DVD ROM

Nof
Editor

Springer

Springer Handbook of Automation

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical sciences and engineering. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of physical and technical information.

The volumes are designed to be useful as readable desk reference books to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook of Automation

Foreword

Automation Is for Humans and for Our Environment

Preparing to write the Foreword for this outstanding *Springer Handbook of Automation*, I have followed Shimon Y. Nof's statement in his Preface vision: "The purpose of this Handbook is to understand automation knowledge and expertise for the solution of human society's significant challenges; automation provided answers in the past, and it will be harnessed to do so in the future." The *significant challenges* are becoming ever more complex, and learning how to address them with the help of automation is significant too. The publication of this *Handbook* with the excellent information and advice by a group of top international experts is, therefore, most timely and relevant.

The core of any automatic system is the idea of feedback, a simple principle governing any regulation process occurring in nature. The process of feedback governs the growth of living organisms and regulates an innumerable quantity of variables on which life is based, such as body temperature, blood pressure, cells concentration, and on which the interaction of living organisms with the environment is based, such as equilibrium, motion, visual coordination, response to stress and challenge, and so on.

Humans have always copied nature in the design of their inventions: feedback is no exception. The introduction of feedback in the design of man-made automation processes occurred as early as in the golden century of Hellenistic civilization, the third century BC. The scholar Ktesibios, who lived in Alexandria circa 240–280 BC and whose work has been handed to us only by the later roman architect Vitruvius, is credited for the invention of the first feedback device. He used feedback in the design of a water clock. The idea was to obtain a measure of time from the inspection of the position of a floater in a tank of water filled at constant velocity. To make this simple principle work, Ktesibios's challenge was to obtain a constant flow of water in the tank. He achieved this by designing a feedback device in which a conic floating valve serves the dual purpose of sensing the level of water in a compartment and of moderating the outflow of water.

The idea of using feedback to moderate the velocity of rotating devices eventually led to the design of the centrifugal governor in the 18th century. In 1787, T. Mead patented such a device for the regulation of the rotary motion of a wind mill, letting the sail area be decreased or increased as the weights in the centrifugal governor swing outward or, respectively, inward. The same principle was applied two years later, by M. Boulton and J. Watt, to control the steam inlet valve of a steam engine. The basic simple idea of proportional feedback was further refined in the middle of the 19th century, with the introduction of integral control to compensate for constant disturbances. W. von Siemens, in the 1880s, designed a governor in which integral action, achieved by means of a wheel-and-cylinder mechanical integrator, was deliberately introduced. The same principle of proportional and integral feedback gave rise, by the turning of the century, to the first devices for the automatic steering of ships, and became one of the enabling technologies that made the birth of aviation possible. The development of sensors, essential ingredients in any automatic control system, resulted in the creation of new companies.

Alberto Isidori
President IFAC

The perception that feedback control and, in a wider domain, automation were taking the shape of an autonomous discipline, occurred at the time of the second world war, where the application to radar and artillery had a dramatic impact, and immediately after. By the early 1950s, the principles of this newborn discipline quickly became a core ingredient of most industrial engineering curricula, professional and academic societies were established, textbooks and handbooks became available. At the beginning of the 1960s, two new driving forces provoked an enormous leap ahead: the rush to space, and the advent of digital computers in the implementation of control system. The principles of optimal control, pioneered by R. Bellman and L. Pontryagin, became indispensable ingredients for the solution of the problem of soft landing on the moon and in manned space missions. Integrated computer control, introduced in 1959 by Texaco for set point adjustment and coordination of several local feedback loops in a refinery, quickly became the standard technique for controlling industrial processes.

Those years saw also the birth of an International Federation of Automatic Control (IFAC), as a multinational federation of scientific and/or engineering societies each of which represents, in its own nation, values and interests of scientists and professionals active in the field of automation and in related scientific disciplines. The purpose of such Federation, established in Heidelberg in 1956, is to facilitate growth and dissemination of knowledge useful to the development of automation and to its application to engineering and science. Created at a time of acute international tensions, IFAC was a precursor of the spirit of the so-called Helsinki agreements of scientific and technical cooperation between east and west signed in 1973. It represented, in fact, a sincere manifestation of interest, from scientists and professionals of the two confronting spheres of influence in which the world was split at that time, toward a true cooperation and common goals. This was the first opportunity, after the Second World War that scientists and engineers had of sharing complementary scientific and technological backgrounds, notably the early successes in the space race in the Soviet Union and the advent of electronic computers in the United States. The first President of IFAC was an engineer from the Unites States, while the first World Congress of the Federation was held in Moscow in 1960. The Federation currently includes 48 national member organizations, runs more than 60 scientific Conferences with a three-year periodicity, including a World Congress of Automatic Control, and publishes some of the leading Journals in the field.

Since then, three decades of steady progresses followed. Automation is now an essential ingredient in manufacturing, in petrochemical, pharmaceutical, and paper industry, in mining and metal industry, in conversion and distribution of energy, and in many services. Feedback control is indispensable and ubiquitous in automobiles, ships and aircrafts. Feedback control is also a key element of numerous scientific instruments as well as of consumer products, such as compact disc players. Despite of this pervasive role of automation in every aspect of the technology, its specific value is not always perceived as such and automation is often confused with other disciplines of engineering. The advent of robotics, in the late 1970s, is, in some sense, an exception to this, because the impact of robotics in modern manufacturing industry is under the eyes of everybody. However, also in this case there is a tendency to consider robotics and the associated impact on industry as an implementation of ideas and principles of computer engineering rather than principles of automation and feedback control.

In the recent years, though, automation and control have experienced a third, tumultuous expansion. Progresses in the automobile industry in the last decade have only been possible because of automation. Feedback control loops pervade our cars: steering, breaking, attitude stabilization, motion stabilization, combustion, emissions are all feedback controlled. This is a dramatic change that has revolutionized the way in which cars are conceived and maintained. Industrial robots have reached a stage of full maturity, but new generations of service robots are on their way. Four-legged and even two-legged autonomous walking machines are able to walk through rough terrains, service robot are able to autonomously interact with uncertain environment and adapt their mission to changing tasks, to explore hostile or hazardous environments and to perform jobs that would be otherwise dangerous for humans. Service robots assist elderly or disabled people and are about to perform routine services at home. Surgical robotics is a reality: minimally invasive micro robots are able to move within the body and to reach areas not directly accessible by standard techniques. Robots with haptic interfaces, able to return a force feedback to a remote human operator, make tele-surgery possible. New frontiers of automation encompass applications in agriculture, in recycling, in hazardous waste disposal, in environment protection, and in safe and reliable transportation.

At the dawn of the 20th century, the deterministic view of classical mechanics and some consequent positivistic philosophic beliefs that dominated the 19th century had been shaken by the advent of relativistic physics. Today, after a century dominated by the expansion of technology and, to some extent, by the belief that no technological goal was impossible to achieve, similar woes are feared. The clear perception that resources are limited, the uncertainty of the financial markets, the diverse rates of development among nations, all contribute to the awareness that the model of development followed in so far in the industrialized world will change. Today's wisdom and beliefs may not be the same tomorrow. All these expected changes might provide yet another great opportunity for automation. Automation will no longer be seen only as *automatic production*, but as a complex of technologies that guarantee reliability, flexibility, safety, for humans as well as for the environment. In a world of limited resources, automation can provide the answer to the challenges of a sustainable development. Automation has the opportunity of making a greater and even more significant impact on society. In the first half of the 20th century, the precepts of engineering and management helped solving economic recession and ease social anxiety. Similar opportunities and challenges are occurring today.

This leading-edge *Springer Handbook of Automation* will serve as a highly useful and powerful tool and companion to all modern-day engineers and managers in their respective profession. It comes at an appropriate time, and provides a fundamental core of basic principles, knowledge and experience by means of which engineers and managers will be able to quickly respond to changing automation needs and to find creative solutions to the challenges of today's and tomorrow's problems.

It has been a privilege for many members of IFAC to participate with Springer Publishers, Dr. Shimon Y. Nof, and the over 250 experts, authors and reviewers, in creating this excellent resource of automation knowledge and ideas. It provides also a full and comprehensive spectrum of current and prospective automation applications, in industry, agriculture, infrastructures, services, health care, enterprise and commerce. A number of recently developed concepts and powerful emerging techniques are presented here for the first time in an organized manner, and clearly illustrated by specialists in those fields. Readers of this original *Springer Handbook of Automation* are offered the opportunity to learn proven knowledge from underlying basic theory to cutting-edge applications in a variety of emerging fields.

Alberto Isidori
Rome, March 2009

Foreword

Automation Is at the Center of Human Progress

As I write this Foreword for the new *Springer Handbook of Automation*, the 2008 United States presidential elections are still in full swing. Not a day seems to go by without a candidate or newscaster opining on the impact of cheaper, offshore labor on the US economy. Similar debates are taking place in other developed countries around the globe.

Some argue that off-shoring jobs leads to higher unemployment and should be prohibited. Indeed some regions have passed legislation prohibiting their local agencies from moving work to lower cost locations.

Proponents argue off-shoring leads to lower unemployment. In their view freeing up of the labor force from lower skilled jobs allows more people to enter higher value jobs which are typically higher paying. This boosts incomes and in turn overall domestic consumption.

Then, what about automation? Is the displacement or augmentation of human labor with an automated machine bad for our economies, too? If so, let's ban it!

So, let's imagine a world in which automation didn't exist. . . .

To begin I wouldn't be writing this Foreword on my laptop computer since the highly sophisticated automation necessary to manufacture semiconductors wouldn't exist. That's okay I'll just use my old typewriter. Oops, the numerical controlled machines required to manufacture the typewriter's precision parts wouldn't exist. What about pencil and paper? Perhaps, but could I afford them given that there would be no sensors and controls needed to manufacture them in high volume?

IBM has been a leader and pioneer in many automation fields, both as a user and a provider of automation solutions. Beyond productivity and cost-effectiveness, automation also enables us to effectively monitor process quality, reveal to us opportunities for improvement and innovation, and assure product and service dependability and service-availability. Such techniques and numerous examples to advance with automation, as users and providers, are included in this *Springer Handbook of Automation*.

The expanding complexity and magnitude of high-priority society's problems, global needs and competition forcefully challenge organizations and companies. To succeed, they need to understand detailed knowledge of many of the topics included in this *Springer Handbook of Automation*. Beyond an extensive reference resource providing the expert answers and solutions, readers and learners will be enriched from inspiration to innovate and create powerful applications for specific needs and challenges.

J. Bruce Harreld
Senior Vice President IBM

The best example I know is one I have witnessed first hand at IBM. Designing, developing, and manufacturing state-of-the art microprocessors have been a fundamental driver of our success in large computer and storage systems. Thirty years ago the manufacturing process for these microprocessors was fairly manual and not very capital intense. Today we manufacture microprocessors in a new state-of-the-art US$ 3 billion facility in East Fishkill, New York. This fabrication site contains the world's most advanced logistics and material handling system including real-time process control and fully automated workflow. The result is a completely *touchless* process that in turn allows us to produce the high quality, error free, and extremely fast microprocessors required for today's high end computing systems.

In addition to chapters devoted to a variety of industry and service automation topics, this *Springer Handbook of Automation* includes useful, well-organized information and examples on theory, tools, and their integration for successful, measurable results.

Automation is often viewed as impacting only the tangible world of physical products and facilities. Fortunately, this is completely wrong! Automation has also dramatically improved the way we develop software at IBM. Many years ago writing software was much like writing a report with each individual approaching the task quite differently and manually writing each line of code. Today, IBM's process for developing software is extremely automated with libraries of previously written code accessible to all of our programmers. Thus, once one person develops a program that performs a particular function, it is quickly shared and reused around the globe. This also allows us to pass a project to and from one team to the next so we can speed up cycle times for our clients by working on their projects 24 hours a day. The physical process of *writing* the lines of code has been replaced with pointing and clicking at objects on a computer screen. The result has been a dramatic reduction in mistakes with a concomitant increase in productivity. But we expect and anticipate even more from automation in support of our future, and the knowledge and guidelines on how to do it are described in this *Springer Handbook of Automation*.

The examples illustrated above highlight an important point. While we seldom touch automation, it touches us everyday in almost everything we do. Human progress is driven by day-to-day improvements in how we live. For more than one hundred years automation has been at the center of this exciting and meaningful journey. Since ancient history, humans have known how to benefit civilization with automation.

For engineers, scientists, managers and inventors, automation provides an exciting and important opportunity to implement ingenious human intelligence in automatic solutions for many needs, from simple applications, to difficult and complex requirements. Increasingly, multi-disciplinary cooperation in the study of automation helps in this creative effort, as detailed well in this *Springer Handbook of Automation*, including automatic control and mechatronics, nano-automation and collaborative, software-based automation concepts and techniques, from current and proven capabilities to emerging and forthcoming knowledge.

It is quite appropriate, therefore, that this original *Springer Handbook of Automation* has been published now. Its scope is vast and its detail deep. It covers the history as well as the social implications of automation. Then it dives into automation theory and techniques, design and modeling, and organization and management. Throughout the 94 chapters written by leading world experts, there are specific guidelines and examples of the application of automation in almost every facet of today’s society and industry. Given this rich content I am confident that this *Handbook* will be useful not only to students and faculty but practitioners, researchers and managers across a wide range of fields and professions.

J. Bruce Harreld
Armonk, January 2009

Foreword

Dawn of Industrial Intelligent Robots

This *Handbook* is a significant educational, professional and research resource for anyone concerned about automation and robotics. It can serve well for global enterprises and for education globally. The impacts of automation in many fields have been and are essential for increasing the intelligence of services and of interaction with computers and with machines. Plenty of illustrations and statistics about the economics and sophistication impacts of automation are included in this *Handbook*.

Automation, in general, includes many computer and communication based applications, computer-integrated design, planning, management, decision support, informational, educational, and organizational resources, analytics and scientific applications, and more. There are also many automation systems involving robots. Robots have emerged from science fiction into industrial reality in the middle of the 20th Century, and are now available worldwide as reliable, industrially made, automated and programmable machines.

The field of robotics application is now expanding rapidly. As widely known, about 35% of industrial robots in the world are operating in Japan. In the 1970s, Japan started to introduce industrial robots, especially automotive spot welding robots, thereby establishing the industrial robot market. As the industries flourished and faced labor shortage, Japan introduced industrial robots vigorously. Industrial robots have since earned recognition as being able to perform repetitive jobs continuously, and produce quality products with reliability, convincing the manufacturing industry that it is keenly important to use them skillfully so as to achieve its global impact and competitiveness.

In recent years, the manufacturing industry faces severe cost competition, shorter lead-time, and skilled worker shortage in the aging society with lower birth rates. It is also required to manufacture many varieties of products in varied quantity. Against this backdrop, there is a growing interest in industrial intelligent robots as a new automation solution to these requirements. Intelligence here is not defined as human intelligence or a capacity to think, but as a capacity comparable to that of a skilled worker, with which a machine can be equipped.

Seiuemon Inaba
Chairman Fanuc Ltd.

Disadvantages of relatively simple, playback type robots without intelligent abilities result in relatively higher equipment costs for the elaborate peripheral equipment required, such as parts feeders and part positioning fixtures. Additionally for simpler robots, human workers must daily pre-position work-pieces in designated locations to operate the robots. In contrast, intelligent robots can address these requirements with their vision sensor, serving as the eye, and with their force sensor, serving as the hand providing sense of touch. These intelligent robots are much more effective and more useful. For instance, combined with machine tools as Robot Cells they can efficiently load/unload work-pieces to/from machine tools, thereby reducing machining costs substantially by enabling machine tools to operate long hours without disruptions. These successful solutions with industrial intelligent robots have established them as a key automation component to improve global competitiveness of the manufacturing industry. It signifies the dawn of the industrial intelligent robot.

Intelligent automation, including intelligent robots, can now help, as described very well in this *Springer Handbook of Automation*, not only with manufacturing, supply and production companies, but increasingly with security and emergency services; with healthcare delivery and scientific exploration; with energy exploration, production and delivery; and with a variety of home and special needs human services. I am most thankful for the efforts of all those who participated in the development of this useful *Springer Handbook of Automation* and contributed their expertise so that our future with automation and robotics will continue to bring prosperity.

Seiuemon Inaba
Oshino-mura, January 2009

“*This page left intentionally blank.*”

Foreword

Automation Is the Science of Integration

In our understanding of the word *automation*, we used to think of manufacturing processes being run by machines without the need for human control or intervention. From the outset, the purpose of investing in automation has been to increase productivity at minimum cost and to assure uniform quality. Permanently assessing and exploiting the potential for automation in the manufacturing industries has, in fact, proved to be a sustainable strategy for responding to competition in the marketplace, thereby securing attractive jobs.

Automation equipment and related services constitute a large and rapidly growing market. Supply networks of component manufacturers and system integrators, allied with engineering skills for planning, implementing and operating advanced production facilities, are regarded as cornerstones of competitive manufacturing. Therefore, the emphasis of national and international initiatives aimed at strengthening the manufacturing base of economies is on holistic strategies for research and technical development, education, socio-economics and entrepreneurship.

Today, automation has expanded into almost every area of daily life: from smart products for everyday use, networked buildings, intelligent vehicles and logistics systems, service robots, to advanced healthcare and medical systems. In simplified terms, automation today can be considered as the combination of processes, devices and supporting technologies, coupled with advanced information and communication technology (ICT), where ICT is now evolving into the most important basic technology.

As a world-leading organization in the field of applied research, the Fraunhofer Society (Fraunhofer-Gesellschaft) has been a pioneer in relation to numerous technological innovations and novel system solutions in the broad field of automation. Its institutes have led the way in research, development and implementation of industrial robots and computer-integrated manufacturing systems, service robots for professional and domestic applications, advanced ICT systems for office automation and e-Commerce as well as automated residential and commercial buildings. Moreover, our research and development activities in advanced manufacturing and logistics as well as office and home automation have been accompanied by large-scale experiments and demonstration centers, the goal being to integrate, assess and showcase innovations in automation in real-world settings and application scenarios.

Hans-Jörg Bullinger
President
Fraunhofer Society

On the basis of this experience, we can state that, apart from research in key technologies such as sensors, actuators, process control and user interfaces, automation is first and foremost the science of integration, mastering the process from the specification, design and implementation through to the operation of complex systems that have to meet the highest standards of functionality, safety, cost-effectiveness and usability. Therefore, scientists and engineers need to be experts in their respective disciplines while at the same time having the necessary knowledge and skills to create and operate large-scale systems.

The *Springer Handbook of Automation* is an excellent means of both educating students and also providing professionals with a comprehensive yet compact reference work for the field of automation. The Handbook covers the broad scope of relevant technologies, methods and tools and presents their use and integration in a wide selection of application contexts: from agricultural automation to surgical systems, transportation systems and business process automation.

I wish to congratulate the editor, Prof. Shimon Y. Nof, on succeeding in the difficult task of covering the multi-faceted field of automation and of organizing the material into a coherent and logically structured whole. The *Handbook* admirably reflects the connection between theory and practice and represents a highly worthwhile review of the vast accomplishments in the field. My compliments go to the many experts who have shared their insights, experience and advice in the individual chapters. Certainly, the Handbook will serve as a valuable tool and guide for those seeking to improve the capabilities of automation systems – for the benefit of humankind.

Hans-Jörg Bullinger
Munich, January 2009

“*This page left intentionally blank.*”

Preface

We love automation when it does what we need and expect from it, like our most loyal partner: wash our laundry, count and deliver money bills, supply electricity where and when it is needed, search and display movies, maps, and weather forecasts, assemble and paint our cars, and more personally, image to diagnose our health problems, or tooth pains, cook our food, and photograph our journeys. Who would not love automation?

We hate automation and may even kick it when it fails us, like a betraying confidant: turn the key or push a button and nothing happens the way we anticipate – a car does not start, a TV does not display, our cellphone is misbehaving, the vending machine delivers the wrong item, or refuses to return change; planes are late *due to mechanical problem* and business transactions are lost or ignored *due to computer glitches*. Eventually those problems are fixed and we turn back to the first paragraph, loving it again.

We are amazed by automation and all those people behind it. Automation thrills us when we learn about its new abilities, better functions, more power, faster computing, smaller size, and greater reliability and precision. And we are fascinated by automation's marvels: in entertainment, communication, scientific discoveries; how it is applied to explore space and conquer difficult maladies of society, from medical and pharmaceutical automation solutions, to energy supply, distant education, smart transportation, and we are especially enthralled when we are not really sure how it works, but it works.

It all starts when we, as young children, observe and notice, perhaps we are bewildered, that a door automatically opens when we approach it, or when we are first driven by a train or bus, or when we notice the automatic sprinklers, or lighting, or home appliances: *How can it work on its own?* Yes, there is so much magic about automation.

This magic of automation is what inspired a large group of us, colleagues and friends from around the world, all connected by automation, to compile, develop, organize and present this unique *Springer Handbook of Automation*: Explain to our readers what automation is, how it works, how it is designed and built, where it is applied, and where and how it is going to be improved and be created even better; what are the scientific principles behind it, and what are emerging trends and challenges being confronted. All of it concisely yet comprehensively covered in the 94 chapters which are included in front of you, the readers.

Flying over beautiful Fall colored forest surrounding Binghamton, New York in the 1970s on my way to IBM's symposium on the future of computing, I was fascinated by the miracle of nature beneath the airplane: Such immense diversity of leaves' changing colors; such magically smooth, wavy movement of the leaves dancing with the wind, as if they are programmed with automatic control to responsively transmit certain messages needed by some unseen listeners. And the brilliance of the sunrays reflected in these beautiful dancing leaves (there must be some purpose to this automatically programmed beauty, I thought). More than once, during reading the chapters that follow, was I reminded of this unforgettable image of multi-layered, interconnected, interoperable, collaborative, responsive waves of leaves (and services): The take-home lesson from that symposium was that mainframe computers hit, about that time, a barrier – it was stated that faster computing was impossible since mainframes would not be able to cool off the heat they generated (unless a miracle happened). As we all know, with superb human ingenuity computing has overcome that barrier and other barriers, and progress, including fast personal computers, better software, and wireless computer communication, resulted in major performance and cost-effective improvements, such as client-server workstations, wireless access and local area networks (LAN), duo- and multi-core architectures, web-based Internetworking, grids, and more has been automated, and there is so much more yet to come. Thus, more intelligent automatic control and more responsive human–automation interfaces could be invented and deployed for the benefit of all.

Progress in distributed, networked, and collaborative control theory, computing, communication, and automation has enabled the emergence of e-Work, e-Business, e-Medicine, e-Service, e-Commerce, and many other significant e-Activities based on automation. It is not that our ancestors did not recognize the tremendous power and value of delegating effort to tools and machines, and furthermore, of synergy, teamwork, collaborative interactions and decision-making, outsourcing and resource sharing, and in general, networking. But only when efficient, reliable and scalable automation reached a certain level of maturity could it be designed into systems and infrastructures servicing effective supply and delivery networks, social networks, and multi-enterprise practices.

In their vision, enterprises expect to simplify their automation utilities and minimize their burden and cost, while increasing the value and usability of all deployed functions and acquirable information by their timely conversion into relevant knowledge, goods, and practices. Streamlined knowledge, services and products would then be delivered through less effort, just when necessary and only to those clients or decision makers who truly need them. Whether we are in business and commerce or in service for society, the real purpose of automation is not merely *better computing* or *better automation*, but *let us increase our competitive agility and service quality!*

This *Springer Handbook* achieves this purpose well. Throughout the 94 chapters, divided into ten main parts, with 125 tables, numerous equations, 1005 figures, and a vast number of references, with numerous guidelines, algorithms, and protocols, models, theories, techniques and practical principles and procedures, the 166 coauthors present proven knowledge, original analysis, best practices and authoritative expertise.

Plenty of case studies, creative examples and unique illustrations, covering topics of automation from the basics and fundamentals to advanced techniques, cases and theories will serve the readers and benefit the students and researchers, engineers and managers, inventors, investors and developers.

Special Thanks

I wish to express my gratitude and thanks to our distinguished Advisory Board members, who are leading international authorities, scholars, experts, and pioneers of automation, and who have guided the development of this *Springer Handbook* and shared with me their wisdom and advice along the challenging editorial process; to our distinguished authors and our esteemed reviewers, who are also leading experts, researchers, practitioners and pioneers of automation. Sadly, my personal friends and colleagues Professor Kazuo Tanie, Professor Heinz Erbe, and Professor Walter Shaufelberger, who took active part in helping create this *Springer Handbook*, passed away before they could see it published. They left huge voids in our community and in my heart, but their legacy will continue.

All the chapters were reviewed thoroughly and anonymously by over 90 reviewers, and went through several critical reviews and revision cycles (each chapter was reviewed by at least five expert reviewers), to assure the accuracy, relevance, and high quality of the materials, which are presented in the *Springer Handbook*. The reviewers included:

Yih-Choung Yu, Lafayette College
Firas Zahr, Cleveland Clinic Foundation

I wish to express my gratitude and appreciation also to my resourceful coauthors, colleagues and partners from IFAC, IFPR, IFIP, IIE, NSF, TRB, RIA, INFORMS, ACM, IEEE-ICRA, ASME, and PRISM Center at Purdue and PGRN, the PRISM Global Research Network, for all their support and cooperation leading to the successful creation of this *Springer Handbook*.

Special thanks to my late parents, Dr. Jacob and Yafa Berglas Nowomiast, whose brilliance, deep appreciation to scholarship, and inspiration keep enriching me; to my wife Nava for her invaluable support and wise advice; to Moriah, Jasmin, Jonathan, Haim, Daniel, Andrew, Chin-Yin, Jose, Moshe, Ed, Ruth, Pornthep, Juan Ernesto, Richard, Wootae, Agostino, Daniela, Tibor, Esther, Pat, David, Yan, Gad, Guillermo, Cristian, Carlos, Fay, Marco, Venkat, Masayuki, Hans, Laszlo, Georgi, Arturo, Yael, Dov, Florin, Herve, Gerard, Gavriel, Lily, Ted, Isaac, Dan, Veronica, Rolf, Yukio, Steve, Mark, Colin, Namkyu, Wil, Aditya, Ken, Hannah, Anne, Fang, Jim, Tom, Frederique, Alexandre, Coral, Tetsuo, and Oren, and to Izzy Vardinon, for sharing with me their thoughts, smiles, ideas and their automation expertise. Deep thanks also to Juan Diego Velásquez, to Springer-Verlag's Tom Ditzinger, Werner Skolaut and Heather King, and the le-tex team for their tremendous help and vision in completing this ambitious endeavor.

The significant achievements of humans with automation, in improving our life quality, innovating and solving serious problems, and enriching our knowledge; inspiring people to enjoy automation and provoking us to learn how to invent even better and greater automation solutions; the wonders and magic, opportunities and challenges with emerging and future automation – are all enormous. Indeed, automation is an essential and wonderful part of human civilization.

Shimon Yeshayahu Nof Nowomiast
West Lafayette, Indiana
May 2009

Advisory Board

Hans-Jörg Bullinger

Fraunhofer-Gesellschaft
Munich, Germany
hans-joerg.bullinger@zv.fraunhofer.de

Hans-Jörg Bullinger is Prof. Dr.-Ing. habil. Prof. e.h. mult. Dr. h. c. mult., President of the Fraunhofer-Gesellschaft, Corporate Management and Research. He obtained MSc and PhD in Manufacturing at University of Stuttgart and joined the Stuttgart Fraunhofer-Institute of Production Technology and Automation, and became a full-time lecturer at the University of Stuttgart. He served there as Chairman of the University, Head of the Institute for Human Factors and Technology Management (IAT) and of Fraunhofer-Institute for Industrial Engineering (IAO). In 2002 he became the President of the Fraunhofer-Gesellschaft. Among his honors are the Kienzle-Medal, the Gold Ring-of-Honour from the German Society of Engineers (VDI), the Distinguished Foreign Colleague Award from the Human Factor Society, the Arthur Burckhardt Award; Honorary Doctorates (DHC) from the Universities of Novi Sad and Timisoara. He has also received the Cross of Order of Merit and the Officer's Cross of Order of Merit of the Federal Republic of Germany, and the Great Cross of the Order of Merit from the Federal President of Germany. Dr. Bullinger is a member of the German Chancellor's "Council on Innovation and Economic Growth".

Rick J. Echevarria

Intel Corporation
Sales and Marketing Group
Enterprise Solution Sales
Santa Clara, CA, USA
rick.j.echevarria@intel.com

Rick J. Echevarria is Vice President of the Sales and Marketing Group and General Manager of the Enterprise Solution Sales division at Intel Corporation. Before assuming his current position, Rick spent seven years leading Intel®Solution Services, Intel's worldwide professional services organization. Earlier, he spent two years as Director of Product Marketing for Intel's Communication Products Group and as Director of Internet Marketing for the Enterprise Server Group. Before joining Intel in 1994, Rick was a software developer for IBM Corporation in Austin, TX. Rick holds a BS degree in industrial engineering from Purdue University and an MS degree in computer systems management from Union College.

Yael Edan

Ben-Gurion University of the Negev
Department of Industrial Engineering
and Management
Beer Sheva, Israel
yael@bgu.ac.il

Yael Edan is a Professor in the Department of Industrial Engineering and Management. She holds a BSc in Computer Engineering and MSc in Agricultural Engineering, both from the Technion-Israel Institute of Technology, and a PhD in Engineering from Purdue University. Her research is robotic and sensor performance analysis, systems engineering of robotic systems; sensor fusion, multi-robot and telerobotics control methodologies, and human-robot collaboration methods with major contributions in intelligent automation systems in agriculture.

Yukio Hasegawa

Waseda University
System Science Institute
Tokyo, Japan
yukioh@green.ocn.ne.jp

Yukio Hasegawa is Professor Emeritus of the System Science Institute at Waseda University, Tokyo, Japan. He has been enjoying construction robotics research since 1983 as Director of Waseda Construction Robot Research Project (WASCOR) which has impacted automation in construction and in other fields of automation. He received the prestigious first Engelberger Award in 1977 from the American Robot ssociation for his distinguished pioneering work in robotics and in Robot Ergonomics since the infancy of Japanese robotics. Among his numerous international contributions to robotics and automation, Professor Hasegawa assisted, as a visiting professor, to build the Robotics Institute at EPFL (Ecole Polytechnic Federal de Lausanne) in Switzerland.

Steven W. Holland

General Motors R&D
Electrical & Controls Integration Lab
Warren, MI, USA
steven.w.holland@gm.com

Steve Holland is a Research Fellow at General Motors R&D, where he pioneered early applications of robotics, vision and computer-based manufacturing. Later, he led GM's robotics development group and then the robotics and welding support operations for GM North American plants. He served as Director of GM's global manufacturing systems research. He is a Fellow of IEEE and received the Joseph F. Engelberger Award for his contributions to robotics. Mr. Holland has a bachelor's degree in Electrical Engineering from GMI and a Master in Computer Science from Stanford.

Clyde W. Holsapple

University of Kentucky
School of Management, Gatton College of Business and Economics
Lexington, KY, USA
cwhols@email.uky.edu

Clyde Holsapple, Rosenthal Endowed Chair at the University of Kentucky, is Editor-in-Chief of the Journal of Organizational Computing and Electronic Commerce. His books include *Foundations of Decision Support Systems, Decision Support Systems – A Knowledge-based Approach, Handbook on Decision Support Systems, and Handbook on Knowledge Management*. His research focuses on multiparticipant systems, decision support systems, and knowledge management.

Rolf Isermann

Technische Universität Darmstadt
Institut für Automatisierungstechnik, Forschungsgruppe Regelungstechnik und Prozessautomatisierung
Darmstadt, Germany
risermann@iat.tu-darmstadt.de

Rolf Isermann served as Professor for Control Systems and Process Automation at the Institute of Automatic Control of Darmstadt University of Technology from 1977–2006. Since 2006 he has been Professor Emeritus and head of the Research Group for Control Systems and Process Automation at the same institution. He has published books on Modelling of Technical Processes, Process Identification, Digital Control Systems, Adaptive Control Systems, Mechatronic Systems, Fault Diagnosis Systems, Engine Control and Vehicle Drive Dynamics Control. His current research concentrates on fault-tolerant systems, control of combustion engines and automobiles and mechatronic systems. Rolf Isermann has held several chair positions in VDI/VDE and IFAC and organized several national and international conferences.

Kazuyoshi Ishii

Kanazawa Institute of Technology
Social and Industrial Management Systems
Hakusan City, Japan
ishiik@neptune.kanazawa-it.ac.jp

Kazuyoshi Ishii received his PhD in Industrial Engineering from Waseda University. Dr. Ishii is a board member of the IFPR, APIEMS and the Japan Society of QC, and a fellow of the ISPIM. He is on the Editorial Board of the International Journal of Production Economics, PPC and Intelligent Embedded Microsystems (IEMS). His interests include production management, product innovation management, and business models based on a comparative advantage.

Alberto Isidori

Univeristy of Rome "La Sapienza"
Department of Informatics and Sytematics
Rome, Italy
albisidori@dis.uniroma1.it

Alberto Isidori is Professor of Automatic Control at the University of Rome since1975 and, since 1989, also affiliated with Washington University in St. Louis. His research interests are primarily in analysis and design of nonlinear control systems. He is the author of the book *Nonlinear Control Systems* and is the recipient of various prestigious awards, which include the "Georgio Quazza Medal" from IFAC, the "Bode Lecture Award" from IEEE, and various best paper awards from leading journals. He is Fellow of IEEE and of IFAC. Currently he is President of IFAC.

Stephen Kahne

Embry-Riddle University
Prescott, AZ, USA
s.kahne@ieee.org

Stephen Kahne is Professor of Electrical Engineering at Embry-Riddle Aeronautical University in Prescott, Arizona where he was formerly Chancellor. Prior to coming to Embry-Riddle in 1995, he had been Chief Scientist at the MITRE Corporation. Dr. Kahne earned his BS degree from Cornell University and the MS and PhD degrees from the University of Illinois. Following a decade at the University of Minnesota, he was Professor at Case Western Reserve University, Professor and Dean of Engineering at Polytechnic Institute of New York, and Professor and President of the Oregon Graduate Center, Portland, Oregon. Dr. Kahne was a Division Director at the National Science Foundation in the early 1980s. He is a Fellow of the IEEE, AAAS, and IFAC. He was President of the IEEE Control Systems Society, a member of the IEEE Board of Directors of the IEEE in the 1980s, and President of IFAC in the 1990s.

Aditya P. Mathur

Purdue University
Department of Computer Science
West Lafayette, IN, USA
apm@cs.purdue.edu

Aditya Mathur received his PhD in 1977 from BITS, Pilani, India in Electrical Engineering. Until 1985 he was on the faculty at BITS where he spearheaded the formation of the first degree granting Computer Science department in India. In 1985 he moved briefly to Georgia Tech before joining Purdue University in 1987. Aditya is currently a Professor and Head in the Department of Computer Science where his research is primarily in the area of software engineering. He has made significant contributions in software testing and software process control and has authored three textbooks in the areas of programming, microprocessor architecture, and software testing.

Hak-Kyung Sung

Samsung Electronics
Mechatronics & Manufacturing
Technology Center
Suwon, Korea
hakksung@samsung.com

Hak-Kyung Sung received the Master degree in Mechanical Engineering from Yonsei University in Korea and the PhD degree in Control Engineering from Tokyo Institute of Technology in Japan, in 1985 and 1992, respectively. He is currently the Vice President in the Mechtronics & Manufacturing Technology Center, Samsung Electronics. His interests are in production engineering technology, such as robotics, control, and automation.

Gavriel Salvendy

Department of Industrial Engineering
Beijing, P.R. China

Gavriel Salvendy is Chair Professor and Head of the Department of Industrial Engineering at Tshinghua University, Beijing, Peoples Republic of China and Professor emeritus of Industrial Engineering at Purdue University. His research deals with the human aspects of design and operation of advanced computing systems requiring interaction with humans. In this area he has over 450 scientific publications and numerous books, including the Handbook of Industrial Engineering and Handbook of Human Factors and Ergonomics. He is a member of the USA National Academy of Engineering and the recipient of the John Fritz Medal.

George Stephanopoulos

Massachusetts Institute of Technology
Cambridge, MA, USA
geosteph@mit.edu

George Stephanopoulos is the A.D. Little Professor of Chemical Engineering and Director of LISPE (Laboratory for Intelligent Systems in Process Engineering) at MIT. He has also taught at the University of Minnesota (1974–1983) and National Technical University of Athens, Greece (1980–1984). His research interests are in process operations monitoring, analysis, diagnosis, control, and optimization. Recently he has extended his research to multi-scale modeling and design of materials and nanoscale structures with desired geometries. He is a member of the National Academy of Engineering, USA.

Kazuo Tanie (△)

Tokyo Metropolitan University
Human Mechatronics System Course,
Faculty of System Design
Tokyo, Japan

Professor Kazuo Tanie (1946–2007), received BE, MS, Dr. eng. in Mechanical Engineering from Waseda University. In 1971, he joined the Mechanical Engineering Laboratory (AIST-MITI), was Director of the Robotics Department and of the Intelligent Systems Institute of the National Institute of Advanced Industrial Science and Technology, Ministry of Economy, Trade, and Industry, where he led a large humanoid robotics program.
In addition, he held several academic positions in Japan, USA, and Italy. His research interests included tactile sensors, dexterous manipulation, force and compliance control for robotic arms and hands, virtual reality and telerobotics, human-robot coexisting systems, power assist systems and humanoids. Professor Tanie was active in IEEE Robotics and Automation Society, served as its president (2004–2005), and led several international conferences. One of the prominent pioneers of robotics in Japan, his leadership and skills led to major automation initiatives, including various walking robots, dexterous hands, seeing-eye robot (MEL Dog), rehabilitative and humanoid robotics, and network-based humanoid telerobotics.

Tibor Vámos

Hungarian Academy of Sciences
Computer and Automation Institute
Budapest, Hungary
vamos@sztaki.hu

Tibor Vámos graduated from the Budapest Technical University in 1949. Since 1986 he is Chairman of the Board, Computer and Automation Research Institute of the Hungarian Academy of Sciences, Budapest. He was President of IFAC 1981–1984 and is a Fellow of the IEEE, ECCAI, IFAC. Professor Vamos is Honorary President of the John v. Neumann Society and won the State Prize of Hungary in 1983, the Chorafas Prize in 1994, the Széchenyi Prize of Hungary in 2008 and was elected "The educational scientist of the year" in 2005. His main fields of interest cover large-scale systems in process control, robot vision, pattern recognition, knowledge-based systems, and epistemic problems. He is author and co-author of several books and about 160 papers.

