditioning Costs Exceed Fan Costs (Frequency = 5 min)

			Incremental Ramp Adjustment in the Set Points of	
VAV Status	*Airhandler Mode*	*Is PIC Set Point at Its Maximum?*	*TIC*	*PIC*

		No	N.C.	N.C.
	Cooling (AT < RT)	Yes	N.C.	N.C. (at max.)
		No	N.C.	N.C.
More than one at 100% for more than 30 minutes continuously	Heating (AT > RT)	Yes	+1°F	(at max.)
		No	N.C.	+0.25 in. H_2O
	Cooling (AT < RT)	Yes	–1°F	(at max.)
		No	N.C.	+0.25 in. H_2O
More than one at 100% for more than 60 minutes continuously	Heating (AT > RT)	Yes	+2°F	(at max.)
		No	N.C.	+0.5 in H_2O
	Cooling (AT < RT)	Yes	–2°F	(at max.)
		No	N.C.	+0.5 in H_2O

* N.C. = No change.

Although eliminating the chimney effect can lower the operating cost by approximately 10%, few systems with this capability are yet in operation.

Figure 8.2dd shows the required pressure controls. The key element of this control system is the reference riser, which allows all pressure controllers in the building to be referenced to the barometric pressure of the outside atmosphere at a selected elevation. Using this pressure reference allows all zones to the operated at 0.1 in. H_2O (25 Pa) above that reference pressure (PC-7) and permits this constant pressure to be maintained at both ends of all elevator shafts (PC-8 and -9).

If the space pressure is the same on the various floors of a high-rise building, there will be no pressure gradient to motivate the vertical movement of the air, and as a consequence, the chimney effect will have been eliminated. A side benefit of this control strategy is the elimination of all drafts or air movements between zones, which also minimizes the dust content of the air. Another benefit is the capability of adjusting the "pressurization loss" of the building by varying the setting of PC-7, -8, and -9.

Besides reducing operating costs, the use of pressure-controlled elevator shafts increases comfort because drafts and the associated noise are eliminated.

Figure 8.2dd also shows the use of cascaded fan controls. The set points of the cascade slaves (PC-2 and PC-5) are programmed so that the air pressure at the fan is adjusted as the square of flow and the pressure at the end of the distribution headers (cascade masters PC-1 and PC-6) remains constant. This control approach results in the most efficient operation of variable-air volume fans.

If the building is maintained at a constant pressure that equals the pressure at ground elevation plus 0.1 in. H_2O, this will result in higher pressure differentials on the higher floors, as the barometric pressure on the outside drops. Therefore, air losses due to out-leakage and pressure differentials on the windows will both rise. If the pressure reference is taken at some elevation above ground level, these effects will be reduced on the upper floors, but on the lower floors the windows will be under positive pressure from the outside and air infiltration will be experienced.

CONCLUSIONS

The airhandler is just one of the industrial unit operations. The process of air conditioning is similar to all other industrial processes. Fully exploiting state-of-the-art instrumentation and control results in dramatic improvements. There are few other processes in which the use of optimization and of instrumentation know-how alone can halve the operating cost of a process.

The control and optimization strategies described in this chapter can be implemented by pneumatic or electronic

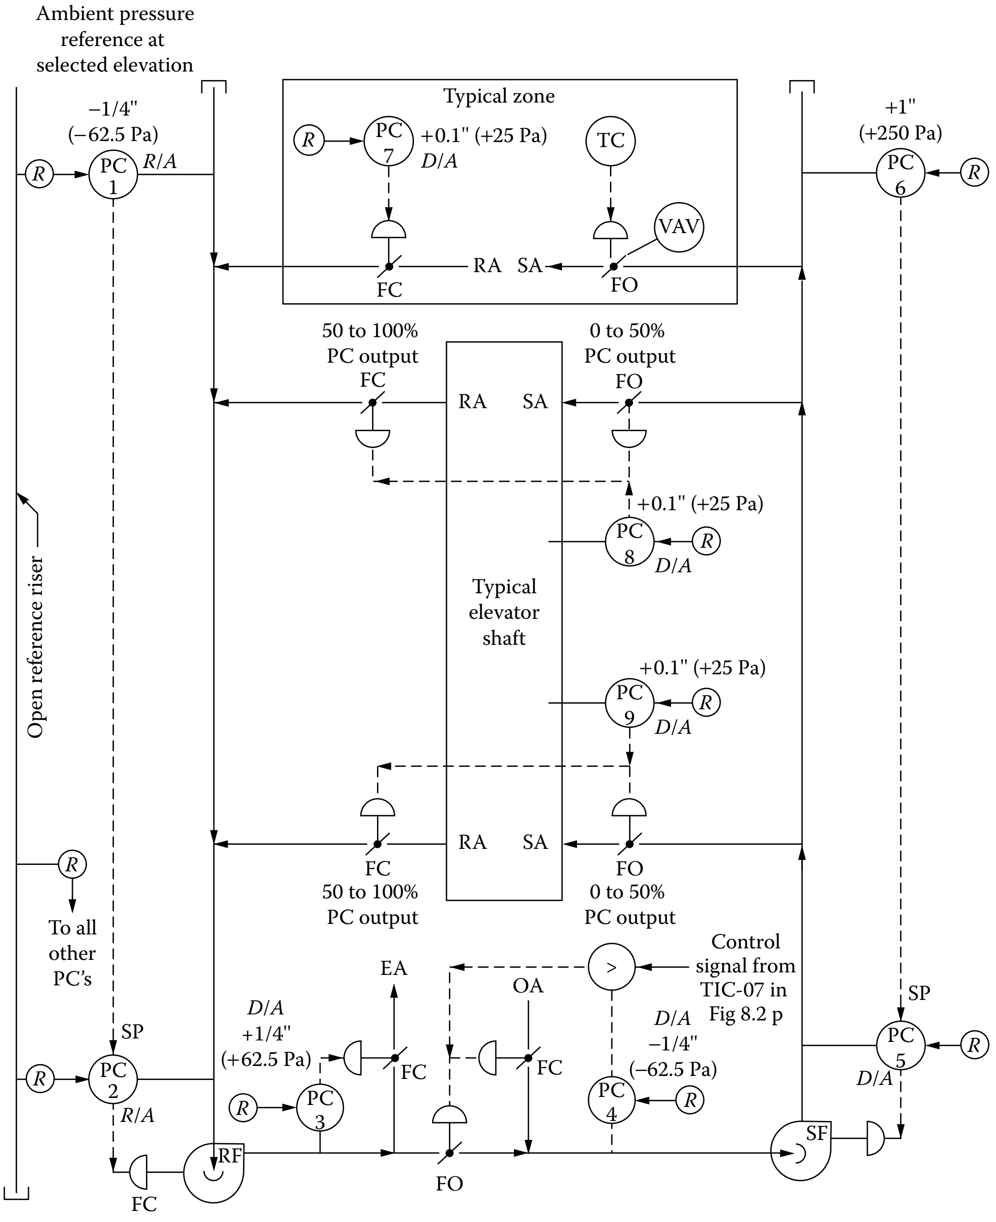

FIG. 8.2dd
Chimney effects in high-rise buildings can be eliminated by using the proper pressure controls.

instruments and can be controlled by analog or digital systems. The type of hardware used in optimization is less important than the understanding of the process and of the control concepts that are to be implemented. The main advantage of digital and computerized systems is their flexibility and convenience in making changes, without the need to modify equipment or wiring.

8.3 Batch Control Description, Terminology, and Standard S88

B. A. JENSEN (1995, 2004)

FEATURE SUMMARY

Batch processing and automation are discussed in this section both from a management point of view and from the perspective of the types of software structures required to implement it. Other sections in this chapter also deal with the subject of batch control. Section 8.4 concentrates on batch processes and their automation, while Sections 8.8 to 8.10 are devoted to the automation of chemical batch reactors.

In 1988, the Instrumentation, Systems and Automation Society (ISA) formed a standards committee to provide guidelines for the design and specifications of batch control systems as used in the process industries. Building upon previous work of the German NAMUR (Normenarbeits-gemeinschaft fur Mess und Regeltechnik in der Chemischen Industrie) and the Purdue Workshop TC-4 committee, the first part of the multipart standard ("Models and Terminology") defined terminology specific to batch control systems to facilitate understanding between manufacturers and users.[1] It also defined a standard batch control architecture that outlined a hierarchical structure relating control equipment and data communications needed for the physical areas involved in batch control and a functional model that showed the relationships between the control activities of recipe management, production scheduling, information management, batch management, unit supervision, and process control (sequential and regulatory control) required in batch control. This evolved into an international standard: IEC 61512-1.[2] As such, the other sections are also turning onto IEC standards including "Part 2: Data Structures and Guidelines for Languages,"[3] IEC 61512-2 standard in 2003.[4] "Part 3: General and Site Recipe Models and Representation" was approved by ISA in March 2003,[5] while "Part 4: Production Records,"[6] is expected shortly.

In addition, a nonprofit, professional organization called the World Batch Forum (WBF) was established in 1994 to promote the exchange of information related to the management, operation, and automation of batch process manufacturing. This association of end users, vendors, consultants, and academics hosts an annual conference with formal presentations and technical papers dedicated to advance batch processing knowledge and technology, with a strict, noncommercial agenda. Other forums include the European Batch Forum (EBF) and Japanese Batch Forum (JBF), which facilitate the same agenda.

Batch automation and batch control is unique depending upon the perspective used to describe it. Unlike continuous processes, a batch process has a finite beginning, middle, and end. Though it has been argued that continuous processes can be thought of as batch processes with very long batch cycle times, the uniqueness of batch control has to do with what procedure is performed, what formulations are used, and on what type of equipment.

Batch processes are event-driven processes that vary with time. Charging, heating, reacting, agitating, cooling, and discharging are examples of sequential events in time requiring corresponding control actions. In the design of a batch control system, time-based process conditions and transition phenomena must be handled. Attention to abnormal events and the interface to the operator may actually take more of the design process than that of the actual automation.

Batch processing can be viewed through three perspectives. One is from a process point of view. The second is an equipment view by which products are processed. The third is a product-based view, or recipe-based view. To that end, the discussion will first begin on the process point of view.

BATCH PROCESS CLASSIFICATION

A batch processing model must consider that a batch can have more than one end product and that production is possible in various plants or plant areas. Thus, batch processes can be classified according to either the number of products made or the physical structure of the process.

Recipe Point of View

A recipe is a batch entity that contains "the necessary set of information that uniquely defines the production requirements for a specific product."[1] That includes the header (purpose, source and recipe version product identification, creator, and issue date) the procedure (the strategy and set of instructions and action needed to carry out the production of a batch), formula (process input values, process parameter variables, and process output data), equipment requirements, and miscellaneous information, such as material safety data sheets (MSDS) and any other material that may be related to the batch.

Batch processes can be classified according to the number of chemicals, substances, or items produced, as follows: single procedure/single formula, single procedure/multiple formula, or multiple procedure/multiple formula. A *single-procedure/single-formula* batch process produces the same product in each batch. The same operations are performed in the same sequence, using the same percentages of the raw materials, though the batch sizes may change. Many of these types of plants can be converted to continuous processes. The *single-procedure/multiple-formula* batch process produces different grades of products that are similar but differ in formula quantities. The same operations are performed in each batch, but the quantity of raw materials or processing conditions are varied. The procedure is the same but the formulas are changed. *Multiple-procedure/multiple-formula* batch processes produce products by utilizing different methods of production or control. The procedures performed, the amounts of raw materials used, the processing conditions encountered, and the equipment used may vary with each batch. This is the most difficult of the three batch-type processes to automate.

Equipment Point of View

Batch facilities can also be characterized according to the physical structure of the process facility. Three basic types of batch structures are series (single-stream) structures, parallel (multistream) structures, and networked structures. A *series structure* is a group of batch equipment through which a batch passes sequentially. It could be a single batch unit, such as a reactor, or several processing units in sequence. In the parallel structure several batches can be undergoing the same (or different) operations at one time. A hybrid of the two structures is a series/parallel batch process, also known as a networked-type structure whereby the batch can pass through any equipment type. This requires the highest degree of sophistication in control equipment to achieve effective batch control.

Product Point of View

The product is the overall objective of any batch process. This view takes into account repeatability and quality of the batches produced. It is information intensive. It is concerned with batch and unit recipe cycle times, cycle time frequency, batch and unit recipe performance ratings, product quality, and other performance-based metrics. Questions are answered, such as, When was batch B-4290 made? What equipment was used? What products were in progress at 14:00, 2 May 2004? How was the product made in 2002? How long does it usually take to make this product? Which reactor typically makes this product the quickest? What other batches were in progress when B-4290 was running? What products have the greatest variability in their production? A fully developed automation system with a historical recipe-based manufacturing execution system is required to support this view.

Table 8.3a lists a variety of factors that can be considered in distinguishing batch processes.

TABLE 8.3a
Variations in Batch Processes and Their Features

Features	*Choices*
Types of recipes	Single procedure/single formula Single procedure/multiple formula Multiple procedure/multiple formula
Topology of plant	Numbers of stages Series/parallel/networked Interconnections: fixed or flexible connections Shared or exclusive use resources allocations
Type of equipment	Single-purpose Multipurpose
Movement of batches	Fixed paths/varying paths from batch to batch predefined in a recipe Dynamic unit assignments coupled with continuous processes Automatic reblending/rework
Control activity levels	Safety interlocking Basic control Unit supervision Batch management Production planning and scheduling Information management Recipe management
Sequence requirements	Number of control actions, inputs, and outputs are small Number of independent sequences and parallel actions are small
Amount of operator intervention	As part of the normal execution includes verification of required manual actions Overriding the recipe in case of abnormal events with return to automatic execution
Exception handling procedures	Permissives for advancing through unit procedure Interlocks continuously checked, system suspends or is held on detection of abnormality Interlocks independent of operations and phases; same interlocks throughout batch; no jumping to other phases Interlocks cause jump to a safe state; interlocks are control-step independent Interlocks are a function of operations and phases; both shutdowns and jumps involved; may be a number of abnormal transitions and states
Requirements for batch data collection	Receiving and storing information on individual batches Producing output information on one or more batches Producing batch reports Maintaining a batch history archive

BATCH AUTOMATION

Automation of batch production is composed of three functional levels:

1. Batch planning: The sequence of production is planned and scheduled taking into account the available resources, including raw materials, personnel, and equipment.
2. Batch control: Production flows and production steps are described. Recipes are processed and executed in this level.
3. Real-time monitoring and control: Basic equipment control is performed at this level. This classical process automation includes safety interlocking input/output processing, and routine sequential, regulatory, and discrete control.

The control activities of an entire batch control system are shown in a hierarchical manner from the sensors and elements to the business planning level in Table 8.3b. In many organizations the lines between the levels may be quite blurred. Additionally, the levels may be compressing though the functions and activities are certainly valid.

Batch planning activities involve process/product management, production/batch management and production planning and scheduling, batch control activities involve batch management and unit supervision, and basic equipment control activities involving sequential/regulatory/discrete control of physical control devices, such as sensors and actuators, and safety interlocking. The following paragraphs describe the control activities as they pertain to batch processes, from the lowest level on up.

Batch automation is planned from top down and implemented from the bottom up.[7]

TABLE 8.3b
Control Activity Model

Level	*Function*	*Activity*
Planning	Process/product management	Production planning, inventory planning, general recipe management, etc.
	Production management	Recipe management, production scheduling, batch history management, etc.
Batch control	Batch management	Recipe generation/selection, batch execution supervision, unit activities coordination, log and report generation, etc.
	Unit supervision	Unit allocation management, unit coordination, etc.
Monitoring and control	Process control	Sequential/regulatory/discrete control: device, loop, and equipment module control, predictive control, model-based control, process interlocking, etc.
	Safety interlocking	—

Process/Product Management

Process/product management is the highest level of control activity. This is where corporate planning for the business is made and is linked to the various operating units. Activities like material and resource planning (MRP), inventory planning, and accounting take place.

Process/product management is an activity that accepts inputs, such as customer orders, and based upon a manufacturing strategy develops a production plan. The production plan can cover such topics as:

What is to be produced?
How much is to be produced?
When is it needed?
Where is it to be produced?
How is it to be packaged?

The output of the production plan becomes an input to the production schedule of the individual plant. Process/product management entails a broad range of corporate planning and provides the basis for management's relationship with its operating units.

Production Management

Production management is made up of three control activities: recipe management, production scheduling, and batch history management.

Recipe Management A recipe is the complete set of data and operations that define the control requirements of a particular type or grade of product. A recipe is composed of the following types of information: (1) header, (2) equipment requirements, (3) formula, and (4) procedure. Headers provide information about the source and version of the recipes, such as recipe and product identification, author, issue, and date and any other pertinent batch information such as MSDS or hazard or toxicity issues specific to the product or processing activities and the like. Equipment requirements specify the type and size of equipment needed, such as glass lining required and 20,000-liter vessel required. Formulas are sets of parameters, such as types and quantities of ingredients, durations, and process condition set points, that distinguish the products defined by procedures. Procedures define and order the actions to be performed and the associated control requirements necessary for making a class of products in the batch process.

The procedure defines the generic strategy for producing a batch product. A procedure is made up of unit procedures.

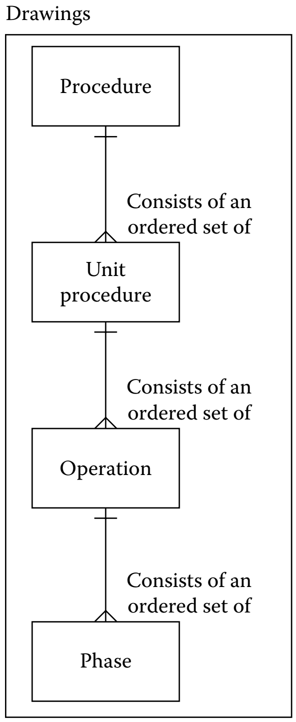

FIG. 8.3c
Procedure model.

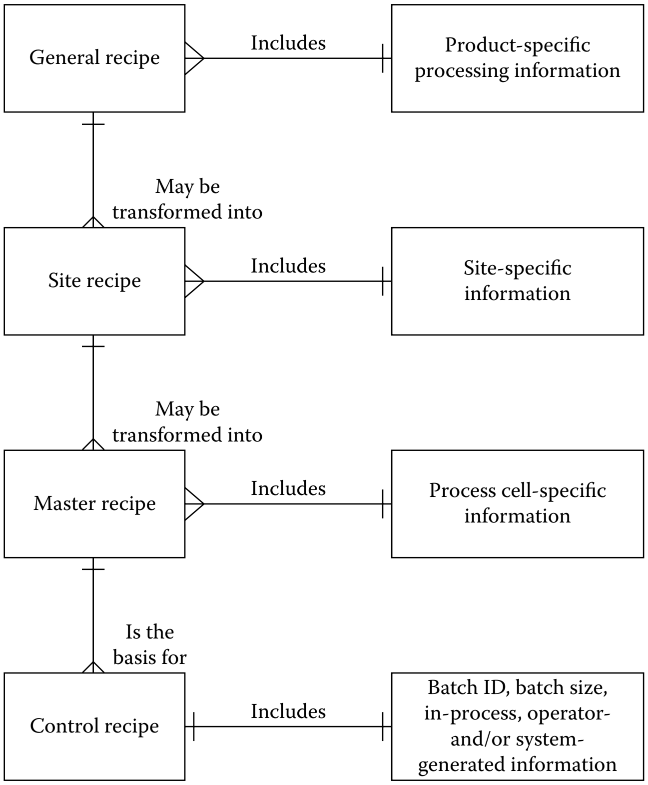

FIG. 8.3d
Recipe model.

Unit procedures are an ordered set of operations that causes a continuous production sequence to occur in a unit. An operation is an ordered set of phases that defines a major processing sequence. And operations are made up of phases that accomplish a process-oriented task. Phases may include the control steps or control instructions that execute the base-level control. The relationship is diagrammed in Figure 8.3c.[1]

The actual executable logic of the control is linked via the recipe information to a particular unit where the unit recipes, operations, or phases are run in the order determined by the recipe.

In the current generation of control systems, the recipe management function maintains a set of master recipes for various products and families of products. Specific information of the batch equipment and units that can run each operation within the procedure are contained within the control recipe. A master recipe is constructed from the site recipe using the formulas, procedures, and equipment-specific information. The master recipe is selected and accessed by the batch management activity, which converts it to a control recipe. This control recipe is the batch-specific recipe that is ready to run. The hierarchy of recipes is shown in Figure 8.3d.[1]

Utilizing process and product knowledge, a process analysis is performed and basic phases are determined. These basic phases, along with product knowledge from the laboratory chemist, are used to construct the general (corporate-wide) recipe. Plant knowledge (for example, raw material availability) from the plant site engineer is used to transform the general recipe to a site-specific recipe. Equipment knowledge (for example, what vessels and piping are available at the plant) is used to transform this site recipe into a master recipe. This master recipe is used as the basis for a control recipe when a batch is ready to be produced. The activities involved during recipe management are summarized in Figure 8.3e.

Production Scheduling Schedules serve as guides for production requirements in terms of availability of equipment, personnel, raw materials, facilities, equipment, and process capacity. The schedule generally has many of the following objectives:

1. Minimize the processing time
2. Minimize the deviation from a master production plan
3. Optimize the production of products within quality guidelines
4. Minimize energy costs
5. Minimize the usage of raw materials
6. Minimize rerun

Production scheduling accepts inputs such as the production plan and based upon a scheduling activity develops a production schedule that typically specifies batches/amounts to be produced, target trains/lines to be used, time targets,

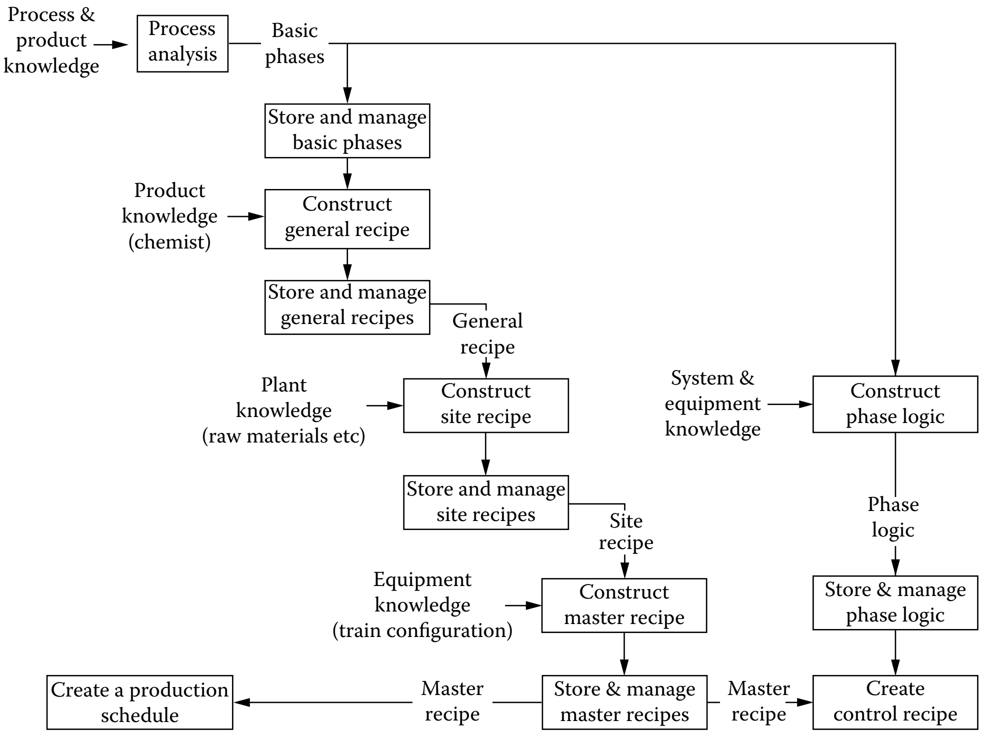

FIG. 8.3e
Recipe activities.

product dispositions, and resource constraints. In essence, the master production schedule answers what to schedule, when to schedule, and how much to schedule.

The production schedule further reduces the production plan, which was developed in the company management layer (process/production management) and directly drives the production of individual batches. The responsibility of the production scheduler is to develop a detailed time-based plan of activities to achieve the production targets set by the production plan. It needs to dynamically allocate a new schedule at any time. It should be feasible to reallocate or create a schedule automatically via some algorithm or manually via user intervention.

Schedulers can be implemented via any number of ways. Linear programs, expert systems, or other multivariable techniques have been used successfully.[8] The scheduler needs to provide a procedure or method for batch sizing and is the logical place where lot or even batch ID assignments are made. A production scheduling model is shown in Figure 8.3f.

As shown by the model, a dynamic scheduler accepts user inputs, master recipe information, and updates from

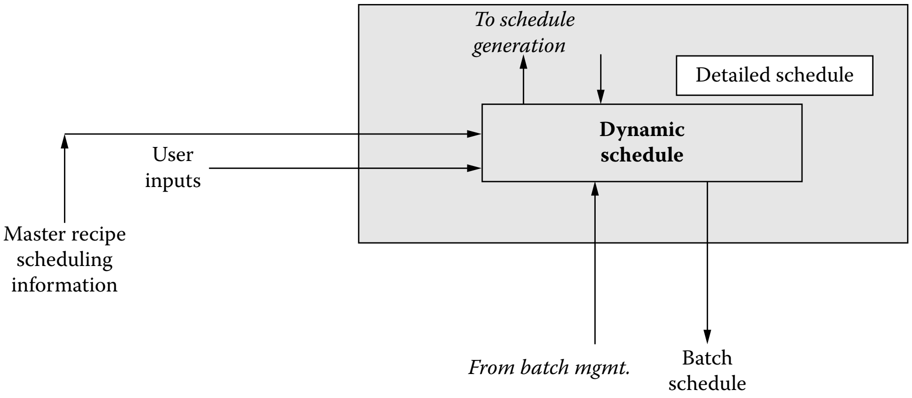

FIG. 8.3f
Production scheduling model.

process management to develop a batch or production schedule. The dynamic scheduler must be able to:

Organize a new schedule at any time
Provide for interactive scheduling
Allow for manual intervention
Determine the availability of resources
Provide for a method to carry out the schedule
Provide a procedure or method for the lot sizing along with a means to organize autonomous orders with this lot size
Determine the feasibility of the schedule

Information about times and availability of resources are key inputs to the scheduler. Because the basic data about the unit operations, master recipes, key times, resources, quantities, priority, and orders and their operations are required, it seems reasonable to conclude that the dynamic scheduler is a real-time activity. The dynamic scheduler requires non-real-time data from production planning and recipe management as well as real-time feedback data from the batch manager and lower-level control activities. The dynamic scheduler can contain some kind of optimizing capability. Batch management provides the updates of information to the scheduler in real time and also provides the status of material and equipment.

The user needs to be advised of the schedule situation continuously. Thus, reporting and status information are important. Information provided to the user can include the control recipe, the lot number, the product being produced, the amount being produced, the train/line being used, the status of the recipe, the mode of operation, priority, start times, and end times. The mode of the lot in the queue determines whether the recipe is to start automatically, semiautomatically, or manually. In the manual mode, stepping through the batch sequence is done by the plant operator via specific commands. In semiautomatic mode, the batch sequence is initiated by the operator and requires operator intervention when proceeding from one phase or operation to another. In the automatic mode, once the sequence is initiated, it can be repeated a predetermined number of times without any operator intervention. The mode of the batches in the queue also determines whether any information in the queue is operator alterable, and whether the control recipe has been bumped or interrupted by another control recipe of higher priority.

Batch History Management Batch history management is the subject of Part 4 of the ISA S88 standard. It has the following main functions:

1. Receiving and storing information from other parts of the overall batch control system on the individual batches
2. Producing output information from single batches, from several batches, or as an overview of multiple batches
3. Producing batch reports on the basis of output information
4. Maintaining production records and batch history archive by supporting data reduction, backup, and deletion features

Although many data logging and reporting techniques for batch processes are similar to those for continuous systems, production records have some significant requirements that may be different. Two needs are batch tracking (some may use the term lot tracking) and the batch end report.

A batch historian must collect and maintain integrated, identifiable sets of dissimilar data. Batch tracking is the collection of this data. It is generally event-triggered and typically contains the following related data:

Continuous process data (flows, temperatures, and pressures)
Event data (operator actions, alarms, notes)
Quality data (lab analysis, inspection notes)
Recipe formula data (quantities desired and used, set points, times)
Calculated data (totalizations, material usage, accounting data)
Manual entries with audit trail (location of change, operator of record)
Stage, batch, lot identification
Time/date stamps on all data

A batch end report may typically include a copy of the master and/or control recipe that was used to make the batch. This may not be identical to the original recipe because of operator modifications, equipment problems, and so on. Events such as alarms, operator instructions, and equipment status changes should also be logged. This log can be designed so that it will retain the total operational sequence chronologically with date and time. A trend chart can also be retained. A recipe expresses the desired approach by which a batch is to be made, while the batch report provides a record of how the batch was actually made. Batch management takes care of the recording and collecting of batch end reports, which are then archived to some other medium. Batch reports are a statutory requirement in some applications (for example, in the pharmaceutical industry); however, because the information is so valuable, it is being demanded in many other batch applications. A simplified batch history management model is shown in Figure 8.3g.

Batch history management is an activity that is not bound to the actual execution time of the batches and not bound to the equipment on which the batches are produced. It involves the process of sorting out the production records and batch end reports, because even a perfect batch may be undeliverable without batch records. Advances in relational databases allow the bridging of data between the process control of current batches and the histories of previous batches. The ability to use standard query language (SQL)-like calls to

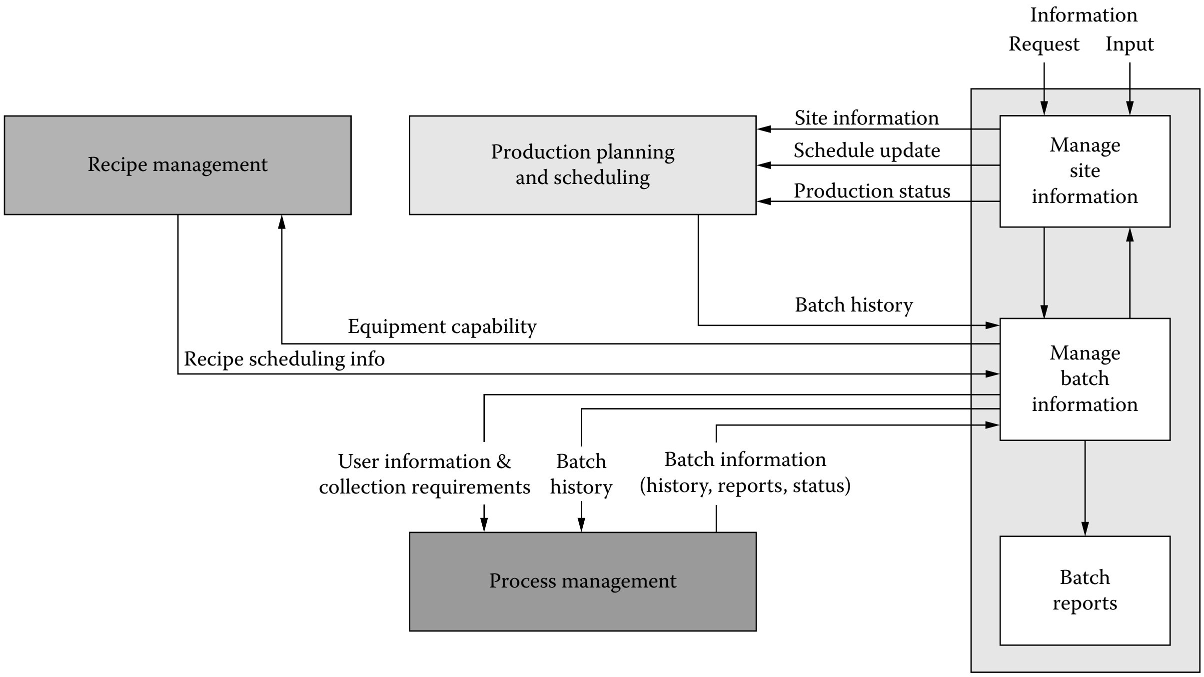

FIG. 8.3g
Batch history management.

access batch history allows new avenues to analyze and report batch histories. Other analysis techniques, such as statistical process control and statistical quality control (SPC and SQC), can be applied at this level.

Batch Management

Batch management interfaces with the user, recipe management, production scheduling, unit management, sequential control, and regulatory and discrete control in performing its functions of (1) recipe selection, transformation, and editing to manage batches; (2) initiation and supervision of batch processes; (3) management of batch resources; and (4) acquisition and management of batch information. A batch management model[1] is shown in Figure 8.3h.

Batch management includes basic functions to managing batches by using control recipe information, batch information, and equipment information to:

1. Select a master recipe from recipe management and transform it to a control recipe that can be used to run a batch
2. Assign a batch identification code
3. Time-stamp the control recipe when the batch identification is entered
4. Verify the information in a control recipe, such as its completeness and its ability to execute on the selected units
5. Maintain the control recipe until the batch is completed

Additionally, the batch management function:

1. Initiates control recipe execution based on time or event
2. Assigns and releases units, and updates their status
3. Distributes the parts of the control recipe to unit supervision
4. Starts the batch based upon start conditions and the detailed schedule, whether upon event or time
5. Regulates the distribution of operation or phases for execution
6. Reports and time-stamps events for information management
7. Allows users to alter normal processing
8. Maintains batch status information
9. Allows batch to be suspended, removed, and later recalled

Managing batch resources takes the detail schedule and master/control recipe information and provides for:

1. Dynamically predicting start and end times for batches and operations and tagging batch events
2. Maintaining the dynamic schedule of all batches, including their current state
3. Dynamically detecting resource requirements and resource availability
4. Updating production scheduling with modifications to the schedule

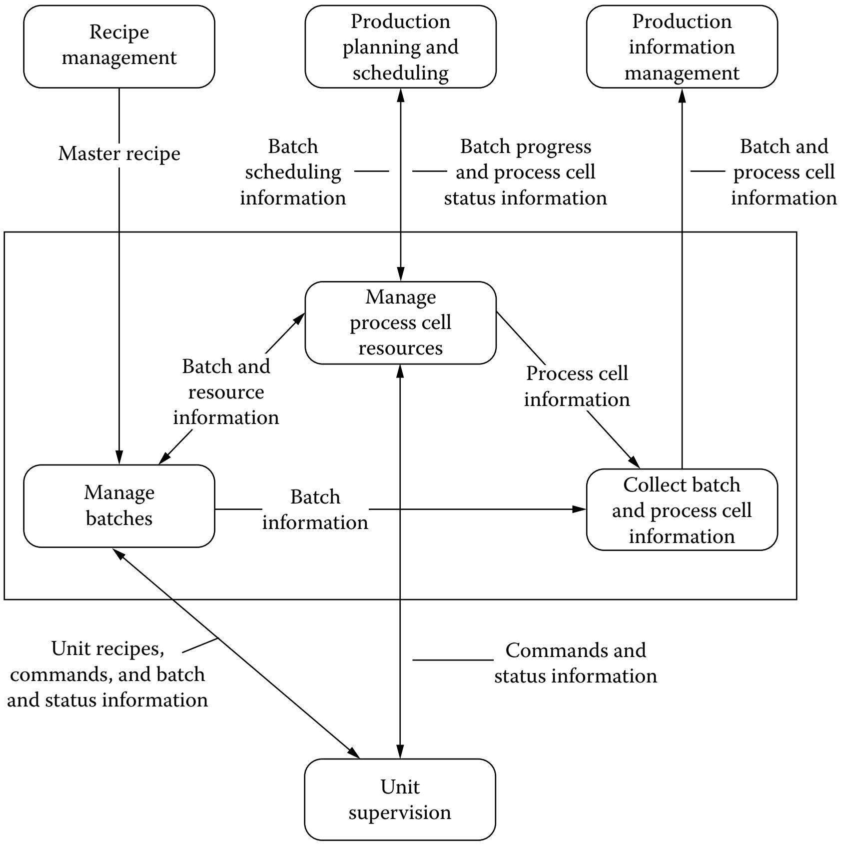

FIG. 8.3h
Batch management model.