François B. Vernadat

Université Paul Verlaine Metz
Laboratoire de Génie Industriel et
Productique de Metz (LGIPM)
Metz, France
Francois.Vernadat@eca.europa.eu

François Vernadat received the PhD in Electrical Engineering and Automatic Control from University of Clermont, France, in 1981. He has been a research officer at the National Research Council of Canada in the 1980s and at the Institut National de Recherche en Informatique et Automatique in France in the 1990s. He joined the University of Metz in 1995 as a full professor and founded the LGIPM research laboratory. His research interests include enterprise modeling, enterprise architectures, enterprise integration and interoperability. He is a member of IEEE and ACM and has been vice-chairman of several technical committees of IFAC. He has over 250 scientific papers in international journals and conferences.

Birgit Vogel-Heuser

University of Kassel
Faculty of Electrical Engineering/
Computer Science, Department Chair of
Embedded Systems
Kassel, Germany
vogel-heuser@uni-kassel.de

Birgit Vogel-Heuser graduated in Electrical Engineering and obtained her PhD in Mechanical Engineering from the RWTH Aachen in 1991. She worked nearly ten years in industrial automation for machine and plant manufacturing industry. After holding the Chair of Automation at the University of Hagen and the Chair of Automation/Process Control Engineering she is now head of the Chair of Embedded Systems at the University of Kassel. Her research work is focussed on improvement of efficiency in automation engineering for hybrid process and heterogeneous distributed embedded systems.

Andrew B. Whinston

The University of Texas at Austin
McCombs School of Business, Center for
Research in Electronic Commerce
Austin, TX, USA
abw@uts.cc.utexas.edu

Andrew Whinston is Hugh Cullen Chair Professor in the IROM department at the McCombs School of Business at the University of Texas at Austin. He is also the Director at the Center for Research in Electronic Commerce. His recent papers have appeared in Information Systems Research, Marketing Science, Management Science and the Journal of Economic Theory. In total he has published over 300 papers in the major economic and management journals and has authored 27 books. In 2005 he received the Leo Award from the Association for Information Systems for his long term research contribution to the information system field.

Contents

5 Social, Organizational, and Individual Impacts of Automation

6 Economic Aspects of Automation

7 Impacts of Automation on Precision

8 Trends in Automation

Part B Automation Theory and Scientific Foundations

Part C Automation Design: Theory, Elements, and Methods

Part D Automation Design: Theory and Methods for Integration

Part F Industrial Automation

62 The Smart Building

63 Automation in Agriculture

64 Control System for Automated Feed Plant

65 Securing Electrical Power System Operation

Part H Automation in Medical and Healthcare Systems

Part I Home, Office, and Enterprise Automation

Part J Appendix

List of Abbreviations

α-HL	α-hemolysin
βCD	β-cyclodextrin
μC	micro controller
*FTTP	fault-tolerance time-out protocol
2-D	two-dimensional
3-D-CG	three-dimensional computer graphic
3-D	three-dimensional
3G	third-generation
3PL	third-party logistics
3SLS	three-stage least-square
4-WD	four-wheel-drive

A

A-PDU	application layer protocol data unit
A/D	analog-to-digital
AAAI	Association for the Advancement of Artificial Intelligence
AACC	American Automatic Control Council
AACS	automated airspace computer system
AAN	appliance area network
ABAS	aircraft-based augmentation system
ABB	Asea Brown Boveri
ABCS	automated building construction system
ABMS	agent-based management system
ABS	antilock brake system
AC/DC	alternating current/direct current
ACARS	aircraft communications addressing and reporting system
ACAS	aircraft collision avoidance system
ACAS	automotive collision avoidance system
ACCO	active control connection object
ACC	adaptive cruise control
ACC	automatic computer control
ACE	area control error
ACGIH	AmericanConference of Governmental Industrial Hygienists
ACH	automated clearing house
ACMP	autonomous coordinate measurement planning
ACM	Association for Computing Machinery
ACM	airport capacity model
ACN	automatic collision notification
ACT-R	adaptive control of thought-rational
AC	alternating-current
ADAS	advanced driver assistance system
ADA	Americans with Disabilities Act
ADC	analog-to-digital converter
ADS-B	automatic dependent surveillance-broadcast
ADSL	asymmetric digital subscriber line
ADT	admission/transfer/discharge
aecXML	architecture, engineering and construction extensive markup language
AFCS	automatic flight control system
AFM	atomic force microscopy
AFP	automated fiber placement
AF	application framework
AGC	automatic generation control
AGL	above ground level
AGV	autonomous guided vehicle
AHAM	Association of Home Appliance Manufacturers
AHP	analytical hierarchy process
AHS	assisted highway system
AIBO	artificial intelligence robot
AIDS	acquired immunodeficiency syndrome
AIM-C	accelerated insertion of materials-composite
AIMIS	agent interaction management system
AIMac	autonomous and intelligent machine tool
AI	artificial intelligence
ALB	assembly line balancing
ALD	atomic-layer deposition
ALU	arithmetic logic unit
AMHS	automated material-handling system
AMPA	autonomous machining process analyzer
ANFIS	adaptive neural-fuzzy inference system
ANN	artificial neural network
ANSI	American National Standards Institute
ANTS	Workshop on Ant Colony optimization and Swarm Intelligence
AOCS	attitude and orbit control system
AOC	airline operation center
AOI	automated optical inspection
AOP	aspect-oriented programming
AO	application object
APC	advanced process control
APFDS	autopilot/flight director system
API	applications programming interface
APL	application layer
APM	alternating pulse modulation
APO	advance planner and optimizer
APS	advanced planning and scheduling
APTMS	3-aminopropyltrimethoxysilane
APT	automatically programmed tool
APU	auxiliary power unit
APV	approach procedures with vertical guidance
AQ	as-quenched
ARCS	attention, relevance, confidence, satisfaction

ARIS	architecture for information systems
ARL	Applied Research Laboratory
ARPANET	advanced research projects agency net
ARPM	the application relationship protocol machine
ARSR	air route surveillance radar
ARTCC	air route traffic control center
ARTS	automated radar terminal system
aRT	acyclic real-time
AS/RC	automated storage/enterprise resource
AS/RS	automatic storage and retrieval system
ASAS	airborne separation assurance system
ASCII	American standard code for information interchange
ASDE	airport surface detection equipment
ASDI	aircraft situation display to industry
ASE	application service element
ASIC	application-specific IC
ASIMO	advanced step in innovation mobility
ASIP	application-specific instruction set processor
ASI	actuator sensor interface
ASME	American Society of Mechanical Engineers
ASP	application service provider
ASRS	automated storage and retrieval system
ASR	airport surveillance radar
ASSP	application-specific standard part
ASTD	American Society for Training and Development
ASW	American Welding Society
ASi	actuator sensor interface
AS	ancillary service
ATCBI-6	ARSR are ATC beacon interrogator
ATCSCC	air traffic control system command center
ATCT	air traffic control tower
ATC	available transfer capability
ATIS	automated terminal information service
ATL	automated tape layup
ATM	air traffic management
ATM	asynchronous transfer mode
ATM	automatic teller machine
ATPG	automatic test pattern generation
AT	adenine–thymine
AUTOSAR	automotive open system architecture
AUV	autonomous underwater vehicle
AVI	audio video interleaved
AWSN	ad hoc wireless sensor network
Aleph	automated library expandable program
awGA	adaptive-weight genetic algorithm
A&I	abstracting and indexing

B

B-rep	boundary representation
B2B	business-to-business
B2C	business-to-consumer
BAC	before automatic control
BALLOTS	bibliographic automation of large library operations using time sharing
BAP	Berth allocation planning
BAS	building automation systems
BA	balancing authority
BBS	bulletin-board system
BCC	before computer control
BCD	binary code to decimal
BDD	binary decision diagram
BDI	belief–desire–intention
BIM	building information model
BI	business intelligence
BLR	brick laying robot
BMP	best-matching protocol
BOL	beginning of life
BOM	bill of material
BPCS	basic process control system
BPEL	business process execution language
BPMN	business process modeling notation
BPM	business process management
BPO	business process outsourcing
BPR	business process reengineering
BP	broadcasting protocol
bp	base pair
BSS	basic service set
BST	biochemical systems theory
BS	base station

C

C2C	consumer-to-consumer
CAASD	center for advanced aviation system development
CAA	National Civil Aviation Authority
CAD/CAM	computer-aided design/manufacture
CADCS	computer aided design of control system
CAEX	computer aided engineering exchange
CAE	computer-aided engineering
CAI	computer-assisted (aided) instruction
CAMI	computer-assisted medical intervention
CAMP	collision avoidance metrics partnership
CAM	computer-aided manufacturing
CANbus	controller area network bus
CAN	control area network
CAOS	computer-assisted ordering system
CAPP	computer aided process planning
CAPS	computer-aided processing system
CASE	computer-aided software engineering
CAS	collision avoidance system
CAS	complex adaptive system
CAW	carbon arc welding
CA	conflict alert
CBM	condition-based maintenance
CBT	computer based training

CCC	Chinese Control Conference
CCD	charge-coupled device
CCGT	combined-cycle gas turbine
CCMP	create–collect–manage–protect
CCM	CORBA component model
CCP	critical control point
CCTV	closed circuit television
CCT	collaborative control theory
CDMS	conflict detection and management system
CDTI	cockpit display of traffic information
CDU	control display unit
CD	compact disc
CEC	Congress on Evolutionary Computation
CEDA	conflict and error detection agent
CEDM	conflict and error detection management
CEDM	conflict and error detection model
CEDP	conflict and error detection protocol
CEDP	conflict and error diagnostics and prognostics
CED	concurrent error detection
CEO	chief executive officers
CEPD	conflict and error prediction and detection
CERIAS	Center of Education and Research in Information Assurance and Security
CERN	European Organization for Nuclear Research
CERT	Computer Emergency Response Team
CE	Council Europe
CFD	computational fluid dynamics
CFG	context-free grammar
CFIT	controlled flight into terrain
cGMP	current good manufacturing practice
CG	computer graphics
CHAID	chi-square automatic interaction detector
CHART	Maryland coordinated highways action response team
CH	cluster-head
CIA	CAN in automation
CICP	coordination and interruption–continuation protocol
CIM	computer integrated manufacturing
CIO	chief information officer
CIP	common industrial protocol
CIRPAV	computer-integrated road paving
CLAWAR	climbing and walking autonomous robot
CLSI	Computer Library Services Inc.
CL	cutter location
CME	chemical master equation
CMI	computer-managed instruction
CML	case method learning
CMM	capability maturity model
CMS	corporate memory system
CMTM	control, maintenance, and technical management
CM	Clausius–Mossotti

CNC	computer numerical control
CNO	collaborative networked organization
CNS	collision notification system
CNS	communication, navigation, and surveillance
CNT	carbon nanotube
COA	cost-oriented automation
COBOL	common business-oriented language
COCOMO	constructive cost model
CODESNET	collaborative demand and supply network
COMET	collaborative medical tutor
COMSOAL	computer method of sequencing operations for assembly lines
COM	component object model
COP	coefficient of performance
COQ	cost of quality
CORBA	common object request broker architecture
CO	connection-oriented
CPA	closest point of approach
CPLD	complex programmable logic device
CPM	critical path method
CPOE	computerized provider order entry
CPU	central processing unit
CP	constraint programming
CP	coordination protocol
CQI	continuous quality improvement
CRF	Research Center of Fiat
CRM	customer relationship management
CRP	cooperation requirement planning
CRT	cathode-ray tube
cRT	cyclic real-time
CSCL	computer-supported collaborative learning
CSCW	computer-supported collaborative work
CSG	constructive solid geometry
CSR	corporate social responsibility
CSS	Control Systems Society
CSU	customer support unit
CSW	curve speed warning system
CTC	cluster tool controller
CTMC	cluster tool module communication
CT	computed tomography
CURV	cable-controlled undersea recovery vehicle
CVT	continuously variable transmission
CV	controlled variables
Co-X	collaborative tool for function X

D

D/A	digital-to-analog
D2D	discovery-to-delivery
DAC	digital-to-analog converter
DAFNet	data activity flow network

DAISY	differential algebra for identifiability of systems
DAM	digital asset management
DARC	Duke Annual Robo-Climb Competition
DAROFC	direct adaptive robust output feedback controller
DARPA	Defense Advanced Research Projects Agency
DARSFC	direct adaptive robust state feedback controller
DAS	driver assistance system
DA	data acquisition
DB	database
DCOM	distributed component object model
DCSS	dynamic case study scenario
DCS	distributed control system
DCS	disturbance control standard
DC	direct-current
DDA	demand deposit account
DDC	direct digital control
DEA	discrete estimator algorithm
DEM	discrete element method
DEP	dielectrophoretic
DES	discrete-event system
DFBD	derived function block diagram
DFI	data activity flow integration
DFM	design for manufacturing
DFT	discrete Fourier transform
DGC	DARPA Grand Challenge
DGPA	discretized generalized pursuit algorithm
DGPS	differential GPS
DHCP	dynamic host configuration protocol
DHS	Department of Homeland Security
DICOM	digital imaging and communication in medicine
DIN	German Institute for Normalization
DIO	digital input/output
DISC	death inducing signalling complex
DLC	direct load control
DLF	Digital Library Foundation
DMC	dynamic matrix control
DME	distance measuring equipment
DMOD	distance modification
DMPM	data link mapping protocol machine
DMP	decision-making processes
DMP	dot matrix printer
DMSA/DMSN	distributed microsensor array and network
DMS	dynamic message sign
DM	decision-making
DNA	deoxyribonucleic acid
DNC	direct numerical control
DNS	domain name system
DOC	Department of Commerce
DOF	degrees of freedom
DOP	degree of parallelism

DOT	US Department of Transportation
DO	device object
DPA	discrete pursuit algorithm
DPC	distributed process control
DPIEM	distributed parallel integration evaluation method
DP	decentralized periphery
DRG	diagnostic related group
DRR	digitally reconstructed radiograph
DR	digital radiography
DSA	digital subtraction angiography
DSDL	domain-specific design language
DSDT	distributed signal detection theoretic
DSL	digital subscriber line
DSL	domain-specific language
DSN	distributed sensor network
DSP	digital signal processor
DSRC	dedicated short-range communication
DSSS	direct sequence spread spectrum
DSS	decision support system
DTC	direct torque control
DTL	dedicated transfer line
DTP	desktop printing
DTSE	discrete TSE algorithm
DUC	distributable union catalog
DVD	digital versatile disk
DVI	digital visual interface
DV	disturbance variables
DXF	drawing interchange format
DoD	Department of Defense
DoS	denial of service

E

E-CAE	electrical engineering computer aided engineering
E-PERT	extended project estimation and review technique
E/H	electrohydraulic
EAI	enterprise architecture interface
EAP	electroactive polymer
EA	evolutionary algorithm
EBL	electron-beam lithography
EBM	evidence-based medicine
EBP	evidence-based practice
EBW	electron beam welding
ebXML	electronic business XML
EB	electron beam
ECG	electrocardiogram
ECU	electronic control unit
EC	European Community
EDA	electronic design automation
EDCT	expected departure clearance time
EDD	earliest due date
EDGE	enhanced data rates for GSM evolution

EDIFACT	Electronic Data Interchange for Administration, Commerce and Transport
EDI	electronic data interchange
EDPA	error detection and prediction algorithms
EDPVR	end-diastolic pressure–volume relationship
EDS	electronic die sorting
EDV	end-diastolic volume
EEC	European Economic Community
EEPROM	electrically erasable programmable read-only memory
EES	equipment engineering system
EFIS	electronic flight instrument system
EFSM	extended finite state machine
EFT	electronic funds transfer
EGNOS	European geostationary navigation overlay service
EHEDG	European Hygienic Engineering and Design Group
EICAS	engine indicating and crew alerting system
EIF	European Interoperability Framework
EII	enterprise information integration
EIS	executive information system
EIU	Economist Intelligence Unit
EI	Enterprise integration
eLPCO	e-Learning professional competency
ELV	end-of-life of vehicle
EL	electroluminescence
EMCS	energy management control systems
EMF	electromotive force
EMO	evolutionary multiobjective optimization
EMR	electronic medical record
EMS	energy management system
EOL	end-of-life
EPA	Environmental Protection Agency
EPC	engineering, procurement, and contsruction
EPGWS	enhanced GPWS
EPROM	erasable programmable read-only memory
EPSG	Ethernet PowerLink Standardization Group
EP	evolutionary programming
ERMA	electronic recording machine accounting
ERM	electronic resources management
ERP	enterprise resource planning
ESA	European Space Agency
ESB	enterprise service bus
ESD	electronic software delivery
ESD	emergency shutdown
ESL	electronic system-level
ESPVR	end-systolic pressure–volume relationship
ESP	electronic stability program
ESR	enterprise services repository
ESSENCE	Equation of State: Supernovae Trace Cosmic Expansion
ESS	extended service set
ES	enterprise system
ES	evolution strategy
ETA	estimated time of arrival
ETC	electronic toll collection
ETG	EtherCAT Technology Group
ETH	Swiss Federal Technical university
ETMS	enhanced traffic management system
ET	evolutionary technique
EURONORM	European Economic Community
EU	European Union
EVA	extravehicular activity
EVD	eigenvalue–eigenvector decomposition
EVM	electronic voting machine
EVS	enhanced vision system
EWMA	exponentially-weighted moving average
EWSS	e-Work support system
EXPIDE	extended products in dynamic enterprise
EwIS	enterprise-wide information system

F

FAA	US Federal Aviation Administration
fab	fabrication plant
FACT	fair and accurate credit transaction
FAF	final approach fix
FAL	fieldbus application layer
FAQ	frequently asked questions
FASB	Financial Accounting Standards Board
FAST	final approach spacing tool
FA	factory automation
FA	false alarm
FBA	flux balance analysis
FBD	function block diagram
FCAW	flux cored arc welding
FCC	flight control computer
FCW	forward collision warning
FCW	forward crash warning
FDA	US Food and Drug Administration
FDD	fault detection and diagnosis
FDL-CR	facility description language–conflict resolution
FDL	facility design language
FESEM	field-emission scanning electron microscope
FFT	fast Fourier transform
FHSS	frequency hopping spread spectrum
FIFO	first-in first-out
FIM	Fisher information matrix
FIPA	Foundation for Intelligent Physical Agents
FIRA	Federation of International Robot-Soccer Associations

FISCUS	Föderales Integriertes Standardisiertes Computer-Unterstütztes Steuersystem – federal integrated standardized computer-supported tax system
FIS	fuzzy inference system
fJSP	flexible jobshop problem
FK	forward kinematics
FLC	fuzzy logic control
FL	fuzzy-logic
FMCS	flight management computer system
FMC	flexible manufacturing cell
FMC	flight management computer
FMEA	failure modes and effects analysis
FMECA	failure mode, effects and criticality analysis
FMS	field message specification
FMS	flexible manufacturing system
FMS	flexible manufacturing system
FMS	flight management system
FM	Fiduccia–Mattheyses
FM	frequency-modulation
FOC	federation object coordinator
FOGA	Foundations of Genetic Algorithms
FOUP	front open unified pod
FOV	field of view
FPGA	field-programmable gate arrays
FPID	feedforward PID
FP	flooding protocol
FSK	frequency shift keying
FSM	finite-state machine
FSPM	FAL service protocol machine
FSSA	fixed structure stochastic automaton
FSS	flight service station
FSW	friction stir welding
FTA	fault tree analysis
FTC	fault tolerant control
FTE	flight technical error
FTE	full-time equivalent
FTL	flexible transfer line
FTP	file transfer protocol
FTSIA	fault-tolerance sensor integration algorithm
FTTP	fault tolerant time-out protocal
FW	framework

G

G2B	government-to-business
G2C	government-to-citizen
G2G	government-to-government
GAGAN	GEO augmented navigation
GAIA	geometrical analytic for interactive aid
GAMP	good automated manufacturing practice
GATT	General Agreement on Tariffs and Trade
GA	genetic algorithms
GBAS	ground-based augmentation system
GBIP	general purpose interface bus
GBS	goal-based scenario
GDP	gross domestic product
GDP	ground delay program
GDSII	graphic data system II
GDSS	group decision support system
GECCO	Genetic and Evolutionary Computation Conference
GEM	generic equipment model
GERAM	generalized enterprise reference architecture and methodology
GIS	geographic information system
GLS	GNSS landing system
GLUT4	activated Akt and PKCζ trigger glucose transporter
GMAW	gas metal arc welding
GMCR	graph model for conflict resolution
GNSS	global navigation satellite system
GPA	generalized pursuit algorithm
GPC	generalized predictive control
GPRS	general packet radio service
GPS	global positioning system
GPWS	ground-proximity warning system
GP	genetic programming
GRAI	graphes de résultats et activités interreliés
GRAS	ground regional augmentation system
GRBF	Gaussian RBF
GSM	global system for mobile communication
GTAW	gas tungsten arc welding
GUI	graphic user interface

H

HACCP	hazard analysis and critical control points
HACT	human–automation collaboration taxonomy
HAD	heterogeneous, autonomous, and distributed
HART	highway addressable remote transducer
HCI	human–computer interaction
HCS	host computer system
HDD	hard-disk drive
HEA	human error analysis
HEFL	hybrid electrode fluorescent lamp
HEP	human error probability
HERO	highway emergency response operator
HES	handling equipment scheduling
HFDS	Human Factors Design Standard
HF	high-frequency
HID	high-intensity discharge
HIS	hospital information system
HITSP	Healthcare Information Technology Standards Panel
HIT	healthcare information technology
HIV	human immunodeficiency virus
HJB	Hamilton–Jacobi–Bellman

HL7	Health Level 7
HMD	helmet-mounted display
HMI	human machine interface
HMM	hidden Markov model
HMS	hierarchical multilevel system
HOMO	highest occupied molecular orbital
HPC	high-performance computing
HPLC	high-performance liquid chromatography
HPSS	High-Performance Storage System
HPWREN	High-Performance Wireless Research and Education Network
HP	horsepower
HRA	human reliability analysis
HR	human resources
HSE	high speed Ethernet
HSI	human system interface
HSMS	high-speed message standard
HTN	hierarchical task network
HTTP	hypertext transfer protocol
HUD	heads up display
HUL	Harvard University Library
HVAC	heating, ventilation, air-conditioning
Hazop	hazardous operation
HiL	hardware-in-the-loop

I

i-awGA	interactive adaptive-weight genetic algorithm
I(P)AD	intelligent (power) assisting device
I/O	input/output
IAMHS	integrated automated material handling system
IAT	Institut Avtomatiki i Telemekhaniki
IAT	interarrival time
IB	internet banking
ICAO	International Civil Aviation Organization
ICORR	International Conference on Rehabilitation Robotics
ICRA	International Conference on Robotics and Automation
ICT	information and communication technology
IC	integrated circuit
IDEF	integrated definition method
IDL	Interactive Data Language
IDM	iterative design model
ID	identification
ID	instructional design
IEC	International Electrotechnical Commission
IFAC	International Federation of Automatic Control
IFC	industry foundation class
IFF	identify friend or foe
IFR	instrument flight rules
IGRT	image-guided radiation therapy
IGS	intended goal structure
IGVC	Intelligent Ground Vehicle Competition
IHE	integrating the healthcare enterprise
IIT	information interface technology
IK	inverse kinematics
ILS	instrument landing system
ILS	integrated library system
IL	instruction list
IMC	instrument meteorological condition
IMC	internal model controller
IML	inside mold line
IMM	interactive multiple model
IMRT	intensity modulated radiotherapy
IMS	infrastructure management service
IMT	infotronics and mechatronics technology
IMU	inertial measurement unit
INS	inertial navigation system
IO	inputoutput
IPA	intelligent parking assist
IPS	integrated pond system
IPv6	internet protocol version 6
IP	inaction–penalty
IP	industrial protocol
IP	integer programming
IP	intellectual property
IP	internet protocol
IRAF	Image Reduction and Analysis Facility
IRB	institutional review board
IRD	interactive robotic device
IROS	Intelligent Robots and Systems
IRR	internal rate of return
IRS1	insulin receptor substrate-1
IR	infrared
ISA	instruction set architecture
ISCIS	intra-supply-chain information system
iSCSI	Internet small computer system interface
ISDN	integrated services digital network
ISELLA	intrinsically safe lightweight low-cost arm
ISIC/MED	Intelligent Control/Mediterranean Conference on Control and Automation
ISM	industrial, scientific, and medical
ISO-OSI	International Standards Organization Open System Interconnection
ISO	International Organization for Standardization
ISO	independent system operator
ISP	internet service provider
ISS	input-to-state stability
IS	information system
ITC	information and communications technology
ITS	intelligent transportation system
IT	information technology
IVBSS	integrated vehicle-based safety system

IVI	Intelligent Vehicle Initiative
IV	intravenous

J

J2EE	Java to Enterprise Edition
JAUGS	joint architecture for unmanned ground system
JCL	job control language
JDBC	Java database connectivity
JDEM	Joint Dark Energy Mission
JDL	job description language
JIT	just-in-time
JLR	join/leave/remain
JPA	job performance aid
JPDO	joint planning and development office
JPL	Jet Propulsion Laboratory
JSR-001	Java specification request
Java RTS	Java real-time system
Java SE	Java standard runtime environment
JeLC	Japan e-Learning Consortium

K

KADS	knowledge analysis and documentation system
KCL	Kirchhoff’s current law
KCM	knowledge chain management
KIF	knowledge interchange format
KISS	keep it simple system
KM	knowledge management
KPI	key performance indicators
KQML	knowledge query and manipulation language
KS	knowledge subsystem
KTA	Kommissiya Telemekhaniki i Avtomatiki
KVL	Kirchhoff’s voltage law
KWMS	Kerry warehouse management system

L

LAAS	local-area augmentation system
LADARS	precision laser radar
LAN	local-area network
LA	learning automata
LBNL	Lawrence Berkeley National Laboratory
LBW	Laser beam welding
LC/MS	liquid-chromatography mass spectroscopy
LCD	liquid-crystal display
LCG	LHC computing grid
LCMS	learning contents management system
LCM	lane change/merge warning
LC	lean construction
LDW	lane departure warning
LDW	lateral drift warning system
LD	ladder diagram
LEACH	low-energy adaptive clustering hierarchy
LED	light-emitting diode
LEEPS	low-energy electron point source
LEO	Lyons Electronic Office
LES	logistic execution system
LFAD	light-vehicle module for LCM, FCW, arbitration, and DVI
LF	low-frequency
LHC	Large Hadron Collider
LHD	load–haul–dump
LIFO	last-in first-out
LIP	learning information package
LISI	levels of information systems interoperability
LISP	list processing
LLWAS	low-level wind-shear alert system
LMFD	left matrix fraction description
LMI	linear matrix inequality
LMPM	link layer mapping protocol machine
LMS	labor management system
LNAV	lateral navigation
LOA	levels of automation
LOCC	lines of collaboration and command
LOC	level of collaboration
LOINC	logical observation identifiers names and codes
LOM	learning object metadata/learning object reference model
LORANC	long-range navigational system
LPV	localizer performance with vertical guidance
LP	linear programming
LQG	linear-quadratic-Gaussian
LQR	linear quadratic regulator
LQ	linear quadratic
LS/AMC	living systems autonomic machine control
LS/ATN	living systems adaptive transportation network
LS/TS	Living Systems Technology Suite
LSL	low-level switch
LSST	Large Synoptic Survey Telescope
LSS	large-scale complex system
LS	language subsystem
LTI	linear time-invariant
LUMO	lowest unoccupied molecular orbital
LUT	look-up table
LVAD	left ventricular assist device
LVDT	linear variable differential transformer

M

m-SWCNT	metallic SWCNT
M/C	machining center
M2M	machine-to-machine

MAC	medium access control
MADSN	mobile-agent-based DSN
MAG	metal active gas
MAN	metropolitan area network
MAP	manufacturing assembly pilot
MAP	mean arterial pressure
MAP	missed approach point
MARC	machine-readable cataloging
MARR	minimum acceptable rate of return
MAS	multiagent system
MAU	medium attachment unit
MAV	micro air vehicle
MBP	Manchester bus powered
MCC	motor control center
MCDU	multiple control display unit
MCP	mode control panel
MCP	multichip package
MCS	material control system
MDF	medium-density fiber
MDI	manual data input
MDP	Markov decision process
MDS	management decision system
MD	missing a detection
MEMS	micro-electromechanical system
MEN	multienterprise network
MERP/C	ERP e-learning by MBE simulations with collaboration
MERP	Management Enterprise Resource Planning
MES	manufacturing execution system
METU	Middle East Technical University
MFD	multifunction display
MHA	material handling automation
MHEM	material handling equipment machine
MHIA	Material Handling Industry of America
MH	material handling
MIG	metal inert gas
MIMO	multi-input multi-output
MIP	mixed integer programming
MIS	management information system
MIS	minimally invasive surgery
MIT	Massachusetts Institute of Technology
MIT	miles in-trail
MKHC	manufacturing know-how and creativity
MLE	maximum-likelihood estimation
MMS	man–machine system
MMS	material management system
MOC	mine operation center
moGA	multiobjective genetic algorithm
MOL	middle of life
MOM	message-oriented middleware
MPAS	manufacturing process automation system
MPA	metabolic pathway analysis
MPC	model-based predictive control
mPDPTW	multiple pick up and delivery problem with time windows
MPEG	Motion Pictures Expert Group
MPLS	multi protocol label switching
MPS	master production schedule
MQIC	Medical Quality Improvement Consortium
MRI	magnetic resonance imaging
MRO	maintenance, repair, and operations
MRPII	material resource planning (2nd generation)
MRPI	material resource planning (1st generation)
MRP	manufacturing resources planning
MRR	material removal rate
MSAS	MTSAT satellite-based augmentation system
MSAW	minimum safe warning altitude
MSA	microsensor array
MSDS	material safety data sheet
MSI	multisensor integration
MSL	mean sea level
MTBF	mean time between failure
MTD	maximum tolerated dose
MTE	minimum transmission energy
MTSAT	multifunction transport satellite
MTTR	mean time to repair
MUX	multiplexor
MVFH	minimum vector field histogram
MV	manipulated variables
MWCNT	multi-walled carbon nanotube
MWKR	most work remaining
McTMA	multicenter traffic management advisor
Mcr	multi-approach to conflict resolution
MeDICIS	methodology for designing interenterprise cooperative information system
MidFSN	middleware for facility sensor network
Mips	million instructions per second
M&S	metering and spacing

N

NAE	National Academy of Engineering
NAICS	North American Industry Classification System
NASA	National Aeronautics and Space Administration
NASC	Naval Air Systems Command
NAS	National Airspace System
NATO	North Atlantic Treaty Organization
NBTI	negative-bias temperature instability
NCS	networked control system
NC	numerical control
NDB	nondirectional beacon
NDHA	National Digital Heritage Archive

NDI	nondestructive inspection
NDRC	National Defence Research Committee
NEAT	Near-Earth Asteroid Tracking Program
NEFUSER	neural-fuzzy system for error recovery
NEFUSER	neuro-fuzzy systems for error recovery
NEMA	National Electrical Manufacturers Association
NEMS	nanoelectromechanical system
NERC	North American Electric Reliability Corporation
NERSC	National Energy Research Scientific Computing Center
NES	networked embedded system
NFC	near field communication
NHTSA	National Highway Traffic Safety Administration
NICU	neonatal intensive care unit
NIC	network interface card
NIR	near-infrared
NISO	National Information Standards Organization
NIST	National Institute of Standards
NLP	natural-language processing
NNI	national nanotechnology initiative
non RT	nonreal-time
NP	nondeterministic polynomial-time
NPC	nanopore channel
NPV	net present value
NP	nominal performance
NRE	nonrecurring engineering
nsGA	nondominated sorting genetic algorithm
nsGA II	nondominated sorting genetic algorithm II
NSS	Federal Reserve National Settlement System
NS	nominal stability
NURBS	nonuniform rational B-splines
NYSE	New York Stock Exchange
NaroSot	Nano Robot World Cup Soccer Tournament
NoC	network on chip

O

O.R.	operations research
O/C	open-circuit
OAC	open architecture control
OAGIS	open applications group
OAI-PMH	open archieves initiative protocol for metadate harvesting
OASIS	Organization for the Advancement of Structured Information Standards
OBB	oriented bounding box
OBEM	object-based equipment model
OBS	on-board software
OBU	onboard unit
OCLC	Ohio College Library Center
ODBC	object database connectivity
ODE	ordinary differential equation
ODFI	originating depository financial institution
OECD	Organization for Economic Cooperation and Development
OEE	overall equipment effectiveness
OEM	original equipment manufacturer
OGSA	open grid services architecture
OHT	overhead hoist transporter
OHT	overhead transport
OLAP	online analytical process
OLE	object linking and embedding
OML	outside mold line
OMNI	office wheelchair with high manoeuvrability and navigational intelligence
OMS	order managements system
ONIX	online information exchange
OOAPD	object-oriented analysis, design and programming
OODB	object-oriented database
OOM	object-oriented methodology
OOOI	on, out, off, in
OOP	object-oriented programming
OO	object-oriented
OPAC	online public access catalog
OPC AE	OPC alarms and events
OPC XML-DA	OPC extensible markup language (XML) data access
OPC	online process control
OPM	object–process methodology
OQIS	online quality information system
ORF	operating room of the future
ORTS	open real-time operating system
OR	operating room
OR	operation research
OSHA	Occupation Safety and Health Administration
OSRD	Office of Scientific Research and Development
OSTP	Office of Science and Technology Policy
OS	operating system
OTS	operator training systems
OWL	web ontology language

P

P/D	pickup/delivery
P/T	place/transition
PACS	picture archiving and communications system
PAM	physical asset management
PAM	pulse-amplitude modulation
PAN	personal area network

PARR	problem analysis resolution and ranking
PAT	process analytical technology
PAW	plasma arc welding
PBL	problem-based learning
PBPK	physiologically based pharmacokinetic
PCA	principal component analysis
PCBA	printed circuit board assembly
PCB	printed circuit board
PCFG	probabilistic context-free grammar
PCI	Peripheral Component Interconnect
PCR	polymerase chain reaction
PC	personal computer
PDA	personal digital assistant
PDC	predeparture clearance
PDDL	planning domain definition language
PDF	probability distribution function
pdf	probability distribution function
PDITC	1,4-phenylene diisothiocyanate
PDKM	product data and knowledge management
PDM	product data management
PDSF	Parallel Distributed Systems Facility
PDT	photodynamic therapy
PD	pharmacodynamics
PECVD	plasma enhanced chemical vapor deposition
PEID	product embedded information device
PERA	Purdue enterprise reference architecture
PERT/CPM	program evaluation and review technique/critical path method
PERT	project evaluation and review technique
PET	positron emission tomography
PE	pulse echo
PFS	precision freehand sculptor
PF	preference function
PGP	pretty good privacy
PHA	preliminary hazard analysis
PHERIS	public-health emergency response information system
PHR	personal healthcare record
PI3K	phosphatidylinositol-3-kinase
PID	proportional, integral, and derivative
PISA	Program for International Student Assessment
PI	proportional–integral
PKI	public-key infrastructure
PKM	parallel kinematic machine
PK	pharmacokinetics
PLA	programmable logic array
PLC	programmable logic controller
PLD	programmable logic device
PLM	product lifecycle management
PMC	process module controller
PMF	positioning mobile with respect to fixed
PM	process module
POMDP	partially observable Markov decision process
POS	point-of-sale
PPFD	photosynthetic photon flux density
PPS	problem processing subsystem
PRC	phase response curve
PROFIBUS-DP	process field bus–decentralized peripheral
PROMETHEE	preference ranking organization method for enrichment evaluation
PR	primary frequency
PSAP	public safety answering point
PSC	product services center
PSF	performance shaping factor
PSH	high-pressure switch
PSK	phase-shift keying
PSM	phase-shift mask
PS	price setting
PTB	German Physikalisch-Technische Bundesanstalt
PTO	power takeoff
PTP	point-to-point protocol
PTS	predetermined time standard
PWM	pulse-width-modulation
PXI	PCI extensions for instrumentation
ProVAR	professional vocational assistive robot
Prolog	programming in logics
P&ID	piping & instrumentation diagram

Q

QAM	quadrature amplitude modulation
QTI	question and test interoperability
QoS	quality of service

R

R.U.R.	Rossum’s universal robots
R/T mPDPSTW	multiple pick up and delivery problem with soft time windows in real time
RAID	redundant array of independent disk
RAID	robot to assist the integration of the disabled
RAIM	receiver autonomous integrity monitoring
rALB	robot-based assembly line balancing
RAM	random-access memory
RAP	resource allocation protocol
RAS	recirculating aquaculture system
RA	resolution advisory
RBC	red blood cell
RBF	radial basis function
rcPSP	resource-constrained project scheduling problem
RCP	rapid control prototyping
RCRBF	raised-cosine RBF
RC	remote control
RC	repair center
RDB	relational database
RDCS	robust design computation system

RDCW FOT	Road Departure Crash Warning System Field Operational Test
RDCW	road departure crash warning
RDF	resource description framework
RET	resolution enhancement technique
RE	random environment
RFID	radiofrequency identification
RF	radiofrequency
RGB	red–green–blue
RGV	rail-guided vehicle
RHC	receding horizon control
RHIO	regional health information organization
RIA	Robotics Industries Association
RISC	reduced instruction set computer
RIS	real information system
RI	reward–inaction
RLG	Research Libraries Group
RLG	ring-laser-gyro
RMFD	right matrix fraction description
RMS	reconfigurable manufacturing systems
RMS	reliability, maintainability, and safety
RMS	root-mean-square
RM	real manufacturing
RNAV	area navigation
RNA	ribonucleic acid
RNG	random-number generator
RNP	required navigation performance
ROBCAD	robotics computer aided design
ROI	return on investment
ROM	range-of-motion
ROT	runway occupancy time
ROV	remotely operated underwater vehicle
RO	read only
RPC	remote procedure call
RPM	revolutions per minute
RPN	risk priority number
RPS	real and physical system
RPTS	robot predetermined time standard
RPU	radar processing unit
RPV	remotely piloted vehicle
RPW	ranked positioned weight
RP	reward–penalty
RRT	rapidly exploring random tree
RSEW	resistance seam welding
RSW	resistance spot welding
RS	robust stability
RT DMP	real-time decision-making processes
RT-CORBA	real-time CORBA
RTA	required time of arrival
RTDP	real-time dynamic programming
RTD	resistance temperature detector
RTE	real-time Ethernet
RTK GPS	real-time kinematic GPS
RTL	register transfer level
RTM	resin transfer molding
RTM	robot time & motion method
RTOS	real-time operating system
RTO	real-time optimization
RTO	regional transmission organization
RTSJ	real-time specification for Java
RT	radiotherapy
RT	register transfer
rwGA	random-weight genetic algorithm
RW	read/write
RZPR	power reserve
RZQS	quick-start reserve
Recon	retrospective conversion
R&D	research and development

S

s-SWCNT	semiconducting MWCNT
S/C	short-circuit
SACG	Stochastic Adaptive Control Group
SADT	structured analysis and design technique
SAGA	Standards und Architekturen für e-Government-Anwendungen – standards and architectures for e-Government applications
sALB	simple assembly line balancing
SAM	self-assembled monolayer
SAM	software asset management
SAN	storage area network
SAO	Smithsonian Astrophysical Observatory
SAW	submerged arc welding
SA	situation awareness
SBAS	satellite-based augmentation system
SBIR	small business innovation research
SBML	system biology markup language
SCADA	supervisory control and data acquisition
SCARA	selective compliant robot arm
SCC	somatic cell count
SCM	supply chain management
SCNM	slot communication network management
SCN	suprachiasmatic nucleus
SCORM	sharable content object reference model
SCST	source-channel separation theorem
SDH	synchronous digital hierarchy
SDSL	symmetrical digital subscriber line
SDSS	Sloan Digital Sky Survey II
SDSS	spatial decision support system
SDS	sequential dynamic system
SDT	signal detection theory
SECS	semiconductor equipment communication standard
SEC	Securities and Exchange Comission
SEER	surveillance, epidemiology, and end result
SEI	Software Engineering Institute
SELA	stochastic estimator learning algorithm
SEMI	Semiconductor Equipment and Material International

SEM	scanning electron microscopy
SEM	strategic enterprise management
SESAR	Single European Sky ATM research
SESS	steady and earliest starting schedule
SFC	sequential function chart
SFC	space-filling curve
SHMPC	shrinking horizon model predictive control
SIFT	scale-invariant feature transform
SIL	safety integrity level
SIM	single input module
SISO	single-input single-output
SIS	safety interlock system
SKU	stock keeping unit
SLAM	simultaneous localization and mapping technique
SLA	service-level agreement
SLIM-MAUD	success likelihood index method-multiattribute utility decomposition
SLP	storage locations planning
SL	sensitivity level
SMART	Shimizu manufacturing system by advanced robotics technology
SMAW	shielded metal arc welding
SMA	shape-memory alloys
SMC	sequential Monte Carlo
SME	small and medium-sized enterprises
SMIF	standard mechanical interface
SMS	short message service
SMTP	simple mail transfer protocol
SMT	surface-mounting technology
SNA	structural network analysis
SNIFS	Supernova Integral Field Spectrograph
SNLS	Supernova Legacy Survey
SNOMED	systematized nomenclature of medicine
SNfactory	Nearby Supernova Factory
SN	supernova
SOAP	simple object access protocol
SOA	service-oriented architecture
SOC	system operating characteristic
SOI	silicon-on-insulator
SONAR	sound navigation and ranging
SO	system operator
SPC	statistical process control
SPF/DB	superplastic forming/diffusion bonding
SPF	super plastic forming
SPIN	sensor protocol for information via negotiation
SPI	share price index
SQL	structured query language
SRAM	static random access memory
SRI	Stanford Research Institute
SRL	science research laboratory
SRM	supplier relationship management
SSADM	structured systems analysis and design method
SSA	stochastic simulation algorithm
ssDNA	single-strand DNA
SSH	secure shell
SSL	secure sockets layer
SSO	single sign-on
SSR	secondary surveillance radar
SSSI	single-sensor, single-instrument
SSV	standard service volume
SS	speed-sprayer
STARS	standard terminal automation replacement system
STAR	standard terminal arrival route
STA	static timing analysis
STCU	SmallTown Credit Union
STEM	science, technology, engineering, and mathematics
STM	scanning tunneling microscope

Developm

Part A Development and Impacts of Automation

Development and Impacts of Automation. Part A The first part lays the conceptual foundations for the whole *Handbook* by explaining basic definitions of automation, its scope, its impacts and its meaning, from the views of prominent automation pioneers to a survey of concepts and applications around the world. The scope, evolution and development of automation are reviewed with illustrations, from prehistory throughout its development before and after the emergence of automatic control, during the Industrial Revolution, along the advancements in computing and communication, with and without robotics, and projections about the future of automation. Chapters in this part explain the significant influence of automation on our life: on individuals, organizations, and society; in economic terms and context; and impacts of precision, accuracy and reliability with automatic and automated equipment and operations.