Additionally, managing batch resources involves:

1. Receiving the detailed schedule
2. Dynamically detecting conflicts between resources needed and those that are available
3. Granting "permission" to unit to establish resource link
4. Arbitrating multiple requests for resources
5. Tracking and maintaining all batches, ready to run, in-progress, completed, or aborted

Finally, batch management provides functions to acquire and manage batch information, such as:

1. Collecting and reporting batch information by batch, operation, phase, time, or event
2. Providing in-progress or complete batch reports
3. Archiving and retrieving batch data in batch history

A batch report can include recipe data, snapshot process data, or batch data in response to the recipe or on an ad hoc basis necessary for documenting the batch. This includes operator modifications, historical trends, reports, and other information that may be available to the operator.

Unit Supervision

A unit consists of a physical grouping of equipment as well as the unit control functions required to carry out the execution of a batch. A process unit consists of a group of mechanical equipment; each piece performs, in a somewhat independent manner, a portion of the chemical process. Examples of process units are filters, batch reactors, heat exchangers, and distillation columns. Process control involves the actions required to perform the unit operations. Examples are charging, heating, cooling, agitating, reacting, discharging, and washing.

Unit supervision interfaces with the user, batch management, sequential control, regulatory control, and discrete control in performing its functions of (1) communication with other units, equipment modules, and control modules; (2) acquisition of resources; (3) unit procedure execution; and (4) exception handling. The unit supervision model as currently defined by the ISA standards committee is shown in Figure 8.3i.

Unit supervision requires certain information from batch management. The most important information is the recipe information required to run the unit. This recipe information contains the executable logic as well as formula information.

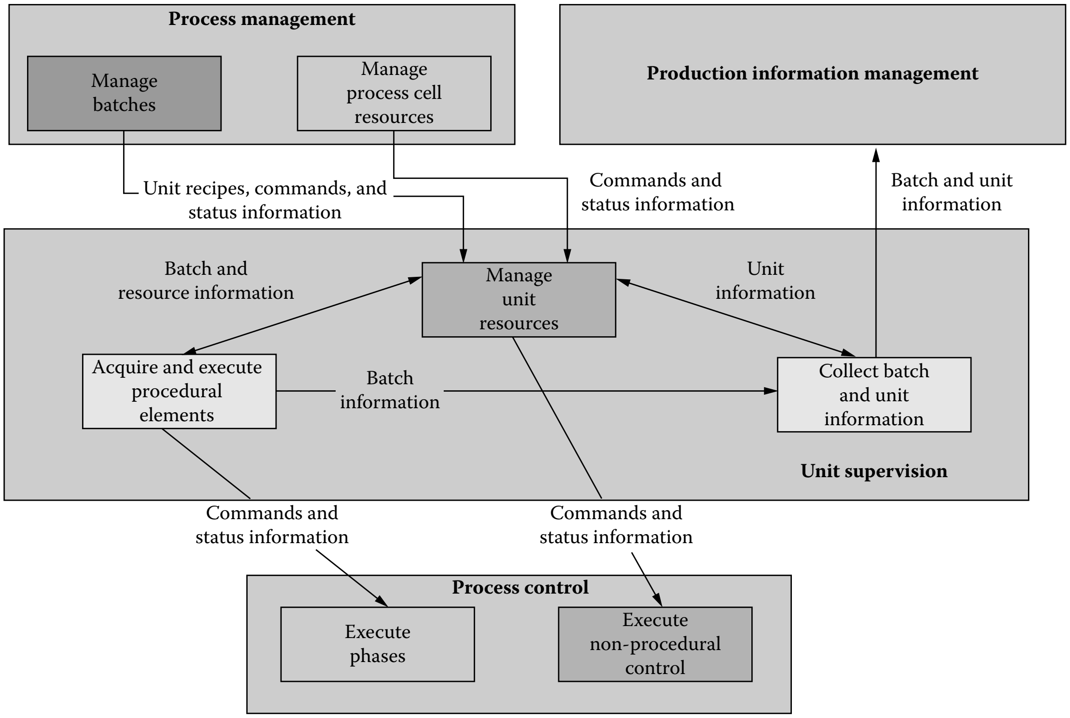

FIG. 8.3i
Unit supervision model.

Unit supervision performs the unit procedures, operations, and phases in the order they are to be run; performs exception logic when some abnormal condition arises during execution; and downloads parameters from the formulas to the control modules.

When more than one processing unit affects the status or use of a resource, the resource is designated as a common resource. Common resources almost always exist with parallel and series/parallel batch process structures. A common resource may either be required exclusively or can be shared. Unit supervision coordinates with other units to account for exclusive-use and shared-use resources.

Exclusive-use resources can be used by only one unit at a time. This means that some mechanism must be in place to prevent more than one batch from trying to use the resource at the same time. Also, the batch scheduling system must take this exclusive resource into consideration. Another problem is associated with distribution of risk in control systems. If a controller module containing the exclusive-use resource fails with no backup, all units utilizing the resource are affected. Shared-use resources are associated with units that can simultaneously use the common resource. A unit should not be able to deactivate the resource while other units are using it, and the capacity of the resource should not be exceeded by multiple users.

The engineering of the equipment into units greatly affects how shared and exclusive resources are handled, which translates into the overall modularity of the batch control. As a batch processes through one unit to the next, the use of the equipment providing the transfers must be coordinated.

Process Control

Sequential, regulatory, and discrete control functions interface directly with elements and actuators to cause changes in the process. Discrete control is concerned with maintaining the process states at a target value chosen from a set of known stable states. Regulatory control serves to maintain the measurements of a process as close as possible to their respective set point values during all events, including set point changes and disturbances. Sequential control sequences the process through a series of distinct states as a function of time.

These types of control functions are implemented using control modules and equipment modules. A control module *device* is an item of process equipment that is operated as a single entity and that may have multiple states or values. Discrete states are initiated (using hardware and software) to control discrete devices such as solenoid valves, pumps, and agitators. A control module *loop* is a combination of elements and control functions that is so arranged that the signals pass between elements for the purpose of measurement or control of the process variable. A proportional, integral, derivative (PID) control algorithm is a common control loop function. An example of *equipment module* control is the sequential control of dehydrator bed control valves in order to put one bed on-line while the other bed is being regenerated according to a time schedule. Most of today's process control systems utilize function blocks as the tools to describe and implement control modules.

Process interlocking and advanced control, in the forms of feedforward, predictive, or model-based control, are additional control functions that reside at this level and serve to achieve a higher level of automation to obtain additional benefits.

As opposed to continuous processing, additional control algorithms and control methodology are normally used in batch processing. Functions such as time-based PID (heat soak ramps), charging algorithms, sequencers, and timers are often required. Techniques such as enabling/disabling control functions based upon a phase state, enabling/disabling alarms on devices and loops, and employing antireset windup protection on PI or PID loops are commonly used. Batch processes tend to be device-oriented, while continuous processes are predominantly loop-oriented.

Safety Interlocking

Safety interlocks ensure the safety of operating personnel, protect the plant equipment, and protect the environment. These types of interlocks are initiated by equipment malfunction and usually cause shutdown. Often, a separate system is used in implementing the safety interlocks. This system includes the necessary redundancy and fault tolerance, and is independent from the other control functions. An example of a safety interlock is the stopping of a centrifugal compressor if its gear oil pump has failed, thus preventing mechanical damage.

Safety interlocking serves a different purpose from process interlocking or permissive interlocking. Process interlocking can be safety-related, but it is primarily associated with the process. An example of a process interlock is to stop charging a material if the agitator is not running. A permissive interlock establishes an orderly progression of sequences. An example would be to not allow the feeding of an extruder before the barrel temperature has reached a minimum value.

ENGINEERING

The effort to automate a batch facility is done to achieve operational benefits. Generally, benefits can be achieved through (1) increased production, (2) reduced utility costs, and (3) higher product quality. Many manufacturers use reduction of off-spec materials due to operator error, which affects all three of the above criteria, as justification for automation.

For batch reactors, benefits acquired through increased production through automation can be achieved via reduced batch cycle times, minimized turnaround time between batches, and better scheduling of reactors for like products. Decreased cycle times for each reactor are certainly measurable and are easy to quantify. A reactor cycle can be thought of as having four separate steps:

1. *Charge times:* Ingredients must be metered accurately and be added to the mixers or reactors as fast as possible. Dribble charging and other anticipatory methods are used to accurately charge the correct amount of an ingredient.
2. *Reaction times:* Good temperature control and accurate pressure detection are essential in order to produce consistent reactions batch after batch. Liquid chromatographs measuring molecular weight distributions and many other analyzers have been used to determine the end of the batch reaction.
3. *Dump time:* Reactor contents are emptied. Level devices or NMR devices have been used here to determine when the batch has been dumped completely.
4. *Turnaround time:* After a batch is dumped, the time until the next batch can be charged should be minimized.

Benefits of automation acquired through reduced utility costs can be achieved by minimizing heating medium usage and minimizing cooling medium usage. Benefits of automation acquired through higher product quality are much more difficult to define. They would normally translate to higher customer satisfaction and less reject material. These benefits can be achieved by achieving tighter control of the batch reactors and higher accuracy and consistency in charging the raw materials.

Once the architecture of the plant is known, the control strategies can be planned. An example of a batch plant is shown in Figure 8.3j.

In his paper presented at the World Batch Forum technical proceedings in 1998, Christie[9] provided his nine points for batch automation design:

1. Understand the process before generating the design.
2. Don't implement until you have designed.
3. Get the user involved in the design.
4. Document the design.

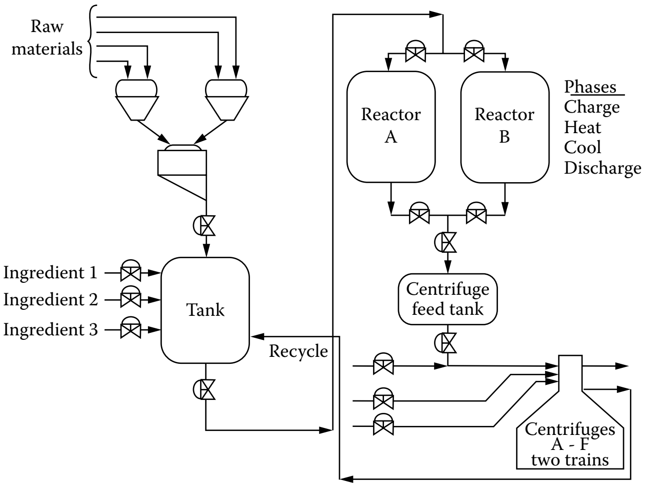

FIG. 8.3j
Batch process example.

5. Agree on the recipes.
6. I/O assignments are important.
7. Don't underestimate the state transition matrix.
8. Pay particular attention to exception handling, the hard part of batch.
9. Batch reports are not an add-on.

Inherent in the message is that the design based upon S88 concepts allows easier implementation and a high degree of modularity, translating into easier modifications and lower maintenance costs. Today's process automation suppliers have embraced the S88 standard concepts into their system architectures, facilitating more modular design and implementation.

With that, Fleming and Schreiber in their 1998 World Batch Forum paper on batch processing design[10] counsels the designer to consider process segmentation so as to:

Identify the process cell first
Identify the units after the boundary of the process cell has been identified
Identify the equipment modules in the process cell and units
Identify control modules in all other modules
Verify equipment module boundaries against defined procedural elements
Verify unit boundaries against defined procedural elements
Finally, verify the process cell boundary against defined procedural elements

The key to design is to segment the process properly so that the controls can be equally identified and segmented. Poor segmentation results in a batch control system that is difficult to support and enhance. A batch control system that fails to exploit the inherent flexibility of the plant and recipe development that requires the assistance of control system developers will result in an implementation that cannot be flexible, resulting in inflexibility of the organization to respond to product needs.[11]

Sequential control functions can be diagrammed to express the logic of batch control. Such diagrams include paradigms such as ladder diagrams (change-oriented), matrix diagrams (state-oriented), flow diagrams (flow-oriented), petri-nets (data/flow-oriented), Gantt charts (state-oriented), and sequential function charts (GRAPHCETS). Many of these tools are listed as possible recipe formats.[12,13] Most all process automation systems claim to be S88 based. In that regard, most, then, utilize function blocks for control modules and sequential function charts for procedures, unit procedures, or operations as their engineering tools to implement batch control automation.

Figure 8.3k is an example of a batch procedure for the batch process shown in Figure 8.3j. It shows the time sequence of activities in making a specific product. Between the active-sequence phases, idling, holding, and waiting states can occur. These states can allow information exchanges with other batch process units or can receive directives from operators. Fail-safe, emergency, or exception handling states can also be defined along with these phases.

Formula information from the recipe is loaded into controllers at the proper time when executing the phases. Formula information is a list of parameters, such as temperature set points, flow set points, quantities or totalization set points for ingredients, transition times, controller modes, and whatever else is needed by the phases.

Finally, at the end of the design and implementation aspects of automation design comes testing of the batch control

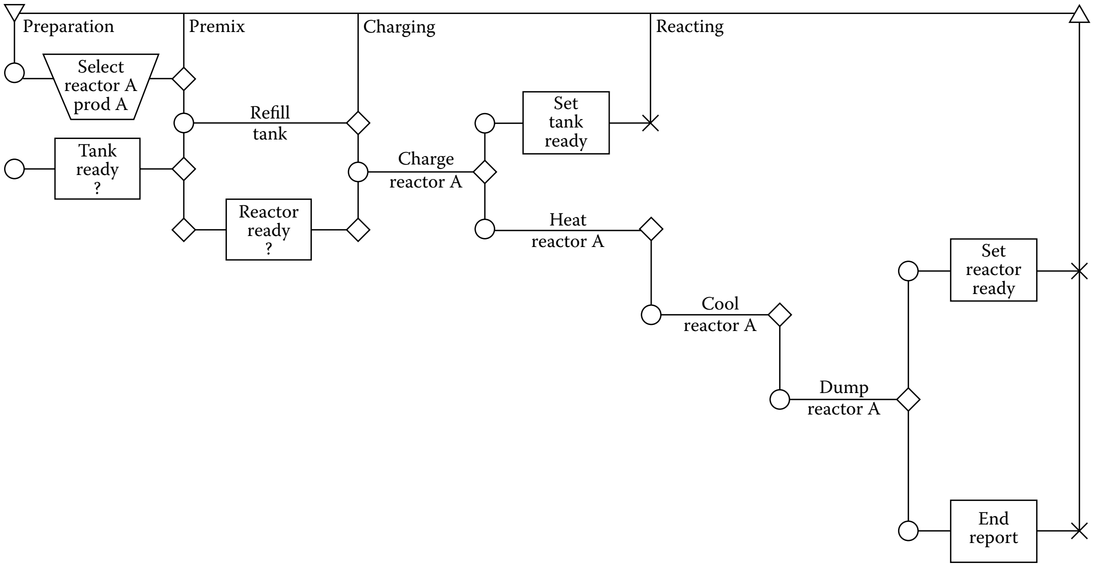

FIG. 8.3k
Batch procedure time sequence.

and automation. Pillai's[14] phase testing guidelines state to clearly define the modules, clearly define the testing strategy, clearly define the test plan, perform the tests, document the test results, and initiate change control.

When the plant configuration is known, the steps necessary to engineer the control of the process can be defined. Figure 8.31 shows the engineering steps performed by the control engineer. However, many other kinds of disciplines

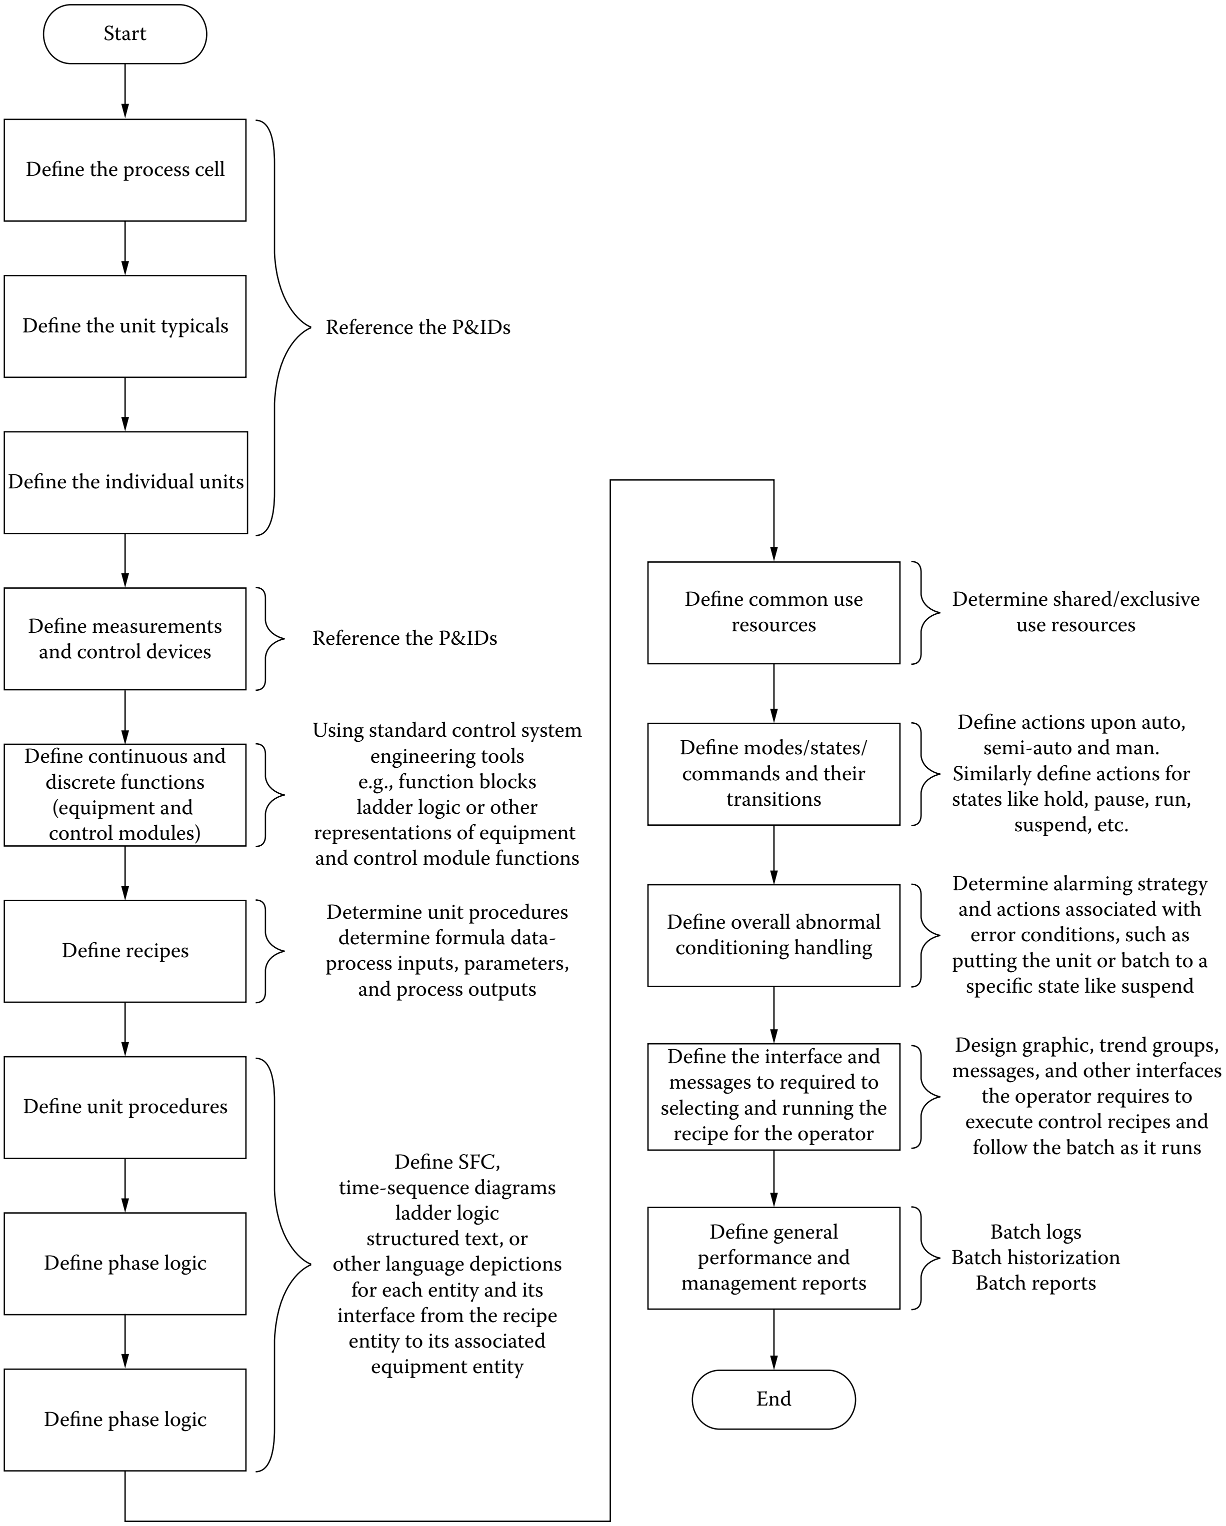

FIG. 8.3l
Batch process control flowchart.

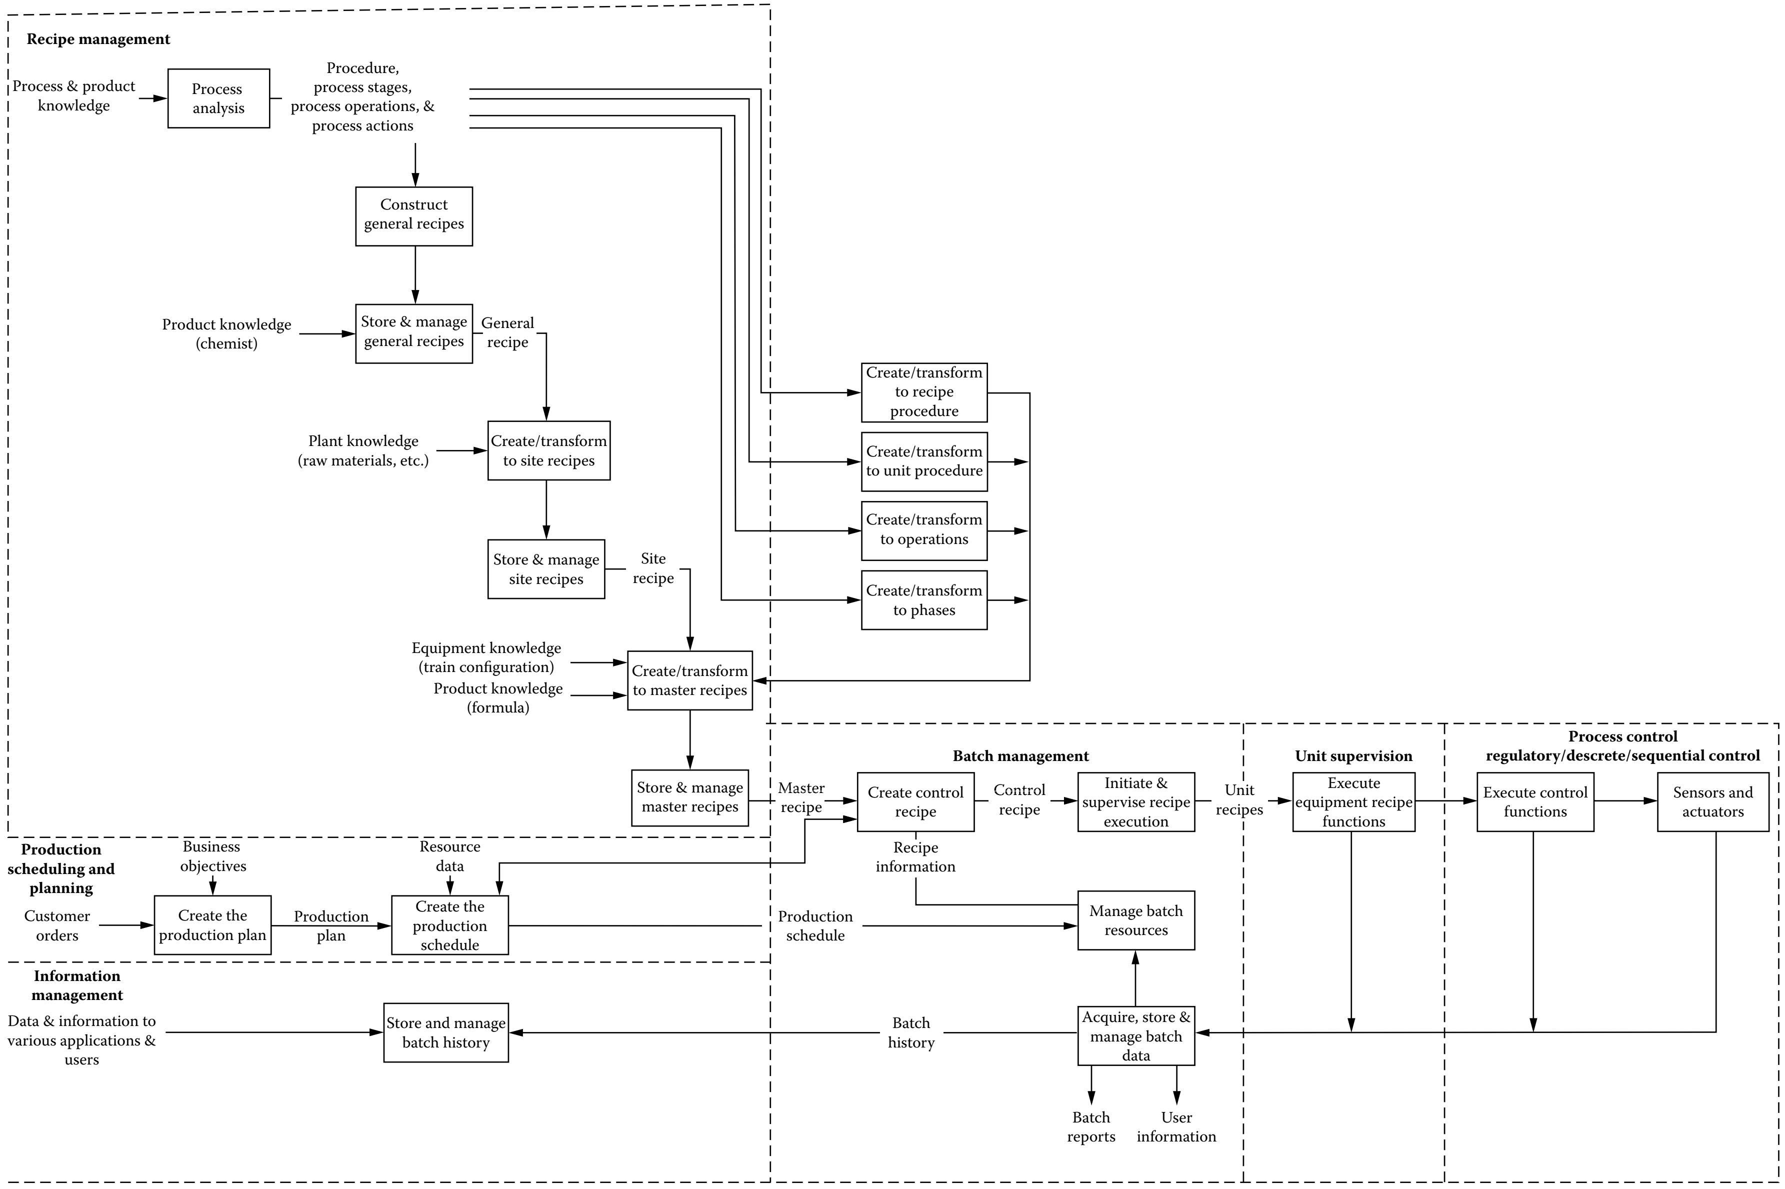

FIG. 8.3m
Consolidated control activities.

are involved in the entire process. Figure 8.3m illustrates the engineering activities required at various levels by people with different backgrounds and qualifications.

Process and product knowledge from central engineering provides the input to construct basic phases for the procedure of making a product. This knowledge combined with product knowledge of the research or development chemist is used to construct general recipes. Plant knowledge provides the information to convert the general recipe to a site-specific recipe. Plant engineers also have the equipment knowledge necessary to construct phase and operation logic and to transform the site recipe into a master recipe by knowing the specific trains/lines on which the product can be made. Process control engineers then are able to use both system knowledge and process knowledge to create the control recipe, which is system-specific and is designed to execute a batch. The control engineers also use their knowledge to design, configure, and implement the lower-level control functions required to provide process control. Management information systems (MIS) people implement process/product management and turn business objectives and customer orders into a production plan that is used to create a production schedule. Batch history archives may be maintained by MIS or plant computer system personnel. Therefore, overall batch control implementation requires the talents of many disciplines.

CONCLUSIONS

Execution of a batch process is a sequence of processing stages, operations, or actions. These stages, operations, or actions are independent process-oriented events within the overall batch operation, such as charging, heating, reacting, agitating, cooling, and discharging. These stages, operations, and actions translate to unit procedures, operations, and phases, which are defined by boundaries that define safe or logical points where one can charge an ingredient or direct a finished product to a different downstream vessel. The set of sequences under which these are performed constitutes the batch operation.

The user must be considered at each level of the control activity. The operator interface allows the operator to interrupt automated commands received from higher activity levels and to enter information or to command the process directly. Data can enter the system at any level. Also, an output can be generated at any level where it is needed and then be transmitted to the next higher or lower levels.

The models defined by the ISA batch control standards committee are designed to be valid for batch processing facilities, regardless of the level of automation involved. The control activity levels are designed to be collapsible in case those functions are not applicable. From plants whose recipes are on paper and whose control is done by manual valves to fully automated paperless batch manufacturing facilities, the descriptions and terminology of the batch process should be understandable by all who participate in it, regardless of the industry or the products involved. The goal is a modular, maintainable, flexible batch automation implementation.

8.4 Batch Processes and Their Automation

A. GHOSH (1995, 2005)

INTRODUCTION

Batch automation and batch control are discussed in this section from both a process characteristics and a modeling point of view. This discussion covers the various control functions, distributed control systems (DCS) capabilities, and reliability aspects. Other sections in this chapter also deal with the subject of batch control. Section 8.3 describes terminology, and Section 8.8 is devoted to the control of batch reactors.

In a continuous process, such as the distillation of crude oil or the manufacture of bulk chemicals and fertilizers, the product is manufactured on a continuous basis. In batch processes, used in the food, pharmaceutical, and fine chemical industries, products are manufactured in batches. Batch processes are sequential, where the control functions (called phases), such as charging, mixing, heating, cooling, and testing, are performed in an ordered fashion. Each phase may require many process steps, such as the opening and closing of valves, starting and stopping of pumps, and setting and resetting of control loops. In addition to the normal step-by-step control actions, batch process control requires many other functions; for example, responding to abnormal or failure conditions, keeping batch records, maintaining recipes, and scheduling batches.

Batch process control is a complex task rather than a difficult one. A difficult problem is one that is mathematically or scientifically difficult to solve and usually has a single solution. A complex problem, on the other hand, is logistically more challenging. A batch process is characterized by numerous interrelationships and constraints, mutually exclusive objectives, and many possible solutions. Most real-life problems tend to be complex. The solution of a complex problem involves its progressive decomposition into simpler functional modules and their proper integration.

This section deals with batch control problems and their solutions in general. Specific details on batch reactor control can be found in Section 8.8.

BATCH CONTROL STANDARDS

The ANSI/ISA-88 (IEC 61512) batch control standard[1–3] is providing significant benefits to users and suppliers of batch control systems worldwide. The standard is in three published parts, while the fourth part is under development (Table 8.4a).

Part 1: Models and Terminology

Part 1 defines standard terminology and a number of models for batch control. The key models are procedure, physical, and control activity (Figure 8.4b). The terminology, structures, and concepts used in the standard are affecting everyone in the batch control business. Most major suppliers have adopted standard terminology and have designing batch control systems with a modular set of functions and hierarchy based on the control activity model. This modularity allows for easier integration of third party-packages to do functions such as production planning, scheduling, and production information management. It also makes a control system easier to integrate with production management and business planning systems.

TABLE 8.4a
Batch Control Standards

Batch standard	Year published	US standard	International standard	Scope
Part 1	1995	ANSI/ISA-88.00.01	IEC 61512-01	Models & terminology
Part 2	2001	ANSI/ISA-88.00.02	IEC 61512-02	Data structures & language guidelines
Part 3	2003	ANSI/ISA-88.00.03	IEC 61512-03	General & site recipes

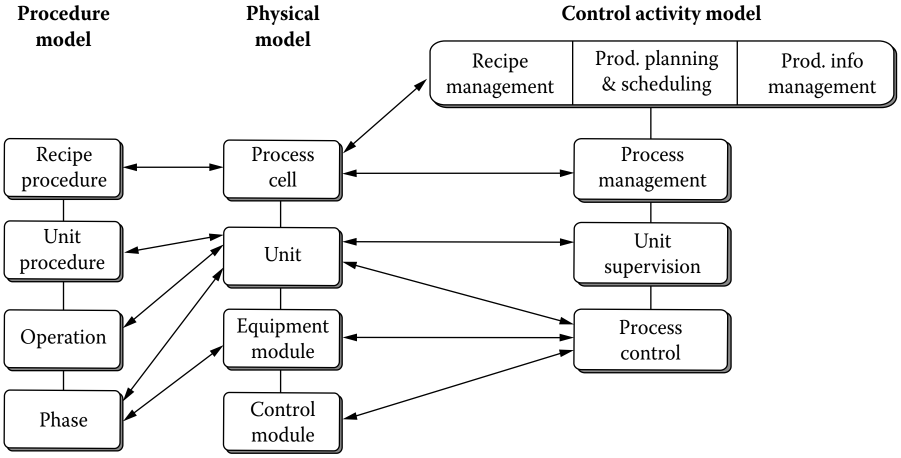

FIG. 8.4b
Batch standard models. (Note: Arrows show relationships, not data flow.)

The main benefits of Part 1 of the batch control standard are:

- Improved communication between suppliers and users of batch control
- Easier identification of end-user needs
- Straightforward recipe development
- Reduced cost of automating batch processes
- Reduced life-cycle engineering effort

Part 2: Data Structures and Language Guidelines

The ISA-88 Part 2 standard is in three parts: data models, information exchange tables, and procedure function charts. The data model section provides formal representation of entities specified in Part 1 of the standard, such as recipe, equipment, planning and scheduling, and information management using Universal Modeling Language (UML) notation. The information exchange section uses SQL relational tables to specify exchange requirements between recipes, process equipment, schedules, and batch production.

The final part of the standard deals with a graphical representation of procedures, such as master and control recipes and using Procedure Function Chart (PFC) notation (Figure 8.4c). PFC is somewhat similar to Sequential Function Chart (SFC) notation as defined in IEC 61131-3 standard.[4] PFC notation addresses procedural control and execution, while SFC notation was developed primarily for state machines. PFC notation meets the requirements of recipe procedures better than SFCs.

PFC notation is intuitive and easy to follow. Users familiar with SFC notation will find many similarities between the two. However, explicit specification of functions such as process equipment allocation and synchronization of phases makes PFC easier to follow than SFC notation.