1. Advances in Robotics and Automation: Historical Perspectives

Yukio Hasegawa

Historical perspectives are given about the impressive progress in automation. Automation, including robotics, has evolved by becoming useful and affordable. Methods have been developed to analyze and design better automation, and those methods have also been automated. The most important issue in automation to make every effort to paying attention to all the details.

The bodies of human beings are smaller than those of wild animals. Our muscles, bones, and nails are smaller and weaker. However, human beings, fortunately, have larger brains and wisdom. Humans initially learned how to use tools and then started using machines to perform necessary daily operations. Without the help of these tools or machines we, as human beings, can no longer support our daily life normally.

Technology is making progress at an extremely high speed; for instance, about half a century ago I bought a camera for my own use; at that time, the price of a conventional German-made camera was very high, as much as 6 months income. However, the price of a similar quality camera now is the equivalent of only 2 weeks of the salary of a young person in Japan.

Seiko Corporation started production and sales of the world's first quartz watch in Japan about 40 years ago. At that time, the price of the watch was about 400 000 Yen. People used to tell me that such high-priced watches could only be purchased by a limited group of people with high incomes, such as airline pilots, company owners, etc. Today similar watches are sold in supermarkets for only 1000 Yen.

Furthermore, nowadays, we are moving towards the automation of information handling by using computers; for instance, at many railway stations, it is now common to see unmanned ticket consoles. Telephone exchanges have become completely automated and the cost to use telephone systems is now very low.

In recent years, robots have become commonplace for aiding in many different environments. Robots are machines which carry out motions and information handling automatically. In the 1970s I was asked to start conducting research on robots. One day, I was asked by the management of a Japanese company that wanted to start the sales of robots to determine whether such robots could be used in Japan. After analyzing robot motions by using a high-speed film analysis system, I reached the conclusion that the robot could be used both in Japan as well as in the USA.

After that work I developed a new motion analysis method named the robot predetermined time standard (RPTS). The RPTS method can be widely applied to robot operation system design and contributed to many robot operation system design projects.

In the USA, since the beginning of the last century, a lot of pioneers in human operation rationalization have made significant contributions. In 1911, Frederik Tailor proposed the scientific management method, which was later reviewed by the American Congress. Prof. Gilbreth of Purdue University developed the new motion analysis method, and contributed to the rationalization of human operations. Mr. Dancan of WOFAC Corporation proposed a human predetermined time standard (PTS) method, which was applied to human operation rationalizations worldwide.

In the robotic field, those contributions are only part of the solution, and people have understood that mechanical and control engineering are additionally important aspects. Therefore, analysis of human operations in robotic fields are combined with more analysis, design, and rationalization [1.1]. However, human operators play a very challenging role in operations. Therefore, study of the work involved is more important than the robot itself and I believe that industrial engineering is going to become increasingly important in the future [1.2]. Prof. Nof developed RTM, the robot time & motion computational method, which was applied in robot selection and program improvements, including mobile robots. Such techniques were then incorporated in ROBCAD, a computer aided design system to automate the design and implementation of robot installations and applications.

A number of years ago I had the opportunity to visit the USA to attend an international robot symposium. At that time the principle of "no hands in dies" was a big topic in America due to a serious problem with guaranteeing the safety of metal-stamping operations. People involved in the safety of metal-stamping operations could not decrease the accident rate in spite of their increasing efforts. The government decided that a new policy to fully automate stamping operations or to use additional devices to hold and place workpieces without inserting operators' hands between dies was needed. The decision was lauded by many stamping robot manufacturers. Many expected that about 50 000 pieces of stamping robots would be sold in the American market in a few years. At that time 700 000 stamping presses were used in the USA. In Japan, the forecast figure was modified to 20 000 pieces. The figure was not small and therefore we immediately organized a stamping robot development project team with government financial support. The project team was composed of ten people: three robot engineers, two stamping engineers, a stamping technology consultant, and four students. I also invited an expert who had previously been in charge of stamping robot development projects in Japan. A few years later, sales of stamping robots started, with very good sales (over 400 robots were sold in a few years).

However, the robots could not be used and were rather stored as inactive machines. I asked the person in charge for the reason for this failure and was told that designers had concentrated too much on the robot hardware development and overlooked analysis of the conditions of the stamping operations. Afterwards, our project team analyzed the working conditions of the stamping operations very carefully and classified them into 128 types. Finally the project team developed an operation analysis method for metal-stamping operations. In a few years, fortunately, by applying the method we were able to decrease the rate of metal-stamping operation accidents from 12 000 per year to fewer than 4000 per year. Besides metal-stamping operations, we worked on research projects for forgings and castings to promote labor welfare. Through those research endeavors we reached the conclusion that careful analysis of the operation is the most important issue for obtaining good results in the case of any type of operations [1.3].

I believe, from my experience, that the most important issue – not only in robot engineering but in all automation – is to make every effort to paying attention to all the details.

2. Advances in Industrial Automation: Historical Perspectives

Theodore J. Williams

Automation is a way for humans to extend the capability of their tools and machines. Self-operation by tools and machines requires four functions: Performance detection; process correction; adjustments due to disturbances; enabling the previous three functions without human intervention. Development of these functions evolved in history, and automation is the capability of causing machines to carry out a specific operation on command from external source. In chemical manufacturing and petroleum industries prior to 1940, most processing was in batch environment. The increasing demand for chemical and petroleum products by World War II and thereafter required different manufacturing setup, leading to continuous processing and efficiencies were achieved by automatic control and automation of process, flow and transfer. The increasing complexity of the control system for large plants necessitated applications of computers, which were introduced to the chemical industry in the 1960s. Automation has substituted computer-based control systems for most, if not all, control systems previously based on human-aided mechanical or pneumatic systems to the point that chemical and petroleum plant systems are now fully automatic to a very high degree. In addition, automation has replaced human effort, eliminates significant labor costs, and prevents accidents and injuries that might occur. The Purdue enterprise reference architecture (PERA) for hierarchical control structure, the hierarchy of personnel tasks, and plant operational management structure, as developed for large industrial plants, and a frameworks for automation studies are also illustrated.

Humans have always sought to increase the capability of their tools and their extensions, i. e., machines. A natural extension of this dream was making tools capable of self-operation in order to:

1. Detect when performance was not achieving the initial expected result
2. Initiate a correction in operation to return the process to its expected result in case of deviation from expected performance
3. Adjust ongoing operations to increase the machine's productivity in terms of (a) volume, (b) dimensional accuracy, (c) overall product quality or (d) ability to respond to a new previously unknown disturbance
4. Carry out the previously described functions without human intervention.

Item 1 was readily achieved through the development of sensors that could continuously or periodically measure the important variables of the process and signal the occurrence of variations in them. Item 2 was made possible next by the invention of controllers that convert knowledge of such variations into commands required to change operational variables and thereby return to the required operational results. The successful operation of any commercially viable process requires the solution of items 1 and 2.

The development of item 3 required an additional level of intelligence beyond items 1 and 2, i. e., the capability to make a comparison between the results achieved and the operating conditions used for a series of tests. Humans can, of course, readily perform this task. Accomplishing this task using a machine, however, requires the computational capability to compare successive sets of data, gather and interpret corrective results, and be able to apply the results obtained. For a few variables with known variations, this can be incorporated into the controller's design. However, for a large number of variables or when possible unknown ranges of responses may be present, a computer must be available.

Automation is the capability of causing a machine to carry out a specific operation on command from an external source. The nature of these operations may also be part of the external command received. The devise involved may likewise have the capability to respond to other external environmental conditions or signals when such responses are incorporated within its capabilities. Automation, in the sense used almost universally today in the chemical and petroleum industries, is taken to mean the complete or near-complete operation of chemical plants and petroleum refineries by digital computer systems. This operation entails not only the monitoring and control of multiple flows of materials involved but also the coordination and optimization of these controls to achieve optimal production rate and/or the economic return desired by management. These systems are programmed to compensate, as far as the plant equipment itself will allow, for changes in raw material characteristics and availability and requested product flow rates and qualities.

In the early days of the chemical manufacturing and petroleum industries (prior to 1940), most processing was carried out in a *batch* environment. The needed ingredients were added together in a *kettle* and processed until the reaction or other desired action was completed. The desired product(s) were then sep-

arated from the byproducts and unreacted materials by decanting, distilling, filtering or other applicable physical means. These latter operations are thus in contrast to the generally chemical processes of product formation. At that early time, the equipment and their accompanying methodologies were highly manpower dependent, particularly for those requiring coordination of the joint operation of related equipment, especially when succeeding steps involved transferring materials to different sets or types of equipment.

The strong demand for chemical and petroleum products generated by World War II and the following years of prosperity and rapid commercial growth required an entirely different manufacturing equipment setup. This led to the emergence of continuous processes where subsequent processes were continued in successive connected pieces of equipment, each devoted to a separate setup in the process. Thus a progression in distance to the succeeding equipment (rather than in time, in the same equipment) was now necessary. Since any specific piece of equipment or location in the process train was then always used for the same operational stage, the formerly repeated filling, reacting, emptying, and cleaning operations in every piece of equipment was now eliminated. This was obviously much more efficient in terms of equipment usage. This type of operation, now called *continuous processing*, is in contrast to the earlier *batch processing* mode. However, the coordination of the now simultaneous operations connected together required much more accurate control of both operations to avoid the transmission of processing errors or *upsets* to downstream equipment.

Fortunately, our basic knowledge of the inherent chemical and physical properties of these processes had also advanced along with the development of the needed equipment and now allows us to adopt methodologies for assessing the quality and state of these processes during their operation, i. e., degree of completion, etc. Likewise, also fortunately, our basic knowledge of the technology of automatic control and its implementing equipment advanced along with knowledge of the

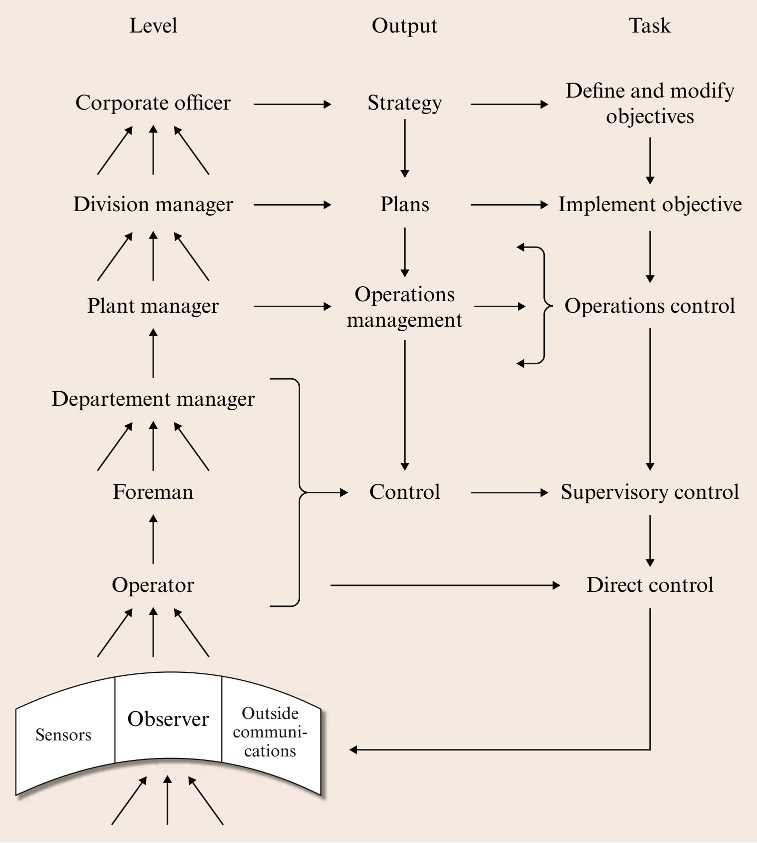

Fig. 2.2 Personnel task hierarchy in a large manufacturing plant

pneumatic and electronic techniques used to implement them. Pneumatic technology for the necessary control equipment was used almost exclusively from the original development of the technique to the 1920s until its replacement by the rapidly developing electronic techniques in the 1930s. This advanced type of equipment became almost totally electronic after the development of solid-state electronic technologies as the next advances. Pneumatic techniques were then used only where severe fire or explosive conditions prevented the use of electronics.

The overall complexity of the control systems for large plants made them objects for the consideration of the use of computers almost as soon as the early digital computers became practical and affordable. The first computers for chemical plant and refinery control were installed in 1960, and they became quite prevalent by 1965. By now, computers are widely used in all large plant operations and in most small ones as well. If automation can be defined as the substitution of computer-based control systems for most, if not all, control systems previously based on human-aided mechanical or pneumatic systems, then for chemical and petroleum plant systems, we can now truly say that they are *fully automated*, to a very high degree.

As indicated above, a most desired byproduct of the automation of chemical and petroleum refining processes must be the replacement of human effort: first in directly handling the frequently dangerous chemical ingredients in the initiation of the process; second, that

of personally monitoring and controlling the carrying out and completion of these processes; and finally that of handling the resulting products. This omits the expenses involved in the employment of personnel for carrying out these tasks, and also prevents unnecessary accidents and injuries that might occur there. The staff at chemical plants and petroleum refineries has thus been dramatically decreased in recent years. In many locations this involves only a *watchman* role and an emergency maintenance function. This capability has further resulted in even further improvements in overall plant design to take full advantage of this new capability – a *synergy effect*. This *synergy effect* was next felt in the automation of the raw material acceptance practices and the product distribution methodologies of these plants. Many are now connected directly to the raw material sources and their customers by pipelines, thus totally eliminating special raw material and product handling and packaging. Again, computers are widely used in the scheduling, monitoring, and controlling of all operations involved here.

Finally, it has been noted that there is a hierarchical relationship between the control of the industrial process plant unit automatic control systems and the duties of the successive levels of management in a large industrial plant from company management down to the final plant control actions [2.2–13]. It has also been shown that all actions normally taken by intermedi-

3. Automation: What It Means to Us Around the World

Shimon Y. Nof

The meaning of the term *automation* is reviewed through its definition and related definitions, historical evolution, technological progress, benefits and risks, and domains and levels of applications. A survey of 331 people around the world adds insights to the current meaning of automation to people, with regard to: *What is your definition of automation? Where did you encounter automation first in your life?* and *What is the most important contribution of automation to society?* The survey respondents include 12 main aspects of the definition in their responses; 62 main types of first automation encounter; and 37 types of impacts, mostly benefits but also two benefit–risks combinations: replacing humans, and humans' inability to complete tasks by themselves. The most exciting contribution of automation found in the survey was to *encourage/inspire creative work; inspire newer solutions*. Minor variations were found in different regions of the world. Responses about the first automation encounter are somewhat related to the age of the respondent, e.g., pneumatic versus digital control, and to urban versus farming childhood environment. The chapter concludes with several emerging trends in bioinspired automation, collaborative control and automation, and risks to anticipate and eliminate.

3.1 The Meaning of Automation

What is the meaning of automation? When discussing this term and concept with many colleagues, leading experts in various aspects of automation, control theory, robotics engineering, and computer science during the development of this *Handbook of Automation*, many of them had different definitions; they even argued vehemently that *in their language, or their region of the world, or their professional domain*, automation has a unique meaning *and we are not sure it is the same meaning for other experts*. But there has been no doubt, no confusion, and no hesitation that automation is powerful; it has tremendous and amazing impact on civilization, on humanity, and it may carry risks.

So what is automation? This chapter introduces the meaning and definition of automation, at an introductory, overview level. Specific details and more theoretical definitions are further explained and illustrated throughout the following parts and chapters of this handbook. A survey of 331 participants from around the world was conducted and is presented in Sect. 3.5.

3.1.1 Definitions and Formalism

Automation, in general, implies *operating or acting, or self-regulating, independently, without human intervention*. The term evolves from *automatos*, in Greek, meaning acting by itself, or by its own will, or spontaneously. Automation involves machines, tools, devices, installations, and systems that are all platforms developed by humans to perform a given set of activities without human involvement during those activities. But there are many variations of this definition. For instance, before modern automation (specifically defined in the modern context since about 1950s), *mechanization* was a common version of automation. When automatic control was added to mechanization as an intelligence feature, the distinction and advantages of automation became clear. In this chapter, we review these related definitions and their evolvement, and survey how people around the world perceive automation. Examples of automation are described, including ancient to early examples in Table 3.1, examples from the Industrial Revolution in Table 3.3, and modern and emerging examples in Table 3.4. From the general definition of automation, the automation formalism is presented in Fig. 3.1 with four main elements: platform, autonomy, process, and power source. Automation platforms are illustrated in Table 3.2.

This automation formalism can help us review some early examples that may also fall under the definition of automation (before the term *automation* was even coined), and differentiate from related terms, such as *mechanization*, *cybernetics*, *artificial intelligence*, and *robotics*.

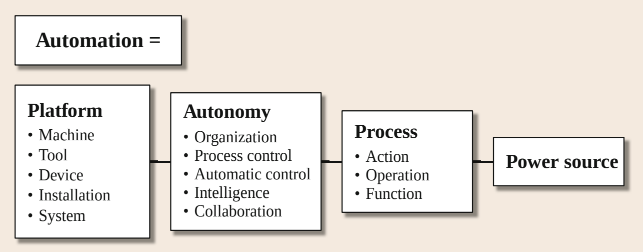

Fig. 3.1 Automation formalism. Automation comprises four basic elements. See representative illustrations of platforms, autonomy, process, and power source in Tables 3.1–3.2, 3.6, and the automation cases below, in Sect. 3.3

Automaton

An *automaton* (plural: automata, or automatons) is an autonomous machine that contains its own power source and can perform without human intervention a complicated series of decisions and actions, in response to programs and external stimuli. Since the term automaton is used for a specific autonomous machine, tool or device, it usually does not include automation platforms such as automation infrastructure, automatic installations, or automation systems such as automation

Table 3.1 Automation examples: ancient to early history

	Machine/system	Autonomous action/ function	Autonomy: control/ intelligence	Power source	Replacing	Process without human intervention
1.	Irrigation channels	Direct, regulate water flow	From-to, on-off gates, predetermined	Gravity	Manual watering	Water flow and directions
2.	Water supply by aqueducts over large distances	Direct, regulate water supply	From-to, on-off gates, predetermined	Gravity	Practically impossible	Water flow and directions
3.	Sundial clocks	Display current time	Predetermined timing	Sunlight	Impossible otherwise	Shadow indicating time
4.	Archytas' flying pigeon (4th century BC); Chinese mechanical orchestra (3rd century BC) Heron's mechanical chirping birds and moving dolls (1st century AD)	Flying; playing; chirping; moving	Predetermined sound and movements with some feedback	Heated air and steam (early hydraulics and pneumatics)	Real birds; human play	Mechanical bird or toy motions and sounds
5.	Ancient Greek temple automatic door opening	Open and close door	Preset states and positions with some feedback	Heated air, steam, water, gravity	Manual open and close	Door movements
6.	Windmills	Grinding grains	Predefined grinding	Winds	Animal and human power	Grinding process

Table 3.2 Automation platforms

Platform	Machine	Tool	Device	Installation	System	System of systems
Example	Mars lander	Sprinkler	Pacemaker	AS/RC (automated storage/ retrieval carousel)	ERP (enterprise resource planning)	Internet

software (even though some use the term *software automaton* to imply computing procedures). The scholar Al-Jazari from al-Jazira, Mesopotamia designed pioneering programmable automatons in 1206, as a set of dolls, or humanoid automata. Today, the most typical automatons are what we define as robots.

Table 3.3 Automation examples: Industrial Revolution to 1920

	Machine/system	Autonomous action/function	Autonomy: control/ intelligence	Power source	Replacing	Process without human intervention
1.	Windmills (17th century)	Flour milling	Feedback keeping blades always facing the wind	Winds	Nonfeedback windmills	Milling process
2.	Automatic pressure valve (Denis Papin, 1680)	Steam pressure in piston or engine	Feedback control of steam pressure	Steam	Practically impossible otherwise	Pressure regulation
3.	Automatic grist mill (Oliver Evans, 1784)	Continuous-flow flour production line	Conveyor speed control; milling process control	Water flow; steam	Human labor	Grains conveyance and milling process
4.	Flyball governor (James Watt, 1788)	Control of steam engine speed	Automatic feedback of centrifugal force for speed control	Steam	Human control	Speed regulation
5.	Steamboats, trains (18–19th century)	Transportation over very large distances	Basic speed and navigation controls	Steam	Practically impossible otherwise	Travel, freight hauling, conveyance
6.	Automatic loom (e.g., Joseph Jacquard, 1801)	Fabric weaving, including intricate patterns	Basic process control programs by interchangeable punched card	Steam	Human labor and supervision	Cloth weaving according to human design of fabric program
7.	Telegraph (Samuel Morse, 1837)	Fast delivery of text message over large distances	On-off, direction, and feedback	Electricity	Before tele-communication, practically impossible otherwise	Movement of text over wires

Table 3.3 (cont.)

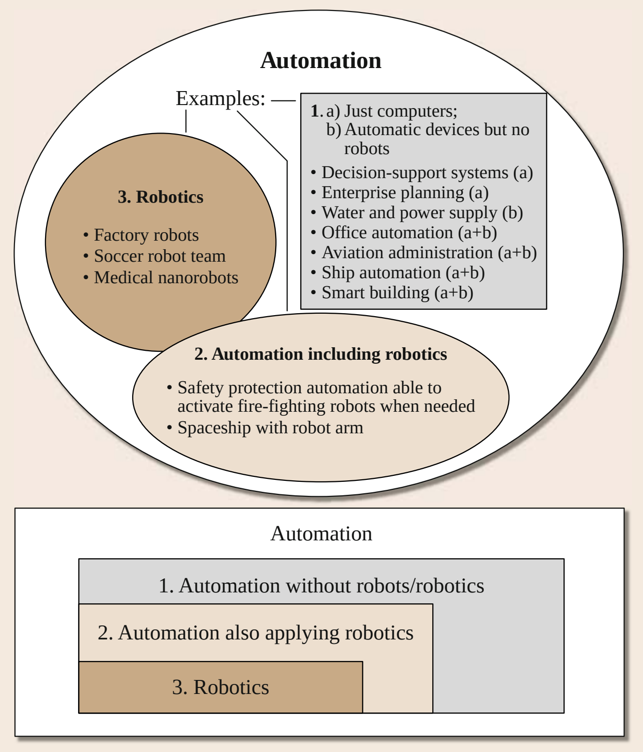
	Machine/system	Autonomous action/function	Autonomy: control/ intelligence	Power source	Replacing	Process without human intervention
8.	Semiautomatic assembly machines (Bodine Co., 1920)	Assembly functions including positioning, drilling, tapping, screw insertion, pressing	Connect/ disconnect; process control	Electricity; compressed air through belts and pulleys	Human labor	Complex sequences of assembly operations
9.	Automatic automobile-chassis plant (A.O. Smith Co., 1920)	Chassis production	Parts, components, and products flow control, machining, and assembly process control	Electricity	Human labor and supervision	Manufacturing processes and part handling with better accuracy

Robot

A *robot* is a mechanical device that can be programmed to perform a variety of tasks of manipulation and locomotion under automatic control. Thus, a robot could also be an automaton. But unlike an automaton, a robot is usually designed for highly variable and flexible, purposeful motions and activities, and for specific operation domains, e.g., surgical robot, service robot, welding robot, toy robot, etc. General Motors implemented the first industrial robot, called UNIMATE, in 1961 for die-casting at an automobile factory in New Jersey. By now, millions of robots are routinely employed and integrated throughout the world.

Robotics

The science and technology of designing, building, and applying robots, computer-controlled mechanical devices, such as automated tools and machines. Science



Automation
Examples:
1. a) Just computers;
b) Automatic devices but no robots
• Decision-support systems (a)
• Enterprise planning (a)
• Water and power supply (b)
• Office automation (a+b)
• Aviation administration (a+b)
• Ship automation (a+b)
• Smart building (a+b)
3. Robotics
• Factory robots
• Soccer robot team
• Medical nanorobots
2. Automation including robotics
• Safety protection automation able to activate fire-fighting robots when needed
• Spaceship with robot arm
Automation
1. Automation without robots/robotics
2. Automation also applying robotics
3. Robotics

Fig. 3.2 The relation between robotics and automation: The scope of automation includes applications: (1a) with just computers, (1b) with various automation platforms and applications, but without robots; (2) automation including also some robotics; (3) automation with robotics

Table 3.4 Automation examples: modern and emerging

	Machine/ system	Autonomous action/function	Autonomy: control/ intelligence	Power source	Replacing	Process without human intervention
1.	Automatic door opener	Opening and closing of doors triggered by sensors	Automatic control	Compressed air or electric motor	Human effort	Doors of buses, trains, buildings open and close by themselves
2.	Elevators, cranes	Lifting, carrying	On-off; feedback; preprogrammed or interactive	Hydraulic pumps; electric motors	Human climbing, carrying	Speed and movements require minimal supervision
3.	Digital computers	Data processing and computing functions	Variety of automatic and interactive control and operating systems; intelligent control	Electricity	Calculations at speeds, complexity, and with amounts of data that are humanly impossible	Cognitive and decision-making functions
4.	Automatic pilot	Steering aircraft or boat	Same as (3)	Electrical motors	Human pilot	Navigation, operations, e.g., landing
5.	Automatic transmission	Switch gears of power transmission	Automatic control	Electricity; hydraulic pumps	Manual transmission control	Engaging/ disengaging rotating gears
6.	Office automation	Document processing, imaging, storage, printing	Same as (3)	Electricity	Some manual work; some is practically impossible	Specific office procedures
7.	Multirobot factories	Robot arms and automatic devices perform variety of manufacturing and production processes	Optimal, adaptive, distributed, robust, self-organizing, collaborative, and other intelligent control	Hydraulic pumps, pneumatics, and electric motors	Human labor and supervision	Complex operations and procedures, including quality assurance

fiction author and scientist *Isaac Asimov* coined the term *robotics* in 1941 to describe the technology of robots and predicted the rise of a significant robot industry, e.g., in his foreword to [3.1]:

> *Since physics and most of its subdivisions routinely have the "-ics" suffix, I assumed that robotics was the proper scientific term for the systematic study of robots, of their construction, maintenance, and behavior, and that it was used as such.*

3.1.2 Robotics and Automation

Robotics is an important subset of automation (Fig. 3.2). For instance, of the 25 automation examples in Tables 3.1, 3.3 and 3.4, examples 4 in Table 3.1 and 7 in Table 3.4 are about robots. Beyond robotics, automation includes:

- Infrastructure, e.g., water supply, irrigation, power supply, telecommunication
- Nonrobot devices, e.g., timers, locks, valves, and sensors
- Automatic and automated machines, e.g., flour mills, looms, lathes, drills, presses, vehicles, and printers
- Automatic inspection machines, measurement workstations, and testers
- Installations, e.g., elevators, conveyors, railways, satellites, and space stations
- Systems, e.g., computers, office automation, Internet, cellular phones, and software packages.

Common to both robotics and automation are use of automatic control, and evolution with computing and communication progress. As in automation, robotics also relies on four major components, including a platform, autonomy, process, and power source, but in robotics, a robot is often considered a machine, thus the platform is mostly a machine, a tool or device, or a system of tools and devices. While robotics is, in a major way, about automation of motion and mobility, automation beyond robotics includes major areas based on software, decision-making, planning and optimization, collaboration, process automation, office automation, enterprise resource planning automation, and e-Services. Nevertheless, there is clearly an overlap between automation and robotics; while to most people a robot means a machine with certain automation intelligence, to many an intelligent elevator, or highly

Table 3.4 (cont.)

	Machine/ system	Autonomous action/function	Autonomy: control/ intelligence	Power source	Replacing	Process without human intervention
8.	Medical diagnostics (e.g., computerized tomography (CT), magnetic resonance imaging (MRI))	Visualization of medical test results in real time	Automatic control; automatic virtual reality	Electricity	Impossible otherwise	Noncontact testing and results presentation
9.	Wireless services	Remote prognostics and automatic repair	Predictive control; interacting with radio frequency identification (RFID) and sensor networks	Electricity	Practically impossible otherwise	Monitoring remote equipment functions, executing self-repairs
10.	Internet search engine	Finding requested information	Optimal control; multiagent control	Electricity	Human search, practically impossible	Search for specific information over a vast amount of data over worldwide systems

automated machine tool, or even a computer may also imply a robot.

Cybernetics

Cybernetics is the scientific study of control and communication in organisms, organic processes, and mechanical and electronic systems. It evolves from *kibernetes*, in Greek, meaning pilot, or captain, or governor, and focuses on applying technology to replicate or imitate biological control systems, often called today bioinspired, or system biology. *Cybernetics*, a book by Norbert Wiener, who is attributed with coining this word, appeared in 1948 and influenced artificial intelligence research. Cybernetics overlaps with control theory and systems theory.

Cyber

Cyber- is a prefix, as in cybernetic, cybernation, or cyborg. Recently, cyber has assumed a meaning as a noun, meaning computers and information systems, virtual reality, and the Internet. This meaning has emerged because of the increasing importance of these automation systems to society and daily life.

Artificial Intelligence (AI)

Artificial intelligence (AI) is the ability of a machine system to perceive anticipated or unanticipated new

Table 3.5 Definitions of automation (after [3.2])

Source	Definition of automation
1. John Diebold, President, John Diebold & Associates, Inc.	*It is a means of organizing or controlling production processes to achieve optimum use of all production resources – mechanical, material, and human. Automation means optimization of our business and industrial activities.*
2. Marshall G. Nuance, VP, York Corp.	*Automation is a new word, and to many people it has become a scare word. Yet it is not essentially different from the process of improving methods of production which has been going on throughout human history.*
3. James B. Carey, President, International Union of Electrical Workers	*When I speak of automation, I am referring to the use of mechanical and electronic devices, rather than human workers, to regulate and control the operation of machines. In that sense, automation represents something radically different from the mere extension of mechanization. Automation is a new technology. Arising from electronics and electrical engineering.*
4. Joseph A. Beirne, President, Communications Workers of America	*We in the telephone industry have lived with mechanization and its successor automation for many years.*
5. Robert C. Tait, Senior VP, General Dynamics Corp.	*Automation is simply a phrase coined, I believe, by Del Harder of Ford Motor Co. in describing their recent supermechanization which represents an extension of technological progress beyond what has formerly been known as mechanization.*
6. Robert W. Burgess, Director, Census, Department of Commerce	*Automation is a new word for a now familiar process of expanding the types of work in which machinery is used to do tasks faster, or better, or in greater quantity.*
7. D.J. Davis, VP Manufacturing, Ford Motor Co.	*The automatic handling of parts between progressive production processes. It is the result of better planning, improved tooling, and the application of more efficient manufacturing methods, which take full advantage of the progress made by the machine-tool and equipment industries.*
8. Don G. Mitchell, President, Sylvania Electric Products, Inc.	*Automation is a more recent term for mechanization, which has been going on since the industrial revolution began. Automation comes in bits and pieces. First the automation of a simple process, and then gradually a tying together of several processes to get a group of subassembly complete.*

Table 3.6 Automation domains

Domain	**Accounting**	**Agriculture**	**Banking**	**Chemical process**	**Communi-cation**	**Construction**	**Design**
Example	Billing software	Harvester	ATM (automatic teller machine)	Refinery	Print-press	Truck	CAD (computer-aided design)
Education	**Energy**	**Engineering**	**Factory**	**Government**	**Healthcare**	**Home**	**Hospital**
Television	Power windmill	Simulation	AGV (automated guided vehicle)	Government web portals	Body scanner	Toaster	Drug delivery
Hospitality	**Leisure**	**Library**	**Logistics**	**Management**	**Manu-facturing**	**Maritime**	**Military**
CRM (customer relations management)	Movie	Database	RFID (radio-frequency identification)	Financial analysis software	Assembly robot	Navigation	Intelligence satellite
Office	**Post**	**Retail**	**Safety**	**Security**	**Service**	**Sports**	**Transportation**
Copying machine	Mail sorter	e-Commerce	Fire alarm	Motion detector	Vending machine	Tread mill	Traffic light

conditions, decide what actions must be performed under these conditions, and plan the actions accordingly. The main areas of AI study and application are knowledge-based systems, computer sensory systems, language processing systems, and machine learning. AI is an important part of automation, especially to characterize what is sometimes called intelligent automation (Sect. 3.4.2).

It is important to note that AI is actually human intelligence that has been implemented on machines, mainly through computers and communication. Its significant advantages are that it can function automatically, i. e., without human intervention during its operation/function; it can combine intelligence from many humans, and improve its abilities by automatic learning and adaptation; it can be automatically distributed, duplicated, shared, inherited, and if necessary, restrained and even deleted. With the advent of these abilities, remarkable progress has been achieved. There is also, however, an increasing risk of *running out of control* (Sect. 3.6), which must be considered carefully as with harnessing any other technology.

3.1.3 Early Automation

The creative human desire to develop automation, from ancient times, has been to recreate natural activities, either for enjoyment or for productivity with less human effort and hazard. It should be clear, however, that the following six imperatives have been proven about automation:

1. Automation has always been developed by people
2. Automation has been developed for the sake of people
3. The benefits of automation are tremendous
4. Often automation performs tasks that are impossible or impractical for humans
5. As with other technologies, care should be taken to prevent abuse of automation, and to eliminate the possibilities of unsafe automation
6. Automation is usually inspiring further creativity of the human mind.

The main evolvement of automation has followed the development of mechanics and fluidics, civil infrastructure and machine design, and since the 20th century, of computers and communication. Examples of ancient automation that follow the formal definition (Table 3.1) include flying and chirping birds, sundial clocks, irrigation systems, and windmills. They all include the four basic automation elements, and have a clear autonomous process without human intervention, although they are mostly predetermined or predefined in terms of their control program and organization. But not all these ancient examples replace previously used human effort: Some of them would be impractical or even impossible for humans, e.g., displaying time, or moving large quantities of water by aqueducts over large distances. This observation is important, since, as evident from the definition surveys (Sect. 3.5):

1. In defining automation, over one-quarter of those surveyed associate automation with *replacing humans*, hinting somber connotation that humans are *losing* certain advantages. Many resources erroneously define automation as *replacement of human workers by technology*. But the definition is not about *replacing* humans, as many automation examples involve activities people cannot practically perform, e.g., complex and fast computing, wireless telecommunication, microelectronics manufacturing, and satellite-based positioning. The definition is about the autonomy of a system or process from human involvement and intervention during the process (independent of whether humans could or could not perform it themselves). Furthermore, automation is rarely disengaged from people, who must maintain and improve it (or at least replace its batteries).
2. Humans are always involved with automation, to a certain degree, from its development, to, at certain points, supervising, maintaining, repairing, and issuing necessary commands, e.g., *at which floor should this elevator stop for me?*

Describing automation, *Buckingham* [3.3] quotes Aristotle (384–322 BC): “When looms weave by themselves human’s slavery will end.” Indeed, the reliance on a process that can proceed successfully to completion autonomously, without human participation and intervention, is an essential characteristic of automation. But it took over 2000 years since Aristotle’s prediction till the automatic loom was developed during the Industrial Revolution.

3.1.4 Industrial Revolution

Some scientists (e.g., *Truxal* [3.4]) define automation as applying machines or systems to execute tasks that involve more elaborate decision-making. Certain decisions were already involved in ancient automation, e.g., where to direct the irrigation water. More control sophistication was indeed developed later, beginning during the Industrial Revolution (see examples in Table 3.3).

During the Industrial Revolution, as shown in the examples, steam and later electricity became the main power sources of automation systems and machines, and autonomy of process and decision-making increasingly involved feedback control models.

3.1.5 Modern Automation

The term *automation* in its modern meaning was actually attributed in the early 1950s to D.S. Harder, a vice-president of the Ford Motor Company, who described it as a philosophy of manufacturing. Towards the 1950s, it became clear that automation could be viewed as substitution by mechanical, hydraulic, pneumatic, electric, and electronic devices for a combination of human efforts and decisions. Critics with humor referred to automation as *substitution of human error by mechanical error*. Automation can also be viewed as the combination of four fundamental principles: mechanization; process continuity; automatic control; and economic, social, and technological rationalization.

Mechanization

Mechanization is defined as the application of machines to perform work. Machines can perform various tasks, at different levels of complexity. When mechanization is designed with cognitive and decision-making functions, such as process control and automatic control, the modern term *automation* becomes appropriate. Some machines can be rationalized by benefits of safety and convenience. Some machines, based on their power, compactness, and speed, can accomplish tasks that could never be performed by human labor, no matter how much labor or how effectively the operation could be organized and managed. With increased availability and sophistication of power sources and of automatic control, the level of autonomy of machines and mechanical system created a distinction between mechanization and the more autonomous form of mechanization, which is automation (Sect. 3.4).

Process Continuity

Process continuity is already evident in some of the ancient automation examples, and more so in the Industrial Revolution examples (Tables 3.1 and 3.3). For instance, windmills could provide relatively uninterrupted cycles of grain milling. The idea of continuity is to increase productivity, the useful output per labor-hour. Early in the 20th century, with the advent of mass production, it became possible to better organize workflow. Organization of production flow and assembly lines, and automatic or semiautomatic transfer lines increased productivity beyond mere mechanization. The emerging automobile industry in Europe and the USA in the early 1900s utilized the concept of moving work continuously, automatically or semiautomatically, to specialized machines and workstations. Interesting problems that emerged with flow automation included balancing the work allocation and regulating the flow.

Automatic Control

A key mechanism of automatic control is feedback, which is the regulation of a process according to its own output, so that the output meets the conditions of a predetermined, set objective. An example is the windmill that can adjust the orientation of it blades by feedback informing it of the changing direction of the current wind. Another example is the heating system that can stop and restart its heating or cooling process according to feedback from its thermostat. Watt's flyball governor applied feedback from the position of the rotating balls as a function of their rotating speed to automatically regulate the speed of the steam engine. Charles Babbage analytical engine for calculations applied the feedback principle in 1840 (see more on the development of automatic control in Chap. 4).

Automation Rationalization

Rationalization means a logical and systematic analysis, understanding, and evaluation of the objectives and constraints of the automation solution. Automation is rationalized by considering the technological and engineering aspects in the context of economic, social, and managerial considerations, including also: human factors and usability, organizational issues, environmental constraints, conservation of resources and energy, and elimination of waste (Chaps. 40 and 41).

Soon after automation enabled mass production in factories of the early 20th century and workers feared for the future of their jobs, the US Congress held hearings in which experts explained what automation means to them (Table 3.5). From our vantage point several generations later, it is interesting to read these definitions, while we already know about automation discoveries yet unknown at that time, e.g., laptop computers, robots, cellular telephones and personal digital assistants, the Internet, and more.

A relevant question is: Why automate? Several prominent motivations are the following, as has been indicated by the survey participants (Sect. 3.5):

1. *Feasibility*: Humans cannot handle certain operations and processes, either because of their scale, e.g., micro- and nanoparticles are too small, the amount of data is too vast, or the process happens too fast, for instance, missile guidance; microelectronics design, manufacturing and repair; and database search.
2. *Productivity*: Beyond feasibility, computers, automatic transfer machines, and other equipment can operate at such high speed and capacity that it would be practically impossible without automation, for instance, controlling consecutive, rapid chemical processes in food production; performing medicine tests by manipulating atoms or molecules; optimizing a digital image; and placing millions of colored dots on a color television (TV) screen.
3. *Safety*: Automation sensors and devices can operate well in environments that are unsafe for humans, for example, under extreme temperatures, nuclear radiation, or in poisonous gas.
4. *Quality and economy*: Automation can save significant costs on jobs performed without it, including consistency, accuracy, and quality of manufactured products and of services, and saving labor, safety, and maintenance costs.
5. *Importance to individuals, to organizations, and to society*: Beyond the above motivations, service- and knowledge-based automation reduces the need for middle managers and middle agents, thus reducing or eliminating the agency costs and removing layers of bureaucracy, for instance, Internet-based travel services and financial services, and direct communication between manufacturing managers and line operators, or cell robots. Remote supervision and telecollaboration change the nature, sophistication, skills and training requirements, and responsibility of workers and their managers. As automation gains intelligence and competencies, it takes over some employment skills and opens up new types of work, skills, and service requirements.
6. *Accessibility*: Automation enables better accessibility for all people, including disadvantaged and disabled people. Furthermore, automation opens up new types of employment for people with limitations, e.g., by integration of speech and vision recognition interfaces.
7. *Additional motivations*: Additional motivations are the competitive ability to integrate complex mechanization, advantages of modernization, convenience, and improvement in quality of life.

To be automated, a system must follow the motivations listed above. The modern and emerging automation examples in Table 3.4 and the automation cases in Sect. 3.3 illustrate these motivations, and the mechanization, process continuity, and automatic control features.

Certain limits and risks of automation need also be considered. Modern, computer-controlled automation must be programmable and conform to definable procedures, protocols, routines, and boundaries. The limits also follow the boundaries imposed by the four principles of automation. Can it be mechanized? Is there continuity in the process? Can automatic control be designed for it? Can it be rationalized? Theoretically, all continuous processes can be automatically controlled, but practically such automation must be rationalized first; for instance, jet engines may be continuously advanced on conveyors to assembly cells, but if the demand for these engines is low, there is no justification to automate their flow. Furthermore, all automation must be designed to operate within safe boundaries, so it does not pose hazards to humans and to the environment.

3.1.6 Domains of Automation

Some unique meanings of automation are associated with the domain of automation. Several examples of well-known domains are listed here:

- *Detroit automation* – Automation of transfer lines and assembly lines adopted by the automotive industry [3.5].
- *Flexible automation* – Manufacturing and service automation consisting of a group of processing stations and robots operating as an integrated system under computer control, able to process a variety of different tasks simultaneously, under automatic, adaptive control or learning control [3.5]. Also known as flexible manufacturing system (FMS), flexible assembly system, or robot cell, which are suitable for medium demand volume and medium variety of flexible tasks. Its purpose is to advance from mass production of products to more customer-oriented and customized supply. For higher flexibility with low demand volume, stand-

alone numerically controlled (NC) machines and robots are preferred. For high demand volume with low task variability, automatic transfer lines are designed. The opposite of flexible automation is *fixed automation*, such as process-specific machine tools and transfer lines, lacking task flexibility. For mass customization (mass production with some flexibility to respond to variable customer demands), transfer lines with flexibility can be designed (see more on automation flexibility in Sect. 3.4).

- *Office automation* – Computer and communication machinery and software used to improve office procedures by digitally creating, collecting, storing, manipulating, displaying, and transmitting office information needed for accomplishing office tasks and functions [3.6, 7]. Office automation became popular in the 1970s and 1980s when the desktop computer and the personal computer emerged.

Other examples of well-known domains of automation have been factory automation (e.g., [3.8]), healthcare automation (e.g., [3.9]), workflow automation (e.g., [3.10]), and service automation (e.g., [3.11]). More domain examples are illustrated in Table 3.6.

Throughout these different domains, automation has been applied for various organization functions. Five hierarchical layers of automation are shown in the automation pyramid (Fig. 3.3), which is a common depiction of how to organize automation implementation.

3.2 Brief History of Automation

Table 3.7 Brief history of automation events

Period	Automation inventions (examples)	Automation generation
Prehistory	Sterilization of food and water, cooking, ships and boats, irrigation, wheel and axle, flush toilet, alphabet, metal processing	First generation: before automatic control (BAC)
Ancient history	Optics, maps, water clock, water wheel, water mill, kite, clockwork, catapult	
First millennium AD	Central heating, compass, woodblock printing, pen, glass and pottery factories, distillation, water purification, wind-powered gristmills, feedback control, automatic control, automatic musical instruments, self-feeding and self-trimming oil lamps, chemotherapy, diversion dam, water turbine, mechanical moving dolls and singing birds, navigational instruments, sundial	
11th–15th century	Pendulum, camera, flywheel, printing press, rocket, clock automation, flow-control regulator, reciprocating piston engine, humanoid robot, programmable robot, automatic gate, water supply system, calibration, metal casting	
16th century	Pocket watch, Pascal calculator, machine gun, corn grinding machine	Second generation: before computer control (BCC)
17th century	Automatic calculator, pendulum clock, steam car, pressure cooker	
18th century	Typewriter, steam piston engine, Industrial Revolution early automation, steamboat, hot-air balloon, automatic flour mill	
19th century	Automatic loom, electric motor, passenger elevator, escalator, photography, electric telegraph, telephone, incandescent light, radio, x-ray machine, combine harvester, lead–acid battery, fire sprinkler system, player piano, electric street car, electric fan, automobile, motorcycle, dishwasher, ballpoint pen, automatic telephone exchange, sprinkler system, traffic lights, electric bread toaster	
Early 20th century	Airplane, automatic manufacturing transfer line, conveyor belt-based assembly line, analog computer, air conditioning, television, movie, radar, copying machine, cruise missile, jet engine aircraft, helicopter, washing machine, parachute, flip–flop circuit	

Automation has evolved, as described in Table 3.7, along three automation generations.

3.2.1 First Generation: Before Automatic Control (BAC)

Early automation is characterized by elements of process autonomy and basic decision-making autonomy, but without feedback, or with minimal feedback. The period is generally from prehistory till the 15th century. Some examples of basic automatic control can be found earlier than the 15th century, at least in conceptual design or mathematical definition. Automation examples of the first generation can also be found later, whenever automation solutions without automatic control could be rationalized.

3.2.2 Second Generation: Before Computer Control (BCC)

Automation with advantages of automatic control, but before the introduction and implementation of the

Table 3.7 (cont.)

Period	Automation inventions (examples)	Automation generation
1940s	Digital computer, Assembler programming language, transistor, nuclear reactor, microwave oven, atomic clock, barcode	Third generation: automatic computer control (ACC)
1950s	Mass-produced digital computer, computer operating system, FORTRAN programming language, automatic sliding door, floppy disk, hard drive, power steering, optical fiber, communication satellite, computerized banking, integrated circuit, artificial satellite, medical ultrasonics, implantable pacemaker	
1960s	Laser, optical disk, microprocessor, industrial robot, automatic teller machine (ATM), computer mouse, computer-aided design, computer-aided manufacturing, random-access memory, video game console, barcode scanner, radiofrequency identification tags (RFID), permanent press fabric, wide-area packet switching network	
1970s	Food processor, word processor, Ethernet, laser printer, database management, computer-integrated manufacturing, mobile phone, personal computer, space station, digital camera, magnetic resonance imaging, computerized tomography (CT), e-Mail, spreadsheet, cellular phone	
1980s	Compact disk, scanning tunneling microscope, artificial heart, deoxyribonucleic acid DNA fingerprinting, Internet transmission control protocol/Internet protocol TCP/IP, camcorder	
1990s	World Wide Web, global positioning system, digital answering machine, smart pills, service robots, Java computer language, web search, Mars Pathfinder, web TV	
2000s	Artificial liver, Segway personal transporter, robotic vacuum cleaner, self-cleaning windows, iPod, softness-adjusting shoe, drug delivery by ultrasound, Mars Lander, disk-on-key, social robots	

computer, especially the digital computer, belongs to this generation. Automatic control emerging during this generation offered better stability and reliability, more complex decision-making, and in general better control and automation quality. The period is between the 15th century and the 1940s. It would be generally difficult to rationalize in the future any automation with automatic control and without computers; therefore, future examples of this generation will be rare.

3.2.3 Third Generation: Automatic Computer Control (ACC)

The progress of computers and communication has significantly impacted the sophistication of automatic control and its effectiveness. This generation began in the 1940s and continues today. Further refinement of this generation can be found in Sect. 3.4, discussing the levels of automation.

See also Table 3.8 for examples discovered or implemented during the three automation generations.

Table 3.8 Automation generations

Generation		Example
BAC before automatic control prehistoric, ancient		Waterwheel
ABC automatic control before computers 16th century–1940		Automobile
CAC computer automatic control 1940–present	*Hydraulic automation*	Hydraulic elevator
	Pneumatic automation	Door open/shut
	Electrical automation	Telegraph
	Electronic automation	Microprocessor
	Micro automation	Digital camera
	Nano automation	Nanomemory
	Mobile automation	Cellular phone
	Remote automation	Global positioning system (GPS)

3.3 Automation Cases

Ten automation cases are illustrated in this section to demonstrate the meaning and scope of automation in different domains.

3.3.1 Case A: Steam Turbine Governor (Fig. 3.4)

Source. Courtesy of Dresser-Rand Co., Houston (http://www.dresser-rand.com/).

Process. Operates a steam turbine used to drive a compressor or generator.

Platform. Device, integrated as a system with programmable logic controller (PLC).

Autonomy. Semiautomatic and automatic activation/deactivation and control of the turbine speed; critical speed-range avoidance; remote, auxiliary, and cascade speed control; loss of generator and loss of utility detection; hot standby ability; single and dual actuator control; programmable governor parameters via operator's screen and interface, and mobile computer. A manual mode is also available: The operator places the system in run mode which opens the governor valve to the full position, then manually opens the T&T valve to idle speed, to warm up the unit. After warm-up, the operator manually opens the T&T valve to full position, and as the turbine's speed approaches the rated (desirable) speed, the governor takes control with the governor valve. In semiautomatic and automatic modes, once the operator places the system in run mode, the governor takes over control.

3.3.2 Case B: Bioreactor (Fig. 3.5)

Source. Courtesy of Applikon Biotechnology Co., Schiedam (http://www.pharmaceutical-technology.com/contractors/process_automation/applikon-technology/).

Process. Microbial or cell culture applications that can be validated, conforming with standards for equipment used in life science and food industries, such as good automated manufacturing practice (GAMP).

Platform. System or installation, including microreactors, single-use reactors, autoclavable glass bioreactors, and stainless-steel bioreactors.

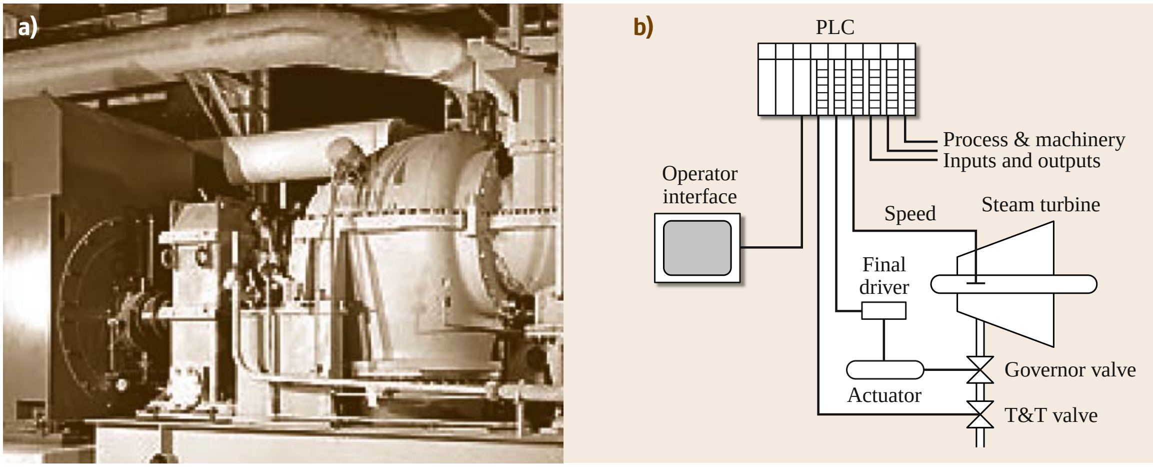

Fig. 3.4 **(a)** Steam turbine generator. **(b)** Governor block diagram (PLC: programmable logic controller; T&T: trip and throttle). A turbine generator designed for on-site power and distributed energy ranging from 0.5 to 100 MW. Turbine generator sets produce power for pulp and paper mills, sugar, hydrocarbon, petrochemical and process industries; palm oil, ethanol, waste-to-energy, other biomass burning facilities, and other installations (with permission from Dresser-Rand)

Autonomy. Bioreactor functions with complete measurement and control strategies and supervisory control and data acquisition (SCADA), including sensors and a cell retention device.

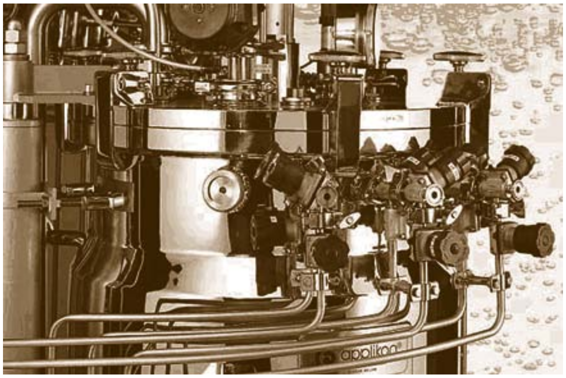

Fig. 3.5 Bioreactor system configured for microbial or cell culture applications. Optimization studies and screening and testing of strains and cell lines are of high importance in industry and research and development (R&D) institutes. Large numbers of tests are required and they must be performed in as short a time as possible. Tests should be performed so that results can be validated and used for further process development and production (with permission from Applikon Biotechnology)

3.3.3 Case C: Digital Photo Processing (Fig. 3.6)

Source. Adobe Systems Incorporated San Jose, California (http://adobe.com).

Process. Editing, enhancing, adding graphic features, removing stains, improving resolution, cropping and sizing, and other functions to process photo images.

Platform. Software system.

Autonomy. The software functions are fully automatic once activated by a user. The software can execute them semiautomatically under user control, or action series can be automated too.

3.3.4 Case D: Robotic Painting (Fig. 3.7)

Source. Courtesy of ABB Co., Zürich (http://www.ABB.com).

Process. Automatic painting under automatic control of car body movement, door opening and closing, paint-pump functions, fast robot motions to optimize finish quality, and minimize paint waste.

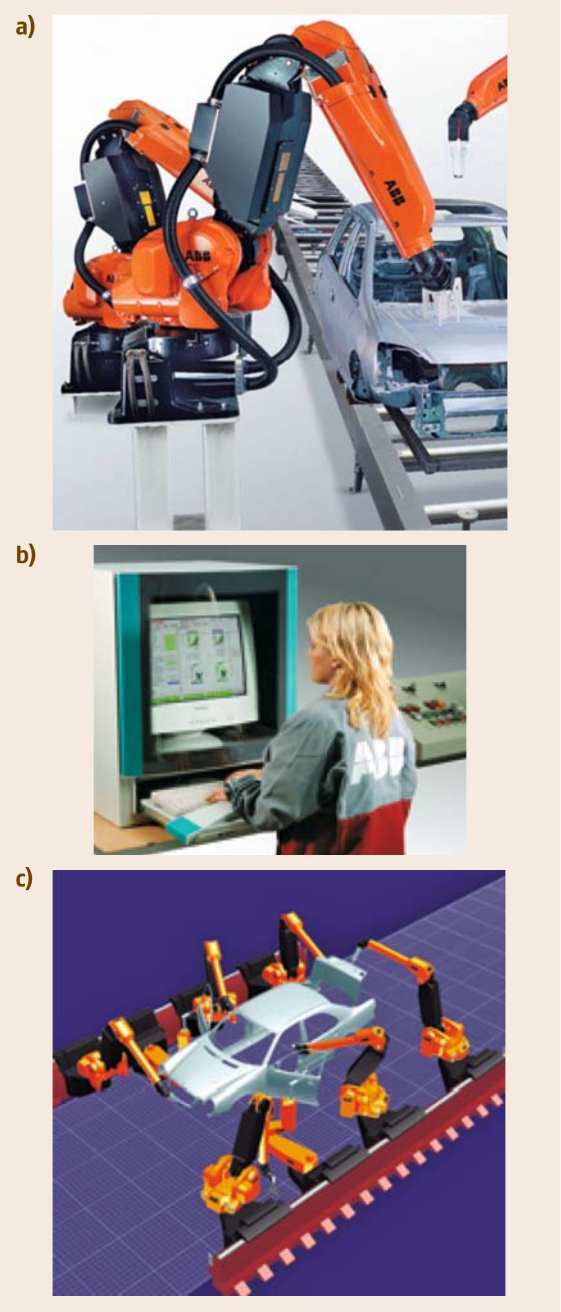

Fig. 3.7a–c A robotic painting line: **(a)** the facility; **(b)** programmer using interface to plan offline or online, experiment, optimize, and verify control programs for the line; **(c)** robotic painting facility design simulator (with permission from ABB)

Platform. Automatic tools, machines, and robots, including sensors, conveyors, spray-painting equipment, and integration with planning and programming software systems.

Autonomy. Flexibility of motions; collision avoidance; coordination of conveyor moves, robots' motions, and paint pump operations; programmability of process and line operations.

3.3.5 Case E: Assembly Automation (Fig. 3.8)

Source. Courtesy of Adapt Automation Inc., Santa Ana, California (www.adaptautomation.com/Medical.html).

Process. Hopper and two bowl feeders feed specimen sticks through a track to where they are picked and placed, two up, into a double nest on a 12-position indexed dial plate. Specimen pads are fed and placed on the sticks. Pads are fully seated and inspected. Rejected and good parts are separated into their respective chutes.

Platform. System of automatic tools, machines, and robots.

Autonomy. Automatic control through a solid-state programmable controller which operates the sequence of device operations with a control panel. Control programs include main power, emergency stop, manual, automatic, and individual operations controls.

3.3.6 Case F: Computer-Integrated Elevator Production (Fig. 3.9)

Process. Fabrication and production execution and management.

Platform. Automatic tools, machines, and robots, integrated with system-of-systems, comprising a production/manufacturing installation, with automated material handling equipment, fabrication and finishing machines and processes, and software and communication systems for production planning and control, robotic manipulators, and cranes. Human operators and supervisors are also included.

Autonomy. Automatic control, including knowledge-based control of laser, press, buffing, and sanding machines/cells; automated control of material handling and material flow, and of management information flow.

3.3.10 Case J: Energy Power Substation Automation (Fig. 3.13)

Source. GE Energy Co., Atlanta (http://www.gepower.com/prod_serv/products/substation_automation/en/downloads/po.pdf).

Process. Automatically monitoring and activating backup power supply in case of breakdown in the power generation and distribution. Each substation automation platform has processing capacity to monitor and control thousands of input–output points and *intelligent electronic devices* over the network.

Platform. Devices integrated with a network of system-of-systems, including substation automation platforms, each communicating with and controlling thousands of power network devices.

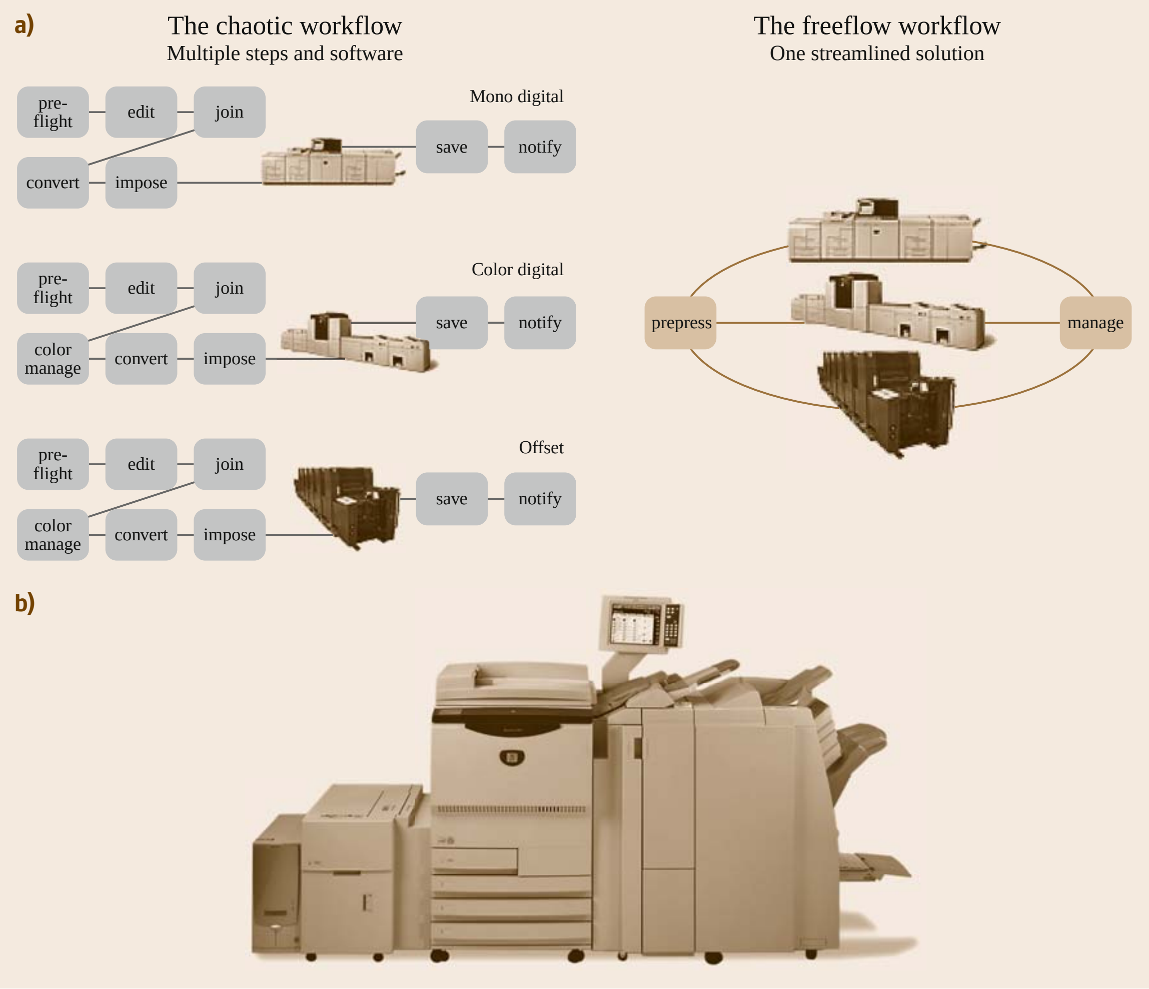

Fig. 3.11a,b Document imaging and color printing workflow: **(a)** streamlined workflow by FreeFlow. **(b)** *Detail* shows document scanner workstation with automatic document feeder and image processing (courtesy of Xerox Co., Norwalk)

Autonomy. Power generation, transmission, and distribution automation, including automatic steady voltage control, based on user-defined targets and settings; local/remote control of distributed devices; adjustment of control set-points based on control requests or control input values; automatic reclosure of tripped circuit breakers following momentary faults; automatic transfer of load and restoration of power to nonfaulty sections if possible; automatically locating and isolating faults to reduce customers' outage times; monitoring a network of substations and moving load off overloaded transformers to other stations as required.

These ten case studies cover a variety of automation domains. They also demonstrate different level of intelligence programmed into the automation application, different degrees of automation, and various types of automation flexibility. The meaning of these automation characteristics is explained in the next section.

3.4 Flexibility, Degrees, and Levels of Automation

Increasingly, solutions of society's problems cannot be satisfied by, and therefore cannot mean the automation of just a single, repeated process. By automating the networking and integration of devices and systems, they are able to perform different and variable tasks. Increasingly, this ability also requires cooperation (sharing of information and resources) and collaboration (sharing in the execution and responses) with other devices and systems. Thus, devices and systems have to be designed with inherent flexibility, which is motivated by the clients' requirements. With growing demand for service and product variety, there is also an increase in the expectations by users and customers for greater reliability, responsiveness, and smooth interoperability. Thus, the meaning of automation also involves the aspects of its flexibility, degree, and levels.

To enable design for flexibility, certain standards and measures have been and will continue to be established. Automation flexibility, often overlapping with the level of automation intelligence, depends on two main considerations:

1. The number of different states that can be assumed automatically
2. The length of time and amount of effort (setup process) necessary to respond and execute a change of state.

The number of different possible states and the cost of changes required are linked with two interrelated measures of flexibility: application flexibility and adaptation flexibility (Fig. 3.14). Both measures are concerned with the possible situations of the system and its environment. Automation solutions may address only switching between undisturbed, standard operations and nominal, variable situations, or can also aspire to respond when operations encounter disruptions and transitions, such as errors and conflicts, or significant design changes.

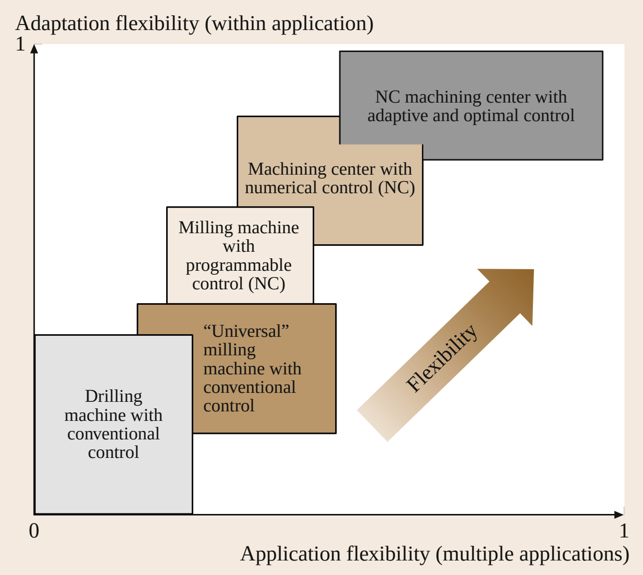
Application flexibility measures the number of different work states, scenarios, and conditions a system can handle. It can be defined as the probability that an arbitrary task, out of a given class of such tasks, can be carried out automatically. A relative comparison between the application flexibility of alternative designs is relevant mostly for the same domain of automation solutions. For instance, in Fig. 3.14 it is the domain of machining.

Adaptation flexibility is a measure of the time duration and the cost incurred for an automation device or system to transition from one given work state to another. Adaptation flexibility can also be measured only relatively, by comparing one automation device or system with another, and only for one defined change of state at a time. The change of state involves being in one possible state prior to the transition, and one possible state after it.

A relative estimate of the two flexibility measures (dimensions) for several implementations of machine tools automation is illustrated in Fig. 3.14. For generality, both measures are calibrated between 0 and 1.

3.4.1 Degree of Automation

Another dimension of automation, besides measures of its inherent flexibility, is the degree of automation. Automation can mean fully automatic or semiautomatic devices and systems, as exemplified in case A (Sect. 3.3.1), with the steam turbine speed governor, and in case E (Sect. 3.3.5), with a mix of robots and operators in elevator production. When a device or system is not fully automatic, meaning that some, or more frequent human intervention is required, they are con-



Adaptation flexibility (within application)
1

Machining center with numerical control (NC)
Milling machine with programmable control (NC)
"Universal" milling machine with conventional control
Drilling machine with conventional control
Flexibility
0
1
Application flexibility (multiple applications)

Fig. 3.14 Application flexibility and adaptation flexibility in machining automation (after [3.14])

sidered *automated*, or *semiautomatic*, equivalent terms implying *partial automation*.

A measure of the degree of automation, between fully manual to fully automatic, has been used to guide the design rationalization and compare between alternative solutions. Progression in the degree of automation in machining is illustrated in Fig. 3.14. The increase of automated partial functions is evident when comparing the drilling machine with the more flexible machines that can also drill and, in addition, are able to perform other processes such as milling.

The degree of automation can be defined as the fraction of automated functions out of the overall functions of an installation or system. It is calculated as the ratio between the number of automated operations, and the total number of operations that need to be performed, resulting in a value between 0 and 1. Thus, for a device or system with partial automation, where not all operations or functions are automatic, the degree of automation is less than 1. Practically, there are several methods to determine the degree of automation. The derived value requires a description of the method assumptions and steps. Typically, the degree of automation is associated with characteristics of:

1. Platform (device, system, etc.)
2. Group of platforms
3. Location, site
4. Plant, facility
5. Process and its scope
6. Process measures, e.g., operation cycle
7. Automatic control
8. Power source
9. Economic aspects
10. Environmental effects.

In determining the degree of automation of a given application, whether the following functions are also supposed to be considered must also be specified:

1. Setup
2. Organization, reorganization
3. Control and communication
4. Handling (of parts, components, etc.)
5. Maintenance and repair
6. Operation and process planning
7. Construction
8. Administration.

For example, suppose we consider the automation of a document processing system (case H, Sect. 3.3.8) which is limited to only the scanning process, thus omitting other workflow functions such as document feeding, joining, virtual inspection, and failure recovery. Then if the scanning is automatic, the degree of automation would be 1. However, if the other functions are also considered and they are not automatic, then the value would be less than 1.

Methods to determine the degree of automation divide into two categories:

- *Relative determination applying a graded scale*, containing all the functions of a defined domain process, relative to a defined system and the corresponding degrees of automation. For any given device or system in this domain, the degree of automation is found through comparison with the graded scale. This procedure is similar to other graded scales, e.g., Mohs' hardness scale, and Beaufort wind-speed scale. This method is illustrated in Fig. 3.15, which shows an example of the graded scale of mechanization and automation, following the scale developed by *Bright* [3.15].
- *Relative determination by a ratio between the autonomous and nonautonomous measures of reference*. The most common measure of reference is the number of decisions made during the process under consideration (Table 3.9). Other useful measures of reference for this determination are the comparative ratios of:
  - Rate of service quality
  - Human labor
  - Time measures of effort
  - Cycle time
  - Number of mobility and motion functions
  - Program steps.

To illustrate the method in reference to decisions made during the process, consider an example for case B (Sect. 3.3.2). Suppose in the bioreactor system process there is a total of seven decisions made automatically by the devices and five made by a human laboratory supervisor. Because these decisions are not similar, the degree of automation cannot be calculated simply as the ratio $7/(7+5) \approx 0.58$. The decisions must be weighted by their complexity, which is usually assessed by the number of control program commands or steps (Table 3.9). Hence, the degree of automation can be calculated as:

$$\begin{aligned}\begin{array}{c}\text{degree of}\\ \text{automation}\end{array} &= \frac{\left(\begin{array}{c}\text{sum of decision steps made}\\ \text{automatically by devices}\end{array}\right)}{(\text{total sum of decision steps made})}\\ &= 82/(82+178) \approx 0.32\,.\end{aligned}$$

Step-No.	Steps of the automation	Energy source	Type of the machine reaction		Origin of the check
1	Manual	Manual	Variable		From the worker
2	Manual hand tools				
3	Powered hand tools				
4	Machine tools, manual controlled				
5	Powered tool, fixed cycle, single function	Mechanical (not done by hand)	Fixed in the machine		Through control-mechanism, testing determined work sequences
6	Powered tool, programmed control with a sequence of functions				
7	Machine system with remote control				
8	Machine actuated by introduction of work-piece or material				
9	Measures characteristics of the execution		React to signals		Through variable influences in the environment
10	Signals pre-selected values of measurement, includig error correction				
11	Registers execution				
12	Changes speed, position change and direction according to the measured signal		Reacts to the execution	Selects from determined processes	
13	Segregates or rejects according to measurements				
14	Identifies and selects operations				
15	Corrects execution after the processing			Changes actions itself inside influences	
16	Corrects execution while processing				
17	Foresees the necessary working tasks, adjusts the execution				
18	Prevents error and self-optimizes current execution				

Fig. 3.15 Automation scale: scale for comparing grades of automation (after [3.15])

Now designers can compare this automation design against relatively more and less elaborate options. Rationalization will have to assess the costs, benefits, risks, and acceptability of the degree of automation for each alternative design.

Whenever the degree of automation is determined by a method, the following conditions must be followed:

1. The method is able to reproduce the same procedure consistently.
2. Comparison is only done between objective measures.
3. Degree values should be calibrated between 0 and 1 to simplify calculations and relative comparisons.