Providing tools for information exchange, as specified in the standard, allows suppliers to design more modular batch control systems. This will reduce the high cost of maintenance and version upgrades. It is felt that PFC notation will soon become the common way for representing procedural elements in a recipe.

Part 3: General and Site Recipes

Recipes are of four types: general, site, master, and control (Figure 8.4d). A general recipe contains generic information for the manufacture of a product and does not include equipment or site-specific information. This is the first recipe that may be generated when a new product has been developed in a pilot plant.

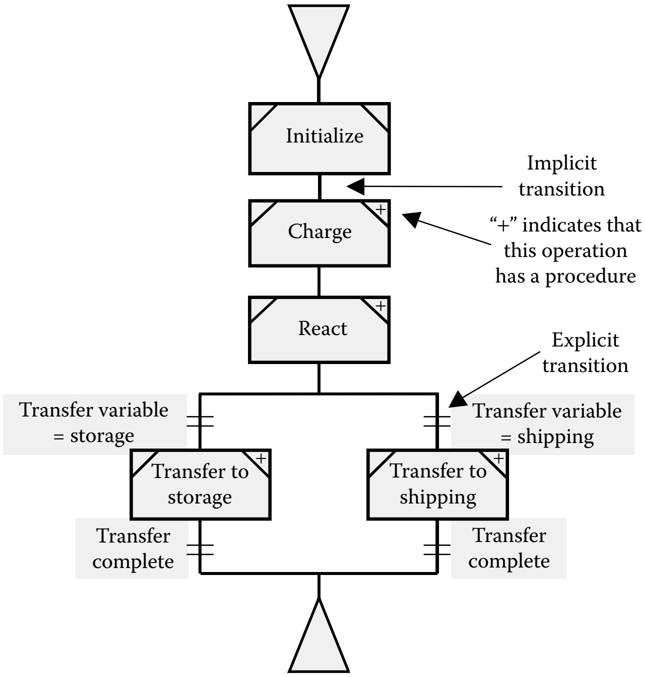

FIG. 8.4c
Unit procedure using procedure function chart (PFC) notation

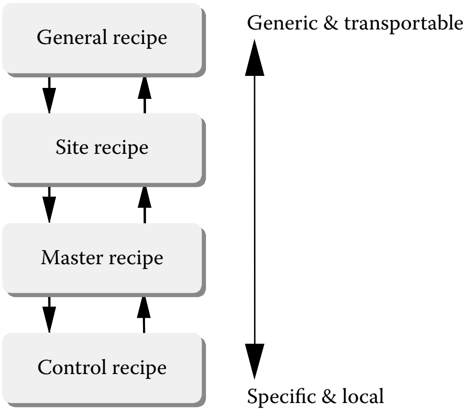

FIG. 8.4d
Recipe model.

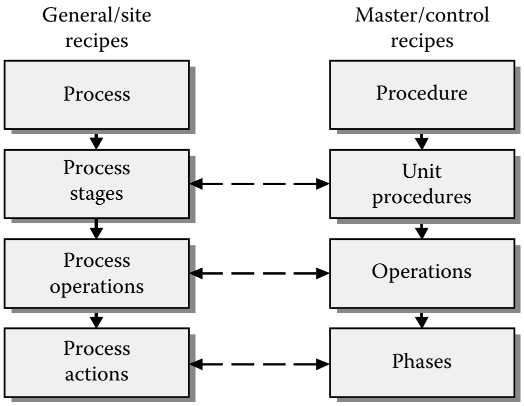

FIG. 8.4e
Mapping between general/site recipes and master/control recipes.

In the increasing complexity of global manufacturing, many process manufacturers find it challenging to maintain a single definition of a product in different manufacturing facilities. General and site recipes provide an equipment-independent means of describing batch manufacturing processes, accelerating both time to market and time to volume production. A standardized general recipe meets this challenge as a central repository for product manufacturing information. General and site recipe functions were identified in Part 1 of the ISA-88 batch control standard, however, little was specified about them in either Part 1 or 2.

Part 3 of the batch standard, which deals with these functions, was published in 2003.

A general recipe is an enterprisewide recipe for a manufactured product that serves as the basis for both site and master recipes. Chemists and chemical engineers with intimate knowledge of both the product's chemistry and processing requirements are generally responsible for creating it. It identifies raw materials, their relative quantities, the required processing, and the order of processing. It may define the processing capabilities required, such as cooling or heating, or the generalized equipment requirements, such as glass-lined reactors, but does not define the specific equipment that may be used to manufacture the product. A general recipe may also serve as input for corporate production planning and standard costing procedures. It is usually the parent of site and master recipes.

A site recipe has the same structure as a general recipe, but the information in a site recipe is tailored for each target location. A site recipe may be modified for the local language, units of measure, regulations, and raw material variability. A site recipe may include only a part of a general recipe that is actually implemented on the site. For example, a single product may have intermediate materials manufactured at one site that are then shipped to a second site for final processing. In that case, each site recipe would be derived from only the portion of the general recipe actually required for the processing to be done at that site.

General and site recipes contain the same categories of information, such as header, formula, procedure, equipment requirements, and other information, as in master and control recipes. The procedure elements of general and site recipes map well with master and control recipes (Figure 8.4e).

Part 4: Production Records

This part of the batch control standard defines a logical data model and means of data exchange for production records containing information about batches and other production segments. The standard is under development.

The Benefits of Standards

The benefits of the ANSI/ISA-88 (IEC 61512) batch control standard reach beyond batch process control. Although the standard is primarily designed for batch processes, it is also being applied successfully in various manufacturing industries. This is because the standard is not just for software, equipment, or procedures. It is a way to conceptualize your production processes that helps you better design your plants and manufacture your products.

The data models and information exchange tables provide significant advantage in the automation and modularization of any manufacturing process. The shift from monolithic centralized control architecture to a modular architecture allows a process to be more flexible in manufacturing different products and allows for easier maintenance and upgrade of control systems. It also facilitates the exchange of information between different systems. Other areas where batch control standards and their underlying concepts may be used include:

- Start-up and shut-down of continuous processes
- Material handling
- Changing products and product grades
- Alarm and exception handling
- Product packaging

The PackML working group within the Open Modular Architecture Controls (OMAC) Packaging Workgroup started using the batch control standard as the basis for defining a more flexible use of packaging systems, which will ensure consistency and quality.

DEFINITION OF BATCH TERMS

Following are explanations of common batch control terms, simplified for easier understanding. For more rigorous definitions, refer to batch control standards.[1–3]

BATCH: A quantity of material produced by the single execution of a batch process. A batch also refers to the intermediate materials during the manufacturing process.

CONTROL MODULE: A set of equipment and functions that can carry out basic control. For example, a control loop consisting of one or more sensors, actuators, and control functions is a control module.

CONTROL RECIPE: An equipment-specific recipe that defines the production of a single batch. It is usually derived from a master recipe.

EQUIPMENT MODULE: A group of equipment that can carry out a finite number of specific minor processing activities. An equipment module may include one or more control modules. It is typically centered around a piece of process equipment, such as a weigh tank, heat exchanger, filter, or weighing scale.

EXCEPTION HANDLING: Procedures and functions that deal with conditions that are outside the normal or desired behavior of a process.

FORMULA: A part of the recipe that include process inputs, process parameters, and process outputs.

GENERAL RECIPE: A type of recipe that expresses equipment- and site-independent processing requirements. It is the highest level of recipes.

LOT: Products produced by a set of similar batches, usually using the same master recipe.

MASTER RECIPE: A recipe for producing a batch of products using a particular set of process equipment.

OPERATION: A procedure that controls the execution of a number of phases in a batch.

PHASE: A set of logic steps that completes a major processing function, such as charge, mix, heat, and reaction. A batch is usually in a stable state at the end of a phase.

PROCESS CELL: A set of equipment required for production of one or more batches. It usually consists of one or more units.

PROCESS INPUTS: Identity and quantity of raw materials and other resources required to make a batch. Other resources include energy and personnel requirements.

PROCESS OUTPUTS: Identity and quantity of products or energy produced at the end of a batch.

PROCESS PARAMETERS: Variables, such as temperature, pressure, and time, which are set points and comparison values that are needed for the production of a batch.

RECIPE: A set of procedures and formula variables that specify the production of a batch. There are four types of recipes: general, site, master, and control.

SITE RECIPE: A recipe that includes site-specific information, such as local language and locally available raw materials.

UNIT: A major piece of process equipment with its associated equipment modules. Mixers, storage tanks, and reactors are examples of units. The associated equipment modules include pumps, valves, heat exchangers, and agitators that are closely associated with the major process equipment. Units operate relatively independently of one another.

UNIT RECIPE: A part of a recipe that defines a part of batch production requirements within a unit. It usually includes a number of operations and phases.

MODELS

This subsection discusses briefly the main models that are specified in Part 1 of the batch control standard. As stated before, these models help modular decomposition of batch control problems and allow suppliers and users to maintain a common view of batch control (Figure 8.4b).

Physical Model

This model shows the physical hierarchy in a process industry. In this model, commands flow from higher to lower levels, and information flows from lower to higher levels. This model generally fits well with batch manufacturing processes. Each manufacturing area may be divided into a number of process cells, where each process cell has the necessary equipment and resources to complete a batch. A process cell consists of a number of units, such as storage tanks, mixing tanks, or reactors.

A unit may also include a number of process equipment or equipment modules, such as agitators, heating systems, pumps, valves, and the like. However, an equipment module may exist independently and may be used by multiple units. A control module, which is either a loop or a device, can be a part of an equipment module or can be directly associated with a unit. A control module may include measuring elements, such as thermocouples and orifice plates, and control elements that manipulate process variables, such as control and on/off valves.

A unit may not acquire another unit but may request its service (for example, to supply a measured amount of ingredient or to accept its product). The control of a unit is carried out by the unit supervision function, which is responsible for acquiring common resources, carrying out inter-unit communications, and performing the step-by-step control actions for the execution of a phase.

Control Activity Model

The control activity model shows the hierarchy of batch control functions. This model shows the hierarchical nature of batch control and thus allows a batch control problem to be broken up into multiple levels for analysis, specification, and design. The need and functional importance of these levels may vary between applications. It should be noted that the desired speed of response of a control system changes as we move from the lower to higher levels. Thus, the lower three levels, process management, unit supervision, and process control, act in real time while transactional-type processing is more appropriate for the upper levels. Each of the functions in the control activity model may be resolved into a number of subfunctions.

Procedure Model

A master recipe, which may be derived from a general or site recipe, contains specifics of the units or unit types that are used in a production plant. Master recipes are stored and maintained in a control system and are used for generating control recipes. A control recipe is used for the actual production of a batch and is generated at the same time a batch is created. The control recipe is generally deleted at the completion of a batch.

A master or control recipe specifies the data and procedure for manufacturing a batch of a given product. The data set is called a formula, which specifies process inputs, process parameters, and process outputs. Process inputs specify the quantity of raw materials and other resources required to make a batch. Other resources may include energy and personnel requirements. Process parameters specify the variables, such as temperature, pressure, and time, which are set points and comparison values that are needed for the production of a batch. Process outputs specify the quantity of products or energy produced at the end of a batch.

Additionally, a recipe contains a header and equipment requirements. The header may contain information such as product and grade identifiers, originator, and date of issue. The equipment requirements specify the type and size of process units, as well as other equipment-related constraints such as the materials of construction.

A recipe procedure may consist of a number of unit procedures. A unit procedure specifies the order of the functions (operations) that are to be carried out within a unit to manufacture a batch of product. An operation specifies the order of phases, such as charge, heat, mix, and store, that are carried out within a unit.

BATCH PROCESS CELL

A cell in a batch process may be classified in a number of ways. One way is by product variation, such as:

- Single product of same grade
- Single product in multiple grades
- Multiple products in multiple grades

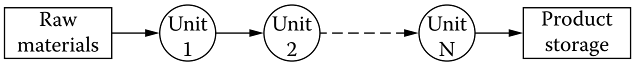

FIG. 8.4f
Single-stream structure.

A process cell that is set up to produce a single product of the same grade requires only one order of processing operations. There, a single recipe is required along with one set of formula variables. When a batch size is changed, the raw materials are scaled accordingly. In many such applications, the formula variables may be embedded in instructions within the phases. A process that produces a single product in many different grades requires a single recipe with multiple sets of formula variables. For manufacturing many products in multiple grades in the same process cell, multiple sets of recipes are required. There, the order of the operations and phases and the formulas vary from product to product.

Physical Structure of a Plant

Another way to classify batch processes is by their physical structure, such as:

- Single stream
- Parallel stream
- Multiple-path

In a single-stream structure, the units are ordered serially in a single train (Figure 8.4f). A batch moves from one unit to another in the predetermined serial order.

A parallel-stream structure is like a multiple single-stream configuration in which there may be common raw material and storage areas (Figure 8.4g), but otherwise each stream is isolated from the others.

In a multiple-path structure (Figure 8.4h), the movement of a batch is not along any fixed path. The choice of a downstream unit is based on the availability of a unit of the type required. The selection is made at the beginning of a batch or as required by the operator, or by a predefined algorithm.

A piece of equipment or service that is used by more than one unit is called a common resource. Common discharge pumps or common steam headers for multiple units are examples of common resources. A resource that can be

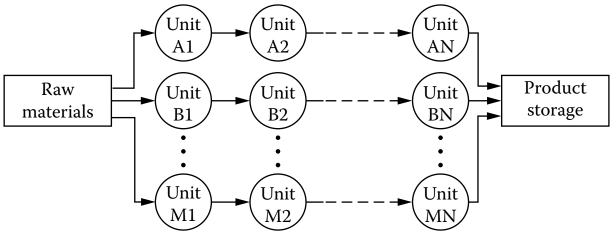

FIG. 8.4g
Parallel-stream structure.

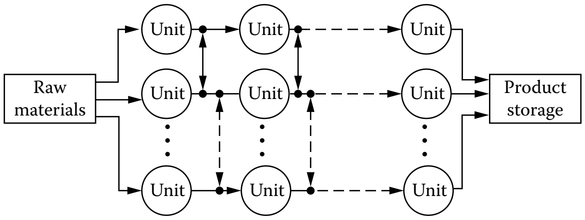

FIG. 8.4h
Multipath structure.

used by only one unit at a time is called an exclusive-use resource. A resource that can be used by several units at a time is called a shared-use resource.

In the case of a shared-use resource, there may be limitations on its capacity to serve. Thus, the common steam header may not be able to heat more than a certain number of units at the same time. In the case of an exclusive-use resource, book and release mechanisms prevent its use by more than one unit at a time. A shared-use resource requires mechanisms to protect it from exceeding its capacity.

EQUIPMENT FOR BATCH AUTOMATION

The types of control equipment commonly used for batch control are:

1. Programmable logic controllers (PLCs)
2. Personal computers (PCs)
3. Distributed control systems (DCS)

In a programmable logic controller the traditional programming environment is ladder logic or other languages specified in the IEC 61131-3 standard.[4] A ladder logic environment is well suited for safety interlocks, as these functions do not change with the state of a batch or the product being manufactured. For sequential control functions, which require step-by-step control actions, ladder logic can be obscure and difficult to follow. In addition, maintaining ladder logic for complicated processes can be expensive.

Traditionally, PLCs excelled in logical control but were weak in their continuous control capabilities. However, these characteristics are changing with the addition of new functions and programming environments, which include high-level procedure-oriented languages, block structures, and sequential function chart representations (Figure 8.4i). In addition, personal computers are also increasingly used as front-end devices to serve as programming and human interfaces.

A personal computer may also be used as a stand-alone controller where it is directly connected to input/output multiplexers. Small batch systems may be controlled in this fashion. The Windows operating system is often used, but capabilities of these systems are generally limited because of the size and throughput and also the limitations of the operating system.

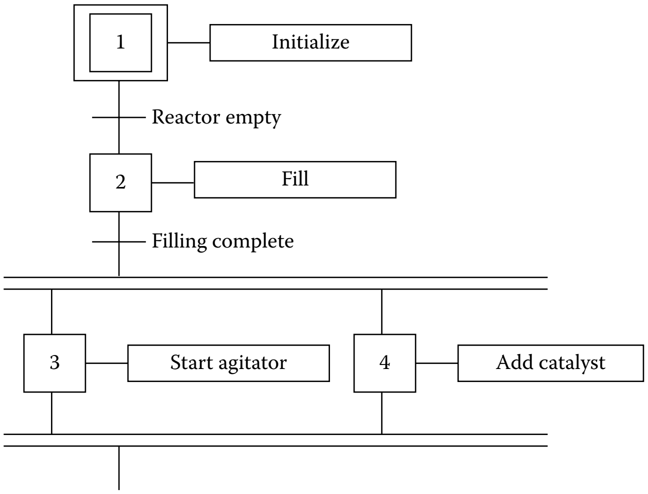

FIG. 8.4i
Illustration of a sequential function chart.

In a DCS system, the control is distributed into a number of controller modules. There are a number of significant advantages of a DCS system over a centralized control system, such as increased availability, ease of incremental expansion, and ease of interfacing with foreign devices. The capabilities of a contemporary DCS include standard communications protocols, industry-standard operating systems, and open information access throughout the system (Figure 8.4j).

Such a system allows easy partitioning of a batch control task horizontally and vertically. The horizontal partitions, based on physical model, are process cells, units, subunits, loops, and devices. The vertical partitions, based on control activity, are process management, unit supervision, sequential/regulatory control, discrete control, and safety interlocking.

BATCH CONTROL FUNCTIONS

Interlock Functions

Interlock functions enforce plant and personnel-related safety and are generally not dependent on the product or the state of the batch under manufacture. Thus, these interlocks, once set, are kept active all the time and are changed only when changes to the plant configuration or personnel safety considerations warrant it. These functions generally override other interlocks that may be active only during certain process phases or conditions. A simple example of such an interlock is if a pump ($P1$) has two outlet valves ($V1$ and $V2$) that are feeding two tanks. In that case, the pump should be switched off if both the valves are closed. This can be expressed by the Boolean equation

$$P1_{\text{off}} = V1_{\text{closed}} \text{ .AND. } V2_{\text{closed}} \qquad \textbf{8.4(1)}$$

Another way to specify interlock functions is by ladder logic. Because of the importance of interlocks in terms of

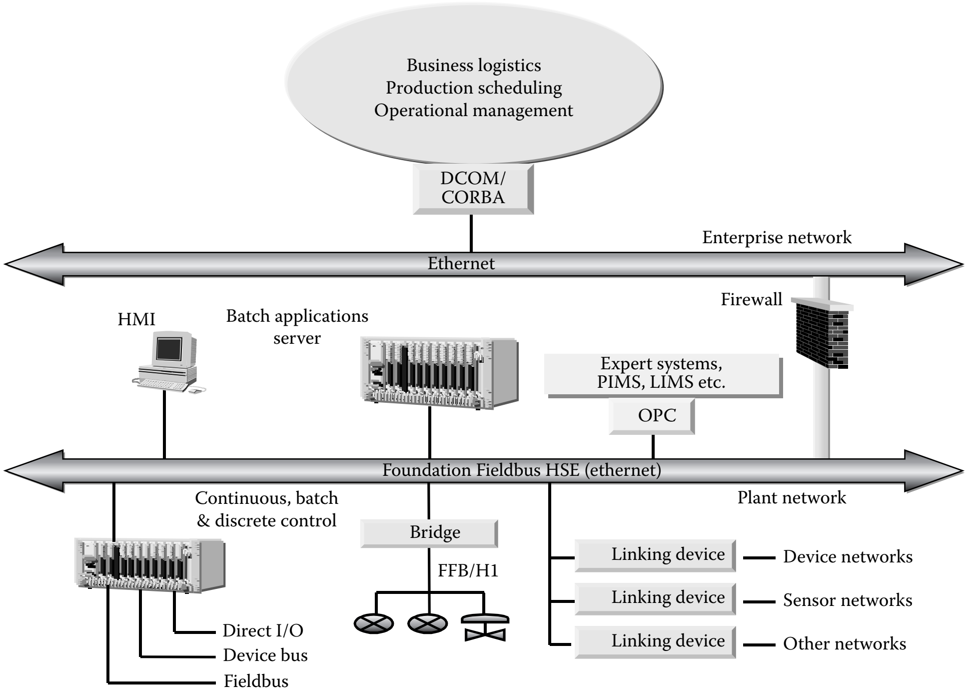

FIG. 8.4j
The main components of a typical DCS system for a batch control application.

safety, many users implement them using distinct hardware modules, either within or outside a DCS system.

Regulatory Control

Regulatory control serves to keep process variables as close as possible to their set points despite process and load disturbance. In a batch process, regulatory control is used extensively for controlling process variables, such as maintaining steady flow during charging, maintaining the agitator speed in a tank while mixing, or ramping up the temperature at a predetermined rate before reaction.

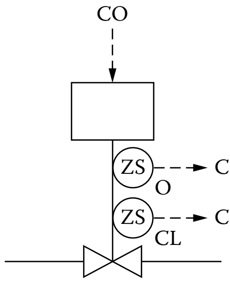
Regulatory control is often done using PID algorithms, through in recent years many modifications to this algorithm have been proposed for improved performance. In a DCS system, the usual method for configuring control loops is by interconnecting inputs and outputs of PID and other blocks. In a batch control system the activation, deactivation, setting of controller constants, and set points are usually carried out by steps in the phase logic.

Discrete Control

Discrete control is a term used for controlling process equipment that has only a limited number of stable states. On/off valves or manifolds are examples of such equipment. The on/off valve (Figure 8.4k) has only two states, which are manipulated by a contact output (CO).

The states of the two limit switches (ZS) specify the state of the valve. In the case of a manifold (Figure 8.4l), the three states are no flow, Tank A to Tank B, and Tank A to Tank C; all other possible states are considered abnormal and set off an alarm indicator. In a DCS system, the discrete control is usually done by a control block designed for this purpose, such as device block or a valve block. Some systems allow users to create blocks with unique functions.

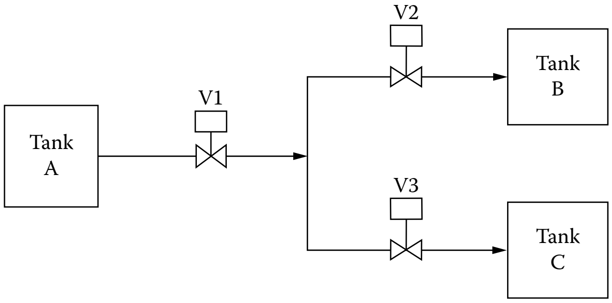
In addition, some DCS systems allow ladder logic or Boolean logic for configuring discrete control. When a large amount of discrete control is required, PLCs are commonly used. In a batch control environment, discrete control functions are usually directed by steps in phase logic.



State	CO	CI1	CI2
Open	On	On	Off
Closed	Off	Off	On

CO - Contact output
CI - Contact input
ZS - Limit switch

FIG. 8.4k
The operation of an on/off valve.



State	V1	V2	V3
No flow	Closed	Closed	Closed
Tank A to tank B	Open	Open	Closed
Tank A to tank C	Open	Closed	Open

FIG. 8.4l
The discrete control states of a manifold.

Sequential Control

Sequential control functions perform real-time control at the equipment level to move a process through a succession of distinct states. Opening a valve and starting a pump to transfer material from one tank to another and then closing the valve and stopping the pump after the transfer is complete is an example of sequential control. So, also, is the setting up of regulatory control loops or sending alarm messages to operators.

The sequential control required to manufacture a batch is usually divided up into a number of phases, such as mixing, heating, and reaction. A phase consists of a number of sequential control steps and can manipulate equipment within a unit boundary. When multiple units have to work in a synchronized fashion, for example, in the transfer of material from one unit to another, each unit will have its own phase. These phases may communicate with each other to set up the required synchronization via the unit supervision function.

Batch control may be divided into three broad categories (Figure 8.4m). The function that specifies the standard control actions is called normal logic. The function that checks the plant and process conditions on a periodic basis is called monitor function. Periodic checking of the state of the pump while a transfer of material is taking place is an example of a monitoring function. Unlike a safety interlock, which is active most of the time, a monitor function is activated by normal logic as and when required.

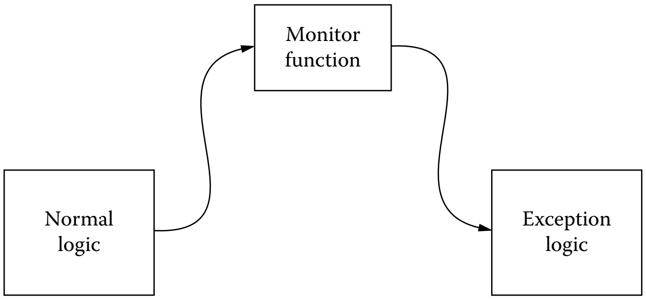


FIG. 8.4m
Sequential control functions. A. Monitor function is activated and deactivated by a normal logic. B. Monitor function calls an exception logic when a failure condition is detected.

"Minispec" For Weighing A Raw Material Using The Weigh Tank:

Get the amount and type of raw material from the control recipe.
Open appropriate raw material tank outlet valve.
Open weigh tank inlet valve 100%.
Start charging pump.
Wait until 90% of the raw material received.
Throttle weigh tank inlet valve to 10% open.
Wait until 100% of the raw material is received.
Close weigh tank inlet valve.
Stop charging pump.
Close the raw material tank outlet valve.
Store the weigh tank amount for batch record.
Inform mixer that weigh tank is ready to charge.
End of "Minispec."

FIG. 8.4n
Example of structured English as a means of specifying sequential logic functions.

When a monitoring function detects a failure condition, it invokes the appropriate exception logic. Exception logic, as the name implies, specifies control functions that are required to take care of failure conditions. Exception logic can be simple or elaborate. Sending an alarm to the operator and waiting until the device is fixed manually is an example of simple exception logic. Shutting down a malfunctioning equipment and starting up an available spare or initiating an emergency shut-down sequence for the whole unit are examples of more elaborate exception logic.

There are many ways of specifying sequential control functions, such as flow charts, state charts, Boolean equations, ladder logic, sequential function charts, and the like. Among these, the sequential function charts (Figure 8.4i) and structured English form (Figure 8.4n) are gaining increased acceptance.

In a DCS system, the normal and exception logic steps are usually implemented in a high-level procedural language or in a tabular state chart format. In a PLC environment, ladder logic and function blocks are commonly used. Block-oriented structures for sequence control are becoming increasingly common in DCS environments, where each phase is specified by a sequence block. Interblock communications are provided by connecting the inputs and outputs of these blocks.

The sequence logic steps are usually specified in a high-level Pascal-like language. Monitor blocks provide monitoring functions in a block-structured environment; otherwise, tables or Boolean equations are used. Block orientation provides modular structure and the ease of interblock communications.

Unit, Batch, and Recipe Management

The unit supervision function performs the control functions in a unit. Each unit has a set of phases (like charge, mix, and heat) that includes normal logic, exception logic, and monitor functions. The recipe specifies the order of these phases and the formula variables for a grade of product. Unit management also performs interunit communications and acquires the services of common resources when required.

The process management function is responsible for the manufacture of a batch of product. It allows the selection of a batch identifier (name) and a master recipe, either manually by an operator or automatically by a higher-level function. It generates a control recipe from the specified master recipe and maintains it during the course of a batch production. It directs the manufacturing of a batch by acquiring units as required and executing unit procedures, operations, and phases in the order specified by the control recipe. It also supplies the formula variables to the pertaining phases via unit supervision function.

Process management allows the scaling of a batch by proper proportioning of relevant formula variables. Process management is also responsible for creating and maintaining batch records during the production of a batch.

As stated before, there are four types of recipes: general, site, master, and control. The recipe management function provides the facilities for generation and maintenance of the general, site, and master recipes. The creation of a control recipe from a master recipe is a process management function.

Unit Modes The operating conditions of a process unit are broadly divided into two different modes: manual and automatic. In the manual mode, the procedural elements for the unit are executed manually. An operator may pause the progression of a batch but may not force transitions from one step to the next. While in this mode, the process inputs may still be monitored by the control system.

In the automatic (auto) mode, the control system controls the production of a batch in the unit. The transitions within phase logic are carried out without manual interruption as appropriate conditions are met. In some situations, operator may pause the progression, but may not force the transition from one step to another.

Unit States Equipment entities such as units and equipment modules may have many different states. The number of possible states of an entity varies with its complexity and its application. A simple on/off valve usually has only a limited number of states, such as open and close when working normally. In the case of a unit a much larger number of possible states have been specified in the batch standard[1] (Figure 8.4o).

Initially, a unit is in an idle state, which transitions to running state at the start of a batch. The running state continues as long as the normal batch production continues. Exception conditions can cause transition to a state, such as pause, held, stopped, or aborted depending on the type and seriousness of the exception condition. The state transition could be automatic or manually initiated. Usually there are transient states, such as pausing, holding, stopping, and aborting before the unit reaches paused, held, stopped, or aborted state. The unit may return to running state from a paused or held state. However, such transitions are not usually possible from states, such as stopped or aborted, which may require discarding the batch and starting anew.

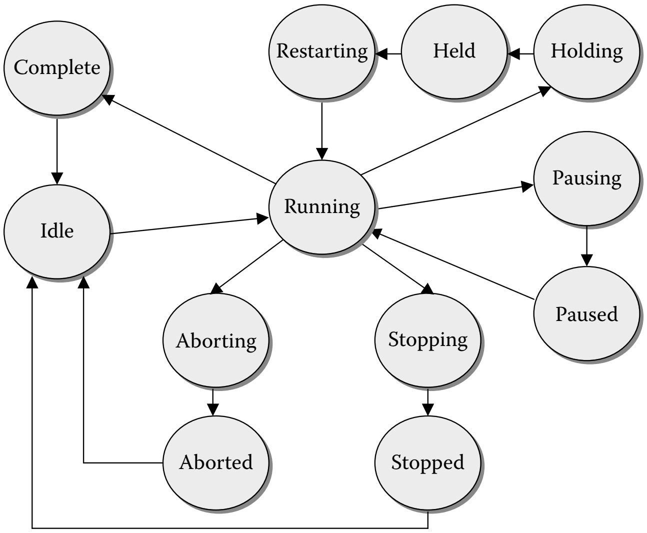

FIG. 8.4o
Typical unit states.

As stated, transitions may be automatic if specified in procedures, such as steps phases or by safety interlock functions. However, an operator can also cause transitions by manual commands. Transitions from paused or held to the running state usually require manual permissives. Detailed analysis of conditions that may lead to state transitions need to be carried out when the normal operations of a unit are specified.

FROM ANALYSIS TO IMPLEMENTATION

As stated before, the analysis, specification, design, and implementation of a batch control system are all complex tasks. That is largely due to the multistate nature of a batch process, which makes it inherently more complicated than a single-state continuous process. Batch processes generally need more sophisticated human interface than continuous processes.

Sharing of equipment and services can increase complexities, and proper booking and releasing mechanisms are required where equipment or a service can only be used for a single batch. Taking care of exception conditions can get very complicated for a critical process where different actions are needed for different alarm conditions and their combinations.

However, the complexities vary significantly from one batch process to another. They are typically based on plant topology (e.g., single stream, parallel stream, or multiple path) and the number of different products manufactured using the same equipment. In addition, complexities vary with the criticality of the process, the amount of exception handling, and the amount and the type of operator intervention required. The amount and complexity of exception handling for a batch process is also of great significance; unfortunately, this point is often ignored at the initial design stage. Finally, complexity depends also on the levels of control activity functions and the requirements of batch tracking and reporting.

Methods of Analysis

The analysis of a batch system requires resolving the problem into the various control levels and then, within each level, decomposing it into functional modules. The two common methods of analysis are structured analysis and object-oriented analysis.

Structured analysis involves starting from a high-level view and decomposing this into more detailed function.[5–7] The main components in this method are data flow diagrams, data dictionary, and minispecs. A data flow diagram consists of one or more bubbles, each representing a function, and arrows representing information or material flow (Figure 8.4p).

The storage of information and material is shown within parallel lines. Each bubble may be decomposed into a number of bubbles, each representing a subfunction. When a function cannot be decomposed into a set of subfunctions, then a minispec is generated for that function in structured English, as was illustrated in Figure 8.4n. All data names used in these diagrams are defined in data dictionaries (Figure 8.4q).

In object-oriented analysis, all functions are defined as objects.[8,9] An object mirrors a real-life entity or a function and contains the required procedure and data for carrying out that function. The key concepts of object orientation are:

- Encapsulation
- Inheritance
- Message passing
- Late binding

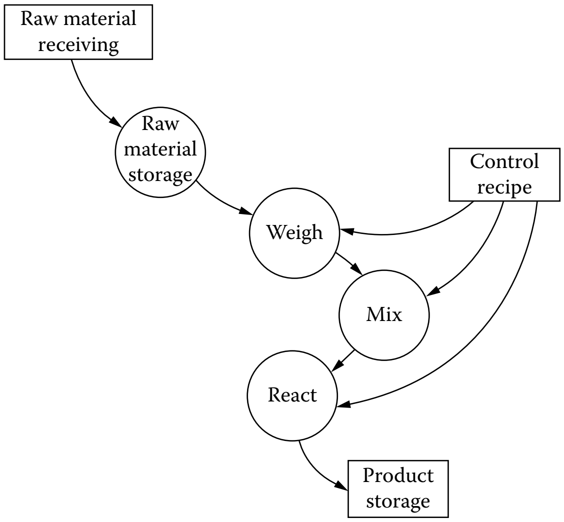

FIG. 8.4p
Example of a data flow diagram.

Control recipe =
Header + Equip Requirement + Formula + Procedure
Procedure = {Operation}
Operation = {Phase}
Phase = [Weigh, Charge, Mix, React, Cool, Transfer]
Formula = [Amount, Mix Time, React Temp, Ramp Rate, Prod Density]

FIG. 8.4q
The data names used are defined in a data dictionary such as this one.

Encapsulation, or information hiding, allows for the creation of an object with its set of data and procedures (Figure 8.4r). An object can be asked to do a certain function, but the user does not require the knowledge of the object's internals. Similar objects can be specified as a class so that their data structure and procedures need to be defined only once.

Inheritance allows a subclass of objects to inherit the data structure and procedures of its super-class (Figure 8.4s). However, a subclass object can have a data structure or procedures of its own, which are in addition to or instead of those inherited. Message passing is telling an object what to do without specifying how to do it. Late binding allows resolving the address of an object at run time rather than at compile time. This allows the ease of adding, deleting, or moving objects without affecting the rest of the system.

Project Application Specification

Batch control design and implementation problems often arise because of the lack of clear and detailed definition up front. This can be addressed by putting in enough effort at the beginning of a project by generating a project application specification (PAS). This document is in three parts:[10]

- Requirement specification
- System functional design
- System acceptance criteria

The requirement specification is the detailed narrative of the requirements, with little consideration for the specifics of the control system to be used. The requirement specification is ideally generated by the user organization before the selection of a particular system. This document can then be used as a bid specification for the control system suppliers to generate quotations.

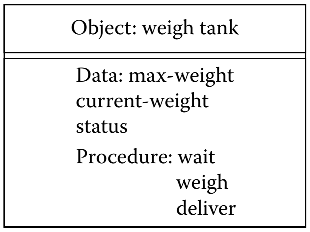

FIG. 8.4r
Object representation of a weigh tank.

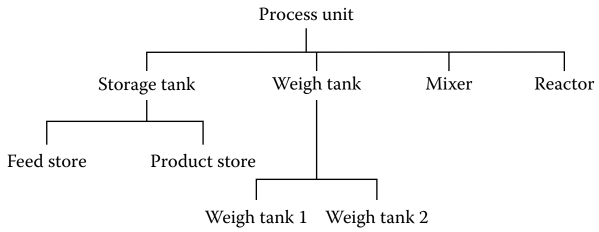

FIG. 8.4s
Example of an object class structure.