3.4.2 Levels of Automation, Intelligence, and Human Variability

There is obviously an inherent relation between the level of automation flexibility, the degree of automation, and the level of intelligence of a given automation ap-

Table 3.9 Degree of automation: calculation by the ratio of decision types

	Automatic decisions								**Human decisions**						**Total**
Decision number	1	2	3	4	5	6	7	Sum	8	9	10	11	12	Sum	
Complexity (number of program steps)	10	12	14	9	14	11	12	*82*	21	3	82	45	27	*178*	*260*

Table 3.10 Levels of automation (updated and expanded after [3.16])

Level	Automation	Automated human attribute	Examples
A_0	Hand-tool; manual machine	None	Knife; scissors; wheelbarrow
A_1	Powered machine tools (non-NC)	Energy, muscles	Electric hand drill; electric food processor; paint sprayer
A_2	Single-cycle automatics and hand-feeding machines	Dexterity	Pipe threading machine; machine tools (non-NC)
A_3	Automatics; repeated cycles	Diligence	Engine production line; automatic copying lathe; automatic packaging; NC machine; pick-and-place robot
A_4	Self-measuring and adjusting; feedback	Judgment	*Feedback about product*: dynamic balancing; weight control. *Feedback about position*: pattern-tracing flame cutter; servo-assisted follower control; self-correcting NC machines; spray-painting robot
A_5	Computer control; automatic cognition	Evaluation	Rate of feed cutting; maintaining pH; error compensation; turbine fuel control; interpolator
A_6	Limited self-programming	Learning	Sophisticated elevator dispatching; telephone call switching systems; artificial neural network models

A_7	Relating cause from effects	Reasoning	Sales prediction; weather forecasting;
			lamp failure anticipation; actuarial analysis;
			maintenance prognostics; computer chess playing

A_8	Unmanned mobile machines	Guided mobility	Autonomous vehicles and planes; nano-flying exploration monitors
A_9	Collaborative networks	Collaboration	Collaborative supply networks; Internet; collaborative sensor networks
A_{10}	Originality	Creativity	Computer systems to compose music; design fabric patterns; formulate new drugs; play with automation, e.g., virtual-reality games
A_{11}	Human-needs and animal-needs support	Compassion	Bioinspired robotic seals (aquatic mammal) to help emotionally challenged individuals; social robotic pets
A_{12}	Interactive companions	Humor	Humorous gadgets, e.g., sneezing tissue dispenser; automatic systems to create/share jokes; interactive comedian robot

NC: numerically controlled; non-NC: manually controlled plication. While there are no absolute measures of any of them, their meaning is useful and intriguing to inventors, designers, users, and clients of automation. Levels of automation are shown in Table 3.10 based on the intelligent human ability they represent.

It is interesting to note that the progression in our ability to develop and implement higher levels of automation follows the progress in our understanding of relatively more complex platforms; more elaborate control, communication, and solutions of computational complexity; process and operation programmability; and our ability to generate renewable, sustainable, and mobile power sources.

3.5 Worldwide Surveys: What Does Automation Mean to People?

With known human variability, we are all concerned about automation, enjoy its benefits, and wonder about its risks. But all individuals do not share our attitude towards automation equally, and it does not mean the same to everyone. We often hear people say:

- *I'll have to ask my grandson to program the video recorder.*
- *I hate my cell-phone.*
- *I can't imagine my life without a cell-phone.*
- *Those dumb computers.*
- *Sorry, I do not use elevators, I'll climb the six floors and meet you there!*

etc.

In an effort to explore the meaning of automation to people around the world, a random, nonscientific survey was conducted during 2007–2008 by the author, with the help of the following colleagues: Carlos Pereira (Brazil), Jose Ceroni (Chile), Alexandre Dolgui (France), Sigal Berman, Yael Edan, and Amit Gil (Israel), Kazayuhi Ishii, Masayuki Matsui, Jing Son, and Tetsuo Yamada (Japan), Jeong Wootae (Korea), Luis Basañez and Raúl Suárez Feijóo (Spain), Chin-Yin Huang (Taiwan), and Xin W. Chen (USA). Since the majority of the survey participants are students, undergraduate and graduate, and since they migrate globally, the respondents actually originate from all continents. In other words, while it is not a scientific survey, it carries a worldwide meaning.

Table 3.11 How do you define automation (do not use a dictionary)?

Definition		Asia–Pacific (%)	Europe + Israel (%)	North America (%)	South America (%)	World-wide (%)
1.	Partially or fully replace human work [a]	6	43	18	5	27
2.	Use machines/computers/robots to execute or help execute physical operations, computational commands or tasks	25	17	35	32	24
3.	Work without or with little human participation	33	20	17	47	24
4.	Improve work/system in terms of labor, time, money, quality, productivity, etc.	9	9	22	5	11
5.	Functions and actions that assist humans	4	3	2	0	3
6.	Integrated system of sensors, actuators, and controllers	6	2	2	0	3
7.	Help do things humans cannot do	3	2	2	0	2
8.	Promote human value	6	1	0	0	2
9.	The mechanism of automatic machines	5	1	0	5	2
10.	Information-technology-based organizational change	0	0	3	0	1
11.	Machines with intelligence that works and knows what to do	1	1	0	5	1
12.	Enable humans to perform multiple actions	0	1	0	0	0

[a] Note: This definition is inaccurate; most automation accomplishes work that humans cannot do, or cannot do effectively

* Respondents: 318 (244 undergraduates, 64 graduates, 10 others)

Table 3.12 When and where did you encounter and recognize automation first in your life (probably as a child)?

First encounter	Asia–Pacific (%)	Europe + Israel (%)	North America (%)	South America (%)	World-wide (%)
1. Automated manufacturing machine, factory	12	9	30	32	16
2. Vending machine: snacks, candy, drink, tickets	14	10	11	5	11

* Respondents: 316 (249 undergraduates, 57 graduates, 10 others)

The survey population includes 331 respondents, from three general categories:

1. Undergraduate students of engineering, science, management, and medical sciences (251)
2. Graduate students from the same disciplines (70)
3. Nonstudents, experts, and novices in automation (10).

Three questions were posed in this survey:

- How do you define automation (do not use a dictionary)?
- When and where did you encounter and recognize automation first in your life (probably as a child)?
- What do you think is the major impact/contribution of automation to humankind (only one)?

The answers are summarized in Tables 3.11–3.13.

3.5.1 How Do We Define Automation?

The key answer to this was question was (Table 3.11, no. 3): operate without or with little human participation (24%). This answer reflects a meaning that corresponds well with the definition in the beginning of this chapter. It was the most popular response in Asia–Pacific and South America.

Overall, the 12 types of definition meanings follow three main themes: How automation works (answer nos. 2, 6, 9, 11, total 30%); automation replaces humans, works without them, or augments their functions (answer nos. 1, 3, 7, 10, total 54%); automation improves (answer nos. 4, 5, 8, 12, total 16%).

Interestingly, the overall most *popular* answer (answer no. 1; 27%) is a partially wrong answer. (It was actually the significantly most popular response only in Europe and Israel.) *Replacing human work* may represent legacy fear of automation. This answer lacks the recognition that most automation applications are performing tasks humans cannot accomplish. The latter is also a partial, yet positive, meaning of automation and is addressed by answer no. 7 (2%).

Answer nos. 2, 6, 9, and 11 (total 29%) represent a factual meaning of how automation is implemented. Answer 10, found only in North America responses, addresses a meaning of automation that narrows it down to

Table 3.13 What do you think is the major impact/contribution of automation to humankind (only one)?

Major impact or contribution	Asia–Pacific (%)	Europe + Israel (%)	North America (%)	South America (%)	World-wide (%)
1. Save time, increase productivity/efficiency; 24/7 operations	26	19	17	42	22
2. Advance everyday life/improve quality of life/ convenience/ease of life/work	10	11	0	0	8
3. Save labor	17	5	3	0	8
4. Encourage/inspire creative work; inspire newer solutions	5	5	7	11	6
5. Mass production and service	0	5	17	5	6
6. Increase consistency/improve quality	5	5	2	16	5
7. Prevent people from dangerous activities	7	2	7	5	5
8. Detect errors in healthcare, flights, factories/ reduce (human) errors	8	2	2	5	4
9. Medicine/medical equipment/medical system/ biotechnology/healthcare	0	8	2	0	4
10. Save cost	7	2	5	0	4
11. Computer	0	5	3	0	3
12. Improve security and safety	0	7	2	0	3
13. Assist/work for people	3	3	0	5	2
14. Car	3	1	2	0	2
15. Do things that humans cannot do	1	2	3	5	2
16. Replace people; people lose jobs	2	2	2	0	2
17. Save lives	0	4	0	0	2
18. Transportation (e.g., train, traffic lights)	1	2	2	0	2
19. Change/improvement in (global) economy	0	1	3	0	1
20. Communication (devices)	0	1	5	0	1
21. Deliver products/service to more people	1	1	0	0	1
22. Extend life expectancy	0	1	0	0	1
23. Foundation of industry/growth of industry	0	2	0	0	1
24. Globalization and spread of culture and knowledge	0	0	3	0	1
25. Help aged/handicapped people	3	1	0	0	1
26. Manufacturing (machines)	1	1	2	0	1
27. Robot; industrial robot	0	0	5	0	1
28. Agriculture improvement	0	1	0	0	0
29. Banking system	0	0	2	0	0
30. Construction	0	0	2	0	0
31. Flexibility in manufacturing	0	1	0	0	0
32. Identify bottlenecks in production	0	0	2	0	0
33. Industrial revolution	0	1	0	0	0
34. Loom	0	0	2	0	0
35. People lose abilities to complete tasks	0	1	0	0	0
36. Save resources	0	1	0	0	0
37. Weather prediction	0	0	2	0	0

* Respondents: 330 (251 undergraduate, 70 graduate, 9 others)

information technology. Answer nos. 4, 5, and 12 (total 14%) imply that automation means improvements and assistance. Finally, answer no. 8, promote human value (2%, but found only in Asia–Pacific, and Europe and Israel) may reflect cultural meaning more than a definition.

In addition to the regional response variations mentioned above, it turns out that the first four answers in Table 3.11 comprise the majority of meaning in each region: 73% for Asia–Pacific; 89% for Europe and Israel and for South America; and 92% for North America (86% worldwide). In Asia–Pacific, four other answer types each comprised 4–6% of the 12 answer types.

3.5.2 When and Where Did We Encounter Automation First in Our Life?

The key answer to this question was: automated manufacturing machine or factory (16%), which was the top answer in North and South America, but only the third response in Asia–Pacific and in Europe and Israel. The top answer in Asia–Pacific is shared by vending machine and automatic door (14% each), and in Europe and Israel the top answer was car, truck, motorcycle, and components (14%). Overall, the 62 types of responses to this question represent a wide range of what automation means to us.

There are variations in responses between regions, with only two answers – no. 1, automated manufacturing machine, factory, and no. 2, vending machine: snacks, candy, drink, tickets – shared by at least three of the four regions surveyed. Automatic door is in the top three only in Asia–Pacific; car, truck, motorcycle, and components is in the top three only in Europe and Israel; computer is in the top three only in North America; and robot is in the top three only in South America.

Of the 62 response types, almost 40 appear in only one region (or are negligible in other regions), and it is interesting to relate the regional context of the first encounter with automation. For instance:

- Answers no. 34, train (unmanned) and no. 36, automated grinding machine for sharpening knives, appear as responses mostly in Asia–Pacific (3%)
- Answers no. 12, dishwasher (4%); no. 35, x-ray machine (2%); and no. 58, traffic light (1%) appear as responses mostly in Europe and Israel
- Answers no. 19, barcode scanner (4%); no. 38, automatic bottle filling (2%); no. 39, automatic toll collection (2%); and no. 59, treadmill, (2%) appear as responses mostly in North America.

3.5.3 What Do We Think Is the Major Impact/Contribution of Automation to Humankind?

Thirty-seven types of impacts or benefits were found in the survey responses overall. The most inspiring impact and benefit of automation found is answer no. 4, *encourage/inspire creative work; inspire newer solutions* (6%).

The most popular response was: save time, increase productivity/efficiency; 24/7 operations (22%). The key risk identified, answer no. 16, was: replace people; people lose jobs (2%, but interestingly, this was not found in South America). Another risky impact identified is answer no. 35, people lose abilities to complete tasks, (1%, only in Europe and Israel). Nevertheless, the majority (98%) identified 35 types of positive impacts and benefits.

3.6 Emerging Trends

Many of us perceive the meaning of the automatic and automated factories and gadgets of the 20th and 21st century as outstanding examples of the human spirit and human ingenuity, no less than art; their disciplined organization and synchronized complex of carefully programmed functions and services mean to us harmonious expression, similar to good music (when they work).

Clearly, there is a mixture of emotions towards automation: Some of us are dismayed that humans cannot usually be as accurate, or as fast, or as responsive, attentive, and indefatigable as automation systems and installations. On the other hand, we sometimes hear the word *automaton* or *robot* describing a person or an organization that lacks consideration and compassion, let alone passion. Let us recall that automation is made *by people and for the people*. But can it run away by its own autonomy and become undesirable? Future automation will advance in micro- and nanosystems and systems-of-systems. Bioinspired automation and bioinspired collaborative control theory will significantly improve artificial intelligence, and the quality of robotics and automation, as well as the engineering of their safety and security. In this context, it is interesting to examine the role of automation in the 20th and 21st centuries.

3.6.1 Automation Trends of the 20th and 21st Centuries

The US National Academy of Engineering, which includes US and worldwide experts, compiled the list shown in Table 3.14 as the top 20 achievements that *have shaped a century and changed the world* [3.17]. The table adds columns indicating the role that automation has played in each achievement, and clearly, automation has been relevant in all of them and essential to most of them.

The US National Academy of Engineers has also compiled a list of the grand challenges for the 21st century. These challenges are listed in Table 3.15 with the anticipated and emerging role of automation in each. Again, automation is relevant to all of them and essential to most of them.

Some of the main trends in automation are described next.

3.6.2 Bioautomation

Bioinspired automation, also known as bioautomation or evolutionary automation, is emerging based on the trend of bioinspired computing, control, and AI. They influence traditional automation and artificial intelligence in the methods they offer for evolutionary machine learning, as opposed to what can be described as *generative methods* (sometimes called *creationist methods*) used in traditional programming and learning. In traditional methods, intelligence is typically programmed from top down: Automation engineers and programmers create and implement the automa-

Table 3.14 Top engineering achievements in the 20th century [3.17] and the role of automation

Achievement		Role of automation		
		Relevant		Irrelevant
		Essential	Supportive	
1.	Electrification	×		
2.	Automobile	×		
3.	Airplane	×		
4.	Water supply and distribution	×		
5.	Electronics	×		
6.	Radio and television	×		
7.	Agricultural mechanization	×		
8.	Computers	×		
9.	Telephone	×		
10.	Air conditioning and refrigeration	×

18.	Laser and fiber optics	×		
19.	Nuclear technologies	×		
20.	High-performance materials		×	

tion logic, and define the scope, functions, and limits of its intelligence. Bioinspired automation, on the other hand, is also created and implemented by automation engineers and programmers, but follows a bottom-up decentralized and distributed approach. Bioinspired techniques often involve a method of specifying a set of simple rules, followed and iteratively applied by a set of simple and autonomous manmade organisms. After several generations of rule repetition, initially manmade mechanisms of self-learning, self-repair, and self-organization enable self-evolution towards more complex behaviors. Complexity can result in unexpected behaviors, which may be robust and more reliable; can be counterintuitive compared with the original design; but can potentially become undesirable, out-of-control, and unsafe behaviors. This subject has been under intense research and examination in recent years.

Natural evolution and system biology (biology-inspired automation mechanisms for systems engineering) are the driving analogies of this trend: concurrent steps and rules of responsive selection, interdependent recombination, reproduction, mutation, reformation, adaptation, and death-and-birth can be defined, similar to how complex organisms function and evolve in nature. Similar automation techniques are used in genetic algorithms, artificial neural networks, swarm algorithms, and other emerging evolutionary automation systems. Mechanisms of self-organization, parallelism, fault tolerance, recovery, backup, and redundancy are being developed and researched for future automation, in areas such as neuro-fuzzy techniques, biorobotics, digital organisms, artificial cognitive models and architectures, artificial life, bionics, and bioinformatics. See related topics in many following handbook chapters, particularly, 29, 75 and 76.

3.6.3 Collaborative Control Theory and e-Collaboration

Collaboration of humans, and its advantages and challenges are well known from prehistory and throughout history, but have received increased attention with the advent of communication technology. Significantly better enabled and potentially streamlined and even optimized through e-Collaboration (based on communication via electronic means), it is emerging as one of the most powerful trends in automation, with telecommunication, computer communication, and wireless communication influencing education and research, engineering and business, healthcare and service industries, and global society in general. Those developments, in turn, motivate and propel further applications and theoretical investigations into this highly intelligent level of automation (Table 3.10, level A_9 and higher).

Table 3.15 Grand engineering challenges for the 21st century [3.17] and the role of automation

Achievement	Anticipated and emerging role of automation		
	Relevant		Irrelevant
	Essential	Supportive	
1. Make solar energy economical	×		
2. Provide energy from fusion	×		
3. Develop carbon sequestration methods	×		
4. Manage the nitrogen cycle	×		
5. Provide access to clean water	×		
6. Restore and improve urban infrastructure		×	
7. Advance health informatics	×		
8. Engineer better medicines	×		
9. Reverse-engineer the brain	×		
10. Prevent nuclear terror	×		
11. Secure cyberspace	×		
12. Enhance virtual reality	×		
13. Advance personalized learning	×		
14. Engineer the tools of scientific discovery	×		

Interesting examples of the e-Collaboration trend include *wikis*, which since the early 2000s have been increasingly adopted by enterprises as collaborative software, enriching static intranets and the Internet. Examples of e-Collaborative applications that emerged in the 1990s include project communication for coplanning, sharing the creation and editing of design documents as codesign and codocumentation, and mutual inspiration for collaborative innovation and invention through cobrainstorming.

Beyond human–human automation-supported collaboration through better and more powerful communication technology, there is a well-known but not yet fully understood trend for collaborative e-Work. Associated with this field is collaborative control theory (CCT), which is under development. Collaborative e-Work is motivated by significantly improved performance of humans leveraging their collaborative automatic agents. The latter, from software automata (e.g., constructive *bots* as opposed to spam and other destructive bots) to automation devices, multisensors, multiagents, and multirobots can operate in a parallel, autonomous cyberspace, thus multiplying our productivity and increasing our ability to design sustainable systems and operations. A related important trend is the emergence of *active middleware* for collaboration support of device networks and of human team networks and enterprises.

More about this subject area can be found in several chapters of this handbook, particularly in Chaps. 12, 14, 26, and 88.

3.6.4 Risks of Automation

As civilization increasingly depends on automation and looks for automation to support solutions of its serious problems, the risks associated with automation must be understood and eliminated. Failures of automation on a very large scale are most risky. Just a few examples of disasters caused by automation failures are nuclear accidents; power supply disruptions and blackout; Federal Aviation Administration control systems failures causing air transportation delays and shutdowns; cellular communication network failures; and water supply failures. The impacts of severe natural and manmade disasters on automated infrastructure are therefore the target of intense research and development. In addition, automation experts are challenged to apply automation to enable sustainability and better mitigate and eliminate natural and manmade disasters, such as security, safety, and health calamities.

3.6.5 Need for Dependability, Survivability, Security, and Continuity of Operation

Emerging efforts are addressing better automation dependability and security by structured backup and recovery of information and communication systems. For instance, with service orientation that is able to survive, automation can enable gradual and degraded services by sustaining critical continuity of operations until the repair, recovery, and resumption of full services. Automation continues to be designed with the goal of preventing and eliminating any conceivable errors, failures, and conflicts, within economic constraints. In addition, the trend of collaborative flexibility being designed into automation frameworks encourages reconfiguration tools that redirect available, safe resources to support the most critical functions, rather that designing absolutely failure-proof system.

With the trend towards collaborative, networked automation systems, dependability, survivability, security, and continuity of operations are increasingly being enabled by autonomous self-activities, such as:

- Self-awareness and situation awareness
- Self-configuration
- Self-explaining and self-rationalizing
- Self-healing and self-repair
- Self-optimization
- Self-organization
- Self-protection for security.

Other dimensions of emerging automation risks involve privacy invasion, electronic surveillance, accuracy and integrity concerns, intellectual and physical property protection and security, accessibility issues, confidentiality, etc. Increasingly, people ask about the meaning of automation, how can we benefit from it, yet find a way to contain its risks and powers. At the extreme of this concern is the *automation singularity* [3.18].

Automation singularity follows the evident acceleration of technological developments and discoveries. At some point, people ask, is it possible that superhuman machines can take over the human race? If we build them too autonomous, with collaborative ability to self-improve and self-sustain, would they not eventually be able to exceed human intelligence? In other words, superintelligent machines may autonomously, automatically, produce discoveries that are too complex for humans to comprehend; they may even act in ways that we consider out of control, chaotic, and even aimed at damaging and overpowering people. This emerging trend of thought will no doubt energize future research on how to prevent automation from running on its own without limits. In a way, this is the 21st century human challenge of *never play with fire*.

3.7 Conclusion

This chapter explores the meaning of automation to people around the world. After review of the evolution of automation and its influence on civilization, its main contributions and attributes, a survey is used to summarize highlights of the meaning of automation according to people around the world. Finally, emerging trends in automation and concerns about automation are also described. They can be summarized as addressing three general questions:

1. How can automation be improved and become more useful and dependable?
2. How can we limit automation from being too risky when it fails?
3. How can we develop better automation that is more autonomous and performs better, yet does not take over our humanity?

These topics are discussed in detail in the chapters of this handbook.

4. A History of Automatic Control

Christopher Bissell

Automatic control, particularly the application of feedback, has been fundamental to the development of automation. Its origins lie in the level control, water clocks, and pneumatics/hydraulics of the ancient world. From the 17th century onwards, systems were designed for temperature control, the mechanical control of mills, and the regulation of steam engines. During the 19th century it became increasingly clear that feedback systems were prone to instability. A stability criterion was derived independently towards the end of the century by Routh in England and Hurwitz in Switzerland. The 19th century, too, saw the development of servomechanisms, first for ship steering and later for stabilization and autopilots. The invention of aircraft added (literally) a new dimension to the problem. Minorsky's theoretical analysis of ship control in the 1920s clarified the nature of three-term control, also being used for process applications by the 1930s. Based on servo and communications engineering developments of the 1930s, and driven by the need for high-performance gun control systems, the coherent body of theory known as *classical control* emerged during and just after WWII in the US, UK and elsewhere, as did cybernetics ideas. Meanwhile, an alternative approach to dynamic modeling had been developed in the USSR based on the approaches of Poincaré and Lyapunov.

Information was gradually disseminated, and *state-space* or *modern control* techniques, fuelled by Cold War demands for missile control systems, rapidly developed in both East and West. The immediate post-war period was marked by great claims for automation, but also great fears, while the digital computer opened new possibilities for automatic control.

4.1 Antiquity and the Early Modern Period

Feedback control can be said to have originated with the float valve regulators of the Hellenic and Arab worlds [4.1]. They were used by the Greeks and Arabs to control such devices as water clocks, oil lamps and wine dispensers, as well as the level of water in tanks. The precise construction of such systems is still not entirely clear, since the descriptions in the original Greek or Arabic are often vague, and lack illustrations. The best known Greek names are Ktsebios and Philon (third century BC) and Heron (first century AD) who were active in the eastern Mediterranean (Alexandria, Byzantium). The water clock tradition was continued in the Arab world as described in books by writers such as Al-Jazari (1203) and Ibn al-Sa-ati (1206), greatly influenced by the anonymous Arab author known as Pseudo-Archimedes of the ninth–tenth century AD, who makes specific reference to the Greek work of Heron and Philon. Float regulators in the tradition of Heron were also constructed by the three brothers Banu Musa in Baghdad in the ninth century AD.

The float valve level regulator does not appear to have spread to medieval Europe, even though translations existed of some of the classical texts by the above writers. It seems rather to have been reinvented during the industrial revolution, appearing in England, for example, in the 18th century. The first independent European feedback system was the temperature regulator of Cornelius Drebbel (1572–1633). Drebbel spent most of his professional career at the courts of James I and Charles I of England and Rudolf II in Prague. Drebbel himself left no written records, but a number of contemporary descriptions survive of his invention. Essentially an alcohol (or other) thermometer was used to operate a valve controlling a furnace flue, and hence the temperature of an enclosure [4.2]. The device included screws to alter what we would now call the set point.

If level and temperature regulation were two of the major precursors of modern control systems, then

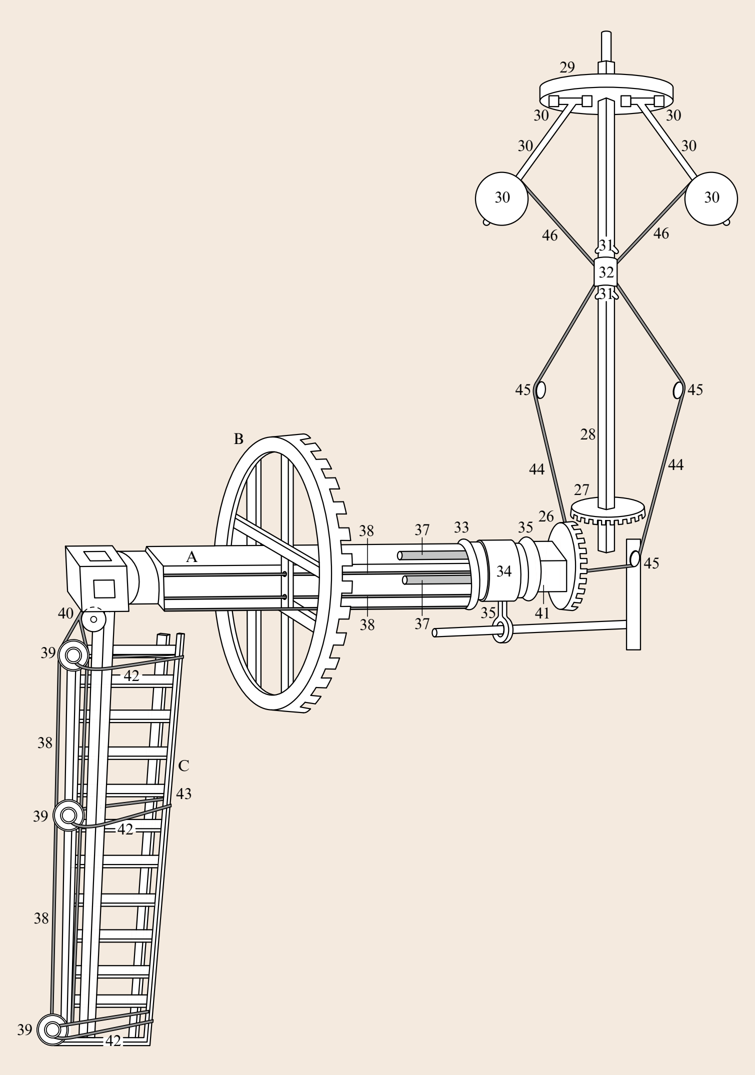

Fig. 4.1 Mead's speed regulator (after [4.1])

a number of devices designed for use with windmills pointed the way towards more sophisticated devices. During the 18th century the mill fantail was developed both to keep the mill sails directed into the wind and to automatically vary the angle of attack, so as to avoid excessive speeds in high winds. Another important device was the lift-tenter. Millstones have a tendency to separate as the speed of rotation increases, thus impairing the quality of flour. A number of techniques were developed to sense the speed and hence produce a restoring force to press the millstones closer together. Of these, perhaps the most important were *Thomas Mead*'s devices [4.3], which used a centrifugal pendulum to sense the speed and – in some applications – also to provide feedback, hence pointing the way to the centrifugal governor (Fig. 4.1).

The first steam engines were the reciprocating engines developed for driving water pumps; James Watt's rotary engines were sold only from the early 1780s. But it took until the end of the decade for the centrifugal governor to be applied to the machine, following a visit by Watt's collaborator, Matthew Boulton, to

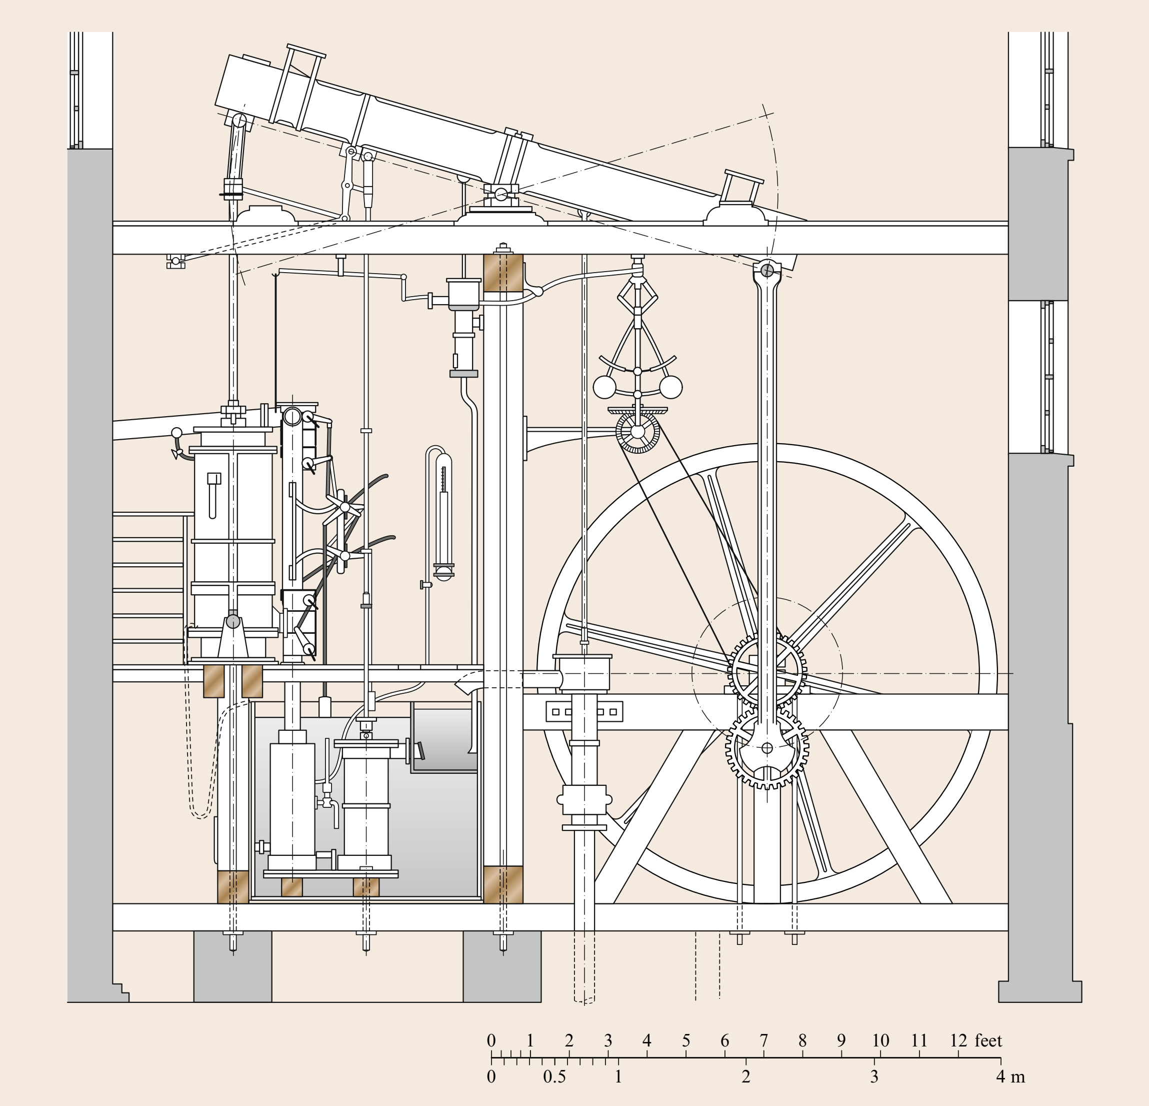

Fig. 4.2 Boulton & Watt steam engine with centrifugal governor (after [4.1])

the Albion Mill in London where he saw a lift-tenter in action under the control of a centrifugal pendulum (Fig. 4.2). Boulton and Watt did not attempt to patent the device (which, as noted above, had essentially already been patented by Mead) but they did try unsuccessfully to keep it secret. It was first copied in 1793 and spread throughout England over the next ten years [4.4].

4.2 Stability Analysis in the 19th Century

With the spread of the centrifugal governor in the early 19th century a number of major problems became apparent. First, because of the absence of integral action, the governor could not remove offset: in the terminology of the time it could not *regulate* but only *moderate*. Second, its response to a change in load was slow. And thirdly, (nonlinear) frictional forces in the mechanism could lead to *hunting* (limit cycling). A number of attempts were made to overcome these problems: for example, the Siemens chronometric governor effectively introduced integral action through differential gearing, as well as mechanical amplification. Other approaches to the design of an *isochronous* governor (one with no offset) were based on ingenious mechanical constructions, but often encountered problems of stability.

Nevertheless the 19th century saw steady progress in the development of practical governors for steam engines and hydraulic turbines, including spring-loaded designs (which could be made much smaller, and operate at higher speeds) and relay (indirect-acting) governors [4.6]. By the end of the century governors of various sizes and designs were available for effective regulation in a range of applications, and a number of graphical techniques existed for steady-state design. Few engineers were concerned with the analysis of the dynamics of a feedback system.

In parallel with the developments in the engineering sector a number of eminent British scientists became interested in governors in order to keep a telescope directed at a particular star as the Earth rotated. A formal analysis of the dynamics of such a system by *George Bidell Airy*, Astronomer Royal, in 1840 [4.7] clearly demonstrated the propensity of such a feedback system to become unstable. In 1868 James Clerk Maxwell analyzed governor dynamics, prompted by an electrical experiment in which the speed of rotation of a coil had to be held constant. His resulting classic paper *On governors* [4.8] was received by the Royal Society on 20 February. Maxwell derived a third-order linear model and the correct conditions for stability in terms of the coefficients of the characteristic equation. Unable to derive a solution for higher-order models, he expressed the hope that the question would gain the attention of mathematicians. In 1875 the subject for the Cambridge University Adams Prize in mathematics was set as *The criterion of dynamical stability*. One of the examiners was Maxwell himself (prizewinner in 1857) and the 1875 prize (awarded in 1877) was won by Edward James Routh. *Routh* had been interested in dynamical stability for several years, and had already obtained a solution for a fifth-order system. In the published paper [4.9] we find derived the Routh version of the renowned Routh–Hurwitz stability criterion.

Related, independent work was being carried out in continental Europe at about the same time [4.5]. A summary of the work of I.A. Vyshnegradskii in St. Petersburg appeared in the French *Comptes Rendus de l'Academie des Sciences* in 1876, with the full version appearing in Russian and German in 1877, and in French in 1878/79. Vyshnegradskii (generally transliterated at the time as Wischnegradski) transformed a third-order differential equation model of a steam en-

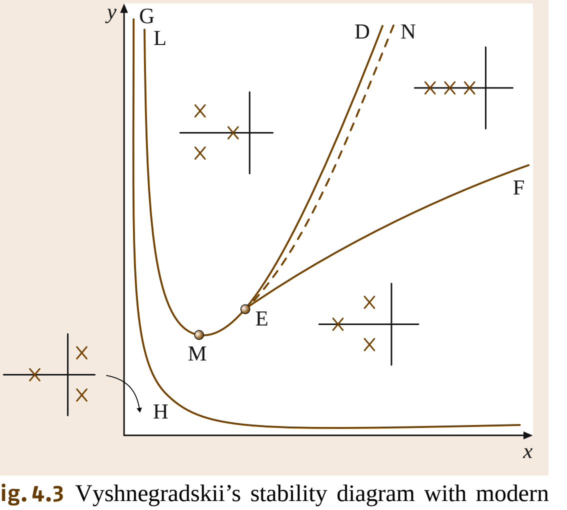

Fig. 4.3 Vyshnegradskii's stability diagram with modern pole positions (after [4.5])

gine with governor into a standard form

$$\varphi^3 + x\varphi^2 + y\varphi + 1 = 0 ,$$

where x and y became known as the Vyshnegradskii parameters. He then showed that a point in the x–y plane defined the nature of the system transient response. Figure 4.3 shows the diagram drawn by Vyshnegradskii, to which typical pole constellations for various regions in the plane have been added.

In 1893 Aurel Boreslav Stodola at the Federal Polytechnic, Zurich, studied the dynamics of a high-pressure hydraulic turbine, and used Vyshnegradskii's method to assess the stability of a third-order model. A more realistic model, however, was seventh-order, and Stodola posed the general problem to a mathematician colleague *Adolf Hurwitz*, who very soon came up with his version of the Routh–Hurwitz criterion [4.10]. The two versions were shown to be identical by *Enrico Bompiani* in 1911 [4.11].

At the beginning of the 20th century the first general textbooks on the regulation of prime movers appeared in a number of European languages [4.12, 13]. One of the most influential was *Tolle*'s *Regelung der Kraftmaschine*, which went through three editions between 1905 and 1922 [4.14]. The later editions included the Hurwitz stability criterion.

4.3 Ship, Aircraft and Industrial Control Before WWII

The first ship steering engines incorporating feedback appeared in the middle of the 19th century. In 1873 Jean Joseph Léon Farcot published a book on servomotors in which he not only described the various designs developed in the family firm, but also gave an account of the general principles of position control. Another important maritime application of feedback control was in gun turret operation, and hydraulics were also extensively developed for transmission systems. Torpedoes, too, used increasingly sophisticated feedback systems for depth control – including, by the end of the century, gyroscopic action (Fig. 4.4).

During the first decades of the 20th century gyroscopes were increasingly used for ship stabilization and autopilots. Elmer Sperry pioneered the *active stabilizer*, the gyrocompass, and the gyroscope autopilot, filing various patents over the period 1907–1914. Sperry's autopilot was a sophisticated device: an inner loop controlled an electric motor which operated the steering engine, while an outer loop used a gyrocompass to sense the heading. Sperry also designed an *anticipator* to replicate the way in which an experienced helmsman would *meet* the helm (to prevent oversteering); the anticipator was, in fact, a type of adaptive control [4.16].