The system functional design, which is generated only after a specific control system has been selected, specifies the detailed design based on the requirement specification and the capabilities and constraints of the system chosen. The design part of the document is generated by the group responsible for integrating the system and doing the application engineering (system developer) and must be approved by the user before the actual implementation (configuration and coding) starts.

The final section of the PAS is the system acceptance criteria, which defines the tests that are to be carried out during and after the system's construction to ensure its proper functioning. The system acceptance criteria include detailed procedures for the systematic testing of all the significant functions. This section should preferably be written jointly by the user and the system developer.

A PAS is a single consistent document for the procurement and implementation of a batch control system. It is a "living" document, which requires updating and modification to accommodate changes in requirements. Appropriate mechanisms for suggesting and approving modifications need to be in place during the execution of a project. A PAS requires considerable effort and financial investment up front, but the return on investment is very significant in terms of the implementation efficiency and the quality of the product.

The solution of a batch control problem requires not only the selection of a suitable control system but also the creation or assembling of appropriate strategies for control. Object-oriented environments are changing the way a control system is configured and programmed. In the future, the competitive advantages of control companies will come more from exploiting new software techniques rather than from the hardware employed.

RELIABILITY AND AVAILABILITY

The reliability of a batch control system is of greater significance than is the reliability of a continuous control system. On failure, the fallback system needs to know the exact state of a batch in order to be able to continue the production or to bring the process to a safe condition. Reliability is defined as the probability a piece of equipment is performing its required function for a specified time interval under stated condition:

$$R(t) = e^{-\lambda t} \qquad \textbf{8.4(2)}$$

where
$R(t)$ = reliability
λ = failure rate
t = time

This definition, however, does not take into account that a piece of equipment can be repaired and put back to service. The definition of availability takes care of that:

$$A = \text{MTBF}/(\text{MTBF} + \text{MTTR}) \qquad \textbf{8.4(3)}$$

where
A = availability
MTBF = mean time between failures
MTTR = mean time to repair

The above equation shows that the availability of a given system can be increased significantly by merely reducing its mean time to repair.

The degree of reliability needed for a batch control system varies with the criticality of the process under control, but more importantly, it varies with the different levels of control (Table 8.4t). Thus, the reliability at the device control level is more critical than at the recipe control level.

In a DCS, where these control levels are controlled by different hardware modules, this need for reliability is generally taken care of by fault-tolerant pairs as required. In this arrangement, two identical processors are configured as a married pair, where both the processors run in parallel using the same inputs, and the outputs of one of the modules is used for control at any given time. The outputs of both the processors are periodically compared to ensure that they are synchronized and are in good health. If they disagree, then diagnostics are invoked to allow the good partner to continue the control, and appropriate messages are generated to fix the other.

In a dual-processor arrangement, the failure of the primary module causes the backup to take over. Timely detection and exact synchronization of the two processors before the failure are important for an effective takeover. In a triple modular redundant (TMR) system, these problems are avoided. In such an arrangement (Figure 8.4u), three or more identical processors run in parallel using the same set of inputs. The outputs are fed to a voting circuit, which allows the immediate detection of a faulty module.

The theoretical availability of a TMR system is lower than that of a fault-tolerant dual pair. However, it is claimed that a fault-tolerant pair with less-than-perfect failure detection and takeover mechanism is actually less reliable.[11]

TMR systems are available for process control but are generally more expensive because of the need for three processors. The dual fault-tolerant pair arrangement is currently more common in the DCS environment.

In evaluating the reliability of a batch control system, both hardware and software reliabilities should be taken into consideration. In recent years, the hardware has become more

TABLE 8.4t
Requirements of Fault Tolerance

Control Level	*Fault Tolerance Requirements*	*Ways of Achieving Fault Tolerance*
Sensing elements	+	Minimal for most, crucial for a limited number. Manual backup for those not crucial. Double- or triple-redundant sensors for the most crucial
Safety interlocks	+ + +	Mostly by dedicated hardware modules, within or independent of the control system
Continuous control	+ +	Backup controller or manual control stations
Device control	+ + +	Backup controller
Sequence control	+ + +	Backup controller or triple-redundant system
Batch management	+ +	Backup controller where required
Recipe management	+	Backup controller where required
Scheduling management	X	Manual backup
Information management	+ +	Redundant bulk storage and backup processors where needed
Human interface	+	Multiple human interface equipment (printers, CRTs, and keyboards)
Interprocessor communications	+ +	Redundant communication channels

Key: X: Little or no requirement
+: Some requirement
+ +: Significant requirement
+ + +: Crucial requirement

reliable and less expensive. This in turn has increased the demands for features and capabilities of the control system and thus has made the software effort much larger and more complex. The software reliability problem is not similar to the hardware reliability problem, because software does not degrade with use. Unreliability in software is caused by the presence of programming "bugs," which may stay undetected even after rigorous testing.

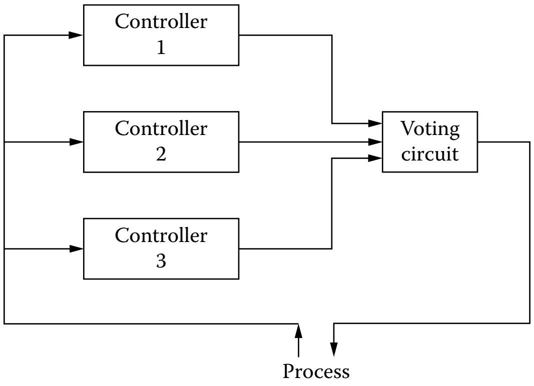

FIG. 8.4u
TMR system with voting circuit.

The reliability of a piece of software is dependent on the probability of its performance without fault for a given period of time and on the time to correct the fault after its detection. While testing a piece of software, an error detection curve may be drawn (Figure 8.4v), which can provide some indication of its reliability.

The standard software modules, such as the operating system, control packages, and utilities, are generally more reliable as they are used in multiple systems. When an error is reported, the system supplier usually generates a correction for all the installed systems. However, this is not the case with application-specific software, as they tend to be unique for each system. In addition, changes in control requirements require additions and modifications to existing software with

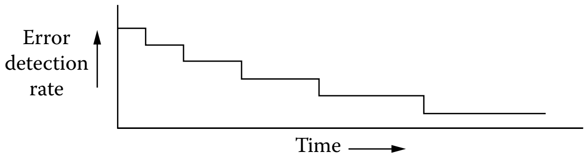

FIG. 8.4v
Software error detection curve.

the possibility of introducing new bugs. The ways for increasing the reliability and modifiability of software should be considered early in a project. These ways include:

1. Detailed analysis of control problem, breaking it into small manageable modules
2. Specification and design of the modules with clear definition of their interrelations
3. Proper design reviews
4. Modular programming using off-the-shelf software wherever possible and generating common routines for similar functions
5. Desk checking and walk-throughs for generated code
6. Rigorous testing of intramodule and intermodule functions with appropriate simulations

The object-oriented approach in specification, design, and implementation of software is gaining increased acceptance. This forces a modular approach and reduces the duplication of common code to a minimum. Object-oriented programming environments also allow for maintaining libraries of objects, which may be used in many different projects, thus reducing rework.

CONTROL SYSTEM SELECTION

For batch control system users, the most important criterion for supplier selection is the software and hardware functionalities. Additional criteria in order of importance are services capability, knowledge of the industry and its processes, local support, the cost of application services, and cost of hardware and software.

The selection of an appropriate control system for a manufacturing plant is largely dependent on the type and complexity of the application. The complexity of an application is dependent on many factors such as the plant's topology, the number of different products and grades, the criticality of the application, and the size of the plant.

Some batch processes are critical, because a control failure may result in a hazardous situation, equipment damage, or loss of very high-value product. The most common hazardous processes involve very fast exothermic reactions in which all corrective actions need to be taken automatically to ensure a safe operation.

The manufacture of PVC is an example of a fast exothermic process, and pharmaceutical and biotech manufacturing processes involve very high-value products. Critical applications generally require a high level of fault tolerance, a high level of safety interlocking, and extensive exception handling logic to take care of abnormal conditions. This combination of requirements significantly increases the complexity of the control solution.

PC-, PLC-, or DCS-based batch control systems perform similar functions, but some of their characteristics such as capacity, fault tolerance, and human interface, vary significantly. PC-based systems provide a lower-cost alternative to either a PLC- or DCS-based system, but offer little or no fault tolerance, and thus are not generally well suited for critical applications.

PLCs are well suited for logic control, permissives, and fast interlocking. PLCs also perform sequence control quite well and some continuous control. Some PLCs also provide good fault tolerance, making them suitable for critical applications. However, PLCs are generally not as good as DCS-based systems in the areas of expandability and flexibility. Modular programming is more difficult in PLCs, where only ladder logic is used for configuration. PLC-based systems are well suited for small- to medium-sized batch control applications and are generally not used for complex batch applications or those applications that require a high degree of flexibility (Figure 8.4w).

DCSs are well suited for continuous, sequential, and some basic logic control. They are generally not as good as PLCs at safety interlocking and other high-speed logic functions. Most DCS controllers can be configured in a redundant manner, with automatic switchover for a high degree of fault tolerance. DCSs also offer more flexible programming facilities than PLCs and easier-to-use human interfaces. However, the key strengths of many DCSs are their scalability, expandability, and the ability to interface seamlessly with PLCs and other types of controllers and business systems.

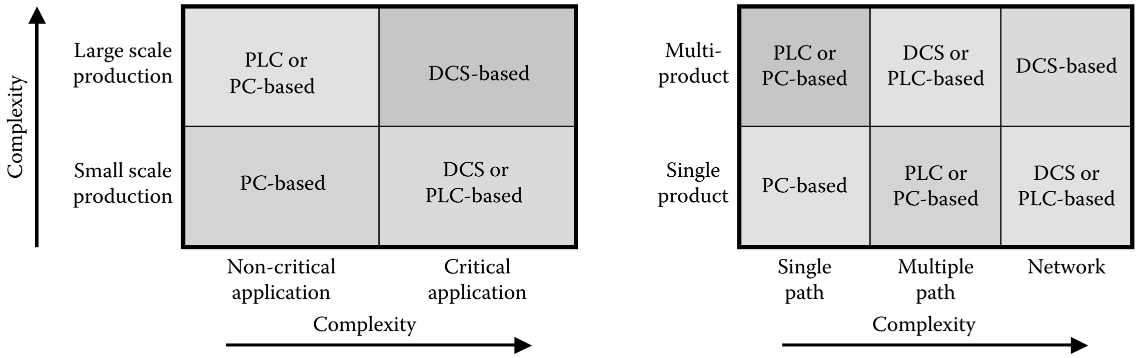

FIG. 8.4w
Recommended batch control systems based on process complexity.

These attributes make DCS-based batch control systems technically suitable for a wide range of batch applications. However, they are generally more expensive than PC or PLC systems, which make them less attractive for small- and medium-sized applications. Thus, DCS-based systems are most ideally suited for flexible, large, complex applications.

The lines that separate DCS- and PLC-based systems are starting to blur. A new type of system, called a hybrid system, is now being targeted for batch and discrete control applications. A typical hybrid system has a DCS architecture but uses controllers that are similar to PLCs. The functionality and scalability of hybrid systems are similar to that of the DCSs.

Examples of these new hybrid control systems include the DeltaV from Fisher-Rosemount, PlantScape from Honeywell, and ProcessLogix from Rockwell. It is also important to note that PC-based systems are beginning to acquire many DCS attributes.

To meet users' requirements in batch process automation, suppliers must exhibit many important characteristics. These include experience in batch process control, specific industry applications, enterprisewide integration, project management, and applying appropriate regulatory requirements.

Successful batch process control solutions have been elusive, and it is important to work with suppliers with proven records of accomplishment. Experience in your industry and specific application area is also very important in the selection process. Knowledge of specific industry segment characteristics, such as regulatory requirements, can be critical to the success of the project.

INTRODUCTION

In addition to this section, blending and ratio control is also discussed in other sections of this handbook. Section 2.23 covers the theory of ratio control, while Section 2.12 discusses the interaction and decoupling in blending systems. Section 2.25 covers the relative gain aspects of ratio controls and also covers distribution control among a number of destinations.

Blending control is applied when the control objective is to mix two or more flows to achieve a specific composition. Ratio control keeps the proportion between two or more variables, often flows, at the desired set point. Blending controls are required in the production of solvents, paints, reactor feeds, foams, fertilizers, soaps, and liquid cleaners in the chemical industry. In the petroleum industry it is used in the production of gasoline, asphalt, lube and fuel oils, and distillates. In the food industry, in the making of wine, beer, candy, soap, ice cream mix, and cake mix. In the construction industry, in the making of cement, wire insulation, and asbestos products. Another example of ratio control is the control of the air/fuel ratio in a boiler or a furnace.

These applications provide the processor with economic advantages by controlling the consumption of materials (costly components and additives can be blended more precisely) and by reducing investment in floor space and batch tanks (costly blend tanks are eliminated). Through using continuous systems, the time lags resulting from batch methods are eliminated, productivity is increased, personnel needs are reduced, and inventory can be in the form of component base stocks rather than as partially blended or finished products.

Blending systems give technical advantages by accurately controlling the quality of the product and by providing the flexibility to blend a variety of finished products with minimum time required to change from one product to another.

This control approach achieves continuous control of the flow of each component with fixed ratios around components, so that when the streams are combined to form the finished blend at a fixed throughput rate, the composition of the finished product is within specifications.

In this section, blending systems will be described from the standpoint of control techniques. Analog and digital blending systems will be studied. A number of typical blending systems will be described to show the operating principles involved. A brief discussion of scaling procedures will be showed. Future trends on blending systems are illustrated, and some journals and papers with a practical point of view are available in the References. Finally, conclusions are presented.

BLENDING METHODS

Automatic, continuous, in-line blending systems provide control of gases, liquids, and solids in predetermined proportions at a desired total blend flow rate. Typical applications of blending and ratio control include maintaining a stoichiometric ratio of reactants to a reactor, keeping the air/fuel ratio to a boiler of furnace, and holding a reflux ratio for a distillation column at the optimum value. The blending systems consist of flow transmitters (to detect controlled variables), ratio relays (to set proportions), and controllers (to complete the closed-loop control).

A two-stream blending system is illustrated in Figure 8.5a. The component "A" flow controller is set by the total blend flow controller, and the component "B" flow is ratioed to "A."

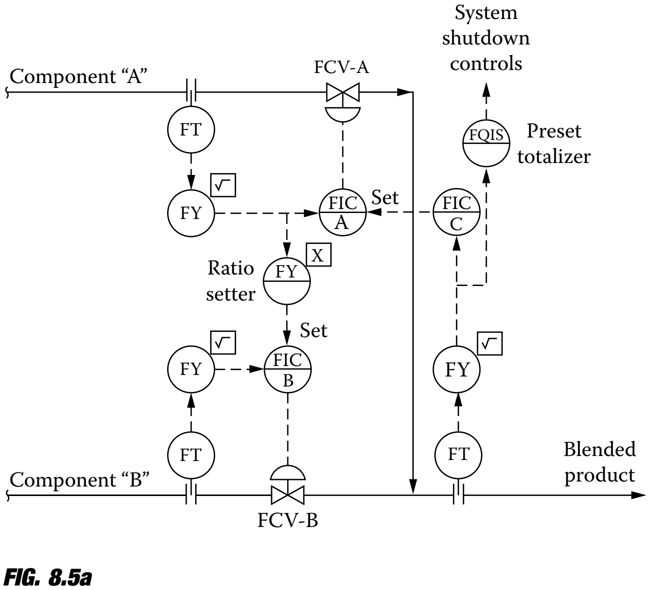

FIG. 8.5a
Analog rate blending of two components.

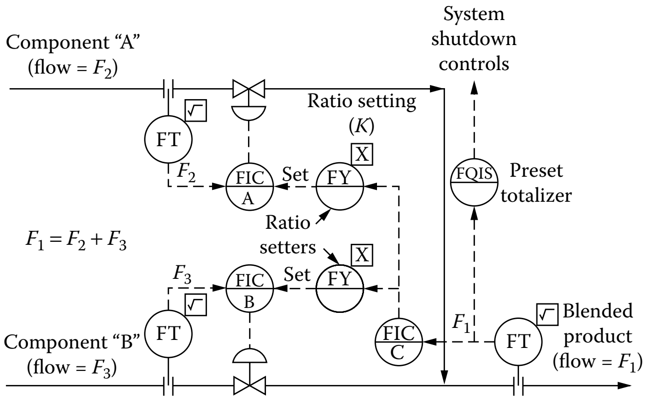

FIG. 8.5b
Both components can be directly ratioed to the total flow in an analog blending system.

It is also possible to have both blending components ratioed to the total blend flow, as shown in Figure 8.5b. In either case, the blending system maintains the blending ratio as well as the total flow rate. Incorporation of a preset totalizer with automatic system shutdown facilities provides batching capability, as well.

In both of these control configurations the total-flow controller is the cascade master, while the cascade slaves are the individual flow controllers. The only difference is that in Figure 8.5b the slaves are configured in parallel, while in Figure 8.5a they are in series. These control configurations can be further simplified by, for example, eliminating FIC-A in Figure 8.5a and allowing FIC-C to manipulate FCV-A directly. Because the time constants of the master and slave loops are similar in these cascade configurations, it is often necessary to detune the master (FIC-C), because otherwise it might change the set points of the slaves faster than they can respond to these changes.

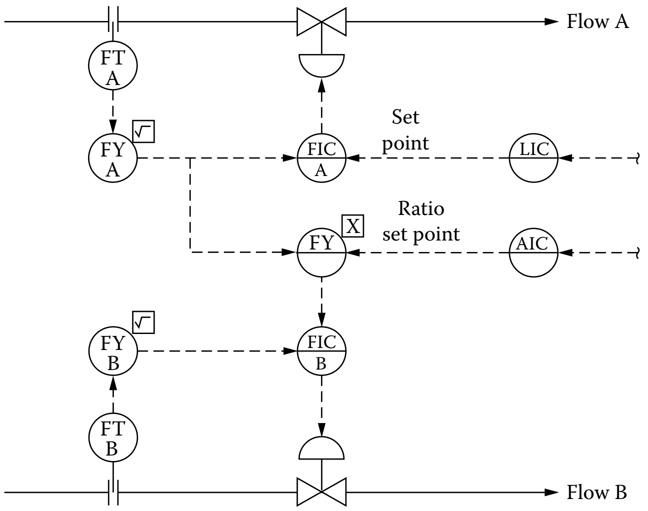

FIG. 8.5c
The level controller LIC manipulates the flow rate of "A," while the composition controller AIC manipulates the A/B flow ratio.

It is also possible to automatically control not only the total flow rate but also the composition of the blended stream. When composition control is also required (Figure 8.5c), it is recommended to let the total-flow master control the larger of the two streams and let composition set the set point of the smaller of the two streams. If the two blended streams are close to each other, such control systems will interact, and a change in one of the cascade loops will upset the other.

Such interactions can be decoupled by replacing the flow-based slave controllers (FIC-A and FIC-B) with slave controllers whose measurements have been modified as shown in Figure 8.5d. If total flow is the master of the slave that measures ($A + B$), while composition is the master of the slave that measures $A/(A + B)$, the interaction will be eliminated.

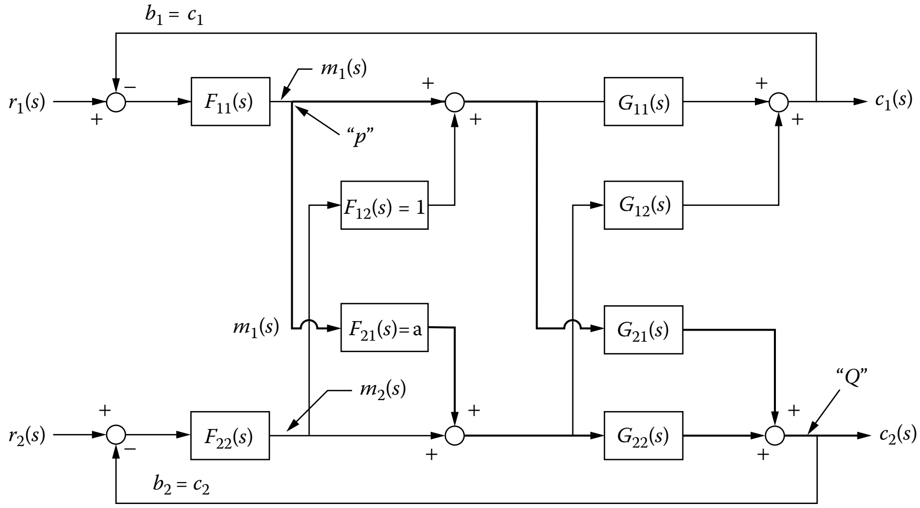

FIG. 8.5d
A generalization of a two-variable control system, which provides noninteracting control.

Many of the commercially available blending systems provide such accessories as flow alarm indications, system shutdown features, temperature compensation circuitries, scalers for conversion of transmitted signals to easily understood engineering units, pacing controls to slow down or shut down automatically, and manual or automatic adjustment of blend rate and ratio. All of these systems share one type or another of a ratioing mechanism. The methods of blending will be examined here. The working principles of components will be detailed in the latter part of this section.

Rate Blending

The blending system shown in Figure 8.5a is commonly found in the chemical industry for blending gas or liquid flows. A typical example is the manufacture of hydrochloric acid, which is done at fixed concentration and regulated flow rate by the absorption of anhydrous hydrogen chloride gas in water. The flow rate of hydrochloric acid from the absorption tower is measured to set the water flow, thereby maintaining the desired throughput, and the anhydrous hydrogen chloride gas is ratioed to water flow to give constant concentration.

A system in which all the blend components are ratioed to the total blend flow is illustrated in Figure 8.5b. A well-known example of this application is in the continuous or semicontinuous charging of a batch reactor, in which the recipe is given to set only the ratios of each ingredient and the total reactant charging rate. In the semicontinuous batch operation, a preset totalizer is used to terminate the charging operation when all ingredients have been charged. Numerous streams can be blended by incorporation of additional ratio devices and related controls.

Totalizing Blending

When totalized flows are ratioed, the integrated quantity of each component (over a period) is controlled in a direct ratio to the total quantity of the blended product. A schematic diagram of a totalizing blending system is shown in Figure 8.5e.

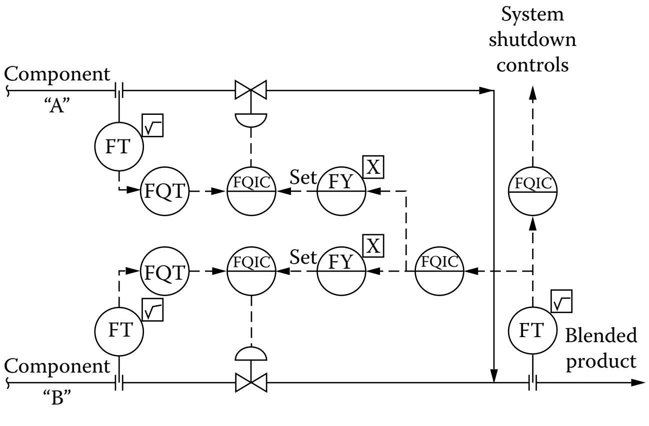

FIG. 8.5e
Analog totalizing blending system.

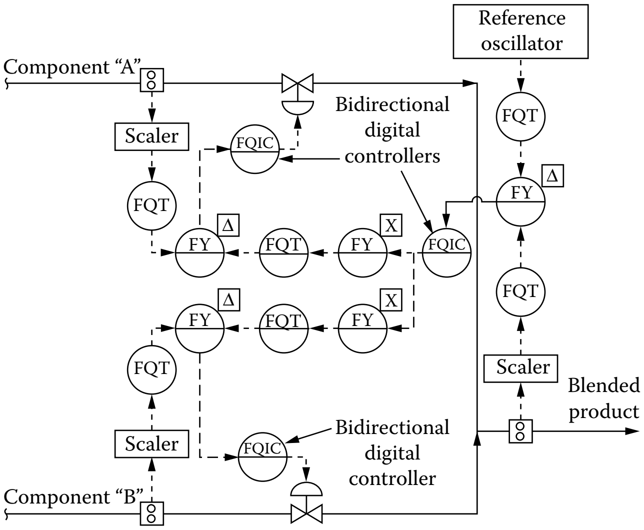

FIG. 8.5f
Digital totalizing blending system.

This system provides more precise control over the amount of each component than is possible with a rate-blending system. In the rate-blending system corrections are made to the ratio controller flow only after deviations have occurred (feedback control) and without correction for errors that have already occurred. In other words, the control system has no memory. Totalizing the flows and comparing the totals ensures the precise percentage of each component in the total blend.

Digital techniques have also been applied to digital blending systems, as shown in Figure 8.5f. Turbine meters or other pulse-generating devices can be used to generate digital flow signals. A bidirectional counter is used to integrate the flow measurement and demand signals and to compare them in order to generate a corrective control signal whenever the counts in the bidirectional counter memory are not zero.

The totalizing blending system (analog or digital) finds use in continuous in-line blending of petroleum products, such as gasoline and asphalts, in which long runs and batching operations require precise control of ingredients to ensure in-spec blending and uniform end products. The accuracy of this system allows for on-line blending of many petroleum, chemical, food, and cement products, with the product being sent directly to final shipping and storage containers. Multicomponent blending systems can be obtained by the addition of more flow ratio controllers.

Optimizing Blending

Almost the entire commercially available ratio relays and controllers are able to accept remote set points. Therefore, the blend ratios and total blend flow rates can be automatically adjusted by a process variable (output temperature, output pressure, composition, and so on). Thus, an optimizing blending system has the added capability of automatically manipulating ratio settings or the total rate, or both, based

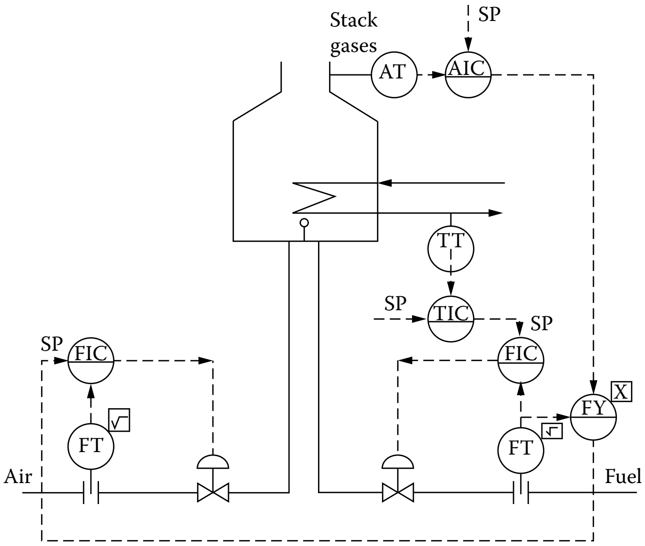

FIG. 8.5g
Control system where the air/fuel ratio is automatically adjusted to control the CO concentration in the stack gas.

on certain optimal criteria. Following this optimizing blending application, some approaches are illustrated.

The conventional air/fuel ratio control system is not versatile enough to maintain the air/fuel ratio in the range of high conversion efficiency at all operating conditions, especially in transient state or if the fuel characteristics change. Also, minimum pollution is desired in the stack gases. A ratio control based on an analysis of the stack gases in a furnace is shown in Figure 8.5g.

The control strategy adjusts the fuel/air ratio, optimizing CO percentage composition of the stack gases. Environmental and economical reasons require more complex configuration than classic control ratio, because an incomplete combustion results in the inefficient use of fuel and pollution. Optimizing ratio control employs a feedback signal based on the analyzer transmitter (AT), to regulate the fuel/air ratio. Thus, the temperature controller sets the reference value of the fuel control loop. The reference value of air loop control is set not only by fuel flow value (like classic ratio control) but also by CO analyzer information. This control approach optimizes the fuel/air ratio, avoiding atmosphere pollution and loss of energy.

A schematic of an optimizing blending system is shown in Figure 8.5c, in which the blend analyzer is used to measure composition and to adjust the ratio setting, while the level in some downstream tank is used to set the total flow rate.

A densitometer can be used to detect the solution concentration and to correct the ratio settings, avoiding set point deviations in the hydrochloric manufacturing process. A chromatographic analysis or Reid vapor pressure measurement of gasoline provides automatic adjustment of the blending ratio of components such as butane to give the proper octane number.

Another application is reactor feed rate control of jacketed exothermic reactors, based on the heat transfer coefficient and plant cooling capacity.

ANALOG BLENDING

The heart of the analog blending system is the mechanism for ratio control. This is often a separate component, although it may be housed with the controller. As shown in Figure 8.5a, a blending system can be constructed by ratio controlling the blend components with the total blend flow. Thus, the total blend rate is controlled together with the individual blend ratios. With incorporation of a preset totalizer, system shutdown can be initiated when batch blending is completed.

The ratio control relationship is derived with reference to the system shown in Figure 8.5b. It is assumed that C_1 and C_2 are the flow constants for the flow-measuring orifices. Then,

$$F_1 = C_1\sqrt{P_1} \quad \text{or} \quad P_1 = (F_1/C_1)^2 \qquad \textbf{8.5(1)}$$

and

$$F_2 = C_2\sqrt{P_2} \quad \text{or} \quad P_2 = (F_2/C_2)^2 \qquad \textbf{8.5(2)}$$

where

F_1 = total flow rate
F_2 = component "A" flow rate
P_1 = output signal of total flow transmitter
P_2 = output signal of component "A" flow transmitter

If K is the desired ratio setting,

$$P_2 = KP_1 \qquad \textbf{8.5(3)}$$

By substituting Equation 8.5(3) into Equation 8.5(2),

$$F_2 = C_2\sqrt{KP_1} \qquad \textbf{8.5(4)}$$

and by substituting Equation 8.5(1) into Equation 8.5(4) and simplifying,

$$F_2 = (C_1/C_2)(\sqrt{K})(F_1) \qquad \textbf{8.5(5)}$$

Using the same mathematical derivation, a ratioing system with linear input signals can be expressed as

$$F_2 = (C_1/C_2)(K)(F_1) \qquad \textbf{8.5(6)}$$

A graphical representation of Equation 8.5(6) is shown in Figure 8.5h, top, and the inverse-ratio controller characteristic is illustrated on the bottom. From Equation 8.5(5) it can be seen that the square root input signals from the

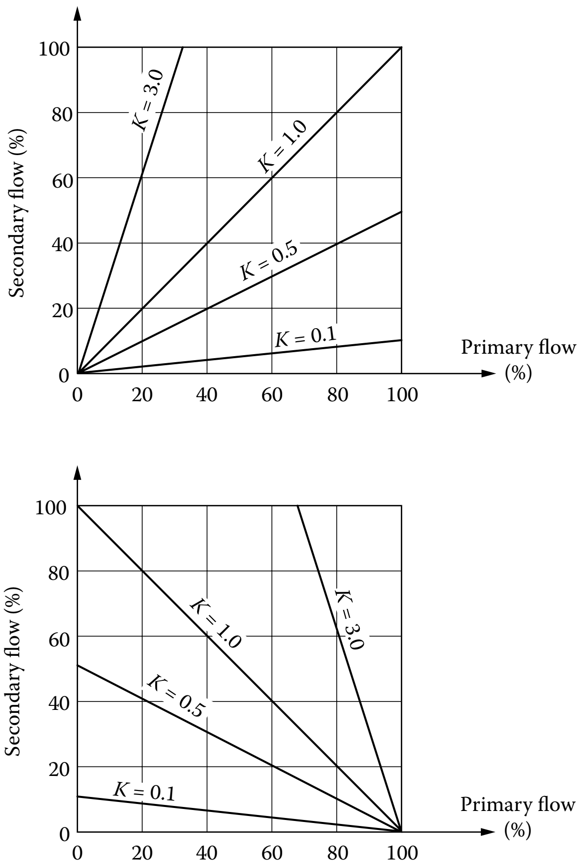

FIG. 8.5h
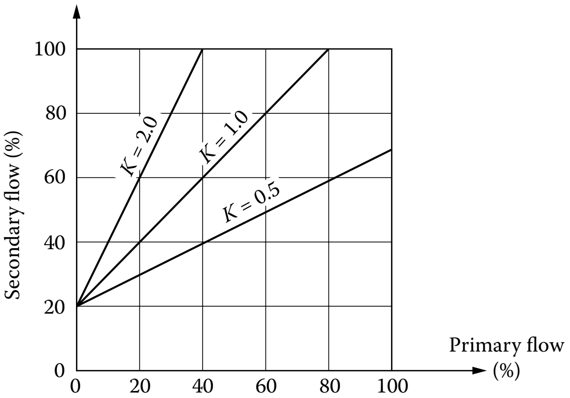
Direct ratio relationship (top) and inverse ratio relationship (bottom).

flowmeters can be used as in Figure 8.5f, with the ratio flow control circuit based on a linear relationship. The only modification is the square root calibration of the ratio setting dial and of the indicating dials.

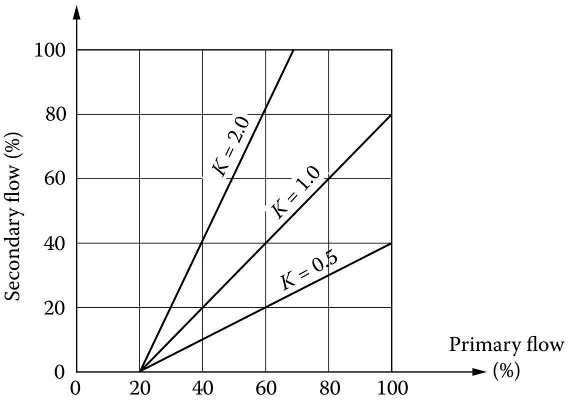
The ratio setting dial is graduated and calibrated as the square root of the linear ratio. Most ratio control mechanisms provide for bias adjustments to change the basic characteristics shown in Figure 8.5h, to meet various process requirements. Figure 8.5i shows some of these biased relationships in which the secondary flow has a preset minimum value or is kept at zero until the primary flow reaches some value.

Mechanical Ratio Control

The mechanical ratio control system consists of a proportioning mechanism, pneumatic or electronic flow signal receivers, and a case-mounted controller. The adjusting system resets the control point at a preset ratio by means of an adjustable mechanical linkage. The receivers are linked to a pen assembly, and output motion from the pen assembly operates the proportioning mechanism. Subsequent output motion from the proportioning mechanism positions the input lever of the pneumatic controller.



Secondary flow with minimum limit (positive bias)



Negative bias

FIG. 8.5i
Biased ratio relationships.

Figure 8.5j illustrates that each pen assembly spindle connects to one of the proportioning mechanism input levers through an adjustable link. Each input lever positions an

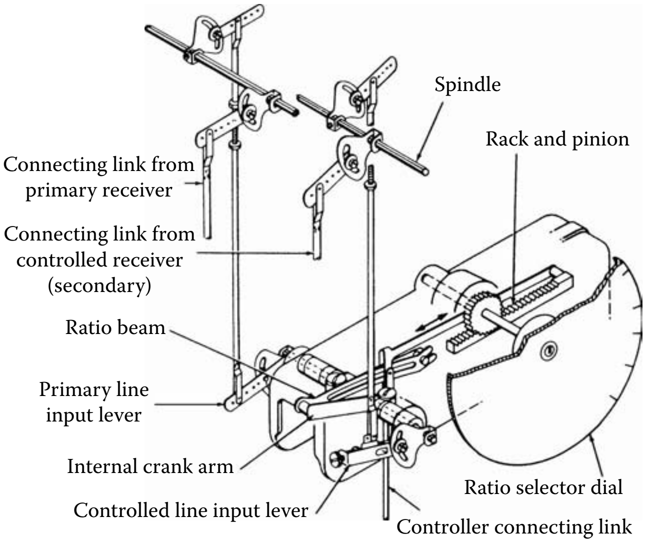


FIG. 8.5j
Ratio proportioning mechanism.

internal crank arm assembly and raises or lowers one end of the ratio beam. In turn, the link from the ratio beam connects to the input lever of the controller. The overall result is that controller output pressure changes whenever a receiver moves an input lever.