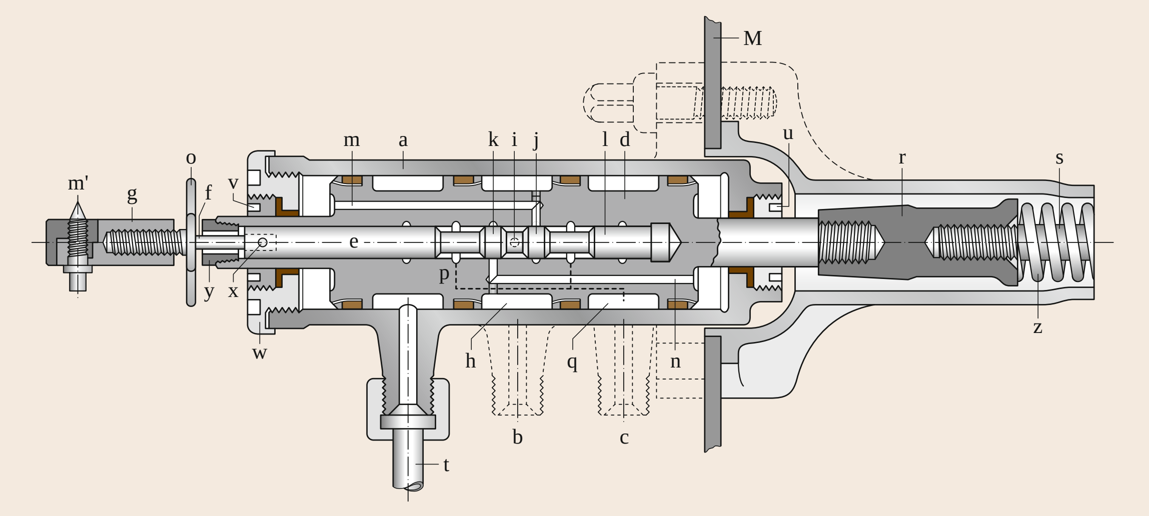

Fig. 4.4 Torpedo servomotor as fitted to Whitehead torpedoes around 1900 (after [4.15])

Sperry and his son Lawrence also designed aircraft autostabilizers over the same period, with the added complexity of three-dimensional control. *Bennett* describes the system used in an acclaimed demonstration in Paris in 1914 [4.17]:

> *For this system the Sperrys used four gyroscopes mounted to form a stabilized reference platform; a train of electrical, mechanical and pneumatic components detected the position of the aircraft relative to the platform and applied correction signals to the aircraft control surfaces. The stabilizer operated for both pitch and roll [...] The system was normally adjusted to give an approximately deadbeat response to a step disturbance. The incorporation of derivative action [...] was based on Sperry's intuitive understanding of the behaviour of the system, not on any theoretical foundations. The system was also adaptive [...] adjusting the gain to match the speed of the aircraft.*

Significant technological advances in both ship and aircraft stabilization took place over the next two decades, and by the mid 1930s a number of airlines were using Sperry autopilots for long-distance flights. However, apart from the stability analyses discussed

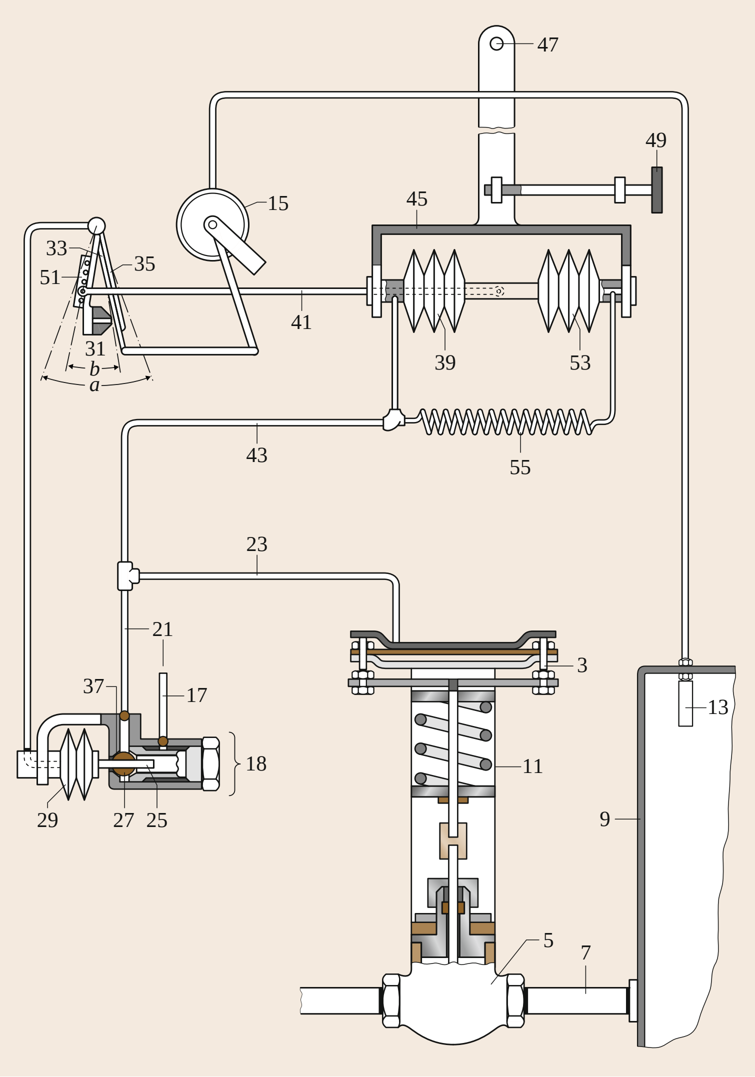

Fig. 4.5 The *Stabilog*, a pneumatic controller providing proportional and integral action [4.18]

in Sect. 4.2 above, which were not widely known at this time, there was little theoretical investigation of such feedback control systems. One of the earliest significant studies was carried out by *Nicholas Minorsky*, published in 1922 [4.19]. Minorsky was born in Russia in 1885 (his knowledge of Russian proved to be important to the West much later). During service with the Russian Navy he studied the ship steering problem and, following his emigration to the USA in 1918, he made the first theoretical analysis of automatic ship steering. This study clearly identified the way that control action should be employed: although Minorsky did not use the terms in the modern sense, he recommended an appropriate combination of proportional, derivative and integral action. Minorsky's work was not widely disseminated, however. Although he gave a good theoretical basis for closed loop control, he was writing in an age of heroic invention, when intuition and practical experience were much more important for engineering practice than theoretical analysis.

Important technological developments were also being made in other sectors during the first few decades of the 20th century, although again there was little theoretical underpinning. The electric power industry brought demands for voltage and frequency regulation; many processes using driven rollers required accurate speed control; and considerable work was carried out in a number of countries on systems for the accurate pointing of guns for naval and anti-aircraft gunnery. In the process industries, measuring instruments and pneumatic controllers of increasing sophistication were developed. Mason's *Stabilog* (Fig. 4.5), patented in 1933, included integral as well as proportional action, and by the end of the decade three-term controllers were available that also included *preact* or derivative control. Theoretical progress was slow, however, until the advances made in electronics and telecommunications in the 1920s and 30s were translated into the control field during WWII.

4.4 Electronics, Feedback and Mathematical Analysis

The rapid spread of telegraphy and then telephony from the mid 19th century onwards prompted a great deal of theoretical investigation into the behaviour of electric circuits. *Oliver Heaviside* published papers on his operational calculus over a number of years from 1888 onwards [4.20], but although his techniques produced valid results for the transient response of electrical networks, he was fiercely criticized by contemporary mathematicians for his lack of rigour, and ultimately he was blackballed by the establishment. It was not until the second decade of the 20th century that Bromwich, Carson and others made the link between Heaviside's operational calculus and Fourier methods, and thus proved the validity of Heaviside's techniques [4.21].

The first three decades of the 20th century saw important analyses of circuit and filter design, particularly in the USA and Germany. *Harry Nyquist* and Karl Küpfmüller were two of the first to consider the problem of the maximum transmission rate of telegraph signals, as well as the notion of *information* in telecommunications, and both went on to analyze the general stability problem of a feedback circuit [4.22]. In 1928 Küpfmüller analyzed the dynamics of an automatic gain control electronic circuit using feedback. He appreciated the dynamics of the feedback system, but his integral equation approach resulted only in a approximations and design diagrams, rather than a rigorous stability criterion. At about the same time in the USA, Harold Black was designing feedback amplifiers for transcontinental telephony (Fig. 4.6). In a famous epiphany on the Hudson River ferry in August 1927 he realized that negative feedback could reduce distortion at the cost of reducing overall gain. Black passed on the problem of the stability of such a feedback loop to his Bell Labs colleague *Harry Nyquist*, who published his celebrated frequency-domain encirclement criterion in 1932 [4.23]. Nyquist demonstrated, using results derived by Cauchy, that the key to stability is whether or not the open loop frequency response locus in the complex plane encircles (in Nyquist's original convention) the point $1+\mathrm{i}0$. One of the great advantages of this approach is that no analytical form of the open loop frequency response is required: a set of measured data points can be plotted without the need for a mathematical model. Another advantage is that, unlike the Routh–Hurwitz criterion, an assessment of the transient response can be made directly from the Nyquist plot in terms of gain and phase margins (how close the locus approaches the critical point).

Black's 1934 paper reporting his contribution to the development of the negative feedback amplifier included what was to become the standard closed-loop analysis in the frequency domain [4.24].

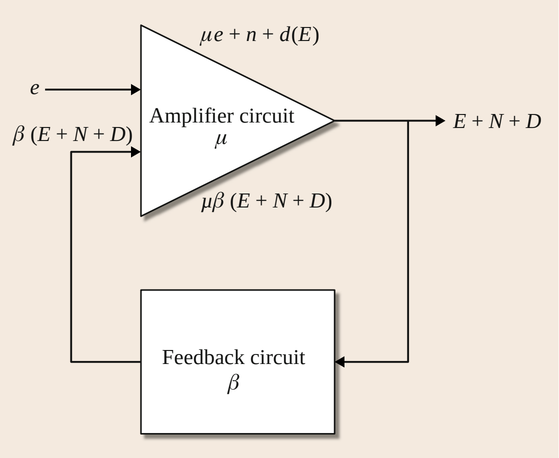

Fig. 4.6 Black's feedback amplifier (after [4.24])

The third key contributor to the analysis of feedback in electronic systems at Bell Labs was *Hendrik Bode* who worked on equalizers from the mid 1930s, and who demonstrated that attenuation and phase shift were related in any realizable circuit [4.25]. The dream of telephone engineers to build circuits with fast cutoff and low phase shift was indeed only a dream. It was Bode who introduced the notions of gain and phase margins, and redrew the Nyquist plot in its now conventional form with the critical point at $-1+\mathrm{i}0$. He also introduced the famous straight-line approximations to frequency response curves of linear systems plotted on log–log axes. *Bode* presented his methods in a classic text published immediately after the war [4.26].

If the work of the communications engineers was one major precursor of classical control, then the other was the development of high-performance servos in the 1930s. The need for such servos was generated by the increasing use of analogue simulators, such as network analysers for the electrical power industry and differential analysers for a wide range of problems. By the early 1930s six-integrator differential analysers were in operation at various locations in the USA and the UK. A major center of innovation was MIT, where Vannevar Bush, Norbert Wiener and Harold Hazen had all contributed to design. In 1934 *Hazen* summarized the developments of the previous years in *The theory of servomechanisms* [4.27]. He adopted normalized curves, and parameters such as time constant and damping factor, to characterize servo-response, but he did not given any stability analysis: although he appears to have been aware of Nyquists's work, he (like almost all his contemporaries) does not appear to have appreciated the close relationship between a feedback servomechanism and a feedback amplifier.

The 1930s American work gradually became known elsewhere. There is ample evidence from prewar USSR, Germany and France that, for example, Nyquist's results were known – if not widely disseminated. In 1940, for example, *Leonhard* published a book on automatic control in which he introduced the inverse Nyquist plot [4.28], and in the same year a conference was held in Moscow during which a number of Western results in automatic control were presented and discussed [4.29]. Also in Russia, a great deal of work was being carried out on nonlinear dynamics, using an approach developed from the methods of Poincaré and Lyapunov at the turn of the century [4.30]. Such approaches, however, were not widely known outside Russia until after the war.

4.5 WWII and *Classical* Control: Infrastructure

Notwithstanding the major strides identified in the previous subsections, it was during WWII that a discipline of feedback control began to emerge, using a range of design and analysis techniques to implement high-performance systems, especially those for the control of anti-aircraft weapons. In particular, WWII saw the coming together of engineers from a range of disciplines – electrical and electronic engineering, mechanical engineering, mathematics – and the subsequent realisation that a common framework could be applied to all the various elements of a complex control system in order to achieve the desired result [4.18, 31].

The so-called fire control problem was one of the major issues in military research and development at the end of the 1930s. While not a new problem, the increasing importance of aerial warfare meant that the control of anti-aircraft weapons took on a new significance. Under manual control, aircraft were detected by radar, range was measured, prediction of the aircraft position at the arrival of the shell was computed, guns were aimed and fired. A typical system could involve up to 14 operators. Clearly, automation of the process was highly desirable, and achieving this was to require detailed research into such matters as the dynamics of the servomechanisms driving the gun aiming, the design of controllers, and the statistics of tracking aircraft possibly taking evasive action.

Government, industry and academia collaborated closely in the US, and three research laboratories were of prime importance. The Servomechanisms Laboratory at MIT brought together Brown, Hall, Forrester and others in projects that developed frequency-domain methods for control loop design for high-performance servos. Particularly close links were maintained with Sperry, a company with a strong track record in guidance systems, as indicated above. Meanwhile, at MIT's Radiation Laboratory – best known, perhaps, for its work on radar and long-distance navigation – researchers such as James, Nichols and Phillips worked on the further development of design techniques for auto-track radar for AA gun control. And the third institution of seminal importance for fire-control development was Bell Labs, where great names such as Bode, Shannon and Weaver – in collaboration with Wiener and Bigelow at MIT – attacked a number of outstanding problems, including the theory of smoothing and prediction for gun aiming. By the end of the war, most of the techniques of what came to be called classical control had been elaborated in these laboratories, and a whole series of papers and textbooks appeared in the late 1940s presenting this new discipline to the wider engineering community [4.32].

Support for control systems development in the United States has been well documented [4.18, 31]. The National Defence Research Committee (NDRC) was established in 1940 and incorporated into the Office of Scientific Research and Development (O.R.) the following year. Under the directorship of Vannevar Bush the new bodies tackled anti-aircraft measures, and thus the servo problem, as a major priority. Section D of the NDRC, devoted to Detection, Controls and Instruments was the most important for the development of feedback control. Following the establishment of the O.R. the NDRC was reorganised into divisions, and Division 7, Fire Control, under the overall direction of Harold Hazen, covered the subdivisions: ground-based anti-aircraft fire control; airborne fire control systems; servomechanisms and data transmission; optical rangefinders; fire control analysis; and navy fire control with radar.

Turning to the United Kingdom, by the outbreak of WWII various military research stations were highly active in such areas as radar and gun laying, and there were also close links between government bodies and industrial companies such as Metropolitan–Vickers, British Thomson–Houston, and others. Nevertheless, it is true to say that overall coordination was not as effective as in the USA. A body that contributed significantly to the dissemination of theoretical developments and other research into feedback control systems in the UK was the so called Servo-Panel. Originally established informally in 1942 as the result of an initiative of Solomon (head of a special radar group at Malvern), it acted rather as a *learned society* with approximately monthly meetings from May 1942 to August 1945. Towards the end of the war meetings included contributions from the US.

Germany developed successful control systems for civil and military applications both before and during the war (torpedo and flight control, for example). The period 1938–1941 was particularly important for the development of missile guidance systems. The test and development center at Peenemünde on the Baltic coast had been set up in early 1936, and work on guidance and control saw the involvement of industry, the government and universities. However, there does not appear to have been any significant national coordination of R&D in the control field in Germany, and little development of high-performance servos as there was in the US and the UK. When we turn to the German situation outside the military context, however, we find a rather remarkable awareness of control and even cybernetics. In 1939 the *Verein Deutscher Ingenieure*, one of the two major German engineers' associations, set up a specialist committee on control engineering. As early as October 1940 the chair of this body *Herman Schmidt* gave a talk covering control engineering and its relationship with economics, social sciences and cultural aspects [4.33]. Rather remarkably, this committee continued to meet during the war years, and issued a report in 1944 concerning primarily control concepts and terminology, but also considering many of the fundamental issues of the emerging discipline.

The Soviet Union saw a great deal of prewar interest in control, mainly for industrial applications in the context of five-year plans for the Soviet command economy. Developments in the USSR have received little attention in English-language accounts of the history of the discipline apart from a few isolated papers. It is noteworthy that the *Kommissiya Telemekhaniki i Avtomatiki* (KTA) was founded in 1934, and the *Institut Avtomatiki i Telemekhaniki* (IAT) in 1939 (both under the auspices of the Soviet Academy of Sciences, which controlled scientific research through its network of institutes). The KTA corresponded with numerous western manufacturers of control equipment in the mid

1930s and translated a number articles from western journals. The early days of the IAT were marred, however, by the *Shchipanov affair*, a classic Soviet attack on a researcher for *pseudo-science*, which detracted from technical work for a considerable period of time [4.34]. The other major Russian center of research related to control theory in the 1930s and 1940s (if not for practical applications) was the University of Gorkii (now Nizhnii Novgorod), where Aleksandr Andronov and colleagues had established a center for the study of nonlinear dynamics during the 1930s [4.35]. Andronov was in regular contact with Moscow during the 1940s, and presented the emerging control theory there – both the nonlinear research at Gorkii and developments in the UK and USA. Nevertheless, there appears to have been no coordinated wartime work on control engineering in the USSR, and the IAT in Moscow was evacuated when the capital came under threat. However, there does seem to have been an emerging control community in Moscow, Nizhnii Novgorod and Leningrad, and Russian workers were extremely well-informed about the open literature in the West.

4.6 WWII and *Classical* Control: Theory

Design techniques for servomechanisms began to be developed in the USA from the late 1930s onwards. In 1940 Gordon S. Brown and colleagues at MIT analyzed the transient response of a closed loop system in detail, introducing the *system operator* $1/(1 + \text{open loop})$ as functions of the Heaviside differential operator p. By the end of 1940 contracts were being drawn up between the NDRC and MIT for a range of servo projects. One of the most significant contributors was *Albert Hall*, who developed classic frequency-response methods as part of his doctoral thesis, presented in 1943 and published initially as a confidential document [4.37] and then in the open literature after the war [4.36]. Hall derived the frequency response of a unity feedback servo as $KG(\mathrm{i}\omega)/[1 + KG(\mathrm{i}\omega)]$, applied the Nyquist criterion, and introduced a new way of plotting system response that he called M-circles (Fig. 4.7), which were later to inspire the Nichols Chart. As *Bennett* describes it [4.38]:

> *Hall was trying to design servosystems which were stable, had a high natural frequency, and high damping. [...] He needed a method of determining, from the transfer locus, the value of K that would give the desired amplitude ratio. As an aid to finding the value of K he superimposed on the polar plot curves of constant magnitude of the amplitude ratio. These curves turned out to be circles... By plotting the response locus on transparent paper, or by using an overlay of M-circles printed on transparent paper, the need to draw M-circles was obviated...*

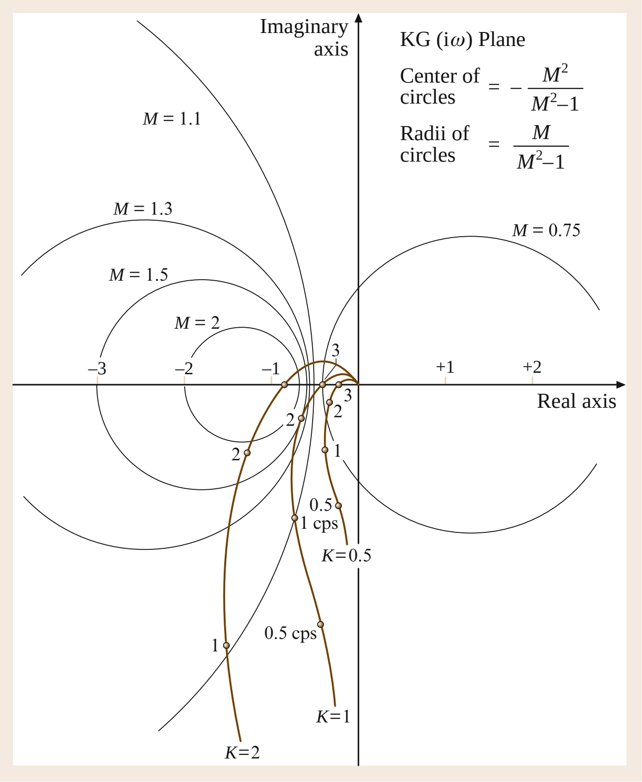

Fig. 4.7 Hall's M-circles (after [4.36])

A second MIT group, known as the Radiation Laboratory (or RadLab) was working on auto-track radar systems. Work in this group was described after the war in [4.39]; one of the major innovations was the introduction of the Nichols chart (Fig. 4.8), similar to Hall's M-circles, but using the more convenient decibel measure of amplitude ratio that turned the circles into a rather different geometrical form.

The third US group consisted of those looking at smoothing and prediction for anti-aircraft weapons – most notably Wiener and Bigelow at MIT together with others, including Bode and Shannon, at Bell Labs. This work involved the application of correlation techniques to the statistics of aircraft motion. Although the prototype Wiener predictor was unsuccessful in attempts at practical application in the early 1940s, the general approach proved to be seminal for later developments.

Formal techniques in the United Kingdom were not so advanced. Arnold Tustin at Metropolitan–Vickers (Metro–Vick) worked on gun control from the late 1930s, but engineers had little appreciation of dynamics. Although they used harmonic response plots they appeared to have been unaware of the Nyquist criterion until well into the 1940s [4.40]. Other key researchers in the UK included *Whitely*, who proposed using the inverse Nyquist diagram as early as 1942, and introduced his *standard forms* for the design of various categories of servosystem [4.41]. In Germany, Winfried Oppelt, Hans Sartorius and Rudolf Oldenbourg were also coming to related conclusions about closed-loop design independently of allied research [4.42, 43].

The basics of sampled-data control were also developed independently during the war in several countries. The z-transform in all but name was described in a chapter by *Hurewizc* in [4.39]. Tustin in the UK developed the bilinear transformation for time series models, while Oldenbourg and Sartorius also used difference equations to model such systems.

From 1944 onwards the design techniques developed during the hostilities were made widely available in an explosion of research papers and text books – not only from the USA and the UK, but also from Germany and the USSR. Towards the end of the decade perhaps the final element in the classical control toolbox was added – *Evans*' root locus technique, which enabled plots of changing pole position as a function of loop gain to be easily sketched [4.44]. But a radically different approach was already waiting in the wings.

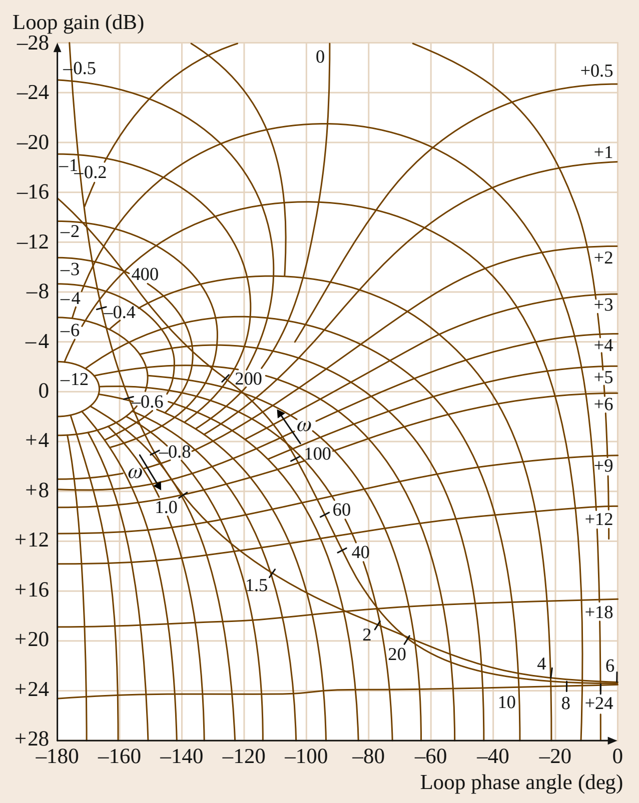

Fig. 4.8 Nichols Chart (after [4.38])

4.7 The Emergence of *Modern* Control Theory

The *modern* or *state space* approach to control was ultimately derived from original work by Poincaré and Lyapunov at the end of the 19th century. As noted above, Russians had continued developments along these lines, particularly during the 1920s and 1930s in centers of excellence in Moscow and Gorkii (now Nizhnii Novgorod). Russian work of the 1930s filtered slowly through to the West [4.45], but it was only in the post war period, and particularly with the introduction of cover-to-cover translations of the major Soviet journals, that researchers in the USA and elsewhere became familiar with Soviet work. But phase plane approaches had already been adopted by Western control engineers. One of the first was *Leroy MacColl* in his early textbook [4.46].

The cold war requirements of control engineering centered on the control of ballistic objects for aerospace applications. Detailed and accurate mathematical models, both linear and nonlinear, could be obtained, and the classical techniques of frequency response and root locus – essentially approximations – were increasingly replaced by methods designed to optimize some measure of performance such as minimizing trajectory time or fuel consumption. Higher-order models were expressed as a set of first order equations in terms of the state variables. The state variables allowed for a more sophisticated representation of dynamic behaviour than the classical single-input single-output system modelled by a differential equation, and were suitable for multivariable problems. In general, we have in matrix form

$$\boldsymbol{x} = \mathbf{A}\boldsymbol{x} + \mathbf{B}\boldsymbol{u} \,,$$
$$\boldsymbol{y} = \mathbf{C}\boldsymbol{x} \,,$$

where $\boldsymbol{x}$ are the state variables, $\boldsymbol{u}$ the inputs and $\boldsymbol{y}$ the outputs.

Automatic control developments in the late 1940s and 1950s were greatly assisted by changes in the engineering professional bodies and a series of international conferences [4.47]. In the USA both the American Society of Mechanical Engineers and the American Institute of Electrical Engineers made various changes to their structure to reflect the growing importance of servomechanisms and feedback control. In the UK similar changes took place in the British professional bodies, most notably the Institution of Electrical Engineers, but also the Institute of Measurement and Control and the mechanical and chemical engineering bodies. The first conferences on the subject appeared in the late 1940s in London and New York, but the first truly international conference was held in Cranfield, UK in 1951. This was followed by a number of others, the most influential of which was the Heidelberg event of September 1956, organized by the joint control committee of the two major German engineering bodies, the VDE and VDI. The establishment of the International Federation of Automatic Control followed in 1957 with its first conference in Moscow in 1960 [4.48]. The Moscow conference was perhaps most remarkable for Kalman's paper *On the general theory of control systems* which identified the duality between multivariable feedback control and multivariable feedback filtering and which was seminal for the development of optimal control.

The late 1950s and early 1960s saw the publication of a number of other important works on dynamic programming and optimal control, of which can be singled out those by *Bellman* [4.49], *Kalman* [4.50–52] and *Pontryagin* and colleagues [4.53]. A more thorough discussion of control theory is provided in Chaps. 9, 11 and 10.

4.8 The Digital Computer

The introduction of digital technologies in the late 1950s brought enormous changes to automatic control. Control engineering had long been associated with computing devices – as noted above, a driving force for the development of servos was for applications in analogue computing. But the great change with the introduction of digital computers was that ultimately the approximate methods of frequency response or root locus design, developed explicitly to avoid computation, could be replaced by techniques in which accurate computation played a vital role.

There is some debate about the first application of digital computers to process control, but certainly the introduction of computer control at the Texaco Port Arthur (Texas) refinery in 1959 and the Monsanto ammonia plant at Luling (Louisiana) the following year are two of the earliest [4.54]. The earliest systems were supervisory systems, in which individual loops were controlled by conventional electrical, pneumatic or hydraulic controllers, but monitored and optimized by computer. Specialized process control computers followed in the second half of the 1960s, offering direct digital control (DDC) as well as supervisory control. In DDC the computer itself implements a discrete form of a control algorithm such as three-term control or other procedure. Such systems were expensive, however, and also suffered many problems with programming, and were soon superseded by the much cheaper minicomputers of the early 1970s, most notably the Digital Equipment Corporation PDP series. But, as in so many other areas, it was the microprocessor that had the greatest effect. Microprocessor-based digital controllers were soon developed that were compact, reliable, included a wide selection of control algorithms, had good communications with supervisory computers, and comparatively easy to use programming and diagnostic tools via an effective operator interface. Microprocessors could also easily be built into specific pieces of equipment, such as robot arms, to provide dedicated position control, for example.

A development often neglected in the history of automatic control is the programmable logic controller (PLC). PLCs were developed to replace individual relays used for sequential (and combinational) logic control in various industrial sectors. Early plugboard devices appeared in the mid 1960s, but the first PLC proper was probably the Modicon, developed for General Motors to replace electromechanical relays in automotive component production. Modern PLCs offer a wide range of control options, including conventional

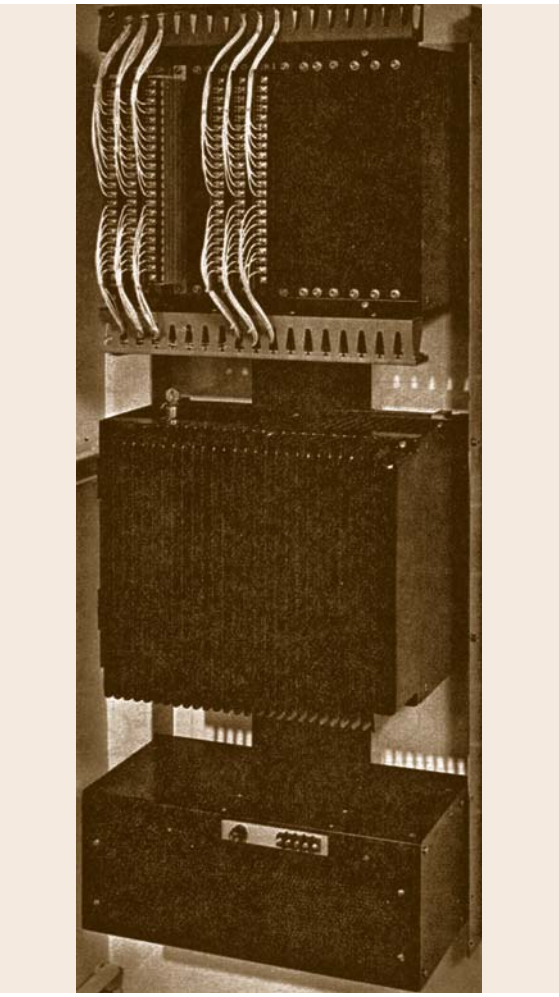

Fig. 4.9 The Modicon 084 PLC (after [4.55])

closed loop control algorithms such as PID as well as the logic functions. In spite of the rise of the ruggedized PCs in many industrial applications, PLCs are still widely used owing to their reliability and familiarity (Fig. 4.9).

Digital computers also made it possible to implement the more advanced control techniques that were being developed in the 1960s and 1970s [4.56]. In adaptive control the algorithm is modified according to circumstances. Adaptive control has a long history: so called gain scheduling, for example, when the gain of a controller is varied according to some measured parameter, was used well before the digital computer. (The classic example is in flight control, where the altitude affects aircraft dynamics, and needs therefore to be taken into account when setting gain.) Digital adaptive control, however, offers much greater possibilities for:

1. Identification of relevant system parameters
2. Making decisions about the required modifications to the control algorithm
3. Implementing the changes.

Optimal and robust techniques too, were developed, the most celebrated perhaps being the linear-quadratic-Gaussian (LQG) and H_∞ approaches from the 1960s onwards. Without digital computers these techniques, that attempt to optimize system rejection of disturbances (according to some measure of behaviour) while at the same time being resistant to errors in the model, would simply be mathematical curiosities [4.57].

A very different approach to control rendered possible by modern computers is to move away from purely mathematic models of system behaviour and controller algorithms. In fuzzy control, for example, control action is based on a set of rules expressed in terms of *fuzzy* variables. For example

IF the speed is "high"
AND the distance to final stop is "short"
THEN apply brakes "firmly".

The fuzzy variables *high*, *short* and *firmly* can be translated by means of an appropriate computer program into effective control for, in this case, a train. Related techniques include *learning control* and *knowledge-based control*. In the former, the control system can *learn* about its environment using artificial intelligence techniques (AI) and modify its behaviour accordingly. In the latter, a range of AI techniques are applied to reasoning about the situation so as to provide appropriate control action.

4.9 The Socio-Technological Context Since 1945

This short survey of the history of automatic control has concentrated on technological and, to some extent, institutional developments. A full social history of automatic control has yet to be written, although there are detailed studies of certain aspects. Here I shall merely indicate some major trends since WWII.

The wartime developments, both in engineering and in areas such as operations research, pointed the way towards the design and management af large-scale, complex, projects. Some of those involved in the wartime research were already thinking on a much larger scale. As early as 1949, in some rather prescient remarks at an ASME meeting in the fall of that year, *Brown* and *Campbell* said [4.58–60]:

> *We have in mind more a philosophic evaluation of systems which might lead to the improvement of product quality, to better coordination of plant operation, to a clarification of the economics related to new plant design, and to the safe operation of plants in our composite social-industrial community. [. . .] The conservation of raw materials used in a process often prompts reconsideration of control. The expenditure of power or energy in product manufacture is another important factor related to control. The protection of health of the population adjacent to large industrial areas against atmospheric poisoning and water-stream pollution is a sufficiently serious problem to keep us constantly alert for advances in the study and technique of automatic control, not only because of the human aspect, but because of the economy aspect.*

Many saw the new technologies, and the prospects of automation, as bringing great benefits to society; others were more negative. *Wiener*, for example, wrote [4.61]:

> *The modern industrial revolution is [. . .] bound to devalue the human brain at least in its simpler and more routine decisions. Of course, just as the skilled carpenter, the skilled mechanic, the skilled dressmaker have in some degree survived the first industrial revolution, so the skilled scientist and the skilled administrator may survive the second. However, taking the second revolution as accomplished, the average human of mediocre attainments or less has nothing to sell that it is worth anyone's money to buy.*

It is remarkable how many of the wartime engineers involved in control systems development went on to look at social, economic or biological systems. In addition to Wiener's work on cybernetics, Arnold Tustin wrote a book on the application to economics of control ideas, and both Winfried Oppelt and Karl Küpfmüller investigated biological systems in the postwar period.

One of the more controversial applications of control and automation was the introduction of the computer numerical control (CNC) of machine tools from the late 1950s onwards. Arguments about increased productivity were contested by those who feared widespread unemployment. We still debate such issues today, and will continue to do so. *Noble*, in his critique of automation, particularly CNC, remarks [4.62]:

> *[. . .] when technological development is seen as politics, as it should be, then the very notion of progress becomes ambiguous: What kind of progress? Progress for whom? Progress for what? And the awareness of this ambiguity, this indeterminacy, reduces the powerful hold that technology has had upon our consciousness and imagination [. . .] Such awareness awakens us not only to the full range of technological possibilities and political potential but also to a broader and older notion of progress, in which a struggle for human fulfillment and social equality replaces a simple faith in technological deliverance. . . .*

4.10 Conclusion and Emerging Trends

Technology is part of human activity, and cannot be divorced from politics, economics and society. There is no doubt that automatic control, at the core of automation, has brought enormous benefits, enabling modern production techniques, power and water supply, environmental control, information and communication technologies, and so on. At the same time automatic control has called into question the way we organize our societies, and how we run modern technological enterprises. Automated processes require much less human intervention, and there have been periods in the recent past when automation has been problematic in those parts of industrialized society that have traditionally relied on a large workforce for carrying out tasks that were subsequently automated. It seems unlikely that these socio-technological questions will be settled as we move towards the next generation of automatic control systems, such as the transformation of work through the use of information and communication technology ICT and the application of control ideas to this emerging field [4.63].

Future developments in automatic control are likely to exploit ever more sophisticated mathematical models for those applications amenable to exact technological modeling, plus a greater emphasis on human–machine systems, and further development of human behaviour modeling, including decision support and cognitive engineering systems [4.64]. As safety aspects of large-scale automated systems become ever more important, large scale integration, and novel ways of communicating between humans and machines, are likely to take on even greater significance.

5. Social, Organizational, and Individual Impacts of Automation

Tibor Vámos

Society and information from the evolutionary early beginnings. The revolutionary novelties of our age: the possibility for the end of a human being in the role of draught animal and the symbolic representation of the individual and of his/her property by electronic means, free of distance and time constraints. As a consequence, changing human roles in production, services, organizations and innovation; changing society stratifications, human values, requirements in skills, individual conscience. New relations: centralization and decentralization, less hierarchies, discipline and autonomy, new employment relations, less job security, more free lance, working home, structural unemployment, losers and winners, according to age, gender, skills, social background. Education and training, levels, life long learning, changing methods of education. Role of memory and associative abilities. Changes reflected in linguistic relations, multilingual global society, developments and decays of regional and social vernaculars. The social–political arena, human rights, social philosophies, problems and perspectives of democracy. The global agora and global media rule. More equal or more divided society. Some typical society patterns: US, Europe, Far East, India, Latin America, Africa.

Automation and closely related information systems are, naturally, innate and integrated ingredients of all kinds of objects, systems, and social relations of the present reality. This is the reason why this chapter treats the phenomena and problems of this automated/information society in a historical and structural framework much broader than any chapter on technology details. This process transforms traditional human work, offers freedom from burdensome physical and mental constraints and freedom for individuals and previously subjugated social layers, and creates new gaps and tensions. After detailed documentation of these phenomena, problems of education and culture are treated as main vehicles to adaptation. Legal aspects related to privacy, security, copyright, and patents are referred to, and then social philosophy, impacts of globalization, and new characteristics of information technology–society relations provide a conclusion of future prospects.

5.1 Scope of Discussion: Long and Short Range of Man–Machine Systems

Regarding the social effects of automation, a review of concepts is needed in the context of the purpose of this chapter. Automation, in general, and especially in our times, means all kinds of activity perfected by machines and not by the intervention of direct human control. This definition involves the use of some energy resources operating without human or livestock physical effort and with some kind of information system communicating the purpose of automated activity desired by humans and the automatic execution of the activity, i. e., its control.