For remote adjustment of ratio set point, the manual set ratio mechanism can be replaced by a pneumatic receiver. In that case an external 3–15 PSIG (0.2–1.0 bar) set-point signal is used to position the receiver in proportion with the desired ratio. The ratio proportioning mechanism is precalibrated at the factory for the specific application, and all that is normally required is to check before use that the match marks are aligned and that the recorder pens and the transmitting meters are synchronized.

Lubrication is seldom required, but the mechanism should be periodically inspected, cleaned, and checked so that the proportioning mechanism operates frictionlessly.

An output inaccuracy of ±2% full scale can be obtained. Rangeability of this type of proportioning mechanism is approximately 40:1.

Pneumatic Ratio Control

The pneumatic ratio controllers contain no friction-producing mechanical links. The ratio relay modifies the input signal by means of the pneumatic circuit illustrated in Figure 8.5k.

The primary variable signal is tubed through a fixed restriction (FO) into an adjustable area restriction. If the variable restriction valve is closed, the signal is not modified. This condition represents 100% ratio, because the controlled variable signal (the set point of the secondary flow controller) must equal the primary variable signal for the control circuit to be satisfied.

If the adjustable area restriction is opened, the pressure between the two restrictions will drop until the flow through the fixed area restriction equals the flow through the adjustable area restriction. Thus, the pressure is modified as a function of the opening of the adjustable area restriction. By calibrating the adjustable restriction in terms of percentage ratio, one can set the relay for any desired ratio within its limits.

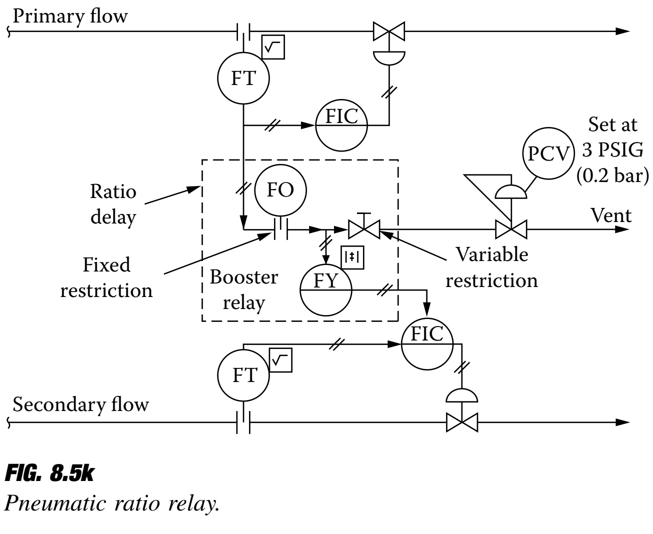

FIG. 8.5k
Pneumatic ratio relay.

A booster relay should be used to ensure rapid transmission of the modified signal from the ratio relay to the controller. For applications in which the secondary variable set point will always be less than 100% of the primary, a 1:1 booster relay is recommended. In other cases a 2:1 or higher booster may be used.

The pneumatic set ratio circuit is identical to the manual set ratio relay, except that the adjustable restriction opening is set by a pneumatic diaphragm motor. This allows for continuous automatic adjustment of the ratio in accordance with a pneumatic signal received from a quality controller or other optimizing device (Figure 8.5c). Incorporation of reset in the quality controller is recommended to eliminate the necessity for vernier adjustments to obtain the exact ratio and to compensate for the linearity limitations of the ratio unit.

The ratio relay should be calibrated at a specific ratio setting under actual operating conditions, even though the ratio setting is to be changed with operating conditions, to obtain maximum system accuracy. The accuracy (secondary flow set point) of ±1% of full scale can be expected. Signal rangeabilities of 50:1 can be obtained, but system rangeability is determined by the flowmeters used. Most pneumatic ratio control systems are not designed to operate below 20% of full-scale flow with square root signals or below 10% of full-scale flow with linear signals.

Electronic Ratio Control

Electronic ratio control systems operate on the Wheatstone bridge principle, shown in Figure 8.5l.

The bridge is said to be in a null, or balanced, condition when the ratios of resistance are such that $R_c/R_1 = R_f/R_2$, and no potential difference exists between points "A" and "B." If the ratio R_c/R_1 changes, then R_f/R_2 must also change by a like amount and in the same direction in order to maintain a null, or balanced, condition.

Figure 8.5m illustrates the operating principle of a Wheatstone bridge control system. Here, the fixed resistors, or bridge arms, are replaced by potentiometers so that the ratios previously mentioned are easily varied. Assuming an initial balance, an increase or decrease in the setting of the command potentiometer (primary) causes an error signal to

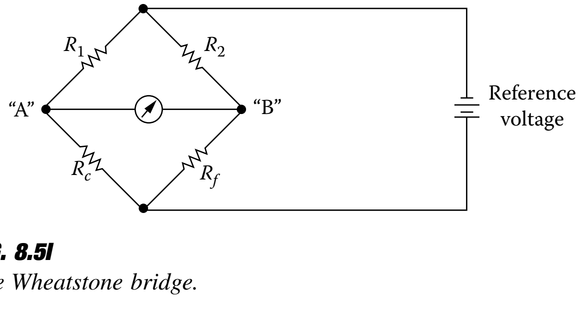

FIG. 8.5l
The Wheatstone bridge.

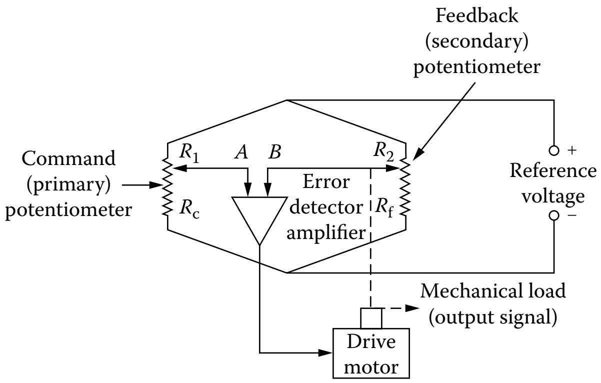

FIG. 8.5m
Wheatstone bridge operation.

appear at the input of a servo amplifier, which supplies power to the driven load.

The direction of movement is dependent upon the polarity (or phase) of the error signal. The brush arm of the feedback potentiometer is mechanically geared to the driven load (secondary) and thus rotates until $R_f/R_2 = R_c/R_1$. At this point a null again exists (error signal equals zero), and positioning ceases. The actual position of each pot wiper, expressed as a fraction of its total possible travel, may be written

$$\frac{R_c}{R_c + R_1} \quad \text{and} \quad \frac{R_f}{R_f + R_2} \tag{8.5(7)}$$

At null, $R_c/(R_2 + R_1) = R_f/(R_f + R_2)$. This is shown graphically in Figure 8.5n for a 0–100% movement of the command.

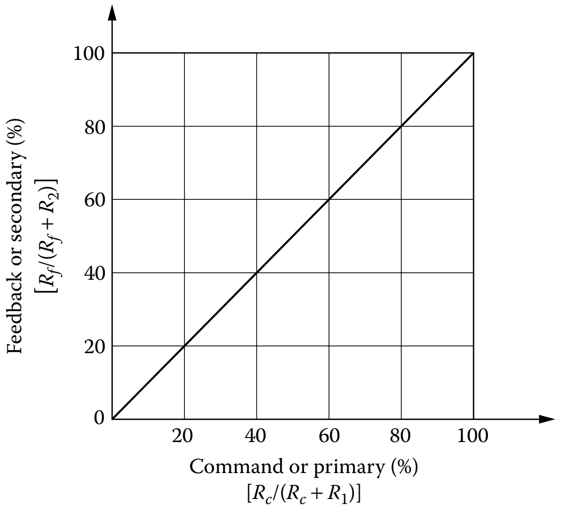

FIG. 8.5n
Command-to-feedback relationship.

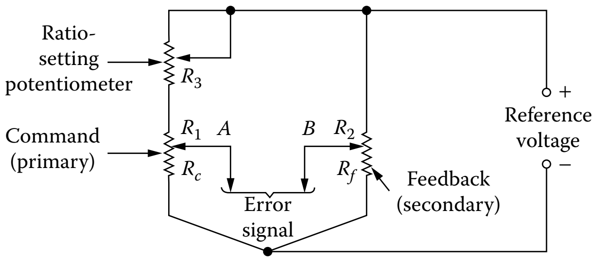

FIG. 8.5o
Electronic ratio circuit.

In this example the feedback signal is a measurement of actual movement or displacement, but when used in a flow ratio application, the feedback signal will be related to the secondary set point, and the command becomes the primary (wild) flow variable signal. Introduction of a fixed resistance in series with the command pot causes a change in the slope of the characteristic curve in Figure 8.5n.

By making this additional resistance a potentiometer, as shown in Figure 8.5o, one can limit the full-range travel of the feedback pot and of the driven load (secondary) to any desired degree for a 0–100% movement of the command.

In Figure 8.5o the feedback pot position at null will be

$$\frac{R_f}{R_f + R_2} = \frac{R_c}{R_c + R_1 + R_3} = K_1\left(\frac{R_c}{R_c + R_1}\right) \tag{8.5(8)}$$

where $K_1 = (R_c + R_1)/(R_c + R_1 + R_3)$. The slope of the characteristic curve in Figure 8.5p is K_1, and its value is dependent upon the setting of R_3, which is usually calibrated to represent K_1, the ratio setting.

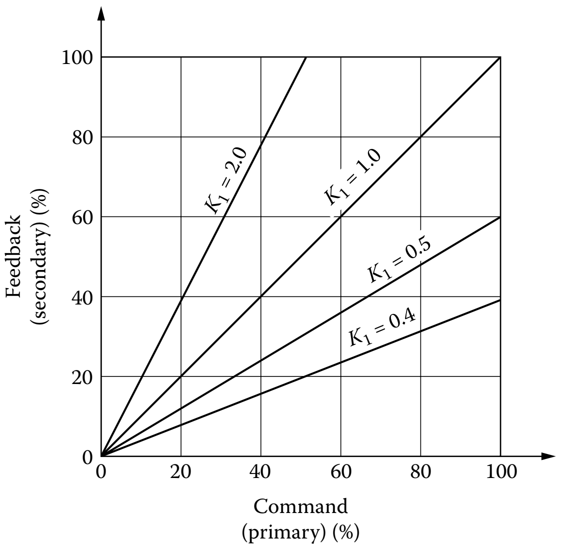

FIG. 8.5p
Command-to-feedback relationships.

Electronic ratio control provides fast, accurate, and adjustable ratios between input and output signals. Accuracy of ±0.5% of span is attainable.

Care should be exercised to provide a constant supply voltage and frequency. A change of 10% from the nominal voltage will cause a zero shift of as much as 0.5% of input value, and a change of 10 Hz over the range of 47–63 Hz will cause a zero shift of 0.25% of input value.

RATIO DIAL SETTING

The setting of the ratio relay is a function of the ranges of the transmitters. If the transmitters are measuring over the same range and in identical units, the graduations on the ratio dial represent the exact ratio between the primary and secondary flows. However, where maximum capacities and primary meter measurement units differ, the ratio selector dial-setting must be calculated for each ratio desired.

Commercially available ratio control units are graduated to handle signals of the same characteristics (either linear or square root) and of the same units. The following equation is used to calculate ratio dial settings:

$$\text{ratio dial setting} = \frac{(F_{\text{pm}})}{(F_{\text{sm}})}(R) \qquad \textbf{8.5(9)}$$

where

F_p = flow rate through primary
F_s = flow rate through secondary
F_{pm} = maximum capacity of primary flow transmitter
F_{sm} = maximum capacity of secondary flow transmitter
R = desired ratio of F_s/F_p

If F_{pm} is 50 GPM (189 1/m) and F_{sm} is 25 GPM (95 1/m), and it is desired to maintain the secondary at exactly 25% of the primary flow, then the ratio dial setting is (50/25)(0.25) = 50%. In selecting the ratio dial settings, one should keep in mind the rangeability limitations of the flow transmitters. (See Chapter 2, *Process Measurement and Analysis*.)

SCALING PROCEDURES

At this point a brief discussion of scaling in general may be helpful. Scaling is required not only in blending or ratio systems but in all control systems where calculations must be based on normalized (0–100%) transmitted signals, which represent different engineering quantities. The discussion on scaling here will consider the nature of traditional pneumatic relays (multiplying and dividing) in addition to analog electronic or DCS systems and will provide two examples.

The first example will be the scaling of a multiplier relay used in mass flow calculations, while the second example will describe the scaling of two relays (a multiplying one and a subtracting one), which are combined together to make a heat transfer calculation.

Multiplying and Dividing

Pneumatic multipliers typically have only two inputs, but several adjustable coefficients are available to facilitate scaling. The general formula for a multiplier is

$$A = a + f(B - b)[C(1 - c) + c] \qquad \textbf{8.5(10)}$$

Coefficients a, b, and c are bias or zero adjustments for the three signals, f is the gain of the device with both inputs at 100%, and $1 - c$ is the span of the C input. The formula for a divider is found by solving Equation 8.5(10) for signal B:

$$B = b + \frac{A - a}{f[C(1 - c) + c]} \qquad \textbf{8.5(11)}$$

Each instrument in a computing system, including indicators, recorders, and transmitters, should be calibrated against a common standard where possible. The most reliable standard to use is a mercury column, accurate to ±0.1% of the 3–15 PSIG (0.2–1.0 bar) range.

Calibrating multipliers and dividers is particularly painstaking because the adjustments must be made in a specific order. Referring to Equation 8.5(10) for a multiplier:

1. Zero adjustment “a” must be made with signals B and C at zero.
2. Zero adjustment “b” must be made with signal B at zero and C at 100%.
3. Zero adjustment “c” must be made with signal B at 100% and signal C at zero.
4. Span adjustment $1 - c$ must be made with B at some specified intermediate value and C at 100%.

A similar procedure must be followed with dividers.

After all components are calibrated individually, the system must be calibrated as a whole, to offset systematic (non-statistical) errors. Almost any of the adjustments can be used to calibrate the system at a single operating point, but the wrong choice may cause a greater error at some other point.

So, the accuracy of the system should be evaluated at several sets of conditions to determine which of the available adjustments would minimize the average error for all sets. Often more than one coefficient may require adjustment.

Scaling a Multiplier

Consider the example where a gas flowmeter requires compensation for absolute pressure:

$$W = k\sqrt{hP} \qquad \textbf{8.5(12)}$$

where W is the mass flow, h is the orifice differential pressure, and P is the absolute pressure. The orifice and differential range are selected so that 100% differential equals 100% flow at the normal operating pressure. With this in mind, scaling requires knowing only the normal pressure and the range of the pressure transmitter.

Let the normal pressure be 64.7 psia and the transmitter range be 0–75 PSIG with a base of 14.7 psia. Compensation requires that the multiplier exhibit a gain of 1.00 at the normal pressure. The absolute pressure range is 14.7–89.7 psia; therefore,

$$P = 14.7 + 75C \qquad \textbf{8.5(13)}$$

Here, signal C represents the pressure input to the multiplier. Then, the compensating factor determined at the normal pressure is

$$\frac{P}{64.7} = 0.227 + 1.160C \qquad \textbf{8.5(14)}$$

To conform with Equation 8.5(10), the maximum value of the compensating factor is extracted as $f = 89.7/64.7 = 1.387$:

$$\frac{P}{64.7} = 1.387(0.836C + 0.164) \qquad \textbf{8.5(15)}$$

Then, the scaled equation for the multiplier is

$$A = 1.38B(0.836C + 0.164) \qquad \textbf{8.5(16)}$$

where A is the multiplier output and B and C are the orifice differential and pressure inputs, respectively. A square-root extractor following the multiplier completes the calculation.

Scaling a Heat-Transfer Calculation

A simple yet highly effective procedure to be followed when scaling is:

1. Write the equation to be solved, including all conversion factors, with all signals given in the units in which they are to be measured or displayed.
2. Relate each input and output signal (having a range of 0–1.0) to the range of each variable, by a set of "normalizing" equations.
3. Substitute the normalizing equations into the original equation and solve for the output signal.

As an example, apply this procedure to the calculation of the rate of heat transfer, Q, to a liquid cooling medium. The liquid is flowing at rate F, with an inlet temperature T_1 and a higher outlet temperature T_2. The conditions are given in Table 8.5q.

The equation to be solved is

$$Q = Fk(T_2 - T_1) \qquad \textbf{8.5(17)}$$

TABLE 8.5q
Heat Exchanger Operating Conditions

Signal	Variable	Range	Normal Value
B	F	0–100 gpm (0–0.38 m^3/m)	60 gpm (0.23 m^3/m)
A	T_2	25–75°F (–3.9–23.9°C)	50°F (10°C)
C	T_1	0–50°F (–18–10°C)	30°F (–1.1°C)
E	Q	0–60,000 BTU/hr (0–17,400 W)	48,000 BTU/hr (13,920 W)

Coefficient k includes liquid density and specific heat, but it can be calculated from the normal operating conditions given in Table 8.5q.

$$k = \frac{Q}{F(T_1 - T_2)} = \frac{48,000}{60(50-30)} = 40 \qquad \textbf{8.5(18)}$$

Next, the normalizing equations are written, relating signals A, B, C, and E to the variables in Equation 8.5(17):

$$Q = 60,000E \qquad \textbf{8.5(19)}$$
$$F = 100B \qquad \textbf{8.5(20)}$$
$$T_2 = 25 + 50A \qquad \textbf{8.5(21)}$$
$$T_1 = 50C \qquad \textbf{8.5(22)}$$

Note that when signal A is 0, T_2 is actually 25°F, and when signal A is 100% (1.0), T_2 is 75°F.

Substituting the normalized equation into Equation 8.5(17) yields

$$60,000E = (100B)40(25 + 50A - 50C) \qquad \textbf{8.5(23)}$$

Solving for E,

$$E = 3.33B(0.5 + A - C) \qquad \textbf{8.5(24)}$$

Equation 8.5(24) must be solved by a subtractor and multiplier in combination, as shown in Figure 8.5r.

Because it is solved in two operations, Equation 8.5(24) must be separated into two pieces. Let the intermediate variable be identified as D:

$$D = 0.55 + A - C \qquad \textbf{8.5(25)}$$
$$E = 3.33BD \qquad \textbf{8.5(26)}$$

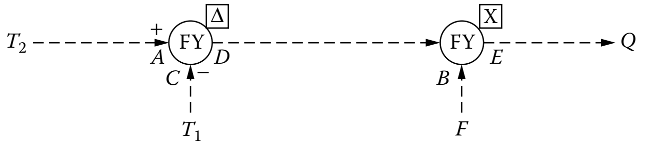

FIG. 8.5r
Scaling a heat-transfer calculation.

The entire factor 3.33 in the equation is shown applied to the multiplier. This is not altogether necessary; for example, the subtractor could have a gain of 2.0 and the multiplier a gain of 1.67. In that case:

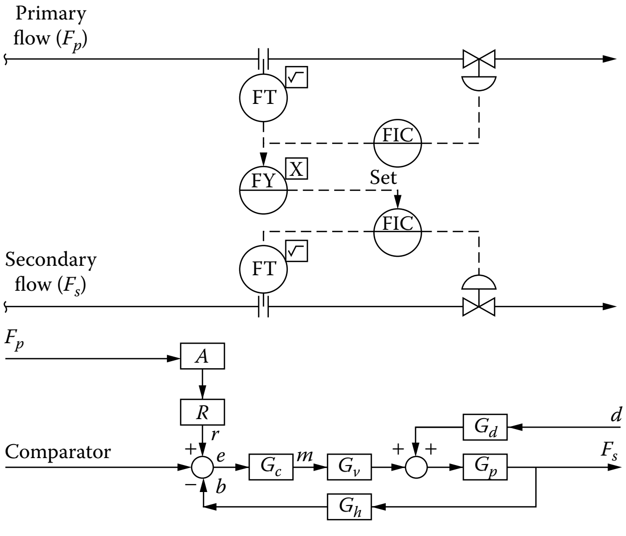
$$D = 1.0 + 2.0(A - C) \qquad \textbf{8.5(27)}$$

$$E = 1.67BD \qquad \textbf{8.5(28)}$$

This tends to improve the accuracy of the calculation but increases the danger of saturating the subtractor. Whenever more than one device is used in this way, each operation should be tested for saturation with reasonable combinations of inputs. In this example, a combination of 75°F for T_2 and 0°F for T_1 would not be reasonable.

RATIO CONTROLLER TUNING

A block diagram of a simple ratio control system is shown in Figure 8.5s. In the ratio control system, the set point of the secondary controller is directly related to the output of the primary flow transmitter. As the primary flow changes, the secondary controller assumes a new set point to maintain the desired ratio.



A = Input element.
b = Feedback variable.
d = Disturbance or load variable.
e = Error (deviation) signal.
F_p = Primary flow.
F_s = Secondary flow.
G_c = Controller transfer function.
G_d = Disturbance or load transfer function.
G_h = Feedback sensor transfer function.
G_p = Process transfer function.
G_v = Control valve transfer function.
m = Manipulated variable.
r = Reference (set-point) input.
R = Desired ratio.

FIG. 8.5s
Ratio control loop.

If simple characteristics are assumed for the transfer functions in the block diagram, the overall system transfer function for set-point disturbances can be expressed as:

$$F_s = RF_p \left(\frac{T_s(s+1)}{T_p(s+1)} \right) \times \left(\frac{T_i(s+1)}{(T_iT_s/K_c)s^2 + T_i(1/K_c+1)(s+1)} \right) \qquad \textbf{8.5(29)}$$

where

T_p = lag of primary flow measuring element
T_s = lag of secondary flow measuring element
T_i = integral time of controller
K_c = controller gain

As can be seen from Equation 8.5(29), the best regulation of the controlled secondary variable (with primary variable changes) can be obtained when the lags T_p, T_s, and T_i are minimum and the controller gain K_c is maximum, without creating instability. This statement is true not only for ratio loops but for feedback loops of all types.

DIGITAL BLENDING SYSTEM

The application of digital techniques to ratioing and blending may result in the total elimination of control system errors. This system continuously compares the total accumulated flows from each additive line with the total accumulated signal from a master oscillator. If there is a difference between these two values the corresponding control valve is repositioned to correct the deviation.

An overall digital blending system is illustrated in Figure 8.5t. The flow of each component is digitized by a turbine or displacement-type flowmeter or by an analog-to-pulse generator, producing a pulse train whose frequency is proportional to flow rate. A standardizer is used to scale the transmitter output frequency to a common reference basis, such as 1000 pulses per gallon (265 pulses per liter). This frequency is compared with a reference frequency produced by a numerically controlled frequency generator, which is commonly referred to as a *binary multiplier.*

The inputs to the multiplier consist of a numerical quantity and a pulse frequency, and the output is a new pulse train whose frequency is the product of the two inputs. The multiplier produces two reference frequencies proportional to the manually set numerical ratio settings of K and $(1 - K)$.

Each digitized flow rate is compared with its corresponding demand signal generated by the ratio set module (binary multiplier). This comparison is performed by a *bidirectional binary counter.* The bidirectional counter counts in the positive direction on pulses from one input and in the negative direction on pulses from the other input.

The set-point pulses produce "add" pulses, and the measurement pulses produce "subtract" pulses. Hence, if the flow-generated pulses equal the demand pulses, the algebraic sum is zero and no change will occur in the binary memory, and no corrective action is taken.

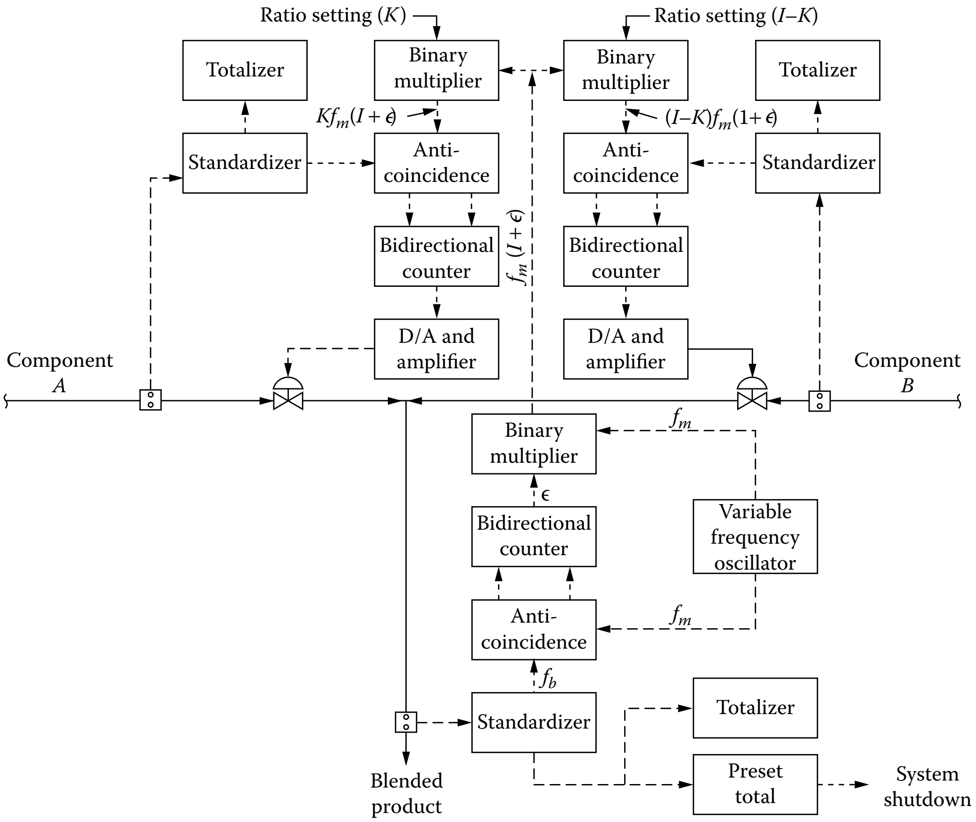


FIG. 8.5t
Schematic diagram of a two-element digital blending system.

Should the rate from one input exceed that from the other, an error count will accumulate in the memory, causing the valve-control logic to generate a proportional correction. This correction signal, after conversion and amplification, positions the control valve. Thus, the quantitatively controlled flow rates of the blend components are maintained at the prescribed ratio.

For applications requiring precise control of total flow rate as well as of the blend ratios, a further digital control loop is provided, as shown in Figure 8.5t. Here a variable frequency oscillator is manually set so that its frequency is proportional to the desired total blend flow rate. This reference signal (f_m), together with the signal generated by the actual total blended flow rate (f_b), is synchronized by anti-coincidence logic and accumulated in a bidirectional binary counter. The instantaneous counts (accumulation) of this counter are a measure of the difference between the total number of pulses generated by the reference oscillator and by the flowmeter, respectively. Thus,

$$\varepsilon = \Sigma f_m - \Sigma f_b \qquad \textbf{8.5(30)}$$

where

ε = instantaneous error accumulation in bidirectional counter
f_m = reference oscillator frequency
f_b = total blend flowmeter-generated frequency

This instantaneous error (ε) serves as the numerical input into a binary multiplier whose input frequency is f_m. Therefore, the multiplier output frequency is εf_m. This output is then mixed with f_m in such a manner as to avoid time coincidence, and it thereby yields a pulse train having the average frequency of $f_m(1 + \varepsilon)$. Thus, if the blend operation produces a flow rate that is less than the sum of the constituent flow rates, or if the blend output flow rate must be controlled while the blend ratios are kept constant, then the error term (ε) provides the necessary augmentation to the total flow rate reference frequency. The frequency input to the ratio setting binary multipliers is $f_m(1 + \varepsilon)$, and the resulting ratio demand outputs are

$$Kf_m(1 + \varepsilon) \quad \text{and} \quad (1 - K)f_m(1 + \varepsilon) \qquad \textbf{8.5(31)}$$

for the two-component blending system.

This principle can also be used automatically to slow down the total blend flow rate, by substitution of the master demand frequency (f_m) with a component flow frequency as an input to the master bidirectional counter. This feature is useful when one component may fall behind at start-up, when a strainer is plugged, or when a pump cannot meet the flow requirements.

When this occurs, the component controller takes over the pacing from the master demand unit if a predetermined error has been accumulated and adjusts the total flow rate to a value that the component can maintain. An alarm and automatic shutdown logic circuitry can also be incorporated to signal alarm conditions or automatically shut down the system if any of the components fall below their preset minimum rates.

The total blended product requirement may be preset on a totalizer to initiate batch shutdown. Analyzers or optimizers can be added to adjust automatically the blend ratios or the total blend flow rate as required.

The inaccuracy of the overall control system can exceed ±0.25%, with repeatability of better than 0.1%. The blend ratio setting can cover a range from 0.001 to 1.999, using four-digit thumbwheels. In a digital blending system, the dynamic response is limited only by the control valve stroke speeds, because the control system itself has practically no dead time.

TRENDS IN BLENDING SYSTEMS

High accuracy and optimal quality with easy recipe changes are the capabilities of microprocessor-based blending controls (Figure 8.5u). Nowadays, advanced control strategies are being applied to accurately compute and to track the target blending percentages and to obtain the quality of the products and flexibility to blend a variety of final products.

The following sections in this volume cover some of the more advanced control strategies that can be considered in optimizing blending systems: expert systems (Section 2.8), neural networks for process modeling (Section 2.18), hierarchical control (Section 2.11), genetic algorithms (Section 2.10), fuzzy logic control (Section 2.31) have been used in pilot plants and in some industrial processes to achieve these objectives.

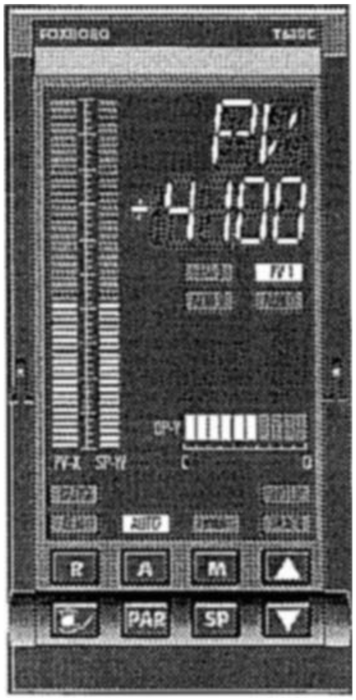

FIG. 8.5u
Microprocessor-based blending or ratio controller. (Courtesy of Foxboro Co.)

Application Examples

It is difficult to maintain constant product quality in coal preparation plants, because the properties of the raw coal supplies are highly variable. A fuzzy logic ash monitor can be used in a coal blending control system to stabilize the quality of the blend. Ash monitor has been used to achieve optimal blending of the coal supply. This approach allows coal loading for different clients having diverse requirements regarding the blending quality.[1]

An integrated approach to planning and coordinating the short-term scheduling of multiproduct blending with nonlinear recipe optimization can be achieved by hierarchical control. The resulting blending recipes and production volumes are provided as goals for scheduling level. The planning and scheduling approach is capable of switching between different recipes to obtain a high efficiency in solving industrial blending problems.[2]

When ratio control is done in software, it usually is resident in the "user layer" or Layer 8.[5] Ratio is a relatively simple function block to provide the "multiply" function. It is used in blending and other processes to establish one operator or recipe set value as a master, and to slave many different set point values based on the master.

In blending, a master flow is set as a constant with other flows proportional to the master flow. A ratio block would be configured in front of each set point of the flow control loops for each blended ingredient. As the master flow is changed, each ingredient flow will then be changed in constant ratio to the master flow.

An expert control strategy using neural networks, mathematical models, and rule models is applied to the coal blending process in an iron and steel plant. The complex model is constructed by using statistical data and empirical knowledge of the process and by forward-chaining and model-based reasoning. The predictions of the coal blend and coke quality are used to accurately compute the blending percentages. Target percentages are achieved by a distributed control technique employing PI control algorithms.[3]

Using traditional blending control, the desired ratio may be kept during a steady-state operation; however, during transients this ratio is hard to maintain. This is a serious problem, because blending control is applied to the process where the flows and blending ratios change frequently.

A blend control station that improves the ratio control performance during transients is applied in a paper mill process. The purpose of the controlled process is to add hydrosulfite to the pulp flow to bleach it. The goal is to keep the ratio between the pulp flow and the hydrosulfite flow constant. The control structure utilizes adaptive techniques to adjust on-line parameters based on the actual values of the pulp and hydrosulfite flows. In the adaptive blend station, no extra parameter tuning is required.[4]

CONCLUSIONS

In this section blending and ratio methods have been explained. In addition, methods of applying scaling procedures to blending and ratio systems been described. The industrial control configurations for rate blending, totalizing blending, and optimized blending have been shown.

Whether the blending system is designed by a user or is a package purchased from a manufacturer, the measuring and transmitting devices should be matched against the selected blending system in accuracy, rangeability, and flexibility. It is inconsistent to install an accurate digital blending system with low-accuracy sensors.

Also, the time lags in the flow measuring elements have a decisive role in the blending systems, because a good dynamic performance requires that the time constant of the transmitter be small. In-line blending systems have special importance when there is no downstream tank to accumulate and mix the blended product, because in such cases the blend composition must be maintained all the time. Advanced blending systems can economically improve the quality of the product and can provide flexibility to blend a variety of products.

INTRODUCTION

This section is subdivided into four parts. The first part describes the characteristics of the boiler and its associated equipment (fans, dampers, and so on). The second part is devoted to a description of the conventional boiler controls, including steam pressure and temperature, air/fuel ratio, draft pressure, and feedwater controls. The third part describes the pollution control systems. And the fourth part discusses optimization and describes the methods of steam pressure floating, air/fuel ratio optimization, soot blower optimization, and blowdown controls.

Boilers are available in two basic designs: fire tube and water tube. Fire-tube boilers are generally limited in size to approximately 25,000 lb/hr (11,340 kg/hr) and 250 PSIG (1.7 MPa) saturated steam. Although they are noted for their ability to respond to changing demands, their size and pressure limitations preclude their use in large industrial facilities. Because of thermodynamic considerations, boilers should produce steam at high pressure and temperature to realize a maximum work efficiency. These conditions are achievable only with water-tube boilers—hence, they will be given prime consideration in this section.

Steam boilers are used by the electric utility industry to produce steam for power generation and by manufacturing and process industries (nonelectric utility) to produce steam for both power generation and process heating and energy conversion. Electric utility boilers tend to be larger and operate at higher pressures: A typical coal-fired utility boiler might produce 3 million lb/hr (1.36 million kg/hr) of superheated steam at 2400 PSIG (16.5 MPa). A typical nonelectric utility industrial boiler might produce 400,000 lb/hr (181,000 kg/hr) of steam at 900 PSIG (6.2 MPa). Industrial boilers are commonly referred to as co-generation or combined heat and power (CHP) applications.

In this section, the controls of both the electric utility and the process industry boilers are described. In general, the loads on the electric utility boilers are more stable, and when they change, they change slower than the often drastically varying loads that process industry boilers have to handle. As a consequence of this difference, the utility industry boiler control system shown in Figure 8.6l does not include the type of lead/lag compensation that is described in Figure 8.6s. Therefore, the overall controls shown in Figure 8.6l are for reference only, and the reader should study the discussion of the individual loops and select the appropriate ones for the type of load dynamics at hand.

The basic components of a water-tube steam boiler are the furnace, where air and fuel are combined and burned to produce combustion gases, and a water-tube system, the contents of which are heated by the combustion process. The tubes are connected to the steam drum, where liquid and vapor are separated and the generated water vapor withdrawn. If superheated steam is to be generated, the steam from the drum is

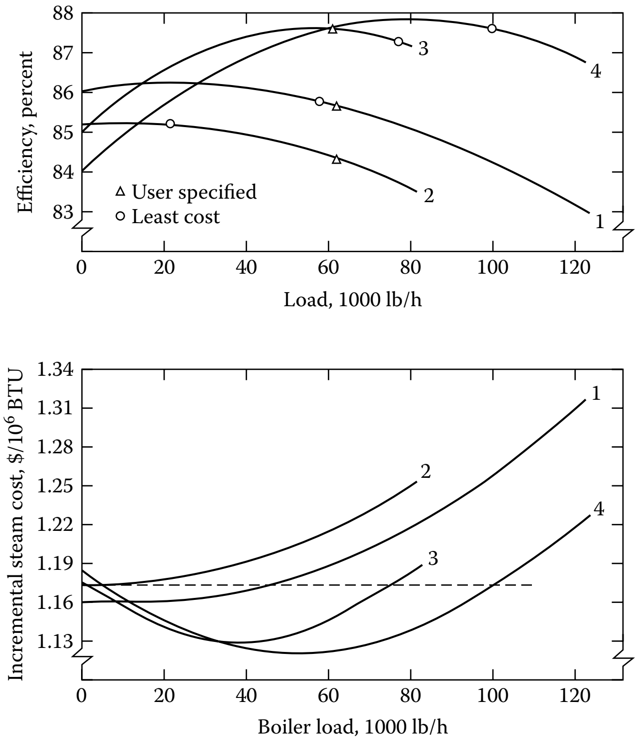

FIG. 8.6a

Boiler efficiencies and steam costs vary with both the design of the boiler and its loading.[25]

passed through the superheater tubes, which are exposed to the combustion gases. Supercritical or "once-through" boilers operate above the critical point of water where there is not a distinction between liquid and vapor; these boilers are not equipped with steam drums.

THE BOILER

Efficiency

The thermal efficiency of a steam generator is defined as the ratio of the heat transferred to the water (steam) to the heat input with the fuel. One of the goals associated with the operation, maintenance, and control of a boiler is to maximize its thermal efficiency.

The boiler efficiency is influenced by many factors. A fully loaded large boiler that is clean and properly tuned (with blowdown losses and pump and fan operating costs disregarded) is expected to have the following efficiencies:[1]

On coal: 88%, with 4% excess oxygen; 89%, with 3% excess oxygen
On oil: 87%, with 3% excess oxygen; 87.5%, with 2% excess oxygen
On gas: 82%, with 1.5% excess oxygen; 82.5%, with 1% excess oxygen

Boiler efficiencies seldom exceed 90% or drop below 60%. Efficiencies will tend to vary with individual design and with loading, as shown in Figure 8.6a. Efficiencies will also vary as a function of excess air, flue-gas temperature, and boiler maintenance. A 1% loss in efficiency on a 100,000 lb/hr (45,360 kg/hr) boiler will increase its yearly operating cost by about $20,000. A 1% efficiency loss can result from a 2% increase in excess oxygen[1] or from about a 50°F (28°C) increase in exit flue-gas temperature.[2]

Efficiency can be computed by the *direct* or the *indirect* method.[3] The direct method uses the ratio of the rate of heat transferred to the water (outlet steam specific enthalpy × steam mass flow−feedwater specific enthalpy × feedwater mass flow) to the rate of heat input by the fuel (higher heating value × fuel mass feed rate).

The indirect method uses fuel, ash, and stack gas analysis to do a per-unit-basis accounting of all heat losses, subtracting all losses from the higher heating value of the fuel and dividing the result by the higher heating value. The indirect method is more accurate, because it does not rely on the relatively inaccurate steam and fuel flow measurements. The major losses considered by the boiler indirect efficiency calculation equations are:[4]

Dry gas loss: sensible heat carried out of the stack with the combustion air and combustion products
Moisture loss: loss due to vaporizing the moisture in the fuel and the moisture produced from combustion of the hydrogen in the fuel
Incomplete combustion loss: loss due to combustion of carbon that results in carbon monoxide (CO), instead of the complete combustion product, carbon dioxide (CO_2)
Unburned carbon loss: loss due to carbon that does not get combusted and ends up in the refuse (ash)
Moisture in the combustion air loss: loss due to heating up water vapor contained in the combustion air
Radiation loss: heat lost from the external furnace walls to the surrounding air and other surfaces

If variations in only the dry gas loss are of primary interest (normally the largest source of energy loss[5]), then the efficiency can be approximated using Equation 8.6(1),[6] which assumes nominal fixed values for most of the above losses, based upon the type of fuel.

$$E = 100\left[1 - 10^{-3}\left(0.22 + \frac{K''y}{1 - y/0.21}\right)(T_s - T_a) - \frac{\Delta H_c}{H_c}\right] \qquad \textbf{8.6(1)}$$

where y is the mole fraction of oxygen in the flue gas, and K'' is a coefficient assigned to each fuel: 1.01 for coal, 1.03 for oil, and 1.07 for natural gas. The term $\Delta H_c/H_c$ is about 0.02 for coal, 0.05 for oil, and 0.09 for gas; the terms T_s and T_a are the stack and ambient temperatures (°F).

Where accuracy of the calculated efficiency is important, such as validation against performance guarantees, it is best to refer to the full indirect method calculations; a generally accepted standard for steam generating unit efficiency calculations is the ANSI/ASME Power Test Code (PTC) 4.1.[3]

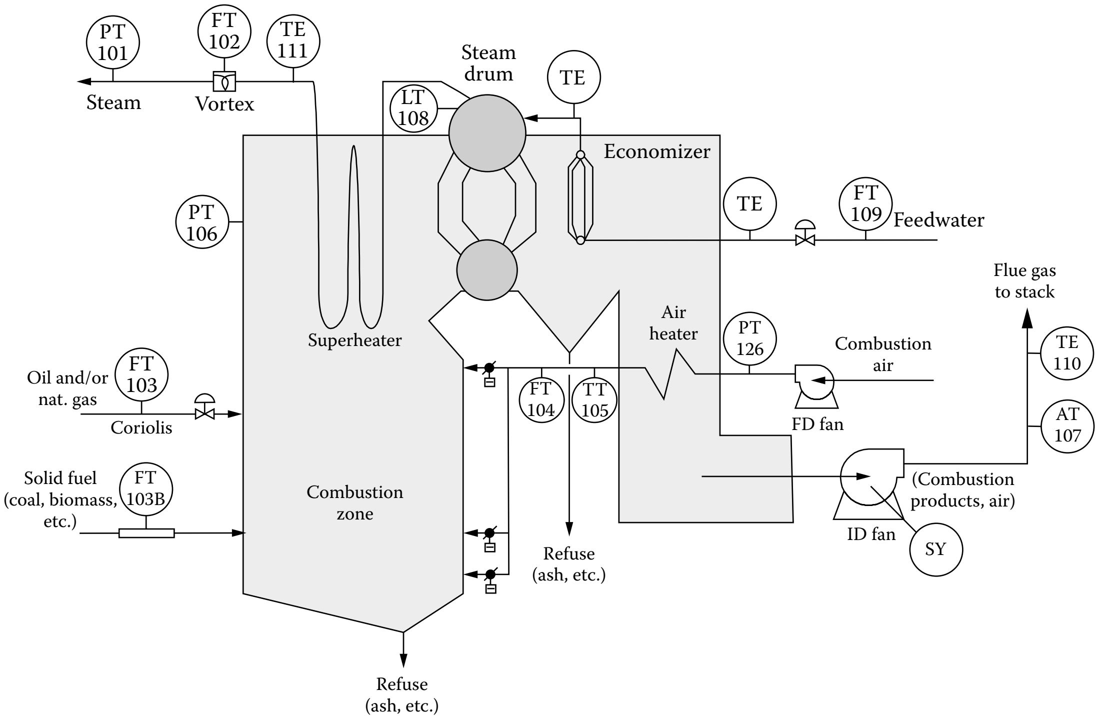

FIG. 8.6b

The main in-line instruments are shown here for a drum-type boiler.

Equipment

Steam boilers referred to in this section are drum-type boilers. Very large, supercritical pressure boilers are the "once-through" type and are found only in the largest electric generating plants.

In electric utility applications, a boiler is typically part of a *generating unit:* one boiler dedicated to one steam turbine. In industrial applications, often two or more steam boilers are connected to a common header supplying process steam users and, commonly, one or more turbine generators. The "load" on a steam boiler refers to the amount of steam demanded by the steam users (including turbines).

The boiler steaming rate must follow the steam demands arising from process heat or power generation requirements. The equipment and the control system often must be capable of satisfying rapid changes in load. Load changes can be a result of rapidly changing process requirements, power demand changes, or cycling control equipment. Whereas load may be constant and steady over prolonged periods, the boiler must have sufficient "turndown" to stay in operation at reduced capacities as portions of the plant may be shut down. This consideration usually leads to a greater "turndown" requirement for the boilers than for any other portion of the plant. At the same time, it is desirable to maximize boiler efficiency at all loads.

Boiler designs, in terms of air and gas flow configuration, are generally either forced-draft (FD) or balanced-draft boilers. Forced-draft boilers operate at positive pressure with air supplied to the boiler by a forced-draft fan. Balanced-draft boilers usually operate at slightly negative pressure with air supplied by an FD fan and flue gas withdrawn by an induced-draft (ID) fan (larger than the FD, due to the combustion products). Most boiler air and flue-gas fans are centrifugal (typically with backward-curved blades). Axial flow fans are used less often due to the nature of the axial flow static-pressure vs. capacity curve and the possibility of stall conditions.[7]

The Role of Sensors

Figure 8.6b shows a typical boiler arrangement for gas, oil, or solid fuel. It also shows the in-line instruments used on a boiler, together with some advice on the type of sensor to be used.

The normal "on-line" requirements for steam boilers serve to control steam pressure within ±1% of the desired pressure; air/fuel ratio within ±2% of excess air (±0.4% of excess oxygen), based on a desired "load" vs. "excess air" curve; steam drum water level within ±1 in. of desired level; and steam temperature (where provision is made for its control) within ±10°F (5.6°C) of desired temperature. In addition, the efficiency of the boiler should be monitored within ±1%.

In order to reach these performance goals, it is necessary to install accurate sensors and to make sure that the load does not change more than 10–35% of full scale per minute, depending on the size, fuel type, boiler design, and that there are no boiler design problems limiting this ability. The various loops tend to interact, so that integration into an overall system is necessary both during design and when the loops are being "field-tuned."

Flow Detectors Important and often disregarded are the flow detectors, which provide the basis for both material and heat balance controls. Outlet steam flow measurement, particularly if it is used as part of the boiler firing rate control strategy, for environmental permit compliance, or for on-line efficiency or energy use calculations, should be pressure- and temperature-corrected to a true mass flow. Most steam flow sensors in use (orifice, flow nozzle, vortex-shedding meters, and so on) measure velocity, which translates directly to volumetric flow.

Multivariable transmitters with integrated pressure and temperature inputs and mass flow computation in the meter are preferred. If an uncompensated velocity or volumetric flow signal is all that is available, then it should be compensated to a true mass flow measurement in the control system using Equation 8.6(2):

$$F_C = F_A\left(\frac{P+P_0}{P_R}\right)\left(\frac{T_R}{T+T_0}\right)\left(\frac{X}{X_R}\right)\left(\frac{Q_R}{Q}\right) \qquad \textbf{8.6(2)}$$

where

F_C = compensated flow (mass flow)
F_A = uncompensated flow (velocity or volumetric measurement)
P = actual measured steam pressure
P_0 = conversion to absolute pressure (14.7 psi for imperial units and P in PSIG)
P_R = reference pressure (pressure at which primary flow element was specified and sized, converted to same units as $P + P_0$)
T = actual measured steam temperature
T_0 = conversion to Rankine or Kelvin scale (459.69 for °F to °R, 273.15 for °C to °K)
T_R = reference temperature (temperature at which primary flow element was specified and sized, converted to same units as $T + T_0$)
X = measured actual steam compressibility
X_R = reference steam compressibility (at conditions for which primary flow element was specified and sized)
Q = measured actual steam quality
Q_R = reference steam quality (at conditions for which primary flow element was specified and sized)

In practice, the compressibility and quality terms are often dropped, lacking a good measure of the actual values for these. In most steam flow applications, the pressure compensation term is the most important one. Note also that the above equation assumes that, for a differential pressure-type flow measurement, the process variable, F_A, has already had square root extraction applied to convert it to velocity.

For successful control of the air/fuel ratio, combustion air flow measurement is important. In the past it was impossible to obtain ideal flow detection conditions. Therefore, the practice was to provide some device in the flow path of combustion air or combustion gases and to field-calibrate it by running combustion tests on the boiler.

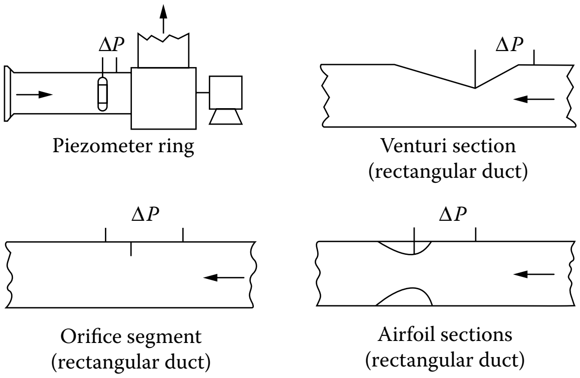

FIG. 8.6c
The various methods of air flow measurement.

These field tests, carried out at various boiler loads, used fuel flow measurement (direct or inferred from steam flow) and measurements of percentage of excess air by gas analysis; they also used the combustion equations to determine air flow. Because what is desired is a relative measurement with respect to fuel flow, the air flow measurement under these circumstances has historically been calibrated and presented on a relative basis.

Flow vs. differential pressure characteristics, compensations for normal variations in temperature, and variations in desired excess air as a function of load are all included in the calibration. With this traditional approach, using relative measurements, the desired result is to have the air flow signal match the steam or fuel flow signals when combustion conditions are as desired.

The following sources of pressure differential are normally considered:

- Burner differential (windbox pressure minus furnace pressure)
- Boiler differential (differential across baffle in combustion gas stream)
- Air heater differential (gas side differential)
- Air heater differential (air side differential)
- Venturi section or flow tube (installed in stack)
- Piezometer ring (at forced-draft fan inlet)
- Venturi section (section of forced-draft duct)
- Orifice segments (section of forced-draft duct)
- Airfoil segments (section of forced-draft duct)

Of these, the most desirable are the last four, because they use a primary element designed for the purpose of flow detection and measure flow on the clean-air side. Some of these typical traditional installations are shown in Figure 8.6c; none of these sensors meet the dual requirement of high accuracy and rangeability. In fact, they are of little value at 30% flow or less.

Flow Sensor Accuracy Table 8.6d lists some better flow sensors, such as the multipoint thermal flow probe or the area-averaging pitot stations provided with “hexcel”-type straightening vanes and with membrane-type pressure balancing *d/p* cells. Area-averaging pitot stations are also available in two-dimensional arrays, in a circular or rectangular

TABLE 8.6d
Flow Sensor Errors on Boilers

Flow Streams Measured	*Type of Flowmeter*	*Inaccuracy (% of flow)*			*Rangeability*	*Limitation*
		At 10%	*33%*	*100%*		
Fuel (oil)	Coriolis mass flow	0.5	0.5	0.5	20:1	
Fuel (natural gas)	Coriolis	0.5	0.5	0.5	20:1	
	Thermal	5.75	2.27	1.25	100:1	
	Turbine	0.5	0.5	0.5	10:1 to 100:1	
	Ultrasonic	0.1–1.0	0.1–1.0	0.1–1.0	30:1 to 50:1	
Fuel (solid: coal, wood, etc.)	Gravimetric feeders or belt scales	0.25–0.5	0.25–0.5	0.25–0.5	3:1	
Fuel (pulverized coal)	Coriolis			0.5	3:1	Max. rate ~29 tons/hr
	Microwave			5.0	5:1	
Steam and water	Vortex shedding					
	Steam	1–1.5	1–1.5	1–1.5	10:1	Min. R_e = 20,000
	Water	0.5–1	0.5–1	0.5–1		Max. temp = 750°F (400°C)
	Orifice	NG*	2–5	0.5	3:1	Rangeability can be increased if using two conventional *d/p* cells or a "smart" *d/p* cell
Air	Area averaging pitot traverse station	NG	2–10	0.5–2	3:1	
	Multipoint thermal	5–20	2–5	1–2	10:1	Dual-range unit required
	Piezometer ring, orifice segment Venturi section airfoil section	NG	3–20	2–3	3:1	Cannot be used below 25% of max. flow

*NG = Not Good.

mounting, that can average the entire flow-field. Thermal (hot-wire anemometer) sensor arrays can also be fairly accurate, offer good turndown, and produce a signal in direct proportion to mass flow. These represent major advances in combustion air flow detection.

This table shows the measurement errors that can be anticipated. Unfortunately, as the flow is reduced, the error—in percentage of actual measurement—increases in all cases except the first two. With linear flowmeters, the error increases linearly with turndown of 10:1. In case of nonlinear flowmeters, the error increases exponentially with turndown. Therefore, at a turndown of 10:1, the orifice or pitot error increases 100-fold and causes these devices to become useless. This situation can be alleviated somewhat by the use of two *d/p* cells on the same element or by the use of "smart" units.

Based on the data in Table 8.6d, if the boiler efficiency is to be monitored on the basis of time-averaged fuel and steam flows, the lowest error that can be hoped for is around 1%.

Similarly, the air/fuel ratio cannot be measured to a greater accuracy than the air flow. At high turndown ratios, this error can be very high. Considering that a 2% reduction in excess oxygen will increase the boiler efficiency by 1%, both the accurate measurement and the precise control of air flows are essential in boiler optimization. If combustion air temperature and pressure vary significantly, then air flow measurement can also be pressure- and temperature-compensated to a true mass flow, again, either with multivariable transmitters, or with Equation 8.6(2), dropping the compressibility and quality terms.

The impact of sensor inaccuracy on performance optimization elsewhere is not as critical. Standard instrumentation allows for the control of steam pressure within ±1%, furnace pressure within ±0.1 in. H_2O (25 Pa), water level within ±1 in. of desired level, and steam temperature to within ±10°F (5.6°C).

Inferential Measurements Inferential measurements, or soft sensors, are finding application in boiler measurement and control due to the difficulty or expense in directly measuring many of the important process variables related to operation of a boiler. Variables such as NO_x emissions, steaming rate, and turbine shaft temperature have been successfully measured inferentially. Two techniques that have successfully been employed are *neural networks* and *principal component analysis*. See Section 2.18 in Chapter 2 of this volume for discussion of neural networks. Regulatory agencies have accepted neural network-based emissions measurement and reporting in certain parts of the United States.

Safety Interlocks

Many of the interlocks related to the start-up, shutdown, and operation of a boiler are implemented for the purposes of protecting personnel and equipment. Most of the interlock and safety features directly related to the boiler can be classified as either *burner management* or *combustion control.* This delineation is made because boiler safety standards define very specific functions for burner management and require it to be implemented in a dedicated system, separate and apart from other control functions.[8]

A burner management system (BMS) is primarily concerned with the interlock, sequence, and timing functions required to safely put burners into service and to stop fuel and trip the boiler on detection of potentially unsafe conditions (*master fuel trip*). Other combustion control interlocks and protection functions, not necessarily a part of BMS, include furnace draft (implosion protection) control, fuel/air cross-limiting, and "runbacks."

An overview of some of the most common boiler safety interlocks is as follows:

PURGE INTERLOCK Prevents fuel from being admitted to an unfired furnace until the furnace has been thoroughly air purged.

LOW AIR FLOW INTERLOCK OR FAN INTERLOCK Fuel is shut off upon loss of air flow or combustion air fan or blower.

LOW FUEL SUPPLY INTERLOCK Fuel is shut off upon loss of fuel supply that would otherwise result in unstable flame conditions.

LOSS FLAME INTERLOCK All fuel is shut off upon loss of flame in the furnace, or fuel to an individual burner is shut off upon loss of flame to that burner.

FAN INTERLOCK Stops forced draft upon loss of induced-draft fan.

LOW WATER INTERLOCK (OPTIONAL) Shuts off fuel on low water level in boiler drum.

HIGH COMBUSTIBLES INTERLOCK (OPTIONAL) Shuts off fuel on highly combustible content in the flue gases.

Where fans are operated in parallel, an additional interlock is required to close the shut-off dampers of either fan when it is not in operation. This is necessary to prevent air recirculation around the operating fan.

Burner Management Systems BMS interlocks must be implemented with dedicated systems. They can be accomplished by hard-wired relay logic, solid-state logic, or programmable logic controllers (PLCs). The BMS is considered a safety instrumented system (SIS). Therefore, if PLC technology is used, it is often based on 1oo2 (one-out-of-two) or 2oo3d (two-out-of-three with diagnostics) logic.

The first one has two channels (two independent CPUs); the second has three channels (three independent CPUs, as in *triple modular redundant* systems). The criterion for selecting a certain type of SIS equipment is based on a safety integrity level (SIL) assessment that determines the degree of integrity required of the SIS based on probability and impact severity of risks. The Instrumentation, Systems, and Automation Society (ISA) has published detailed standards on SIL assessment.

The minimum interlocks required by the National Fire Protection Association (NFPA) for basic furnace protection for a multiple-burner boiler[8] are illustrated in Figure 8.6e. An important part of the burner logic is the purge system, illustrated at the bottom of Figure 8.6e. *Master fuel trip* cannot be reset; i.e. the burner light-off sequence cannot be started unless a proper purge sequence has been executed. The purge helps prevent accumulation of unburned fuel in the boiler after trips or failed start sequences. Furnace explosions are often related to accumulation of unburned fuel.

Automatic start-up sequencing for lighting the burners and for sequencing them in and out of operation is common. Timing for a portion of the typical light-off sequence for a 350 MW dual-fired (oil and coal) burner with gas igniter is illustrated in Figure 8.6f.

Combustion Control Safety Features Additional safety features required by code that are considered the responsibility of the combustion control system (as opposed to the BMS) are primarily aimed at:

1. Maintaining proper combustion zone conditions (air and fuel, air/fuel ratio) to support complete and safe combustion
2. Preventing furnace implosion

Fuel demand should never exceed the capability of the combustion air system to supply necessary air for complete combustion. If an ID or FD fan trips in single-fan systems, then a master fuel trip occurs. If there are fans in parallel, as in large electric utility units, then *runbacks* are employed in the control logic. This technique applies to any of the critical boiler equipment that can be operated in parallel: FD and ID fans, feedwater pumps, and so on.

In these cases, interlocks are provided that "run back" the boiler firing rate to an operating point that can safely be supported by only one fan or pump when one of a pair fails. For example, if one of a pair of FD fans fails, the boiler firing rate must, in a rapid controlled fashion, be brought down to a point that the air supplied by the one fan is more than adequate for complete combustion.

Another feature to ensure sufficient air/fuel ratio for complete combustion is *air/fuel cross-limiting.* This is a safety feature guaranteeing that no change in the firing rate (up or down) can result in a "fuel-rich" mixture. The consequence of this feature is that, on increasing firing rate, air increases before fuel, and, on decreasing firing rate, fuel decreases before air (greater than or equal to the sum of the stoichiometric plus minimum excess air requirement for the fuel being burned).

If the FD and ID fan capacities, combined with the total dynamic head characteristics of the entire air and gas path,

can produce a draft or pressure that will exceed the design pressure ratings of the boiler or its associated ductwork, then the furnace pressure control system becomes more critical. In these cases, the furnace pressure control strategy should include features such as redundant furnace pressure transmitters, feedforward action from master fuel trip, and override action or directional blocking on large furnace draft error (Figure 8.6g).

Design and specification of the various safety interlocks are largely guided and governed by insurance company regulations, standards bodies such as the NFPA, and state regulations. NFPA 85 specifically addresses boilers. Insurance company standards

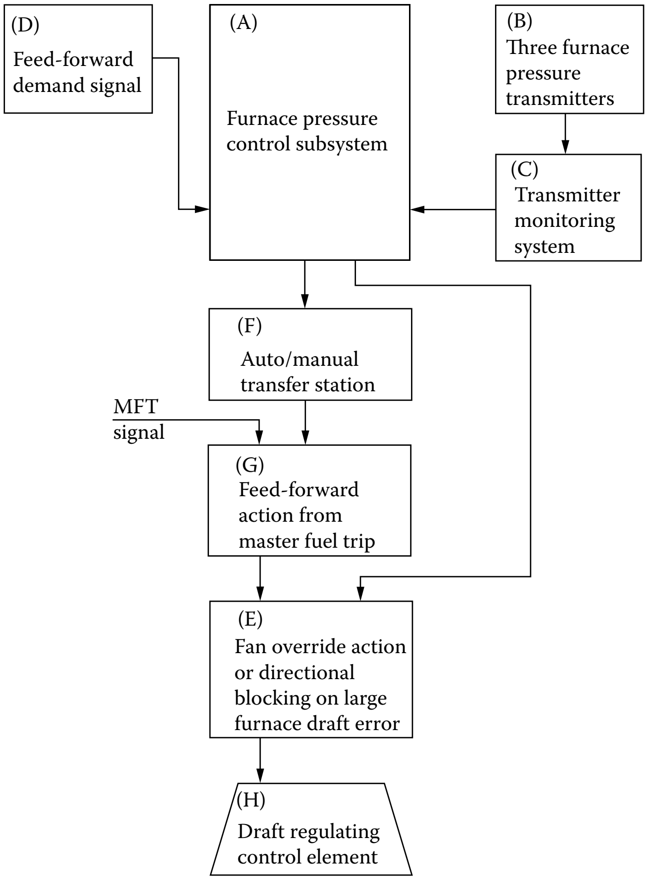

FIG. 8.6g
System requirements for furnace pressure protection and control when such pressure or vacuum can be applied that exceeds boiler or duct pressure ratings. may be more stringent than industry trade and professional organization (such as NFPA) standards.

Soot Blowers

Soot blowers are standard equipment on nearly all types of large water-tube boilers. Soot blowing equipment is used to periodically blow off deposits (fouling) that accumulate on the tubes on the inside of the boiler as a result of the combustion process. A clean heat-transfer surface plays a key role in achieving high thermal efficiency.

Steam, compressed air, or water have all been used as a blowing medium, with steam being the most common. Soot blowers installed in the furnace wall area are short fixed-length blowers (so-called IR blowers). Water lances are sometimes used for the furnace wall region, as well. The blowers located in the convection area, economizer area, and air heater area are long and retractable blowers (so-called IK blowers).

Recently, the water cannon has been introduced to improve cleaning on the furnace wall section.[9] Compared to a regular water lance, the water cannon has the following advantages: less maintenance work, higher cleaning efficiency, reduced NO_x, and longer tube life. Water is never used as a blowing medium, however, in black liquor recovery boilers (used in the pulp and paper industry) due to the potential for explosion from a smelt-water reaction.

Further, proper operation of soot blowers in recovery boilers becomes that much more critical due to the possibility of soot blower steam, directed at a localized area of tubes for too long, causing erosion-induced tube failure and, again, the catastrophic consequences of a smelt-water reaction from the failed water tubes.

In operation, soot blowers are often grouped into sequences based on their physical locations in the boiler. Each sequence consists of multiple steps. Each step may involve several blowers that can run simultaneously. Depending on the blowing medium limitations, normally three or four wall blowers can run at the same time, and one to two retractable blowers can run at the same time.

The operator can run sequences in a fixed schedule, or selectively pick up any individual sequence to run. An individual blow can always be selected whenever needed. Before any soot blower can start to run, the control system logic will first check if all permissives are met. The permissive conditions include whether the requested blower is in service, whether the required blowing medium is available, and whether the medium pressure is adequate.

If all starting permissives are met, the requested blower will start to run. In the retractable blower case, the blower travels forward to the end and reverses back. During the run time, the blower head pressure and the flow of the blowing medium have to be monitored throughout. A significant pressure or flow drop should cause the blower to stop and retract.

The control logic has to be programmed such that whenever abnormal conditions occur, an alarm signal is sent out and the troubled blower stops blowing and, in the IK blower case, fully retracts immediately. The most common failures are the following:

Fail to start: A blower has been commanded to start, but there is no indication that it actually started within an expected time interval.
Blow fail: Blowing medium pressure has dropped below an acceptable level for a specified time interval.
Motor overload or stall: The motor current of a retractable blower has exceeded its normal level by a set amount for a specified time period.
Elapsed time: A blower remained away from its rest position beyond a specified time.

Boiler Dynamics

Boiler response to load changes is usually limited by both equipment design and dead time considerations. Usually the maximum rate of load change that can be handled is from 20 to 100% per minute. This limitation is due to the maximum rates of change in burner flame propagation and to the "shrink/swell" effects on the water level. The period of oscillation of a typical boiler is between 2 and 5 min.

This is the result of a dead time of 30–60 sec and the integrating effect from the storage of energy (similar to tank level). The transportation delay in the boiler is partially due to the displacement volume of the furnace. For example, if the air/fuel ratio is changed, the furnace volume will have to be displaced before the flue-gas composition can reflect that change. The lower the air flow (the lower the load), the longer it will take to displace this fixed volume. Therefore, dead time increases as load is lowered on a boiler.

The transportation delay described above is only one component of the total dead time. The oxygen analyzer also contributes to the total delay, because of its location and its fly ash filter. In addition to the dead time contribution of instruments, control dead time is also created by the fuel/air cross-limiting.

Another way to reduce dead time and thereby increase boiler response is by using feedforward loops. The firing rate demand signal can be made more responsive by feedforward of steam flow, which responds to load changes faster than does steam pressure. Similarly, the induced-draft loop can be made more responsive by adding feedforward off the forced-draft position (damper, inlet vanes, or fan speed). In this system, as soon as the air flow into the furnace changes, the outflow is also modified in the same direction, so that furnace draft pressure is relatively unaffected.

Each of these loops will be discussed in some detail in the following paragraphs.

Air/Fuel Ratio Controls

Performance of air controls on traditional boilers has been limited by inaccurate and unreliable air flow sensors, particularly when air flow rates were less than 25% of maximum rates. This was unfortunate, because it is precisely at low loads that the boiler tends to be the least efficient to start with. Yet, for reasons of equipment inadequacy, some manufacturers will turn off the oxygen trim of the air/fuel ratio at low loads. Contributing to these problems were inaccurate sensors at low flows; leaking, nonlinear dampers with hysteresis and dead band; the use of constant-speed fans; and flame instability at low loads for certain boiler designs and fuels.

Legacy boiler control systems often have workarounds for such historical combustion air measurement and control challenges. In many cases, the firing rate signal itself has been characterized to set the excess air (Figure 8.6h); it has also been used as the oxygen set point on air/fuel ratio trim controls. Frequently, the excess air requirement curve was directly calibrated into the combustion system, and feedback trim based on excess oxygen was not used at all.

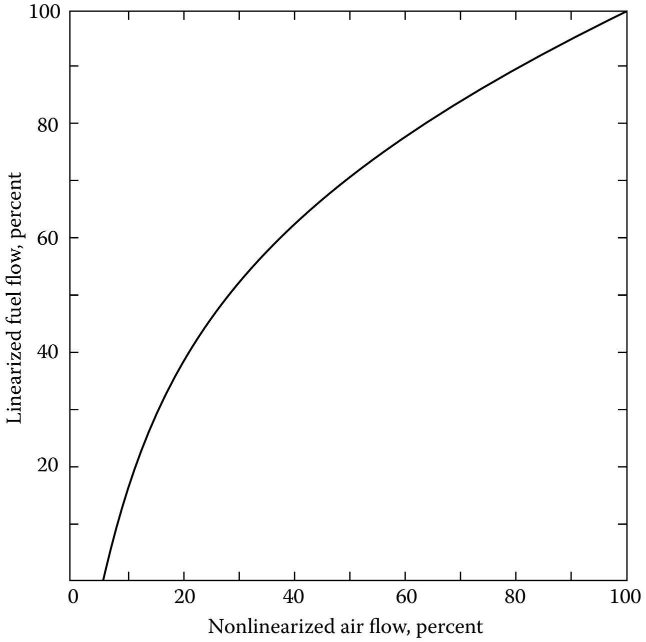

FIG. 8.6h
To apply air flow characterization, the boiler's fuel/air relationship must be determined empirically for the various boiler load levels.[14]

The advocates of this open-loop control strategy argue that the predetermined excess oxygen curve is rather permanent, and if an unmeasured effect necessitates a change in it, that change will be the same throughout the full firing range. This view of the process neglects nonlinearities, hysteresis, dead time, the play in linkages, sticking dampers, and other effects that are now understood.

In many traditional systems, the nonlinearity of dampers (Figure 8.6i) was taken into account by characterizing the fuel valve, the linkage, or the signal to the fan damper actuator. This is no easy task, because louver-type dampers are not only nonlinear, they also lack repeatability. In these systems, the air/fuel ratio trim was disabled below 25% load, because the conventional dampers could not be controlled.

It was argued that closed dampers leak as much as 10% of their full capacity and thus need to be opened only to 2% to deliver 25% flow. Therefore, according to this argument, if the oxygen trim signal were not disabled and it did request a 1% change in air/fuel ratio, this would mean a 1% change in the 2% opening of the damper, or a 0.02% change in its stroke or rotation; this the damper positioner could not handle. Naturally, the argument is correct in all respects except in its assumption that such dampers are a necessary limitation.

Other observations[10] include that PID-type controls cannot handle frequent load changes, because the speed of response of the fuel flow control loop is much faster than that

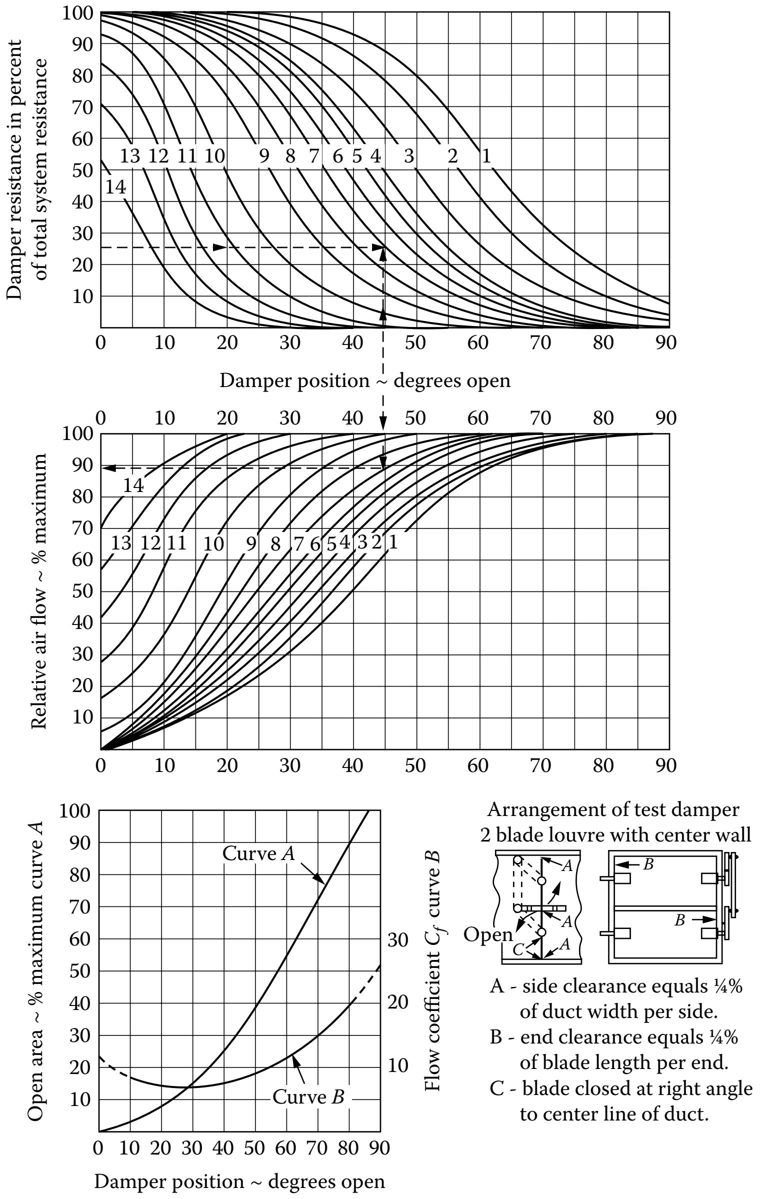

FIG. 8.6i
Multiple-leaf louvers with dividing partitions were used in many traditional systems.[11]

of the air flow control loop. Suppliers attempted to correct this by making the air actuator twice as fast as the fuel actuator.