This definition entails a widely extended view of automation, its relation to information, knowledge control systems, as well as the knowledge and practice of the related human factor. The human factor involves, practically, all areas of science and practice with respect to human beings: education, health, physical and mental abilities, instruments and virtues of cooperation (i. e., language and sociability), environmental conditions, short- and long-range ways of thinking, ethics, legal systems, various aspects of private life, and entertainment.

One of the major theses of this definitional and relational philosophy is the man–machine paradox: the human role in all kinds of automation is a continuously emerging constituent of man–machine symbiosis, with feedback to the same.

From this perspective, the inclusion of a discussion of early historical developments is not surprising. This evolution is of twin importance. First, due to the contradictory speeds of human and machine evolution, despite the fascinating results of machine technology, in most

Fig. 5.1 Timeline of science and technology in Western civilization

applications the very slow progress of the user is critical. Incredibly sophisticated instruments are, and will be, used by creatures not too different from their ancestors of 1000 years ago. This contradiction appears not only in the significant abuse of automated equipment against other people but also in human user reasoning, which is sometimes hysterical and confused in its thinking.

The second significance of this paradox is in our perception of various changes: its reflection in problem solving, and in understanding the relevance of continuity and change, which is sometimes exaggerated, while other times it remains unrecognized in terms of its further effects.

These are the reasons why this chapter treats automation in a context that is wider and somehow deeper than usual, which appears to be necessary in certain application problems. The references relate to the twin peaks of the Industrial Revolution: the first, the classic period starting in the late 18th century with machine power; and the second, after World War II (WWII), in the information revolution.

Practically all measures of social change due to automation are hidden in the general indices of technology effects and, within those, in the effects of automation- and communication-related technology. Human response is, generally, a steady process, apart from dramatic events such as wars, social revolutions, and crises in the economy. Some special acceleration phenomena can be observed in periods of inflation and price changes, especially in terms of decreases in product prices for high technology, and changes in the composition of general price indices and in the spread of high-technology commodities; television (TV), color TV, mobile telephony, and Internet access are typical examples. These spearhead technologies rad-

ically change lifestyles and social values but impact less slowly on the development of human motivations and, as a consequence, on several characteristics of individual and social behavior. The differing speeds of advancement of technology and society will be reflected on later.

5.2 Short History

The history of automation is a lesson in the bilateral conditions of technology and society. In our times wider and deeper attention is focused on the impact of automation on social relations. However, the progress of automation is arguably rather the result of social conditions.

It is generally known that automation was also present in antiquity; ingenious mechanisms operated impressive idols of deities: their gestures, winks, and opening the doors of their sanctuaries. Water-driven clocks applied the feedback principle for the correction of water-level effects. Sophisticated gearing, pumping, and elevating mechanisms helped the development of both human- and water-driven devices for construction, irrigation, traffic, and warfare. Water power was ubiquitous, wind power less so, and the invention of steam power more than 2000 years ago was not used for the obvious purpose of replacing human power and brute strength.

Historians contemplate the reasons why these given elements were not put together to create a more modern world based on the replacement of human and animal power. The hypothesis of the French Annales School of historians (named after their periodical, opened in 1929, and characterized by a new emphasis on geographical, economic, and social motifs of history, and less on events related to personal and empirical data) looks for social conditions: manpower acquired by slavery, especially following military operations, was economically the optimal energy resource. Even brute strength was, for a long time, more expensive, and for this reason was used for luxury and warfare more than for any other end, including agriculture. The application of the more efficient yoke for animal traction came into being only in the Middle Ages. Much later, arguments spoke for the better effect of human digging compared with an animal-driven plough [5.1–3].

Fire for heating and for other purposes was fed with wood, the universal material from which most objects were made, and that was used in industry for metal-producing furnaces. Coal was known but not generally used until the development of transport facilitated the joining of easily accessible coal mines with both industry centers and geographic points of high consumption. This high consumption and the accumulated wealth through commerce and population concentration were born in cities based on trade and manufacturing, creating a need for mass production of textiles. Hence, the first industrial application field of automation flourished with the invention of weaving machines and their punch-card control.

In the meantime, Middle Age and especially Renaissance mechanisms reached a level of sophistication surpassed, basically, only in the past century. This social and secondary technological environment created the overall conditions for the Industrial Revolution in power resources (Fig. 5.1) [5.3–8]. This timeline is composed from several sources of data available on the Internet and in textbooks on the history of science and technology. It deliberately contains many disparate items to show the historical density foci, connections with everyday life comfort, and basic mathematical and physical sciences. Issues related to automation per se are sparse, due to the high level of embeddedness of the subject in the general context of progress. Some data are inconsistent. This is due to uncertainties in historical documents; data on first publications, patents, and first applications; and first acceptable and practically feasible demonstrations. However, the figure intends to give an overall picture of the scene and these uncertainties do not confuse the lessons it provides.

The timeline reflects the course of Western civilization. The great achievements of other, especially Chinese, Indian, and Persian, civilizations had to be omitted, since these require another deep analysis in terms of their fundamental impact on the origins of Western science and the reasons for their interruption. Current automation and information technology is the direct offspring of the Western timeline, which may serve as an apology for these omissions.

The whole process, until present times, has been closely connected with the increasing costs of manpower, competence, and education. Human requirements, welfare, technology, automation, general human values, and social conditions form an unbroken circle of multiloop feedback.

5.3 Channels of Human Impact

Automation and its related control technology have emerged as a partly hidden, natural ingredient of everyday life. This is the reason why it is very difficult to separate the progress of the technology concerned from general trends and usage. In the household of an average family, several hundred built-in processors are active but remain unobserved by the user. They are not easily distinguishable and countable, due to the rapid spread of multicore chips, multiprocessor controls, and communication equipment. The relevance of all of these developments is really expressed by their vegetative-like operation, similar to the breathing function or blood circulation in the body.

An estimate of the effects in question can be given based on the automotive and aerospace industry. Recent medium-category cars contain about 50 electronic control units, high-class cars more than 70. Modern aircrafts are nearly fully automated; about 70% of all their functions are related to automatic operations and in several aerospace equipment even more. The limit is related to humans rather than to technology. Traffic control systems accounts for 30–35% of investment but provide a proportionally much larger return in terms of safety. These data change rapidly because proliferation decreases prices dramatically, as experienced in the cases of watches, mobile phones, and many other gadgets. On the one hand, the sophistication of the systems and by increasing the prices due to more comfort and luxury, on the other.

The silent intrusion of control and undetectable information technology into science and related transforming devices, systems, and methods of life can be observed in the past few decades in the great discoveries in biology and material science. The examples of three-dimensional (3-D) transparency technologies, ultrafast microanalysis, and nanotechnology observation into the nanometer, atomic world and picosecond temporal processes are partly listed on the timeline.

These achievements of the past half-century have changed all aspects of human-related sciences, e.g., psychology, linguistics, and social studies, but above all life expectancy, life values, and social conditions.

5.4 Change in Human Values

The most important, and all-determinant, effect of mechanization–automatization processes is the change of human roles [5.10]. This change influences social stratification and human qualities. The key problem is realizing freedom from hard, wearisome work, first as exhaustive physical effort and later as boring, dull activity. The first historical division of work created a class of clerical and administrative people in antiquity, a comparatively small and only relatively free group of people who were given spare energy for thinking.

The real revolutions in terms of mental freedom run parallel with the periods of the Industrial Revolution, and subsequently, the information–automation society. The latter is far from being complete, even in the most advanced parts of the world. This is the reason why no authentic predictions can be found regarding the possible consequences in terms of human history.

Slavery started to be banned by the time of the first Industrial Revolution, in England in 1772 [5.11, 12], in France in 1794, in the British Empire in 1834, and in the USA in 1865, serfdom in Russia in 1861, and worldwide abolition by consecutive resolutions in 1948, 1956, and 1965, mostly in the order of the development of mechanization in each country.

The same trend can be observed in prohibiting childhood work and ensuring equal rights for women. The minimum age for children to be allowed to work in various working conditions was first agreed on by a 1921 ILO (International Labour Organization) convention and was gradually refined until 1999, with increasingly restrictive, humanistic definitions. Childhood work under the age of 14 or 15 years and less rigorously under 16–18 years, was, practically, abolished in Europe, except for some regions in the Balkans.

In the USA, Massachusetts was the first state to regulate child labor; federal law came into place only in 1938 with the Federal Labor Standards Act, which has been modified many times since. The eradication of child labor slavery is a consequence of a radical change in human values and in the easy replacement of slave work by more efficient and reliable automation. The general need for higher education changed the status of children both in the family and society. This reason together with those mentioned above decreased the number of children dying in advanced countries; human life becomes much more precious after the defeat of infant mortality and the high costs of the required education period. The elevation of human values is a strong argument against all kinds of nostalgia back to the times before our automation–machinery world.

Also, legal regulations protecting women in work started in the 19th century with maternity- and health-

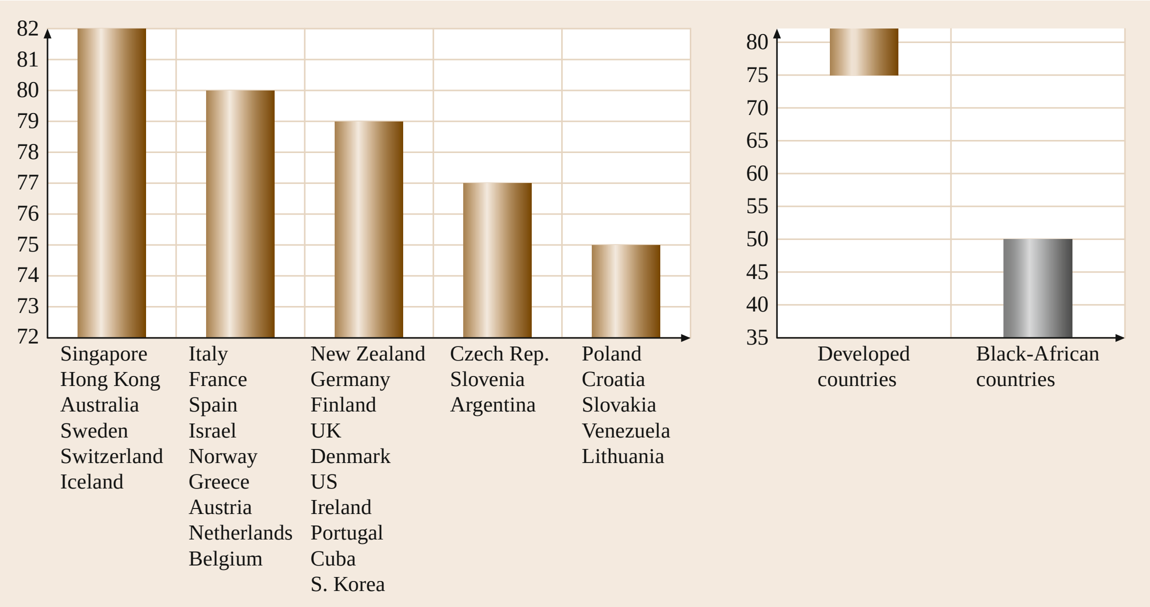

Fig. 5.2 Life expectancy and life conditions (after [5.14])

related laws and conventions. The progress of equal rights followed WWI and WWII, due to the need for female workforce during the wars and the advancement of technology replacing hard physical work. The correlation between gender equality and economic and society–cultural relations is well proven by the statistics of women in political power (Table 5.1) [5.9, 13].

The most important effect is a direct consequence of the statement that the human being is not a draught animal anymore, and this is represented in the role of physical power. Even in societies where women were sometimes forced to work harder than men, this situation was traditionally enforced by male physical superiority. Child care is much more a common bi-gender duty now, and all kinds of related burdens are supported by mass production and general services, based on automation. The doubled and active lifespan permits historically unparalleled multiplicity in life foci.

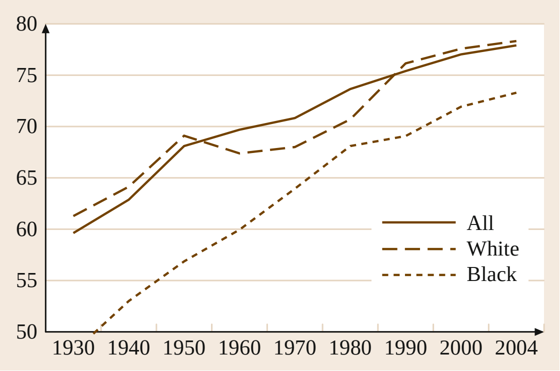

Fig. 5.3 Life expectancy at birth by race in the US (after [5.14])

Another proof of the higher status of human values is the issue of safety at work [5.11, 12]. The ILO and the US Department of Labor issue deep analyses of injuries related to work, temporal change, and social work-related details. The figures show great improvement in high-technology workplaces and better-educated workforces and the typical problems of low educated people, partly unemployed, partly employed under uncertain, dubious conditions. The drive for these values was the bilateral result of automatic equipment for production with automatic safety installations and stronger requirements for the human workforce.

All these and further measures followed the progress of technology and the consequent increase in the wealth of nations and regions. Life expectancy, clean water supplies, more free time, and opportunities for leisure, culture, and sport are clearly reflected in the figures of technology levels, automation, and wealth [5.15] (Figs. 5.2 and 5.3) [5.14, 16].

Life expectancy before the Industrial Revolution had been around 30 years for centuries. The social gap

Table 5.2 Relations of health and literacy (after [5.15])

Country	Approx. year	Life expectancy at birth (years)	Infant mortality to age 5 years per 1000 live births	Adult literacy (%)	Access to safe water (%)

	2001	69.2	44	86.8	76

in life expectancy within one country's lowest and highest deciles, according to recent data from Hungary, is 19 years. The marked joint effects of progress are presented in Table 5.2 [5.17].

5.5 Social Stratification, Increased Gaps

Each change was followed, on the one hand, by mass tragedies for individuals, those who were not able to adapt, and by new gaps and tensions in societies, and on the other hand, by great opportunities in terms of social welfare and cultural progress, with new qualities of human values related to greater solidarity and personal freedom.

In each dynamic period of history, social gaps increase both within and among nations. Table 5.3 and Fig. 5.4 indicate this trend – in the figure markedly both with and without China – representing a promising future for all mankind, especially for long lagging developing countries, not only for a nation with a population of about one-sixth of the world [5.18]. This picture demonstrates the role of the Industrial Revolution and technological innovation in different parts of the world and also the very reasons why the only recipe for lagging regions is accelerated adaptation to the economic–social characteristics of successful historical choices.

The essential change is due to the two Industrial Revolutions, in relation to agriculture, industry, and services, and consequently to the change in professional and social distributions [5.16, 19]. The dramatic picture of the former is best described in the novels of Dickens, Balzac, and Stendhal, the transition to the second in Steinbeck and others. Recent social uncertainty dominates American literature of the past two decades.

This great change can be felt by the decease of distance. The troops of Napoleon moved at about the same speed as those of Julius Caesar [5.20], but mainland communication was accelerated in the USA between 1800 and 1850 by a factor of eight, and the usual 2 week passage time between the USA and Europe of the mid 19th century has decreased now by 50-fold. Similar figures can be quoted for numbers of traveling people and for prices related to automated mass production, especially for those items of high-technology consumer goods which are produced in their entirety by these technologies. On the other hand, regarding the prices of all items and services related to the human workforce, the opposite is true. Compensation in professions demanding higher education is through relative increase of salaries.

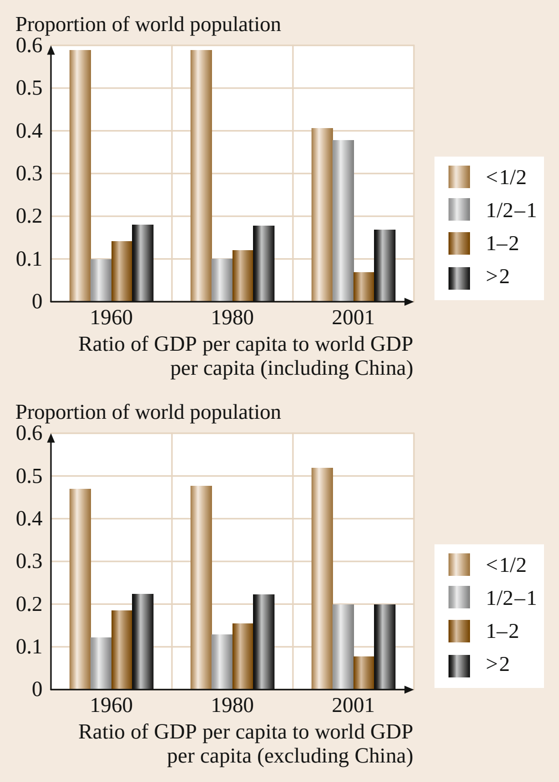

Fig. 5.4 World income inequality changes in relations of population and per capita income in proportions of the world distribution (after [5.21] and UN/DESA)

Due to these changed relations in distance and communication, cooperative and administrative relations have undergone a general transformation in the same sense, with more emphasis on the individual, more freedom from earlier limitations, and therefore, more personal contacts, less according to need and mandatory organization rather than current interests. The most important phenomena are the emerging multinational production and service organizations. The increasing relevance of supranational and international political, scientific, and service organizations, international standards, guidelines, and fashions as driving forces of consumption attitudes, is a direct consequence of the changing technological background.

Figure 5.5 [5.22–24] shows current wages versus social strata and educational requirement distribution of the USA. Under the striking figures of large company CEOs (chief executive officers) and successful capitalists, who amount to about 1–1.5% of the population, the distribution of income correlates rather well with required education level, related responsibility, and adaptation to the needs of a continuously technologically advancing society. The US statistics are based on tax-refund data and reflect a rather growing disparity in incomes. Other countries with advanced economies show less unequal societies but the trend in terms of social gap for the time being seems to be similar. The disparity in jobs requiring higher education reflects a disparity in social opportunity on the one hand, but also probably a realistic picture of requirements on the other.

Figure 5.6 shows a more detailed and informative picture of the present American middle-class cross section.

A rough estimate of social breakdown before the automation–information revolution is composed of several different sources, as shown in Table 5.4 [5.25].

These dynamics are driven by finance and management, and this is the realistic reason for overvaluations in these professions. The entrepreneur now plays the role of the condottiere, pirate captain, discoverer, and adventurer of the Renaissance and later. These roles, in a longer retrospective, appear to be necessary in periods of great change and expansion, and will be consolidated in the new, emerging social order. The worse phenomena of these turbulent periods are the

Population in %	Income in 1000 US$/y	Class distribution		Education
1–2	200 and more	Capitalists, CEO, politicians, celebritics, etc.		?
15	200–60	Upper middle class	Professors managers	Graduate
30	60–30	Middle class	Professional sales, and support	Bachelor deg. significant skill
30	30–10	Lower middle class	Clerical, service, blue collar	Some college
22–23	10 and less	Poor underclass	Part time, unemployed	High school or less

US	22	32	18	9	7	2

political adventurers, the dictators. The consequences of these new imbalances are important warnings in the directions of increased value of human and social relations.

The most important features of the illustrated changes are due to the transition from an agriculture-based society with remnants of feudalist burdens to an industrial one with a bourgeois–worker class, and now to an information society with a significantly different and mobile strata structure. The structural change in our age is clearly illustrated in Fig. 5.7 and in the investment policy of a typical country rapidly joining the welfare world, North Korea, in Fig. 5.8 [5.18].

Most organizations are applying less hierarchy. This is one effect of the general trend towards overall control modernization and local adaptation as leading principles of optimal control in complex systems. The concentration of overall control is a result of advanced, real-time information and measurement technology and related control theories, harmonizing with the local traditions and social relations. The principles developed in the control of industrial processes could find general validity in all kinds of complex systems, societies included.

The change of social strata and technology strongly affects organizational structures. The most characteris-

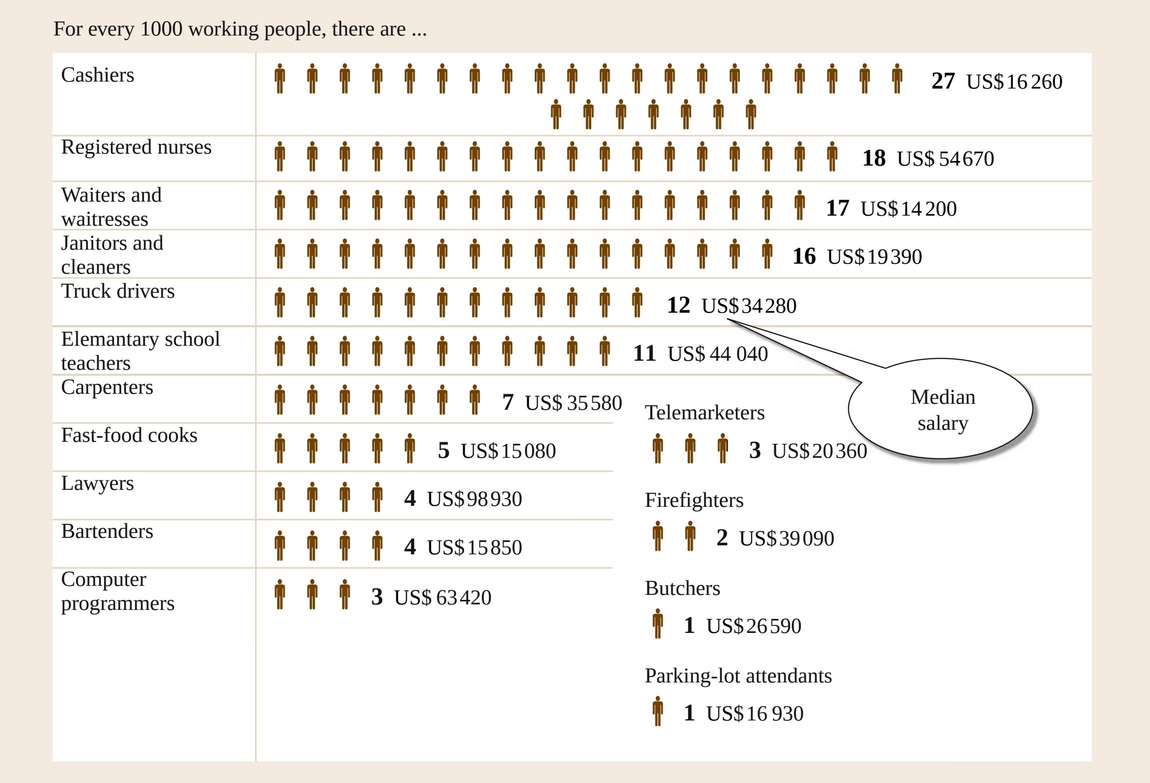

Fig. 5.6 A characteristic picture of the modern society (after [5.22])

tic phenomenon is the individualization and localization of previous social entities on the one hand, and centralization and globalization on the other. Globalization has an usual meaning related to the entire globe, a general trend in very aspect of unlimited expansion, extension and proliferation in every other, more general dimensions.

The great change works in private relations as well. The great multigenerational family home model is over. The rapid change of lifestyles, entertainment technology, and semi-automated services, higher income standards, and longer and healthier lives provoke and allow the changing habits of family homes.

The development of home service robots will soon significantly enhance the individual life of handicapped persons and old-age care. This change may also place greater emphasis on human relations, with more freedom from burdensome and humiliating duties.

5.6 Production, Economy Structures, and Adaptation

Two important remarks should be made at this point. Firstly, the main effect of automation and information technology is not in the direct realization of these special goods but in a more relevant general elevation of any products and services in terms of improved qualities and advanced production processes. The computer and information services exports of India and Israel account for about 4% of their gross domestic product (GDP). These very different countries have the highest figures of direct exports in these items [5.18].

The other remark concerns the effect on employment. Long-range statistics prove that this is more influenced by the general trends of the economy and by the adaptation abilities of societies. Old professions are replaced by new working opportunities, as demonstrated in Figs. 5.9 and 5.10 [5.22, 27, 28].

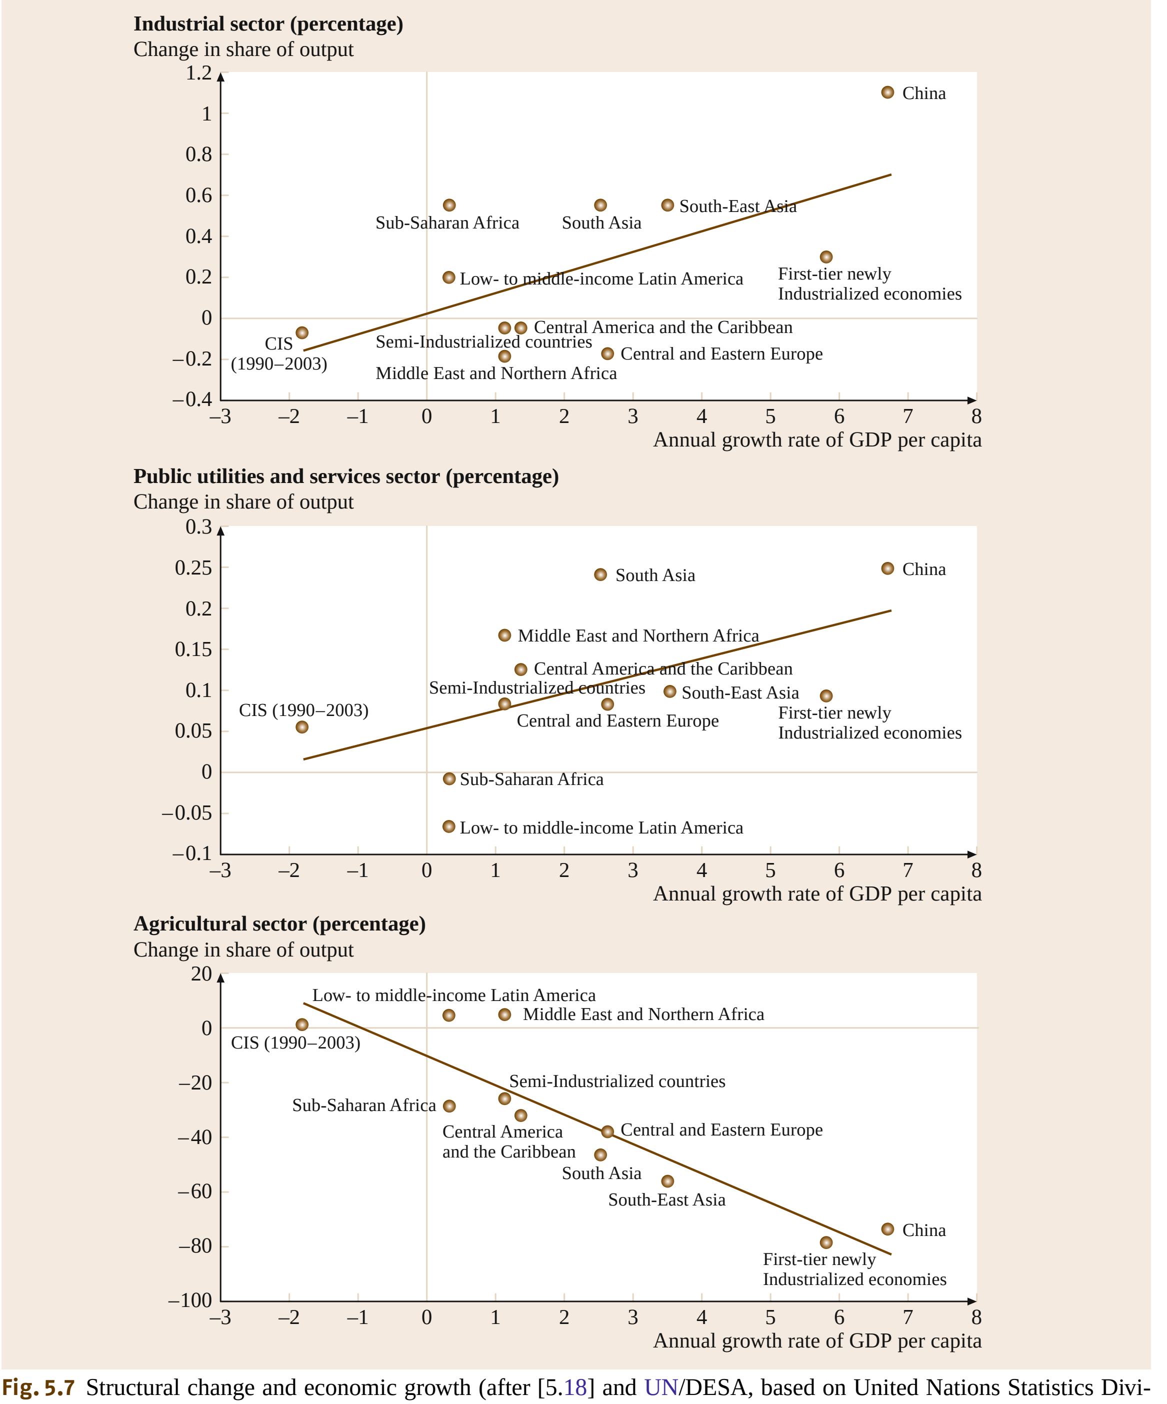

Fig. 5.7 Structural change and economic growth (after [5.18] and UN/DESA, based on United Nations Statistics Division, National Accounts Main Aggregates database. Structural change and economic growth)

–37%	Mail clerks	Computer-software engineers	48%

Fig. 5.9 Growing and shrinking job sectors (after [5.22])

One aspect of changing working conditions is the evolution of teleworking and outsourcing, especially in digitally transferable services. Figure 5.11 shows the results of a statistical project closed in 2003 [5.29].

Due to the automation of production and servicing techniques, investment costs have been completely transformed from production to research, development, design, experimentation, marketing, and maintenance support activities. Also production sites have started to become mobile, due to the fast turnaround of production technologies. The main fixed property is knowhow and related talent [5.30, 31]. See also Chap. 6 on the economic costs of automation.

The open question regarding this irresistible process is the adaptation potential of mankind, which is closely related to the directions of adaptation. How can the majority of the population elevate its intellectual level to the new requirements from those of earlier animal and quasi-animal work? What will be the directions of adaptation to the new freedoms in terms of time, consumption, and choice of use, and misuse of possibilities given by the proliferation of science and technology?

These questions generate further questions: Should the process of adaptation, problem solving, be controlled or not? And, if so, by what means or organizations? And, not least, in what directions? What should be the control values? And who should decide about those, and how? Although questions like these have arisen in all historical societies, in the future, giving the

immensely greater freedom in terms of time and opportunities, the answers to these questions will be decisive for human existence.

Societies may be ranked nowadays by national product per capita, by levels of digital literacy, by estimates of corruption, by e-Readiness, and several other indicators. Not surprisingly, these show a rather strong coherence. Table 5.5 provide a small comparison, based on several credible estimates [5.29, 30, 33].

A recent compound comparison by the Economist Intelligence Unit (EIU) (Table 5.6) reflects the EIU e-Readiness rankings for 2007, ranking 69 countries in terms of six criteria. In order of importance, these are: consumer and business adoption; connectivity and technology infrastructure; business environment; social and cultural environment; government policy and vision; and legal and policy environment.

[a] New to the annual rankings in 2007 (after EIU)

5.7 Education

Radical change of education is enforced by the dramatic changes of requirements. The main directions are as follows:

- Population and generations to be educated
- Knowledge and skills to be learnt
- Methods and philosophy of education.

General education of the entire population was introduced with the Industrial Revolution and the rise of nation states, i. e., from the 18th to the end of the 19th centuries, starting with royal decrees and laws expressing a will and trend and concluding in enforced, pedagogically standardized, secular systems [5.35].

The related social structures and workplaces required a basic knowledge of reading and writing, first of names, simple sentences for professional and civil communication, and elements of arithmetic. The present requirement is much higher, defined (PISA, Program for International Student Assessment of the OECD) by understanding regular texts from the news, regulations, working and user instructions, elements of measurement, dimensions, and statistics.

Progress in education can be followed also as a consequence of technology sophistication, starting with four to six mandatory years of classes and continued by mandatory education from 6 to 18 years. The same is reflected in the figures of higher education beyond the mandatory education period [5.16, 30, 34].

For each 100 adults of tertiary-education age, 69 are enrolled in tertiary education programs in North America and Europe, compared with only 5 in sub-Saharan Africa and 10 in South and West Asia. Six countries host 67% of the world's foreign or mobile students: with 23% studying in the USA, followed by the UK (12%), Germany (11%), France (10%), Australia (7%), and Japan (5%).

An essential novelty lies in the rapid change of required knowledge content, due to the lifecycles of technology, see timeline of Fig. 5.1. The landmarks of technology hint at basic differences in the chemistry, physics, and mathematics of the components and, based on the relevant new necessities in terms of basic and higher-level knowledge, are reflected in application demands. The same demand is mirrored in work-related training provided by employers.

The necessary knowledge of all citizens is also defined by the systems of democracy, and modern democracy is tied to market economy systems. This defines an elementary understanding of the constitutional–legal system, and the basic principles and practice of legal institutions. The concept of constitutional awareness is not bound to the existence of a canonized national constitution; it can be a consciousness, accord on fundamental social principles.

As stated, general education is a double requirement for historical development: professional knowledge for producers and users of technology, and services and civil culture as necessary conditions for democracy. These two should be unified to some extent in each person and generation. This provides another hint at the change from education of children and adolescents towards a well-designed, pedagogically renewed, socially regulated lifelong education schedule with mandatory basic requirements. There should also be mandatory requirements for each profession with greater responsibility and a wide spectrum of free opportunities, including in terms of retirement age (Table 5.7).

In advanced democracies this change strongly affects the principle of equal opportunities, and creates a probably unsolvable contradiction between increasing knowledge requirements, the available amount of different kinds of knowledge, maintenance and strengthening of the cultural–social coherence of societies, and the unavoidable leverage of education. Educating the social–cultural–professional elite and the masses of a democratic society, with given backgrounds in terms of talent, family, and social grouping, is the main concern of all responsible government policies. The US Ivy League universities, British Oxbridge, and the French Grand Écoles represent elite schools, mostly for a limited circle of young people coming from more highly educated, upper society layers.

Table 5.7 Lifelong learning. Percentage of the adult population aged 25–64 years participating in education and training (mostly estimated or reported values), after [5.34]

	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004	2005
EU (25 countries)	–	–	–	–	–	7.5	7.5	7.6	9.0	9.9	10.2
EU (15 countries)	–	–	–	–	8.2	8.0	8.0	8.1	9.8	10.7	11.2
Euro area	4.5	5.1	5.1	–	5.6	5.4	5.2	5.3	6.5	7.3	8.1

The structures of education are also defined by the capabilities of private and public institutions: their regulation according to mandatory knowledge, subsidies depending on certain conditions, the ban on discrimination based on race or religion, and freedom of access for talented but poor people.

The structural variants of education depend on necessary and lengthening periods of professional education, and on the distribution of professional education between school and workplace. Open problems are the selection principles of educational quotas (if any), and the question of whether these should depend on government policy and/or be the responsibility of the individual, the family or educational institutions.

In the Modern Age, education and pedagogy have advanced from being a kind of affective, classical psychology-like quality to a science in the strong sense, not losing but strengthening the related human virtues. This new, science-type progression is strongly related to brain research, extended and advanced statistics and worldwide professional comparisons of different experiments. Brain research together with psychology provides a more reliable picture of development during different age periods. More is known on how conceptual, analogous, and logical thinking, memory, and processing of knowledge operate; what the coherences of special and general abilities are; what is genetically determined and definable; and what the possibilities of special training are. The problem is greater if there are deterministic features related to gender or other inherited conditions. Though these problems are particularly delicate issues, research is not excluded, nor should it be, although the results need to be scrutinized under very severe conditions of scientific validity.

The essential issue is the question of the necessary knowledge for citizens of today and tomorrow. A radical change has occurred in the valuation of traditional cultural values: memorizing texts and poems of acknowledged key authors from the past; the proportion of science- versus human-related subjects; and the role of physical culture and sport in education. The means of social discipline change within the class as a preparation for ethical and collegial cooperation, just like the abiding laws of the community.

The use of modern and developing instruments of education are overall useful innovations but no solution for the basic problems of individual and societal development. These new educational instruments include moving pictures, multimedia, all kinds of visual and auditive aids, animation, 3-D representation, question-answering automatic methods of teaching, freedom of learning schedules, mass use of interactive whiteboards, personal computers as a requisite for each student and school desk, and Internet-based support of remote learning. See Chap. 44 on *Education and Qualification* and Chap. 85 on *Automation in Education/Learning Systems* for additional information.

A special requirement is an international standard for automatic control, system science, and information technology. The International Federation of Automatic Control (IFAC), through its special interest committee and regular symposia, took the first steps in this direction from its start, 50 years ago [5.36]. Basic requirements could be set regarding different professional levels in studies of mathematics, algorithmics, control dynamics, networks, fundamentals of computing architecture and software, components (especially semiconductors), physics, telecommunication transmission and code theory, main directions of applications in system design, decision support and mechanical and sensory elements of complex automation, their fusion, and consideration of social impact.

All these disciplines change in their context and relevance during the lifetime of a professional generation, surviving at least three generations of their subject. This means greater emphasis on disciplinary basics and on the particular skill of adopting these for practical innovative applications, and furthermore on the disciplinary and quality ethics of work.

A major lesson of the current decade is not only the hidden spread of these techniques in every product, production process, and system but also the same spread of specialists in all kinds of professional activities.

All these phenomena and experiments display the double face of education in terms of an automated, communication-linked society. One of the surprising facts from the past few decades is the unexpected increase in higher-education enrolment for humanities, psychology, sociology, and similar curricula, and the decline in engineering- and science-related subjects. This orientation is somehow balanced by the burst of management education, though the latter has a trend to deepen knowledge in human aspects outweighing the previous, overwhelming organizational, structural knowledge.

5.8 Cultural Aspects

The above contradictory, but socially relatively controlled, trend is a proof of the initial thesis: in the period of increasing automation, the human role is emerging more than ever before. This has a relevant linguistic meaning, too. Not only is knowledge of foreign languages (especially that of the modern lingua franca, English) gaining in importance, but so is the need for linguistic and metalinguistic instruments as well, i. e., a syncretistic approach to the development of sensitive communication facilities [5.37, 38].

The resulted plethora of these commodities is represented in the variations of goods, their usage, and in the spectra of quality. The abundance of supply is in accordance not only with material goods but also the mental market.

The end of the book was proclaimed about a decade ago. In the meantime the publication of books has mostly grown by a modest, few percentage points each year in most countries, in spite of the immense reading material available on the Internet. Recent global statistics indicate a growth of about 3–4% per year in the past period in juvenile books, the most sensitive category for future generations.