In general, the nonlinear nature of the loops once created difficulties for the traditional boiler control designs. The need to change the firing rate in exact proportion to load changes was difficult to meet, because it required characterization in the field of the fuel valve and air damper actuators.

As will be discussed on the following pages, distributed microprocessor-based control systems make it much easier to linearize the nonlinear systems through characterizers and greater use of closed-loop control. It is also possible to memorize actuator dead band and speed of response. Still, the capability of state-of-the-art control equipment should not be used as a justification for installing inferior-quality dampers.

Dampers The recommendations for the use of accurate and high-rangeability sensors have already been made in connection with Table 8.6d. Now the desirable damper features will be discussed from a control performance viewpoint.

The reasons why dampers are undesirable as final control elements include their hysteresis, nonlinearity, and leakage. If the flow is accurately measured, the consequences of these undesirable features are easier to handle. For example, assuming that even under proper maintenance the damper displays some hysteresis or dead band, with a reliable flow sensor, the opening and closing characteristics of the damper can be determined.

In most digital control systems, this characterization curve can readily be accommodated, usually input as a series of paired points with linear interpolation point-to-point. The damper characteristic curve can also be automatically updated and corrected, as it might change because of wear, dirt build-up, or other causes.

Figure 8.6i shows the nonlinear characteristics of a multiple-blade damper.[11] Curve *A* on the bottom gives the relationship between damper rotation and open area, while curve *B* relates damper rotation and flow coefficient. The upper portion of Figure 8.6i describes the *installed* performance of the same damper, considering its pressure drop relative to the total system pressure drop.

For example, if the damper resistance is 25% of the total, when the damper rotation is 45%, curve #7 will give the damper characteristics, and actual air flow will be about 88% of maximum. From such curves as these, both the damper leakages and the nonlinearities can be estimated before actual installation.

It can be seen from Figure 8.6i that an increase of 1° in damper rotation that occurs at a 10° opening causes a much greater increase in the actual air flow than a 1° increase that occurs at a 60 or 70° opening. This is undesirable. Stable controls would require constant gain in the loop. Ideally, the change in air flow per increment change in damper opening should be uniform from the tightly closed to the wide-open position. Such inherently linear dampers are hard to manufacture, although the design illustrated in Figure 8.6j does hold such potentials. A more often used solution is the use of compensators and characterizer positioners, so that as the damper gain drops off—as it opens—these compensators introduce more gain into the loop, keeping its total gain nearly constant.

While it is possible to compensate for nonlinearity and hysteresis, leakage must be eliminated by selecting the correct design. Figures 8.2h and 8.6j illustrate some of the tight shut-off designs. If these are used, it is no longer necessary to turn off the excess oxygen-based air/fuel ratio trim when the load is below 25%. With such compensated, low-leakage dampers, trim need not be turned off, and the resulting increase in efficiency need not be abandoned, until load drops to 10%.

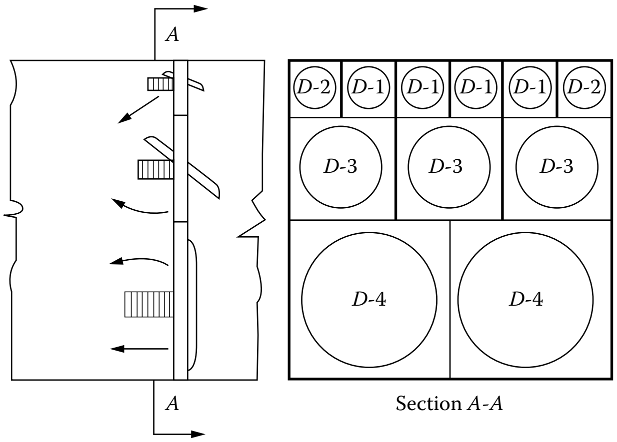

FIG. 8.6j
Improved dampers can be designed to provide low leakage (0.001% of maximum flow). (Courtesy of Mitco Corp.)

Nonlinearity and hysteresis, in the form of stiction and backlash, are often directly the result of the actuator itself. *Electric damper drives* have proven superior to pneumatic and hydraulic cylinder actuators and are becoming the norm for damper modulation.

Fans Even if the best damper is used, damper control will always have a disadvantage, namely that it burns up fan energy in order to control. Therefore, the best method of controlling air flow is at the fan: either by a variable-speed fan or by adjustable inlet vanes. By varying fan speed and eliminating a damper (or running it wide open), it is possible to avoid unnecessary energy loss in the form of damper pressure drop.

Variation of fan speed is accomplished with hydraulic or magnetic couplings, as well as variable-speed AC and DC electric drives. Adjustable inlet vanes, because they are integrated right into the suction area of the fan, are also much more efficient than dampers, though still not as efficient as varying the fan speed. Fan characteristic curves and a comparison of damper vs. inlet-vane vs. variable-speed control are illustrated in Figure 8.6k.

In addition to reducing the overall cost of boiler operation by conserving air transportation energy, variable-speed and variable inlet-vane fans offer better linearity, hysteresis, dead band, and leakage characteristics. For these reasons, the overall control diagram in Figure 8.6l shows fan speed or inlet-vane controls instead of damper controls.

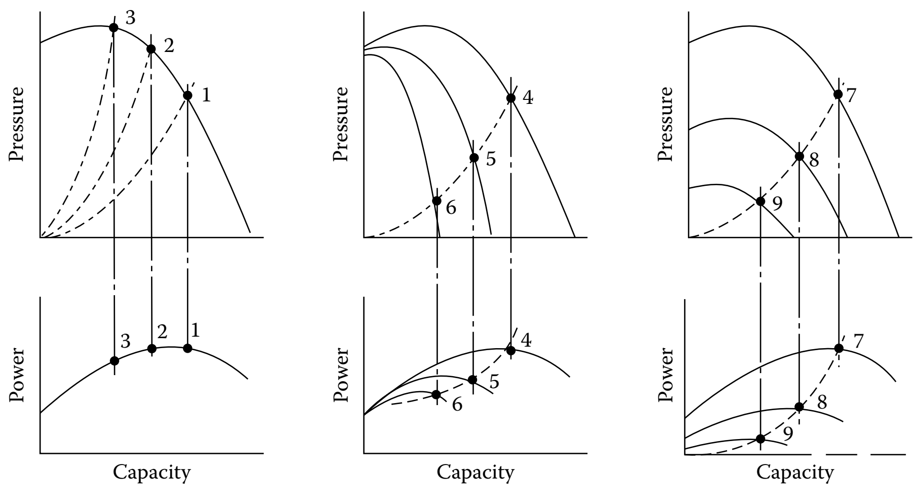
BASIC BOILER CONTROLS

Figure 8.6l shows a possible configuration of the basic boiler control loops and the tie-in points for optimization. Although this is a well-designed control system, it is just one of many possible configurations. Boiler size, steam pressure, and number and type of fuel(s) all can vary, necessitating variations in this scheme. The major loops shown in Figure 8.6l are numbered.

Boiler-Pressure and Firing Rate Controls

Realizing that the boiler is part of a larger plant system, consideration must be given as to how the boiler output will match the load demand placed upon it by the system. From a control perspective, it is useful to distinguish between electric utility and non-electric utility (i.e., industrial) boiler applications.

The firing rate of industrial boilers is most often manipulated to control to a constant header pressure. The primary controller that accomplishes this, whose output is firing rate, is usually termed the *boiler master*. In an industrial application,



(a) Discharge damper control

(b) Suction damper control

(c) Variable speed control

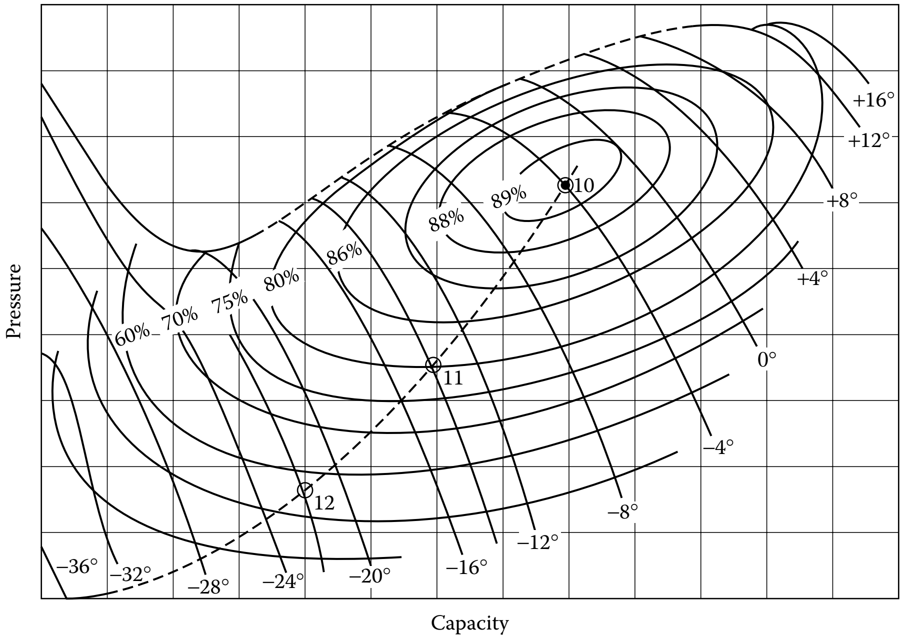


FIG. 8.6k
Axial-flow fans with variable-pitch control help eliminate the need to burn up unneeded air transportation energy in the form of damper pressure drops. Fan characteristics are shown with (a) damper control, (b) variable-inlet vane control, and (c) variable-speed control.[32]

multiple boilers may connect to one steam header, from which multiple turbine generators may be supplied as well as plant heating loads, through extraction turbines or pressure reducing valves (PRVs). In contrast, an electric utility boiler normally operates paired off as a single generation unit with a single turbine generator. The electrical output desired from the unit can be controlled in the following ways:

- *Boiler-following mode:* load demand is controlled first at the turbine generator, with the boiler supplying (following) whatever the turbine requires (header pressure control on boiler firing rate).
- *Turbine-following mode:* load demand is controlled first by boiler firing rate, with the turbine responding to (following) the boiler (throttle pressure control with turbine valves).
- *Boiler-turbine coordinated control mode:* turbine valves and boiler firing rate are manipulated in concert in response to load demand, while header pressure is maintained.
- *Sliding (variable-pressure) and free-pressure control modes:* control strategies that, by design, allow header pressure variation with load, to improve efficiency, speed of response to load changes, and turbine reliability.

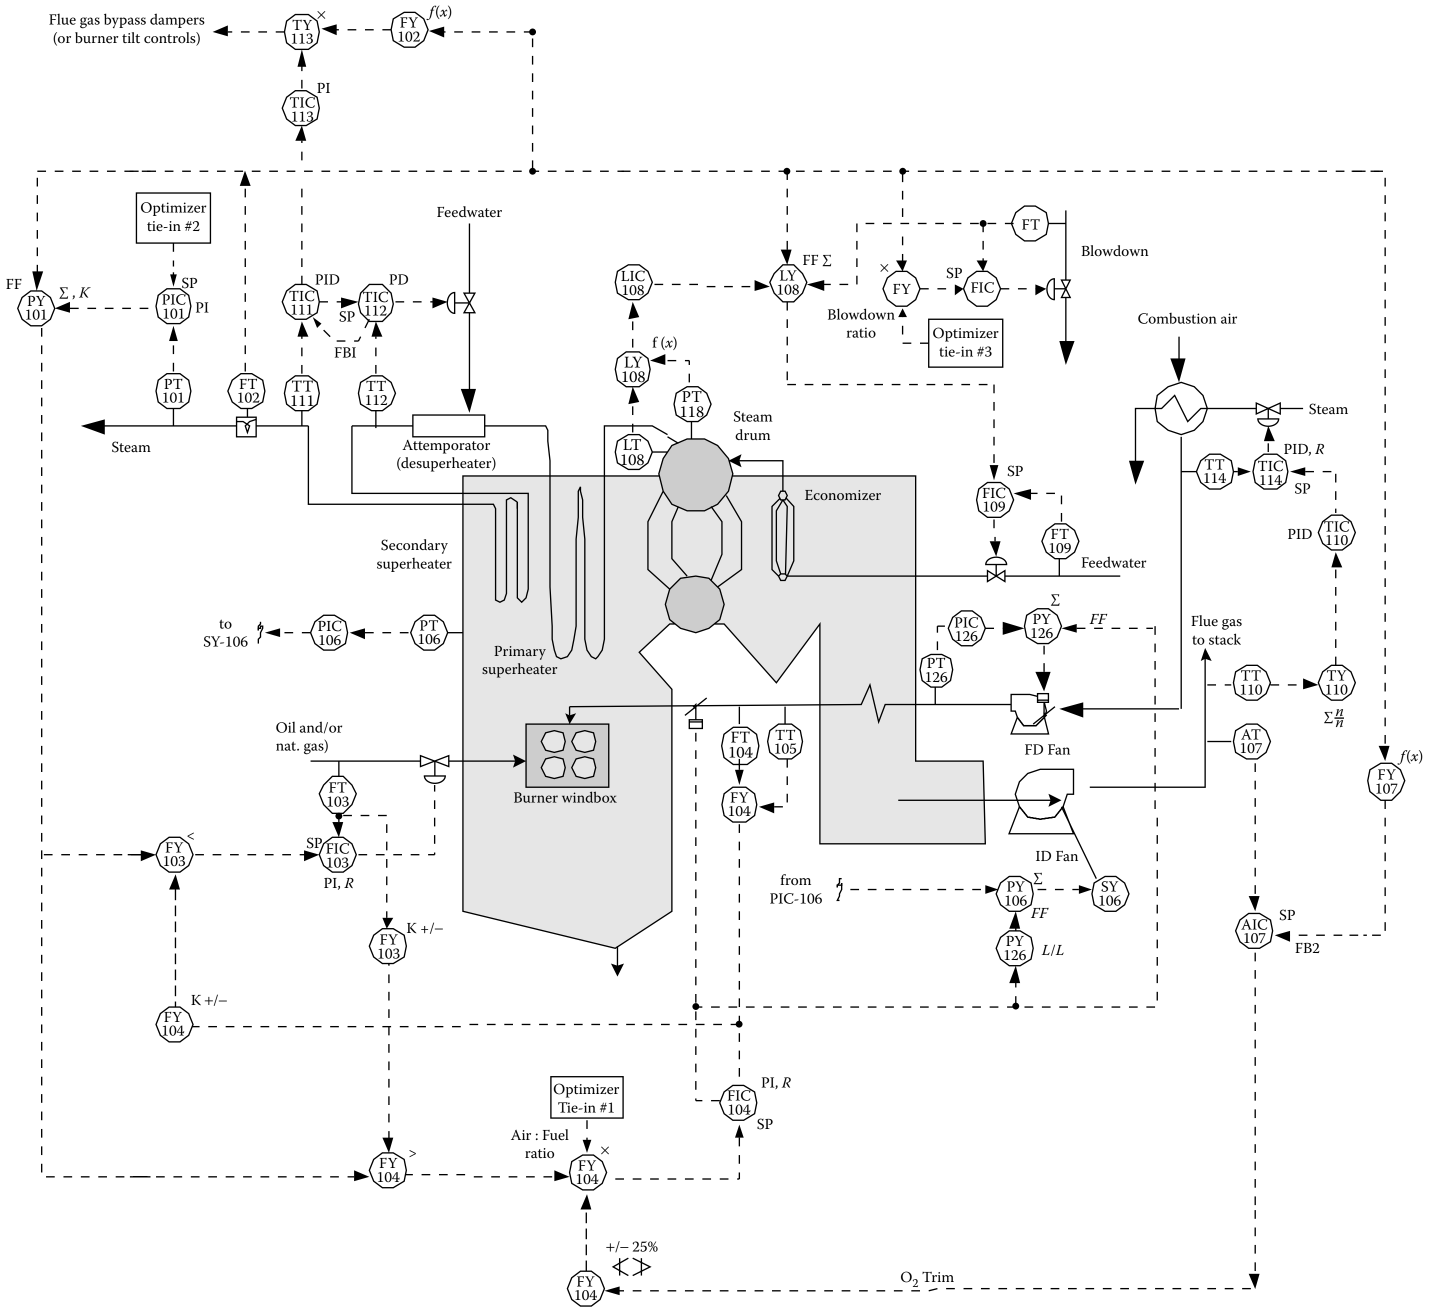

FIG. 8.6I
This diagram shows good boiler controls without optimization.

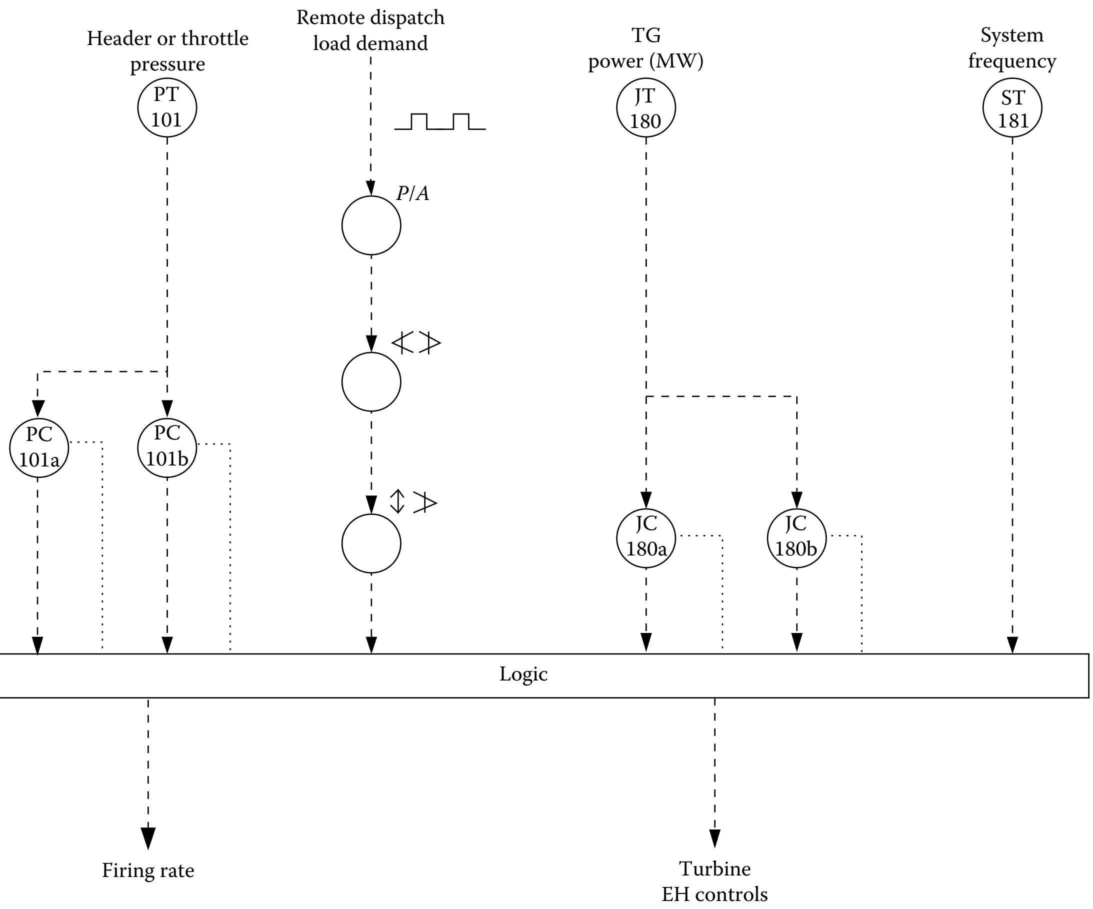

FIG. 8.6m
The load demand control architecture of an electric utility.

Turbine following is the most stable, but slowest mode; boiler following is faster, but limited to a maximum of about 2.5%/min for a controlled load change.[13] The coordinated control mode should be capable of 5%/min or better. Most control systems on large electric utility units are configured to allow selection from among the first two or three of these control modes, and, on some units, all four (some specific variant of the fourth scheme). Additionally, electric utility units usually have provision for the load demand to be generated remotely, referred to as remote dispatch.

A general, simplified structure for load demand control on a typical utility unit is illustrated in Figure 8.6m. The frequency input shown is sometimes necessary as an additional correction to prevent feedback control on turbine generator power (MW) or load demand (e.g., first-stage pressure) from counteracting the turbine generator's own power regulation response to frequency variations when connected to the electric power grid.

Firing Rate The firing rate signal becomes the set point for the fuel and air flow controls that make up the combustion control system. Additionally, *air/fuel ratio controls* provide for the correct stoichiometric amount of air to combust the fuel plus some percentage of excess air to account for nonideal mixing and imperfect combustion conditions. For safety purposes, fuel addition should be limited by the amount of available combustion air, and combustion air may need minimum limiting for flame stability.

Boiler outlet steam pressure is an indication of the balance between the inflow and the outflow of heat between energy supply and load. Therefore, by controlling the steam pressure, one can establish a balance between the demand for steam (process load) and the supply of steam (firing rate). A change in steam pressure will result from a change in firing rate only after a delay of a few seconds to a minute, depending on the boiler and the load level. Therefore, as will be examined in more detail, feedforward control, from load demand, is frequently employed to improve pressure control by adjusting firing rate (fuel and air) as soon as a load change is detected, instead of waiting for pressure to change first.

When more than one boiler is operated from the same master controller, the ability to individually bias and take control of each boiler should be provided, in addition to the ability to bias the master controller signal up or down when in automatic (Figure 8.6n).

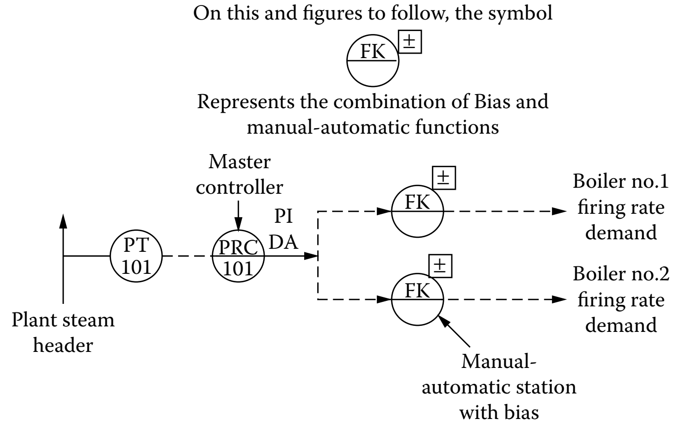

FIG. 8.6n
Load sharing controls among several boilers.

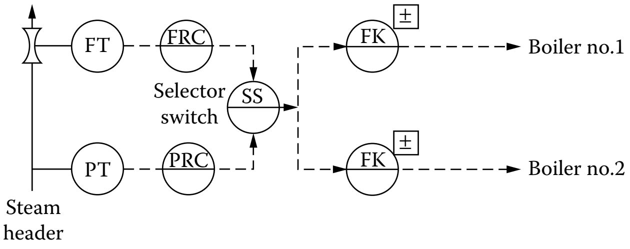

FIG. 8.6o
Boiler control with alternative pressure or flow master.

When steam pressure is controlled by other means, steam flow can be the master controller. If variations in fuel heating value are minor, the master flow controller shown might be eliminated and the master load signal generated by a manual loading station.

Situations may arise when it is desirable to have either flow or pressure control. In these cases, a master control arrangement, as shown in Figure 8.6o, can be used. Although it may appear simpler to switch transmitters, it is desirable to transfer the controller outputs so that the controller does not have to be returned each time the measurement is switched, and to make provision for initialization and bumpless transfer.

Typical proportional gain tuning setting for a pressure-controlled "master" is 6.25 (16% proportional band) and the typical integral setting is about 4.0 min (0.25 repeats per min). For a flow control "master" the comparable settings might be 1 for controller gain (100% proportional band) and 0.33 min for integral time (3.0 repeats per min). (See Sections 2.35 through 2.38 in Chapter 2 for details on controller tuning.)

A flow control master can be used for firing rate control on each of multiple boilers connected to a common header, with the flow controllers cascaded to the header pressure controller (Figure 8.6p).

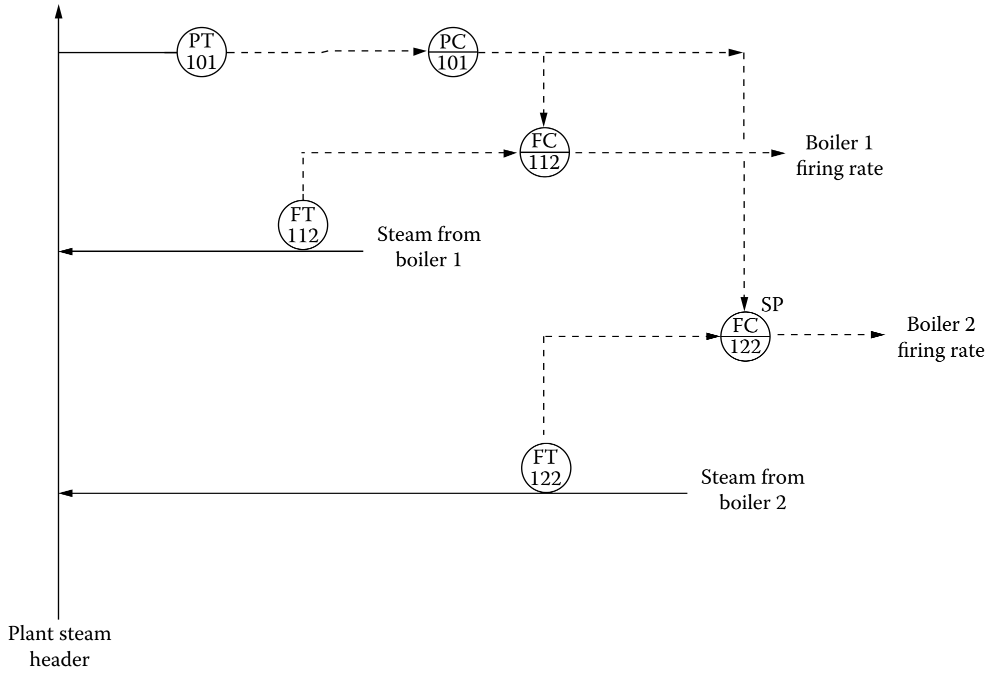

FIG. 8.6p
On multiple boilers connected to a common steam header, the header pressure controller can be the cascade master of a number of flow controllers, measuring the steam flows from the individual boilers.

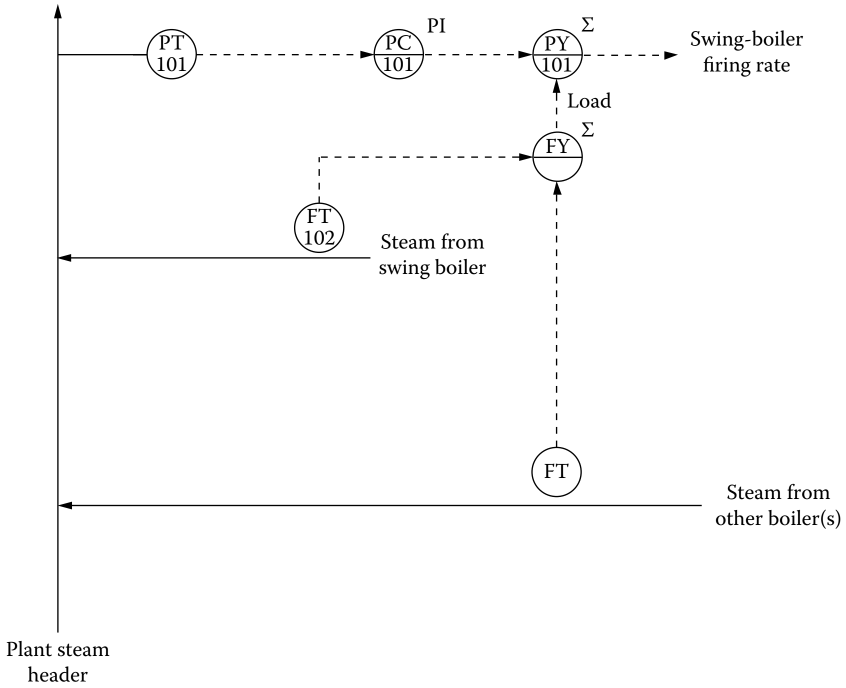

FIG. 8.6q
If the swing boiler is on header pressure control, the control dynamics can be improved by feedforwarding the measurement of the pressure master, by basing it on the sum of the steam flows from all the boilers.

Feedforward Control and Load Demand To improve the speed of response to load changes, a signal that represents load can be fed forward directly to firing rate. In the case of multiple boilers supplying steam to a header, load can be the total steam flow measurement from all boilers (Figure 8.6q) or the output of a high selector, selecting the highest of the steam flows. Steam flow measurements used in feedforward control should use mass flow detectors, either from a multivariable transmitter that computes mass flow or from a mass flow sensor; see Equation 8.6(2) and the paragraph titled The Role of Sensors.

If a boiler's own outlet flow is used as the load to feed forward to firing rate, the result will be positive feedback due to the impact of firing rate on flow. Used in this scenario, steam flow is called a *regenerative* load signal, and it will tend to cause instability and poor control. Even when combined with other steam flow measures (by average or high select) there will remain some amount of positive feedback.

On large electric utility boilers, due to the high temperatures and pressures, and large line sizes, steam flow measurement is often not provided at all. In that case, a good surrogate measure of load is the steam turbine first-stage shell pressure. The flow through the turbine varies almost linearly with first-stage shell pressure (Figure 8.6r).

In some cases (not to include sliding mode or free pressure control), it is also possible to use turbine inlet governor valve positions as an indication of load. However, first-stage shell pressure is generally preferred. These surrogate load parameters will behave more like *nonregenerative* signals, less coupled to boiler firing rate than boiler outlet steam flow. Therefore, even if steam flow is available it will be preferable in single-boiler arrangements to incorporate a surrogate load measurement for the purpose of feedforward firing rate control.

Feedforward Control and Stability The actual steam flow at any point is not necessarily a true indication of demand. For example, an increase in steam flow caused by increased firing should not be interpreted as a load increase—this would create a positive feedback loop, capable of destabilizing the boiler. According to Shinskey, the true load on a boiler can be approximated by $\sqrt{h/p}$, where h is the differential developed by a flow element and p is the steam pressure. Figure 8.6s describes a boiler-pressure control system using this type of feedforward model. Fuel flow is set proportionally to the estimate of load $\sqrt{h/p}$. Dynamic compensation is applied in the form of a lead-lag function to help overcome the heat capacity in the boiler.

The pressure controller adjusts the ratio of firing rate to estimated load, to correct for inaccuracy of the model and variations in heat of combustion of the fuel. The multiplier also changes the gain of the pressure feedback loop proportional to load. This feature is valuable in that boilers seem more difficult to control at lower loads because of lower velocities.

In the firing rate control system shown in Figure 8.6s, the loops 101 and 102 measure the pressure and flow of the generated steam, respectively. The flow transmitter (DPT-102)

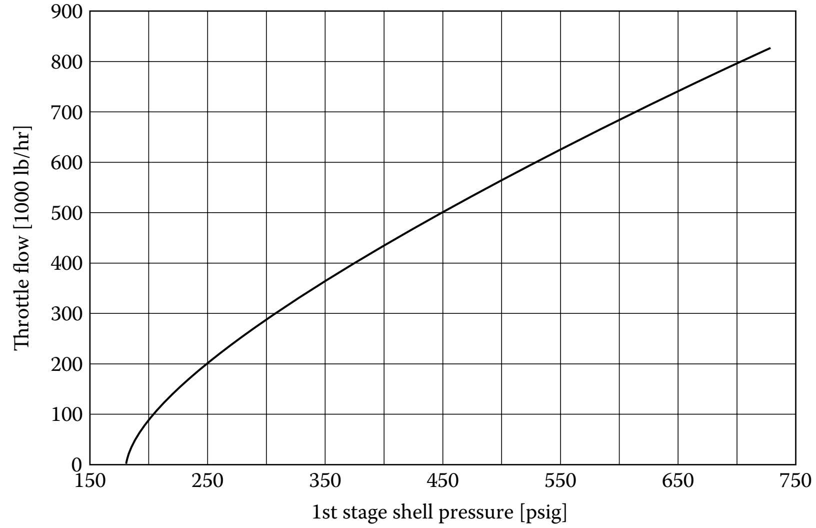

FIG. 8.6r
The relationship between the first-stage shell pressure of a steam turbine and the load (throttle flow); data taken from a typical 45 MW extraction (back-pressure) steam turbine.

is a high rangeability and linear device, capable of accurate measurements even at low loads. The firing rate demand signal is generated in a feedback manner by the pressure controller PIC-101.

In order to speed up the response of this loop to load changes, a feedforward trim is added. This trim is based on steam flow, because this flow is the first to respond to load changes. Therefore, as soon as the demand for steam changes, FY-102 will trim the firing demand signal, without waiting for the steam pressure to change. The dynamics of FY-102 are adjusted to reflect the time constants of the boiler, recognizing the time displacement between a change in firing rate and the resulting change in the rate of steam generation some time later.

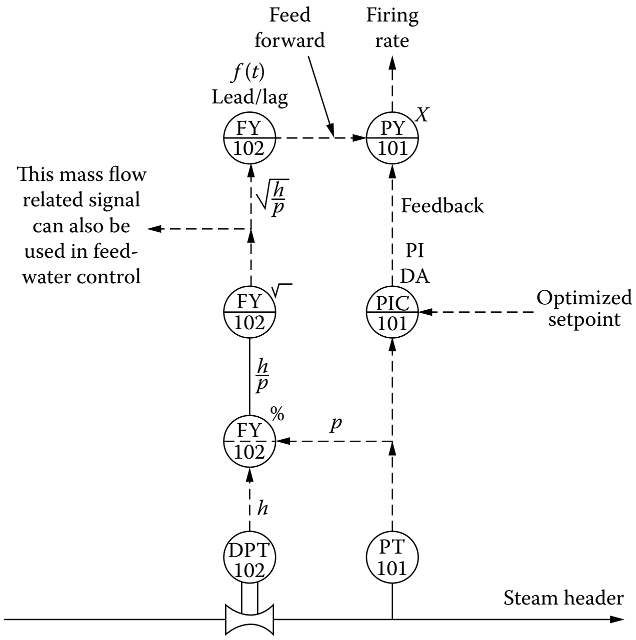

FIG. 8.6s
Firing rate determination using feedforward loop with feedback trim.

Fuel Controls

Measurable Fuels The primary boiler fuels are coal, oil, and gas, but there are a large variety of auxiliary fuels, such as waste gases, waste sludges, and waste wood products (bark, sawdust, hogged fuel, and coffee grounds). In many cases, these auxiliary fuels are dumped to the boiler plant on an uncontrolled basis for immediate burning. There are myriads of these combinations, and only the more common fuel control problems will be covered in the discussion to follow.

The control of gas and oil fuels tends to be straightforward, because they are easily measured and can be regulated with a control valve in the fuel line. If closed-loop control of flow is not available, then a valve positioner capable of providing a linear relationship between flow and control signal is desirable (Figure 8.6t).

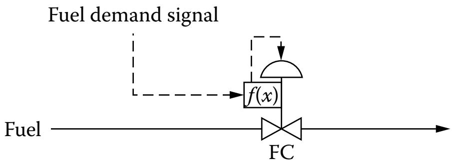

FIG. 8.6t
Positioner used to maintain linear relationship between demand and flow.

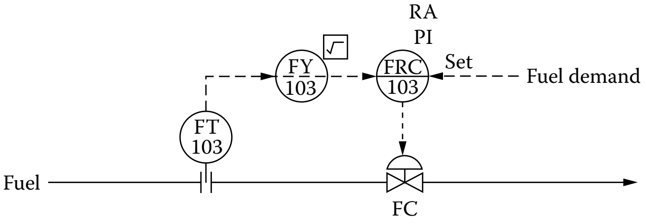

FIG. 8.6u
Fuel flow controller is used to keep demand and flow in linear relationship.

A flow control loop (preferred) is the more usual means of control, providing more precise linearization and immediate response to flow disturbances (Figure 8.6u). In cases in which better than 3:1 turndown and high measurement accuracy is desired, the Coriolis mass flow sensors should be used instead of orifices.

When it is desired to fire the fuels in a predetermined ratio to each other regardless of load, a manually adjustable signal splitter can be used, as shown in Figure 8.6v. The most precise and complex method of ratioing fuel (not shown) is to split the demand signal and send that to individual flow control loops. If the fuel is a gas at variable pressure, a pressure control valve is frequently installed upstream to the flow sensor, as shown in Figure 8.6v.

Both valves affect both variables (pressure and flow), and therefore they will interact. In order to eliminate the resulting oscillations, one should either leave the pressure unregulated and pressure-compensate the flow sensor or assign less pressure drop to the pressure control valve than to the flow control valve (thereby using a larger valve for pressure control than for flow control). Because the burner back-pressure will increase as flow increases, the available pressure differential for the flow control valve will decrease as the flow rises. In order to obtain an approximately linear relationship between fuel flow and valve position, an equal-percentage valve is needed.

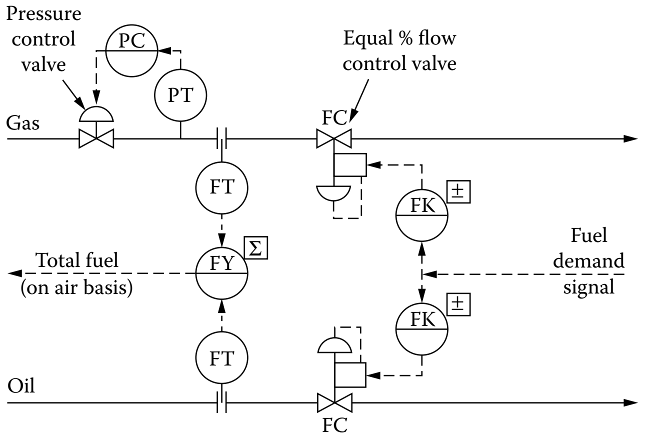

FIG. 8.6v
In this configuration, the fuel demand is manually split between the two fuels on an open-loop basis.

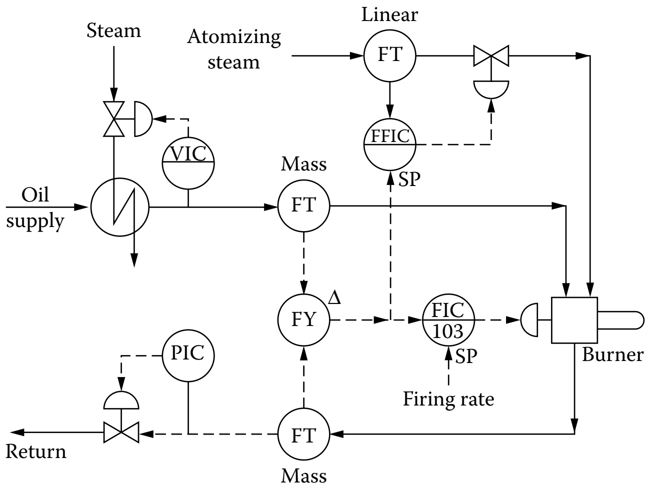

FIG. 8.6w
Oil flow control used for a recirculating burner that is provided with steam atomization.

In the case of oil fuels, proper atomization at the burner, and therefore complete combustion, will be achieved only if the oil is kept at constant pressure and viscosity. When heavy residual oils (e.g., no. 2 and no. 6 fuel oil) are burned, they must be continuously circulated past the burner and back (Figure 8.6w).

The difference between the readings of two Coriolis mass flowmeters indicates the net flow to the burner. The burner back-pressure is controlled by the control valve in the recirculating line, whereas the flow controller set point is adjusted by the firing rate demand signal. The firing rate is controlled by an alteration in the opening of the burner orifice. Atomizing steam is ratioed to the firing rate, and the heating steam is modulated to keep the fuel viscosity constant.

Figure 8.6x illustrates the controls required when the fuel demand is split between two fuels on a closed-loop (automatic)

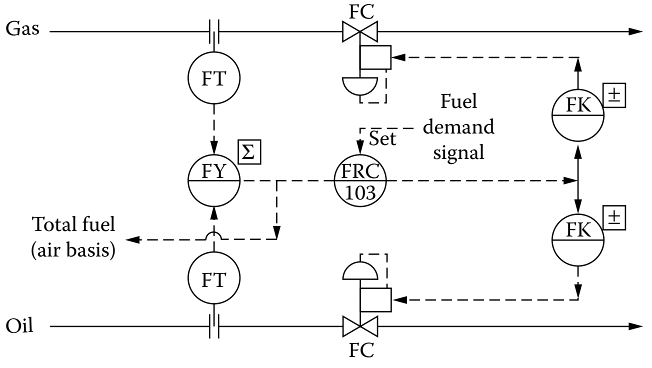

FIG. 8.6x
Fuel demand split between fuels on closed-loop basis.

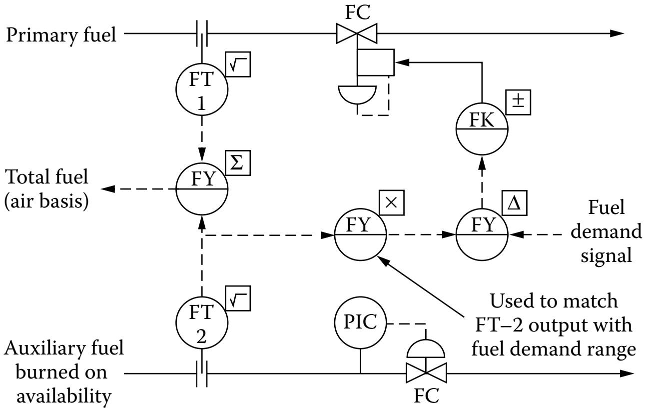

FIG. 8.6y
In this open-loop control configuration, the auxiliary fuel is burned on an uncontrolled-availability basis.

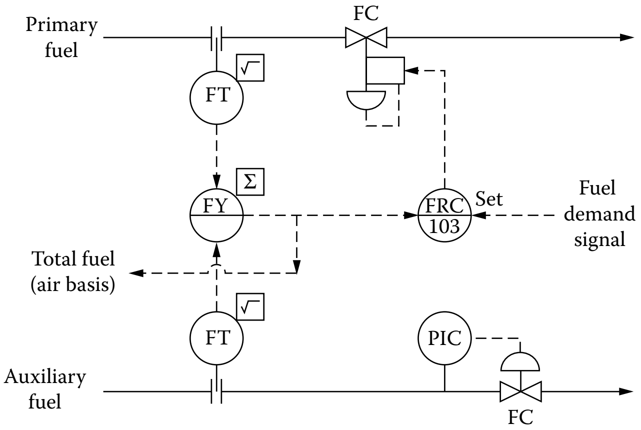

FIG. 8.6z
In this closed-loop control configuration the auxiliary fuel is burned on an uncontrolled-availability basis, while the flow controller throttles the primary fuel flow to meet the total demand.

basis. The instruments shown ("biasing stations") provide the means of manual control plus the ability of automatic control, with bias of one fuel with respect to the other.

Because one of the requirements ultimately is to have fuel ratioed to combustion air, any totalization of fuel for control purposes should be on an "air required for combustion" basis. If totalization is needed on any other basis, such as BTU for other purposes, a separate totalizer should be used.

Waste or Auxiliary Fuel Controls When auxiliary fuel is burned on an uncontrolled-availability basis, the fuel and air control system needs to be able to accommodate sudden changes in auxiliary flow without upsetting the master controller. The master controller should be designed and used to respond to total load demands only and not to correct for fuel upsets. A typical fuel control system for accommodating variations in auxiliary fuel without upsetting the master is shown in Figure 8.6y.

In the basis system without auxiliary fuel, the signal is relayed directly to the control valve. Addition of auxiliary fuel shifts the primary fuel control valve opening to prevent fuel variations from affecting overall boiler performance. A more precise system is shown in Figure 8.6z. Here, the flow controller adjusts the primary fuel control valve to satisfy total fuel demand and prevents auxiliary fuel variations from upsetting the master controller.

Figure 8.6aa describes a slightly more advanced system, in which the allowable maximum percentage of waste fuel that can be burned is set on the ratio relay FY-1. This ratio must be set under 100% if the heating value of the waste is so low that it could cause flameout if not enriched by supplemental fuel. For proper operation, the subtractor FY-2 must be scaled with the flowmeter ranges taken into consideration, and further scaling is required if the heat flow range of the total heat demand does not match that of the waste fuel flowmeter. When waste fuel gas availability becomes limited, waste fuel gas pressure will drop and PY-3 will select it for control, thereby overriding the waste flow controller. FY-2 will respond to this by increasing the supplemental fuel flow.

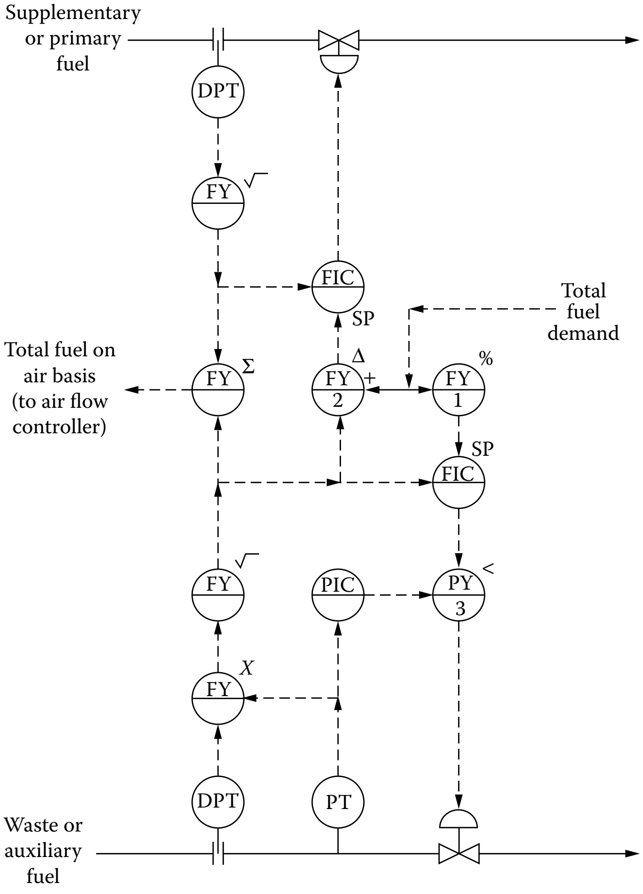

FIG. 8.6aa
Automatic control system for burning limited-availability waste fuel up to preset maximum percentage in the total mixture.

Closed-loop control will give greater precision and better linearization, but the performance can be limited by poor hardware selection or poor installation practices. An example of the first case is the problem of transmitter rangeability if orifices are used instead of turbine or mass flowmeters. An example of poor installation practices is the case of long transmission lines being allowed to introduce dead time into the loop because pneumatic leads were installed without boosters.

Whatever type of fuel control is used, the maximum flexibility in design will be present if all flow signals are linear and all control valve characteristics are also linear. In this manner, the various flows and signals can be combined, subtracted, multiplied, or divided to produce the desired control. One optimal condition is to have the total fuel demand signal linear, with fuel totalized on a basis of required combustion air. The other desired end condition is to have the total fuel control capacity maximum at a value approximately 10% greater than that required for maximum boiler-capacity. This excess is necessary for control flexibility at maximum boiler load. Additional excess capacity should not be considered, because it reduces turndown capability.

Unmeasured Fuels Coal can be an unmeasured fuel. In such cases coal control systems are open loop, wherein a control signal positions a coal-feeding device directly. This is the case with a spreader stoker or cyclone furnace or indirectly with pulverized coal.

A spreader stoker consists of a coal hopper on the boiler front with air jets or rotating paddles that flip the coal into the furnace, where a portion burns in suspension and the rest drops to a grate. Combustion air is admitted under the grate. There is no way to control fuel to a spreader stoker except in an open-loop manner by positioning a feeder lever that regulates coal to the paddles.

In pulverized coal-fired boilers, the coal is ground to a fine powder and is carried into the furnace by an air stream. There are normally two or more pulverizers (in parallel) per boiler. Pulverized coal flow is regulated at the pulverizer, and each manufacturer has a different design requiring different controls. One control arrangement is shown in Figure 8.6bb. Here, the primary air comes from a pressure fan that blows through the pulverizer, picking up the coal and transporting it to the furnace.

In addition to the controls shown, an air temperature control is required. In this loop, cold and hot combustion air is mixed ahead of the primary air fan to control the temperature of the coal air mixture in the pulverizer. This control is necessary to maintain a maximum safe operating temperature in the pulverizer. This is a simple feedback loop, usually involving proportional control only.

A control arrangement for a bowl-type pulverizer is shown in Figure 8.6cc. In this type of pulverizer, the air fan sucks air through the pulverizers with the fan (called an exhauster fan) located between the pulverizer and the burners. The coal-air temperature loop is similar to the one described in Figure 8.6bb.

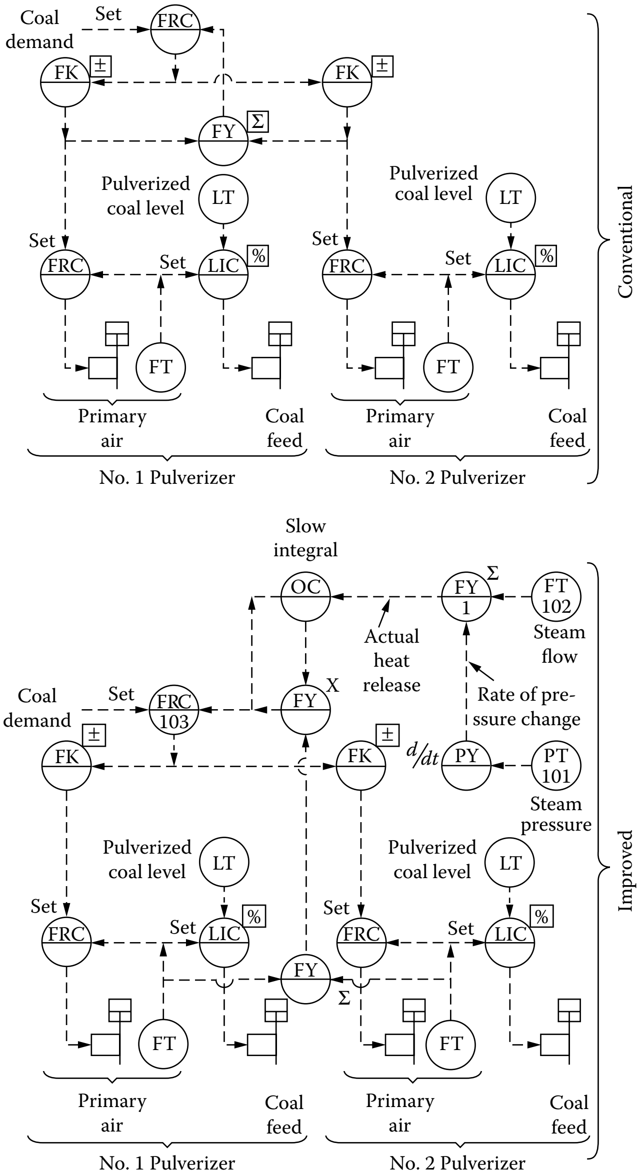

FIG. 8.6bb
Conventional (top) and advanced (bottom) control of ball-type pulverizers.

The control of a ball mill-type pulverizer is again different from a control standpoint. This is shown in Figure 8.6dd, including the application of manual compensation for the number of pulverizers in service.

The ball mill level measurement shown in Figure 8.6dd is normally based on the differential pressure value taken from the dip-tube. This measurement is inaccurate during start-up and during load swings due to large coal particle size. A more delicate control approach maintains mill motor

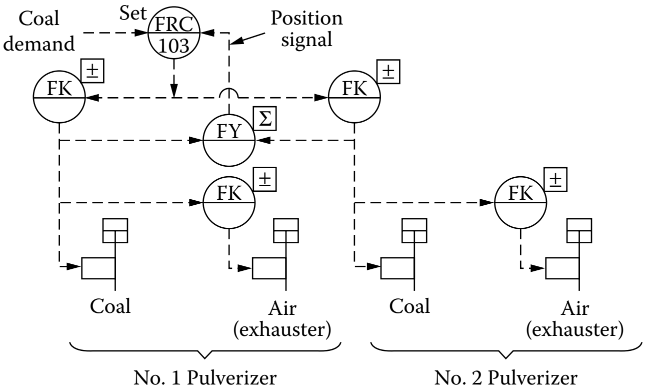

FIG. 8.6cc
Coal fuel control using bowl-type dual pulverizers.

power levels around operator-selected set points. A sonic signal taken from a microphone is often required to assist the control. The underlying mechanism is that the amount of coal charge in the ball mill is functionally related to the mill motor power level and the mill noise level. The weight of the coal charge can be controlled directly through modulation of the associated mill feeder(s).

A simplified control flow diagram is illustrated in Figure 8.6ee. The system utilizes the mill power level (kilowatts), the mill sound level (decibels), and the operator-selected set point (kilowatts) as the principal inputs to the mill process controller (MIC-150). Boiler fuel demand (or steam flow) can be used by the control system as a feedforward signal to anticipate major changes in mill load demand, and to preposition the mill feeder(s) at the proper steady-state speed.

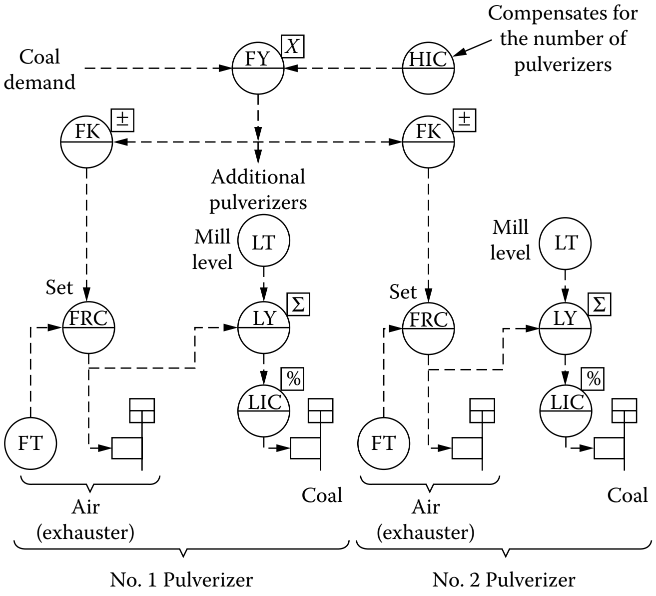

FIG. 8.6dd
Ball mill-type pulverizer controls.

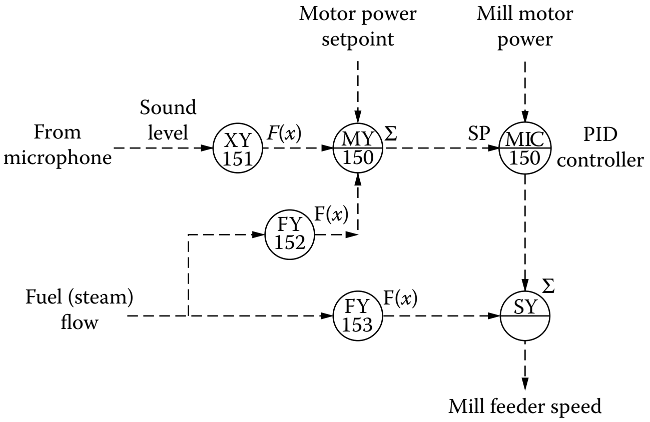

FIG. 8.6ee
Alternative, improved ball mill pulverizer control that utilizes both mill power level and sound level.

Metered Coal Controls When the flow of coal is controlled, it is done at the inlet to the mill, as illustrated in Figure 8.6ff. The capacity of the pulverizer contributes a delay of a few seconds to several minutes, depending on the design of the mill. Hammer mill delays are the shortest, whereas ball and roller mill delays can reach several minutes. If the delay is less than 1 min, a corresponding delay can be inserted into the coal flow transmitter output (FY-1), which will enable the loop to overcome this problem.

If the mill delay exceeds 1 min, the flow of the primary air that conveys the pulverized coal must be manipulated as a function of coal demand. Because the coal loading of the air is not uniform, Shinskey recommends the improvements noted in Figure 8.6bb. These include the determination of the

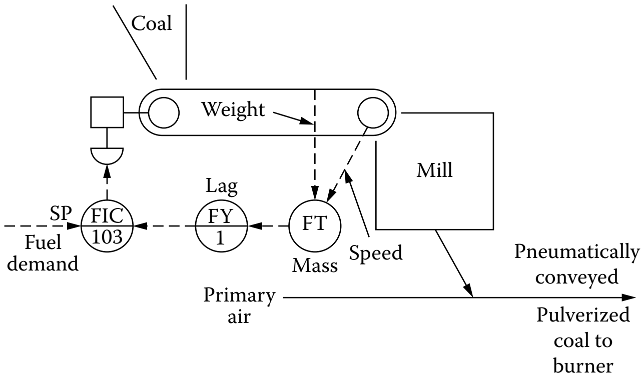

FIG. 8.6ff
Compensation for mill capacity.

actual heat release based on steam reading (FY-1 in Figure 8.6bb) and the slow integral correction of the total flow of primary air until the estimated and actual heat release are matched.

Highly Variable Fuels Solid fuels, such as coal, biomass, and municipal waste, tend to vary significantly in heating calorific value. This variation can be detected and compensated for by comparing the apparent *heat release* of the boiler process to the apparent heat input and adjusting the fuel flow accordingly to achieve the desired heat input. One approach to quantifying heat release is to sum the load indication (e.g., outlet steam flow or turbine first-stage pressure) with the rate of change of pressure in the drum.

Figure 8.6bb shows the use of steam flow (FT-102) for load. PT-101 and PY in Figure 8.6bb are the steam drum pressure and its rate of change. In effect, this is summing the rate of energy out with the rate of change of energy storage (FY-1, Figure 8.6bb). This heat-release measure is then compared to the current compensated fuel flow and the difference, considered to be the error between the two due to heating value variation in the fuel, is integrated slowly and multiplied by the fuel flow, producing an adjusted process variable for the fuel controller.

Air flow Measurement and Control

Combustion air for steam boilers may be supplied by induced draft (suction fan at boiler outlet or stack draft), forced draft (pressure fan at inlet), or a combination of forced and induced draft known as balanced-draft fans. With balanced-draft boilers, a slight negative pressure is maintained in the furnace.

In the control of combustion air (if there are both forced- and induced-draft fans), one fan should be selected for basic control of air flow and the other assigned to maintaining the draft pressure in the furnace. The following discussion is based on a single air flow source (fan) per boiler. Balanced draft and its effects on air flow control will be covered later in this section.

For successful control of the air/fuel ratio, combustion air flow measurement is important; refer back to Boiler Equipment, The Role of Sensors for detailed discussion on air flow measurement issues and techniques (Figure 8.6b).

Primary flow elements in the ducts, as well as the furnace pressure transmitter, will frequently produce noisy signals because of pulsation from the pumping action of the fans or from the combustion process. Provision should be made for dampening the flow signals to facilitate more optimum tuning of the controllers. Normal differential pressure ranges for these measurements are between 1 in. (25.4 mm) H_2O and 6 in. (152.4 mm) H_2O for conventional sensors and as low as 0.1 in. (2.54 mm) H_2O for area-averaging pitot stations.

Damper and Fan Controls Control devices for boiler air flow control on pneumatic installations are double-acting pistons, but in some cases electric motors are also used. In either case, a linear relationship is required between control signal and combustion air flow. Characteristics of most constant-speed fans or dampers approximate those given in Figure 7.1a in Section 7.1 in Chapter 7, and the desired relationship is linear.

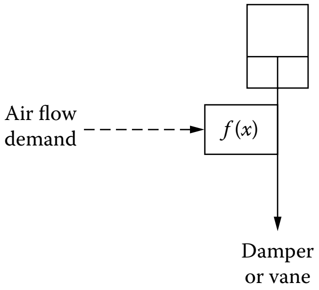

FIG. 8.6gg
Open-loop air control with single damper.

The relationship between open- and closed-loop control that was noted in connection with fuel control also applies to air flow control. Closed-loop air control is more precise and is self-linearizing, if the integrated system does not compare air flow with fuel flow (or as inferred from steam flow) directly in a ratio or difference controller.

Open-loop air control variations that may be used depending on the arrangement of fans are as shown in Figures 8.6gg through 8.6kk. Figure 8.6gg illustrates a single-damper-controlled open loop.

Figure 8.6hh shows a combination of damper and speed control. A system of this sort is often necessary to increase turndown (rangeability) where fan speed is variable. Good response of air flow based on fan speed adjustment alone is normally not attainable below approximately 1/3 maximum speed. Depending on fan design, this may correspond to 50% of boiler capacity. Use of a damper in combination with speed adjustment allows further turndown, because fan speed is blocked at approximately 1/3 speed. Split ranging, as shown in Figure 8.6hh, conserves steam or fan power.

As a result of inlet damper leakage that is normally present, it may be necessary for wide-range low-load or start-up control to parallel inlet and outlet dampers. To save fan

power, the inlet damper may be operated over the full 3–15 PSIG (0.2–1.0 bar) range, whereas the discharge damper can be fully open at 3 PSIG (0.2 bar) and closed at 9 PSIG (0.6 bar).

As shown in Figure 8.6ii, when two fans are operated in parallel or on single-fan operation, the idle fan should have its damper closed to prevent recirculation from the operating fan.

When one fan of a two-fan system is switched on or off, considerable manual operation is required to prevent serious air flow upsets. The system shown in Figure 8.6ii eliminates this problem by automatically compensating the operating fan damper position as the parallel fan is started up or shut down. Separate discharge dampers may be used for shut-off purposes, supplementing the interlocks shown.

Closed-loop versions of the loops illustrated in Figures 8.6gg, 8.6hh, and 8.6ii would consist of flow controllers with air flow feedback superimposed on the components shown. For example, Figure 8.6jj shows the closed-loop version of Figure 8.6ii.

Furnace Draft Control

Whenever both forced draft and induced draft are used together, at some point in the system the pressure will be the same as that of the atmosphere. Balanced-draft boilers are not normally designed for positive furnace pressure. Therefore, the furnace pressure must be negative to prevent hot gas leakage. Excessive vacuum in the furnace, however, produces heat losses through air infiltration. The most desirable condition is thus one in which there is a very slight (approximately 0.1 in. H_2O, or 0.025 kPa) negative pressure at the top of the furnace.

Pressure taps for measuring furnace pressure may be located some distance below the top. Because of the chimney effect of the hot furnace gases, pressures measured below the top of the furnace will be lower by approximately 0.01 in. H_2O per foot (0.008 kPa/m) of elevation. Thus, if the pressure tap is 20 ft (6 m) below the top of the furnace, the desirable pressure to maintain is approximately 0.3 in. H_2O (0.075 kPa) vacuum.

In the case of a balanced-draft boiler, the maintenance of constant furnace pressure or draft keeps the forced and induced draft in balance. The purpose of this balance is to share properly the duty of providing combustion air and to protect furnaces not designed for positive-pressure operation.

The measurement of furnace draft produces a noisy signal, limiting the loop gain to relatively low values. In order to provide control without undue noise effects, it is desirable to use a full span of approximately 4–5 in. H_2O. This is normally a compound range, such as +1 to –4, or +2 to –3, in. H_2O (+0.25 to −1 kPa, or +0.5 to –0.75 kPa). Even with this span and with a set point of –0.1 to –0.3 in. H_2O (0.025–0.075 kPa), the controller gain can still not exceed 1.0. In some cases, it may be necessary to use integral control only to stabilize the loop.

Air Flow and Furnace Pressure Interaction Additionally, stability problems and interactions may occur in the overall system because of measurement lags. It is recommended that the pressure transmitter connections to the boiler furnace be made with pipe at least 1 in. (25 mm) in diameter because of the very low pressures involved. If the distance is less than 25 ft (7.5 m), ¾ in. (18.75 mm) pipe may also be used.

Either the forced- or the induced-draft fan can be used to control the furnace draft, with the other fan performing the basic air flow control function. Interaction cannot be completely eliminated between these two loops, but it can be minimized by system designs such as those shown in Figures 8.6kk and 8.6ll.

The common rule is that air flow should be measured and controlled on the same side (air or combustion gas) of the furnace to minimize interaction between the flow and pressure loops.

If the combustion air is preheated, then its temperature will vary substantially and compensation is needed. The mass flow of air is related to $\sqrt{h / T}$, where h is a differential across a restriction and T is absolute temperature. This loop is shown in Figure 8.6ll, together with an excess oxygen trim on the air flow controller. Pressure and temperature compensation in engineering units can be carried out in the control system with Equation 8.6(2) (drop all but the temperature term if only temperature compensation is required).

The air flow and furnace pressures interact similarly to the phenomenon in Figure 8.6v. Because in the case of air flow controls the dampers are the same size and therefore their pressure drops are similar, decoupling needs to be applied. One might reduce interaction by connecting the two dampers (or fans) in parallel and using the furnace pressure as a trimming signal. (This can also be used to overcome problems resulting from noisy furnace pressure signals and slow response caused by the series relationship between flow and pressure loops.) This control system is illustrated in Figure 8.6ll.

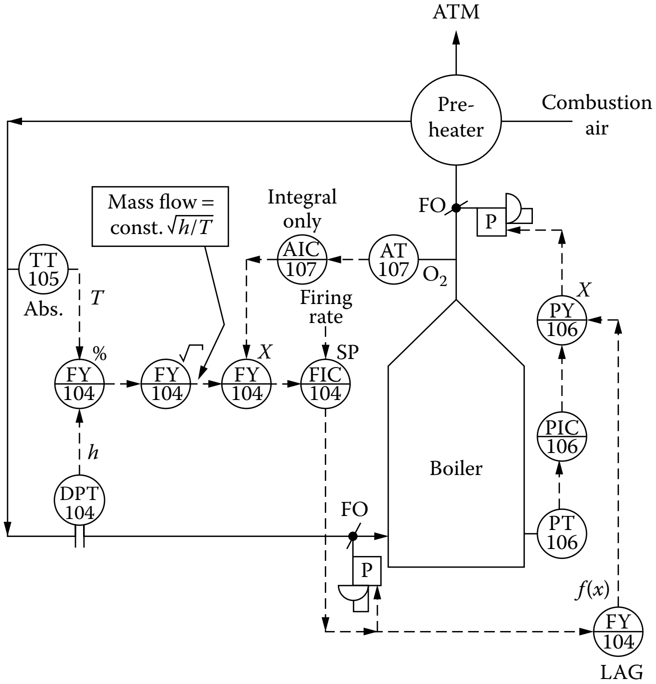

FIG. 8.6ll
Parallel control of inlet and outlet dampers reduces interactions.

In this arrangement the air flow controls move both dampers equally, and the furnace pressure corrects for any mismatch. The furnace pressure might respond faster to a change in the downstream damper opening, and therefore a dynamic lag (FY-104) is provided. In the combined control system shown in Figure 8.6l, basically the same control concept is implemented as shown in Figure 8.6ll. The main difference is that in Figure 8.6l, the furnace draft is throttled not by a discharge damper, but by an induced-draft fan.

The air flow is also detected by a high rangeability flowmeter (FT-104) that is compensated for temperature variations to approximate mass flow.[14] The air/fuel ratio is adjusted by applying a gain to the air flow (FY-104). The continuous optimization of this ratio is one of the major tools of boiler optimization.

The air flow controller throttles the speed or inlet vanes of the forced-draft fan and the signal to the induced-draft fan in a feedforward manner. Dynamic compensation is provided by the lag module (FY-104). Thus, as soon as the air inflow to the furnace is changed, the outflow will also start changing. This improves the control of the furnace draft, as the feedback pressure controller (PIC-106) will need only to trim the feedforward signal at PY-106 to account for measurement and other errors.

Air/Fuel Ratio

When the controls for air/fuel ratio are considered, one point is very important. Because of the combustion gas velocity through the boiler, for safety reasons the fuel/air ratio should be maintained on an instant-by-instant rather than a time-averaged basis.

As a general rule (except for the case of very slow-changing boiler loads), fuel and air should be controlled in parallel rather than in series. This is necessary because a lag of only 1 or 2 sec in measurement or transmission will seriously upset combustion conditions in a series system. This can result in alternating periods of excess and deficient combustion air. Consequently, the discussion here will be limited to parallel air and fuel control systems.

The simplest control of air/fuel ratio is with a system calibrated in parallel, with provision for the operator to make manual corrections (Figure 8.6mm). In this system, the operator uses the bias provision of the panel station (FK) to compensate for variations in fuel pressure, temperature, or heating value or for air temperature, humidity, or other factors. A system of this sort should be commissioned with detailed testing at various loads for characterizing and matching fuel

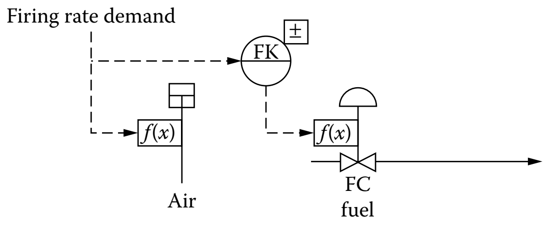

FIG. 8.6mm
Simple parallel air/fuel ratio system.

and air control devices. In addition, simple systems of this type should be adjusted for higher excess air, because they have no means of automatically compensating for the fuel and air variations.

The next higher degree of sophistication is a system with simple proportional compensation. This can be done by balancing fuel burner pressure to the differential produced between windbox and furnace pressures.

In the system shown in Figure 8.6nn, the burner fuel apertures are used to measure fuel flow, and the burner air throat is used as a primary element to detect air flow. There is no square-root extraction (such extraction would not show true flows because of the nature of the primary elements), and therefore the actual controller loop gain changes with load (capacity). Rangeability is limited unless there are multiple burners that can be put into or taken out of service.

The arrangement in this control system can also be reversed, with firing rate demand directly adjusting the fuel and the correction control being on air flow. This choice will be considered later in this section.

As boilers become larger, the need for precise control becomes greater, together with the potential for savings. The following series of diagrams represents further degrees of system sophistication.

The system in Figure 8.6oo is quite similar to that shown in Figure 8.6nn, except that here flows are measured as accurately as possible and are used in a flow controller to readjust the primary loop through the combining relay (FY).