The rapid change of electronic entertainment media from cassettes to CD-DVD and MP3 semiconductor memories and the uncertainties around copyright problems made the market uncertain and confused. In the past 10 years the prices of video-cassettes have fallen by about 50%; the same happened to DVDs in the past 2 years.

All these issues initiate cultural programs for each age, each technological and cultural environment, and each kind of individual and social need, both maintaining some continuity and inducing continuous change.

On the other hand, the market has absorbed the share in the entertainment business with a rapidly changing focus on fashion-driven music, forgotten classics, professional tutoring, and great performances. The lesson is a naturally increasing demand together with more free time, greater income, and a rapidly changing world and human orientation. Adaptation is serviced by a great variety of different possibilities.

High and durable cultural quality is valued mostly later in time. The ratio of transitory low-brow cultural goods to high-brow permanent values has always been higher by orders of magnitude. Automatic, high-quality reproduction technology, unseen and unimaginable purchasing power, combined with cultural democracy is a product of automated, information-driven engineering development. The human response is a further question, and this is one reason why a nontechnical chapter has a place in this technology handbook.

5.9 Legal Aspects, Ethics, Standards, and Patents

5.9.1 Privacy

The close relations between continuity and change are most reflected in the legal environment: the embedding of new phenomena and legal requirements into the traditional framework of the law. This continuity is important because of the natural inertia of consolidated social systems and human attitudes. Due to this effect, both Western legal systems (Anglo-Saxon Common Law as a case-based system and continental rule-based legal practice) still have their common roots in Roman Law. In the progress of other civilizations towards an industrial and postindustrial society, these principles have been gradually accepted. The global process in question is now enforced, not by power, but by the same rationality of the present technology-created society [5.4, 39].

The most important legal issue is the combined task of warranting privacy and security. The privacy issue, despite having some antecedents in the Magna Carta and other documents of the Middle Ages, is a modern idea. It was originated for an equal-rights society and the concept of all kinds of private information properties of people. The modern view started with the paper entitled *The Right to Privacy* by *Warren* and *Brandeis*, at the advent of the 20th century [5.40]. The paper also defines the immaterial nature of the specific value related to privacy and the legal status of the material instrument of (re)production and of immaterial private property.

Three components of the subject are remarkable and all are related to the automation/communication issue: mass media, starting with high-speed wide-circulation printing, photography and its reproduction technologies, and a society based on the equal-rights principle.

In present times the motivations are in some sense contradictory: an absolute defense against any kind of intrusion into the privacy of the individual by alien power. The anxiety was generated by the real experience of the 20th century dictatorships, though executive terror and mass murder raged just before modern information instruments. On the other hand, user-friendly, efficient administration and security of the individual and of the society require well-organized data management and supervision. The global menace of terrorism, especially after the terrorist attacks of 11 September, 2001, has drawn attention to the development and introduction of all kinds of observational techniques.

The harmonization of these contradictory demands is given by the generally adopted principles of human rights, now with technology-supported principles:

- All kind of personal data, regarding race, religion, conscience, health, property, and private life are available only to the person concerned, accessible only by the individual or by legal procedure.
- All information regarding the interests of the citizen should be open; exemption can be made only by constitutional or equivalent, specially defined cases.
- The citizen should be informed about all kinds of access to his/her data with unalterable time and authorization stamps.

Table 5.8 Regulations concerning copyright and patent

Regulations: Article I, Section 8, Clause 8 of the US Constitution, also known as the Copyright Clause, gives Congress the power to enact statutes *To promote the Progress of Science and useful Arts, by securing for limited Times to Authors and Inventors the exclusive Right to their respective Writings and Discoveries.*

Congress first exercised this power with the enactment of the Copyright Act of 1790, and has changed and updated copyright statutes several times since. The Copyright Act of 1976, though it has been modified since its enactment, is currently the basis of copyright law in the USA.

The **Berne Convention for the Protection of Literary and Artistic Works**, usually known as the **Berne Convention**, is an international agreement about copyright, which was first adopted in Berne, Switzerland in 1886.

Paris Convention for the Protection of Industrial Property, signed in Paris, France, on March 20, 1883.

The **Agreement on Trade Related Aspects of Intellectual Property Rights** (**TRIPS**) is a treaty administered by the World Trade Organization (WTO) which sets down minimum standards for many forms of intellectual property (IP) regulation. It was negotiated at the end of the Uruguay Round of the General Agreement on Tariffs and Trade (GATT) treaty in 1994.

Specifically, TRIPS contains requirements that nations' laws must meet for: copyright rights, including the rights of performers, producers of sound recordings, and broadcasting organizations; geographical indications, including appellations of origin; industrial designs; integrated-circuit layout designs; patents; monopolies for the developers of new plant varieties; trademarks; trade address; and undisclosed or confidential information. TRIPS also specified enforcement procedures, remedies, and dispute-resolution procedures.

Patents in the modern sense originated in Italy in 1474. At that time the Republic of Venice issued a decree by which new and inventive devices, once they had been put into practice, had to be communicated to the Republic in order to obtain the right to prevent others from using them. England followed with the Statute of Monopolies in 1623 under King James I, which declared that patents could only be granted for "projects of new invention." During the reign of Queen Anne (1702–1714), the lawyers of the English Court developed the requirement that a written description of the invention must be submitted. These developments, which were in place during the colonial period, formed the basis for modern English and US patent law.

In the USA, during the colonial period and Articles of Confederation years (1778–1789), several states adopted patent systems of their own. The first congress adopted a Patent Act, in 1790, and the first patent was issued under this Act on July 31, 1790.

European patent law covers a wide range of legislations including national patent laws, the Strasbourg Convention of 1963, the European Patent Convention of 1973, and a number of European Union directives and regulations.

The perfection of the above principles is warranted by fast, broadband data links, and cryptographic and pattern recognition (identification) technology. The introduction of these tools and materialization of these principles strengthen the realization of the general, basic statement about the elevation effect of human consciousness. The indirect representation of the Self, and its rights and properties is a continuous, frequently used mirror of all this. And, through the same, the metaphoric high level of the mirror is a self-conscious intelligence test for beings. The system contributes to the legal consciousness of the advanced democracy.

The semi-automatic, data-driven system of administration separates the actions that can, and should be, executed in an automatic procedure by the control and evaluation of data, and follows the privacy and security principles. A well-operating system can save months of civilian inquiries, and hours and days of traveling, which constitutes a remarkable percentage of the administrative cost. A key aspect is the increased concentration on issues that require human judgment. In real human problems, human judgment is the final principle.

Citizens' indirect relationship with the authorities using automatic and telecommunication means evokes the necessity for natural language to be understood by machines, in written and verbal forms, and the creation of user-friendly, natural impression dialogues. The need for bidirectional translation between the language of law and natural communication, and translation into other languages, is emerging in wide, democratic usage. These research efforts are quickly progressing in several communities.

5.9.2 Free Access, Licence, Patent, Copyright, Royalty, and Piracy

Free access to information has different meanings. First of all, it is an achievement and new value of democracy: the right to access directly all information regarding an individual citizen's interests. Second, it entails a new relation to property that is immaterial, i. e., not physically decreased by alienation. Easy access changes the view regarding the right of the owner, the author. Though the classic legal concepts of patent and copyright are still valid and applied, the nonexistence of borders and the differences in local regulations and practice have opened up new discussions on the subject. Several companies and interest groups have been arguing for more liberal regulations. These arguments comprise the advertising interests of even more dynamic companies, the costs and further difficulties of safeguarding ownership rights, and the support of developing countries.

Table 5.8 presents an overview of the progress of these regulations.

5.10 Different Media and Applications of Information Automation

A contradictory trend in information technology is the development of individual user services, with and without centralized control and control of the individual user. The family of these services is characterized by decentralized input of information, centralized and decentralized storage and management, as well as unconventional automation combined with similarly strange freedom of access. Typical services are blog-type entertainment, individual announcements, publications, chat groups, other collaborative and companion search, private video communication, and advertisements. These all need well-organized data management, automatic, and desire-guided browsing search support and various identification and filtering services. All these are, in some sense, new avenues of information service automation and society organization in close interaction [5.26, 41, 42].

Two other services somehow belonging to this group are the information and economic power of very large search organizations, e.g., Google and Yahoo, and some minor, global, and national initiatives. Their automatic internal control has different search and grading mechanisms, fundamentally based on user statistics and subject classifications, but also on statistical categorizations and other pattern-recognition and machine-supported text-understanding instruments.

Wikipedia, YouTube, and similar initiatives have greater or lesser control: principally everybody can contribute to a vast and specific edifice of knowledge, controlled by the voluntary participants of the voluntary-access system. This social control appears to be, in some cases, competing in quality with traditional, professional encyclopedic-knowledge institutions. The contradictory trends survive further: social knowledge bases have started to establish some proved, controlled quality groups for, and of, professionals.

The entertainment/advertisement industry covers all these initiatives by its unprecedented financial interest and power, and has emerged as the leading economic power after the period of automotive and traffic-related industry that followed the iron and steel, textile, and agricultural supremacy. Views on this development are extremely different; in a future period can be judged if these resulted in a better-educated, more able society, or deteriorated essential cultural values.

Behind all these emerging and ruling trends operates the joint technology of automatic control, both in the form of instrumentation and in effects obeying the principles of feedback, multivariate, stochastic and nonlinear, and continuous and discrete system control. These principles are increasingly applied in modeling the social effects of these human–machine interactions, trying not only to understand but also to navigate the ocean of this new–old supernature.

5.11 Social Philosophy and Globalization

Automation is a global process, rapidly progressing in the most remote and least advanced corners of the world. Mass production and World Wide Web services enforce this, and no society can withstand this global trend; recent modernization revolution and its success in China and several other countries provide indisputable evidence. Change and the rapid speed in advanced societies and their most mobile layers create considerable tension among and within countries. Nevertheless, clever policies, if they are implemented, and the social movements evoked by this tension, result in a general progress in living qualities, best expressed by extending lifespans, decreasing famine regions, and the increasing responsibility displayed by those who are more influential. However, this overall historical process cannot protect against the sometimes long transitory sufferings, social clashes, unemployment, and other human social disasters [5.41, 43, 44].

Transitory but catastrophic phenomena are the consequence of minority feelings expressed in wide, national, religious, ideology-related movements with aggressive nature. The state of hopeless poverty is less irascible than the period of intolerance. The only general recommendation is given by *Neumann* [5.45]:

> *The only solid fact is that these difficulties are due to an evolution that, while useful and constructive, is also dangerous. Can we produce the required adjustments with the necessary speed? The most hopeful answer is that the human species has been subjected to similar tests before and seems to have a congenital ability to come through, after varying amounts of trouble. To ask in advance for a complete recipe would be unreasonable. We can specify only the human qualities required: patience, flexibility, and intelligence.*

5.12 Further Reading

Journals and websites listed as references provide continuously further updated information. Recommended periodicals as basic theoretical and data sources are:

6. Economic Aspects of Automation

Piercarlo Ravazzi, Agostino Villa

The increasing diffusion of automation in all sectors of the industrial world gives rise to a deep modification of labor organization and requires a new approach to evaluate industrial systems efficiency, effectiveness, and economic convenience. Until now, the evaluation tools and methods at disposal of industrial managers are rare and even complex. Easy-to-use criteria, possibly based on robust but simple models and concepts, appear to be necessary. This chapter gives an overview of concepts, based on the economic theory but revised in the light of industrial practice, which can be applied for evaluating the impact and effects of automation diffusion in enterprises.

Process automation spread through the industrial world in both production and services during the 20th century, and more intensively in recent decades. The conditions that assured its wide diffusion were first the development of electronics, then informatics, and today information and communication technologies (ICT), as demonstrated in Fig. 6.1a–c. Since the late 1970s, periods of large investment in automation, followed by periods of reflection with critical revision of previous implementations and their impact on revenue, have taken place. This periodic attraction and subsequent revision of automation applications is still occurring, mainly in small to mid-sized enterprises (SME) as well as in several large firms.

Paradigmatic could be the case of Fiat, which reached the highest level of automation in their assembly lines late in the 1980s, whilst during the subsequent decade it suffered a deep crisis in which investments in automation seemed to be unprofitable. However, the next period – the present one – is characterized by significant growth for which the high level of automation already at its disposal has been a driver.

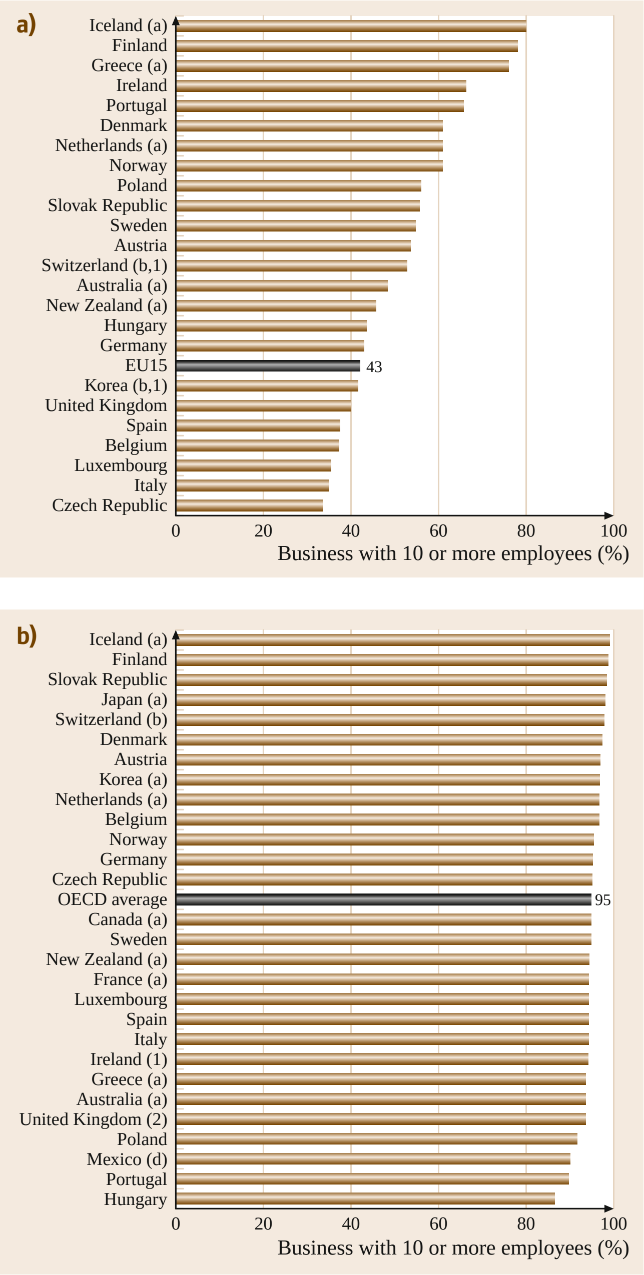

Fig. 6.1 **(a)** Use of information and communication technologies by businesses for returning filled forms to public authorities. The use of the Internet emphasizes the important role of transaction automation and the implementation of automatic control systems and services (source: OECD, ICT database, and Eurostat, community survey on ICT usage in households and by individuals, January 2008). **(b)** Business use of the Internet, 2007, as a percentage of businesses with ten or more employees. **(c)** ▶ Internet selling and purchasing by industry (2007). Percentage of businesses with ten or more employees in each industry group (source: OECD, ICT database, and Eurostat, community survey on ICT usage in enterprises, September 2008)

Automation implementation and perception of its convenience in the electronics sector is different from in the automotive sector. The electronics sector, however, is rather specific since it was born together with – and as the instrument of – industrial automation. All other industrial sectors present a typical attitude of *strong but cautious interest* in automation. The principal motivation for this caution is the difficulty that managers face when evaluating the economic impact of automation on their own industrial organization. This difficulty results from the lack of simple methods to estimate economic impact and obtain an easily usable measure of automation revenue.

The aim of this chapter is to present an evaluation approach based on a compact and simple economic model to be used as a tool dedicated to SME managers, to analyze main effects of automation on production, labor, and costs.

The chapter is organized as follows. First, some basic concepts on which the evaluation of the automation effects are based are presented in Sect. 6.2. Then, a simple economic model, specifically developed for easy interpretation of the impact of automation on the enterprise, is discussed and its use for the analysis of some industrial situations is illustrated in Sect. 6.3. The most important effects of automation within the enterprise are considered in Sect. 6.4, in terms of its impact on production, incentivization and control of workers, and costs flexibility. In the final part of the chapter, mid-term effects of automation in the socioeconomic context are also analyzed. Considerations of such effects in some sectors of the Italian industrial system are discussed in Sect. 6.6, which can be considered as a typical example of the impact of automation on a developed industrial system, easily generalizable to other countries.

6.1 Basic Concepts in Evaluating Automation Effects

The desire of any SME manager is to be able to evaluate how to balance the cost of implementing some automated devices (either machining units or handling and moving mechanisms, or automated devices to improve production organization) and the related increase of revenue.

To propose a method for such an economic evaluation, it is first necessary to declare a simple catalogue of potential automation typologies, then to supply evidence of links between these typologies and the main variables of a SME which could be affected by process and labor modifications due to the applied automation. All variables to be analyzed and evaluated must be the usual ones presented in a standard balance sheet.

Analysis of a large number of SME clusters in ten European countries, developed during the collaborative demand and supply networks (CODESNET) project [6.1] funded by the European Commission, shows that the most important typologies of automation implementations in relevant industrial sectors can be classified as follows:

1. *Robotizing*, i. e., automation of manufacturing operations
2. *Flexibilitization*, i. e., *flexibility through automation*, by automating setup and supply
3. *Monitorizing*, i. e., *monitoring automation* through automating measures and operations control.

These three types of industrial automation can be related to effects on the process itself as well as on personnel. *Robotizing* allows the application of greater operation speed and calls for a reduced amount of direct work hours. *Flexibilitization* is crucial in mass customization, to reduce the lead time in the face of customer demands, by increasing the product mix, and by facilitating producer–client interaction. *Monitorizing* can indeed assure product quality for a wide range of final items through diffused control of work operations. Both automated flexibility and automated monitoring, however, require higher skills of personnel (Table 6.1).

However, a representation of the links between automation and either process attributes or personnel working time and skill, as outlined in Table 6.1, does not correspond to a method for evaluating the automation-induced profit in a SME, or in a larger enterprise. It only shows effects, whereas their impact on the SME balance sheet is what the manager wants to know.

To obtain this evaluation it is necessary:

1. To have clear that an investment in automation is generally relevant for any enterprise, and often critical for a SME, and typically can have an impact on mid/long-term revenue.
2. To realize that the success of an investment in terms of automation depends both on the amount of investment and on the reorganization of the workforce in the enterprise, which is a *microeconomic effect* (meaning to be estimated *within the enterprise*).
3. To understand that the impact of a significant investment in automation, made in an industrial sector, will surely have long-term and wide-ranging effects on employment at the *macroeconomic level* (i. e., at the level of the socioeconomic system or country).

All these effects must be interpreted by a single evaluation model which should be used:

- For a *microeconomic evaluation*, made by the enterprise manager, to understand how the two

Table 6.1 Links between automation and process/personnel in the firm

Automation typology induces ...	**... effects on the process ...**	**... and effects on personnel**
(a) Robotizing	Operation speed	Work reduction
(b) Flexibilitization	Response time to demand	Higher skills
(c) Monitorizing	Process accuracy and product quality	
Then automation calls for ...		**... and search for ...**
Investments		New labor positions
Investments and new labour positions should give rise to an expected target of production, conditioned on investments in high technologies and highly skill workforce utilization.		

above-mentioned *principal factors*, namely investment and workforce utilization, could affect the expected target of production, in case of a given automation implementation
- For a *macroeconomic evaluation*, to be done at the level of the industrial sector, to understand how relevant modification of personnel utilization, caused by the spread of automation, could be reflected in the socioeconomic system.

These are the two viewpoints according to which the automation economic impact will be analyzed upon the introduction of the above-mentioned interpretation model in Sect. 6.2.

6.2 The Evaluation Model

6.2.1 Introductory Elements of Production Economy

Preliminary, some definitions and notations from economics theory are appropriate (see the basic references [6.2–6]):

- A *production technique* is a combination of factors acquired by the market and applied in a product/service unit.
- *Production factors* will be simply limited to the *capital* K (i. e., industrial installation, manufacturing units, etc.), to *labor* L, and to *intermediate goods* X (i. e., goods and services acquired externally to contribute to production).
- A *production function* is given by the relation $Q = Q(K, L, X)$, which describes the output Q, *production of goods/services*, depending on the applied inputs.
- *Technological progress*, of which automation is the most relevant expression, must be incorporated into the capital K in terms of process and labor innovations through investments.
- *Technical efficiency* implies that a rational manager, when deciding on new investments, should make a choice among the available innovations that allow him to obtain the same increase of production without waste of inputs (e.g., if an innovation calls for K_0 units of capital and L_0 units of labor, and another one requires $L_1 > L_0$ units of labor, for the same capital and production, the former is to be preferred).
- *Economic efficiency* imposes that, if the combination of factors were different (e.g., for the same production level, the latter innovation has to use $K_1 < K_0$ capital units), then the rational manager's choice depends on the cost to be paid to implement the innovation, thus accounting also for production costs, not only quantity.

Besides these statements it has to be remarked that, according to economic theory, production techniques can be classified as either *fixed-coefficients technologies* or *flexible-coefficients technologies*. The former are characterized by nonreplaceable and strictly complementary factors, assuming that a given quantity of production can only be obtained by combining production factors at fixed rates, with the minimum quantities required by technical efficiency. The latter are characterized by the possibility of imperfect replacement of factors, assuming that the same production could be obtained through a variable, nonlinear combination of factors.

6.2.2 Measure of Production Factors

Concerning the measure of production factors, the following will be applied.

With regard to labor, the working time h (hours) done by personnel in the production system, is assumed to be a *homogeneous factor*, meaning that different skills can be taken into account through suitable weights.

In case of N persons in a shift and T shifts in unit time (e.g., day, week, month, etc.), the labor quantity L is given by

$$L = hNT \,. \qquad (6.1)$$

In the following, the capital K refers to machines and installations in the enterprise. However, it could also be easily measured in the case of fixed-coefficient technologies: the capital stock, indeed, could be measured in terms of *standard-speed machine equivalent hours*. The capital K can also be further characterized by noting that, *over a short period*, it must be considered a fixed factor with respect to production quantity: excess capacity cannot be eliminated without suffering heavy losses.

Labor and intermediate goods should rather be variable factors with respect to produced quantities: excess stock of intermediate goods can be absorbed by reducing the next purchase, and excess workforce could be reduced gradually through turnover, or suddenly through dismissals or utilization of social measures in favor of unemployees.

In the long term, all production factors should be considered variables.

6.2.3 The Production Function Suggested by Economics Theory

The above-introduced concepts and measures allow to state the *flexible-coefficients production function*, by assuming (for the sake of simplicity and realism) that only the rate of intermediate goods over production is constant ($X/Q = b$)

$$Q = Q(K, L, X) = f(K, L) = X/b\,. \qquad (6.2)$$

The production function is specified by the following properties:

- *Positive marginal productivity* (positive variation of production depending on the variation of a single factor, with the others being fixed, i. e., $\partial Q/\partial K > 0$, $\partial Q/\partial L > 0$)
- *Decreasing returns*, so that marginal productivity is a decreasing function with respect to any production factor, i. e., $\partial Q^2/\partial K^2 < 0$, $\partial Q^2/\partial L^2 < 0$.

In economics theory, from Clark and Marshall until now, the basis of production function analysis was the hypothesis of imperfect replacement of factors, assigning to each the law of decreasing returns.

The first-generation approach is due to *Cobb* and *Douglas* [6.7], who proposed a homogeneous production function whose factors can be additive in logarithmic form: $Q = AL^a K^b$, where the constant A summarizes all other factors except labor and capital. This formulation has been used in empirical investigations, but with severe limitations.

The hypothesis of elasticity from the Cobb–Douglas function with respect to any production factor [such that $(\partial Q/Q)/(\partial L/L) = (\partial Q/Q)/(\partial K/K) = 1$], has been removed by *Arrow* et al. [6.8] and *Brown* and *De Cani* [6.9]. Subsequent criticism by *McFadden* [6.10] and *Uzawa* [6.11] gave rise to the more general form of variable elasticity function [6.12], up to the logarithmic expression due to *Christensen* et al. [6.13, 14], as clearly illustrated in the systematic survey due to *Nadiri* [6.15]. The strongest criticism on the flexible coefficient production function has been provided by *Shaikh* [6.16], but seems to have been ignored. The final step was that of abandoning direct estimation of the production function, and applying indirect estimation of the cost function [6.2, 17–20], up to the most recent theories of *Dievert* [6.21] and *Jorgenson* [6.22].

A significant modification to the analysis approach is possible based on the availability of large statistical databases of profit and loss accounts for enterprises, compared with the difficulty of obtaining data concerning production factor quantities. This approach does not adopt any explicit interpretation scheme, thus upsetting the approach of economics theory (deductive) and engineering (pragmatic), depending only on empirical verification. A correct technological–economic approach should reverse this sequence: with reference to production function analysis, it should be the joint task of the engineer and economist to propose a functional model including the typical parameters of a given production process. The econometric task should be applied to verify the proposed model based on estimation of the proposed parameters. In the following analysis, this latter approach will be adopted.

6.3 Effects of Automation in the Enterprise

6.3.1 Effects of Automation on the Production Function

The approach on which the following considerations are based was originally developed by *Luciano* and *Ravazzi* [6.23], assuming the extreme case of *production only using labor*, i. e., without employing capital (e.g., by using elemental production means). In this case, a typical human characteristic is that a worker can produce only at a rate that decreases with time during his shift. So, the marginal work productivity is decreasing.

Then, taking account of the work time h of a worker in one shift, the decreasing efficiency of workers with time suggests the introduction of another measure, namely the *efficiency unit* E, given by

$$E = h^{\alpha}\,, \qquad (6.3)$$

where $0 < \alpha < 1$ is the *efficiency elasticity* with respect to the hours worked by the worker.

Condition (6.3) includes the assumption of decreasing production rate versus time, because the derivative of E with respect to h is positive but the second derivative is negative.

Note that the efficiency elasticity can be viewed as a measure of the worker's strength.

By denoting λ_{E} as the *production rate of a work unit*, the production function (6.2) can be rewritten as

$$Q = \lambda_{\mathrm{E}} ENT \; . \tag{6.4}$$

Then, substitution of (6.1) and (6.3) into (6.4), gives rise to a representation of the *average production rate*, which shows the decreasing value with worked hours

$$\lambda_{\mathrm{L}} = Q/L = \lambda_{\mathrm{E}} h^{\alpha-1} \; , \tag{6.5}$$

with $\mathrm{d}\lambda_{\mathrm{L}}/\mathrm{d}h = (\alpha - 1)\lambda_{\mathrm{E}} h^{\alpha-2} < 0$.

Let us now introduce the capital K as the auxiliary instrument of work (a computer for intellectual work, an electric drill for manual work, etc.), but *without any process automation*.

Three questions arise:

1. How can capital be measured?
2. How can the effects produced by the association of capital and work be evaluated?
3. How can capital be included in the production function?

With regard to the first question, the usual industrial approach is to refer to the utilization time of the production instruments during the working shift. Then, let the capital K be expressed in terms of *hours of potential utilization* (generally corresponding to the working shift).

Utilization of more sophisticated tools (e.g., through the application of more automation) induces an increase in the production rate per hour. Denoting by $\gamma > 1$ a coefficient to be applied to the production rate λ_{L}, in order to measure its increase due to the effect of capital utilization, the average production rate per hour (6.5) can be rewritten as

$$\lambda_{\mathrm{L}} = \gamma \lambda_{\mathrm{E}} h^{\alpha-1} \; . \tag{6.6}$$

The above-mentioned effect of capital is the only one considered in economics theory (as suggested by the Cobb–Douglas function). However, another significant effect must also be accounted for: the capital's impact on the workers' strength in terms of labor (as mentioned in the second question above).

Automated systems can not only increase production rate, but can also strengthen labor efficiency elasticity, since they reduce physical and intellectual fatigue. To take account of this second effect, condition (6.6) can be reformulated by including a positive parameter $\delta > 0$ that measures the increase of labor efficiency and whose value is bounded by the condition $0 < (\alpha + \delta) < 1$ so as to maintain the hypothesis of decreasing production rate with time

$$\lambda_{\mathrm{L}} = \gamma \lambda_{\mathrm{E}} h^{\alpha+\delta-1} \; . \tag{6.7}$$

According to this model, a *labor-intensive technique* is defined as one in which capital and labor cooperate together, but in which the latter still dominates the former, meaning that a reduction in the labor marginal production rate still characterizes the production process ($\alpha + \delta < 1$), even if it is reduced by the capital contribution ($\delta > 0$).

The answer to the third question, namely how to include capital in the production function, strictly depends on the characteristics of the relevant machinery. Whilst the workers' nature can be modeled based on the assumption of decreasing production rates with time, production machinery does not operate in this way (one could only make reference to wear, although maintenance, which can prevent modification of the production rate, is reflected in capital cost).

On the contrary, it is the human operator who imposes his biological rhythm (e.g., the case of the speed of a belt conveyor that decreases in time during the working shift). This means that capital is linked to production through fixed coefficients: then the marginal production rate is not decreasing with the capital.

Indeed, a *decreasing utilization rate of capital* has to be accounted for as a consequence of the decreasing rate of labor. So, the hours of potential utilization of capital K have to be converted into productive hours through a *coefficient of capital utilization* θ and transformed into production through a *constant capital-to-production rate* parameter v

$$Q = \theta K/v = \theta \lambda_{\mathrm{K}} K \; , \tag{6.8}$$

where $\lambda_{\mathrm{K}} = 1/v$ is a measure of the capital constant productivity, while $0 < \theta < 1$ denotes the ratio between the effective utilization time of the process and the time during which it is available (i. e., the working shift).

Dividing (6.8) by L and substituting into (6.7), it follows that

$$\theta = v \gamma \lambda_{\mathrm{E}} h^{\alpha+\delta-1} \; , \tag{6.9}$$

thus showing how the utilization rate of capital could fit the decreasing labor yield so as to link the mechanical rhythm of capital to the biological rhythm of labor.

Condition (6.9) leads to the first conclusion: *in labor-intensive systems (in which labor prevails over* *capital), decreasing yields occur, but depending only on the physical characteristics of workers and not on the constant production rates of production machinery*.

We should also remark on another significant consideration: *that new technologies also have the function of relieving labor fatigue by reducing undesirable effects due to marginal productivity decrease.*

This second conclusion gives a clear suggestion of the effects of automation concerning reduction of physical and intellectual fatigue. Indeed, automation implies dominance of capital over labor, thus constraining labor to a mechanical rhythm and removing the conditioning effects of biological rhythms.

This situation occurs when $\alpha + \delta = 1$, thus modifying condition (6.7) to

$$\lambda_{\mathrm{L}} = Q/L = \gamma \lambda_{\mathrm{E}} \,, \tag{6.10}$$

which, in condition (6.9), corresponds to $\theta = 1$, i. e., no pause in the labor rhythm.

In this case automation transforms the decreasing yield model into a constant yield model, i. e., the labor production rate is constant, as is the capital production rate, if capital is fully utilized during the work shift. Then, *capital-intensive processes* are defined as those that incorporate high-level automation, i. e., $\alpha + \delta \to 1$.

A number of examples of capital-intensive processes can be found in several industrial sectors, often concerning simple operations that have to be executed a very large number of times. A typical case, even if not often considered, are the new *intensive picking* systems in large-scale automated warehouses, with increasing diffusion in large enterprises as well as in industrial districts.

Section 6.6 provides an overview in several sectors of the two ratios (*capital/labor* and *production/labor*) that, according to the considerations above, can provide a measure of the effect of automation on production rate. Data are referred to the Italian economic/industrial system, but similar considerations could be drawn for other industrial systems in developed countries. Based on the authors' experience during the CODESNET project development, several European countries present aspects similar to those outlined in Sect. 6.6.

6.3.2 Effects of Automation on Incentivization and Control of Workers

Economic theory recognizes three main motivations that suggest that the enterprise can achieve greater wage efficiency than the one fixed by the market [6.24]:

1. The need to minimize costs for hiring and training workers by reducing voluntary resignations [6.25, 26]
2. The presence of information asymmetry between the workers and the enterprise (as only workers know their ability and diligence), so that the enterprise tries to engage the best elements from the market through ex ante incentives, and then to force qualified employees to contribute to the production process (the moral hazard problem) without resulting in too high supervision costs [6.27–29]
3. The specific features of production technologies that may force managers to allow greater autonomy to some worker teams, while paying an incentive in order to promote better participation in teamwork [6.30–32].

The first motivation will be discussed in Sect. 6.4, concerning the flexibility of labor costs, while the last one does not seem to be relevant. The second motivation appears to be crucial for labor-intensive systems, since system productivity cannot only be dependent on technologies and workers' physical characteristics, but also depends greatly on workers propensity to contribute.

So, system productivity is a function of wages, and maximum profit can no longer be obtained by applying the economic rule of marginal productivity equal to wages fixed by market. It is the obligation of the enterprise to determine wages so as to assure maximum profit.

Let the *production rate of a work unit* λ_{E} increase at a given rate in a first time interval in which the *wage* w_{E} *per work unit* plays a strongly incentive role, whilst it could increase subsequently at a lower rate owing to the reduction of the wages marginal utility, as modeled in the following expression, according to the economic hypothesis of the effort function

$$\begin{aligned} &\lambda_{\mathrm{E}} = \lambda_{\mathrm{E}}(w_{\mathrm{E}}), \quad \text{where} \quad \lambda_{\mathrm{E}}(0) = 0; \;\; \mathrm{d}\lambda_{\mathrm{E}}/\mathrm{d}w_{\mathrm{E}} > 0\,; \\ &\text{and} \;\; \mathrm{d}^2\lambda_{\mathrm{E}}/\mathrm{d}w_{\mathrm{E}}^2 \geq 0 \;\; \text{if} \;\; w_{\mathrm{E}} \geq \hat{w}\,; \\ &\qquad \mathrm{d}^2\lambda_{\mathrm{E}}/\mathrm{d}w_{\mathrm{E}}^2 \leq 0 \;\; \text{if} \;\; w_{\mathrm{E}} \leq \hat{w}\,; \end{aligned} \tag{6.11}$$

where $\hat{w}$ is the critical wages which forces a change of yield from increasing to decreasing rate.

In labor-intensive systems, the average production rate given by (6.7) can be reformulated as

$$\lambda_{\mathrm{L}} = \gamma \lambda_{\mathrm{E}} E/h \,. \tag{6.12}$$

Now, let $M = V_{\mathrm{a}} - wL$ be the *contribution margin*, i. e., the difference between the production added value V_{a} and the labor cost: then the *unitary contribution margin* *per labor unit m* is defined by the rate of M over the labor L

$$m = M/L = \hat{p}\lambda_{\mathrm{L}} - w\,, \tag{6.13}$$

where $\hat{p} = (p - p_{\mathrm{X}})\beta$ is the difference between the sale price p and the cost p_{X} of a product's parts and materials, transformed into the final product according to the utilization coefficient $\beta = X/Q$.

It follows that $\hat{p}\lambda_{\mathrm{L}}$ is a measure of the added value, and that the wages w_{E} per work unit must be transformed into real wages through the rate of work units E over the work hours h of an employee during a working shift, according to

$$w = w_{\mathrm{E}}E/h\,. \tag{6.14}$$

The goal of the enterprise is to maximize m, in order to gain maximum profit, i. e.,

$$\max(m) = \left[\hat{p}\gamma\lambda_{\mathrm{E}}(w_{\mathrm{E}}) - w_{\mathrm{E}}\right]E/h\,. \tag{6.15}$$

The first-order optimal condition gives

$$\begin{aligned}\partial m/\partial h &= \left[\hat{p}\gamma\lambda_{\mathrm{E}}(w_{\mathrm{E}}) - w_{\mathrm{E}}\right]\partial(E/h)/\partial h = 0\\ &\Rightarrow \gamma\lambda_{\mathrm{E}}(w_{\mathrm{E}}) = w_{\mathrm{E}}/\hat{p}\,,\end{aligned} \tag{6.16}$$

$$\begin{aligned}\partial m/\partial w_{\mathrm{E}} &= (E/h)\left[\hat{p}\gamma(\partial\lambda_{\mathrm{E}}/\partial w_{\mathrm{E}}) - 1\right] = 0\\ &\Rightarrow \hat{p}\gamma(\partial\lambda_{\mathrm{E}}/\partial w_{\mathrm{E}}) = 1\,.\end{aligned} \tag{6.17}$$

By substituting (6.17) into (6.16), the maximum-profit condition shows that the elasticity of productivity with respect to wages ε_λ will assume a value of unity

$$\varepsilon_\lambda = (\partial\lambda_{\mathrm{E}}/\partial w_{\mathrm{E}})(w_{\mathrm{E}}/\lambda_{\mathrm{E}}) = 1\,. \tag{6.18}$$

So, the enterprise could maximize its profit by forcing the percentage variation of the efficiency wages to be equal to the percentage variation of the productivity $\partial\lambda_{\mathrm{E}}/\lambda_{\mathrm{E}} = \partial w_{\mathrm{E}}/w_{\mathrm{E}}$. If so, it could obtain the optimal values of wages, productivity, and working time.

As a consequence, the duration of the working shift is an endogenous variable, which shows why, in *labor-intensive systems*, the working hours for a worker can differ from the contractual values.

On the contrary, in *capital-intensive systems* with wide automation, it has been noted before that $E/h = 1$ and $\lambda_{\mathrm{E}} = \bar{\lambda}_{\mathrm{E}}$, because the mechanical rhythm prevails over the biological rhythm of work. In this case, efficiency wages do not exist, and the solution of maximum profit simply requires that wages be fixed at the minimum contractual level

$$\max(m) = \hat{p}\lambda_{\mathrm{L}} - w = \hat{p}\gamma\bar{\lambda}_{\mathrm{E}} - w \Rightarrow \min(w)\,. \tag{6.19}$$

As a conclusion, in labor-intensive systems, if λ_{E} could be either observed or derived from λ_{L}, incentive wages could be used to maximize profit by asking workers for optimal efforts for the enterprise. In capital-intensive systems, where automation has canceled out deceasing yield and mechanical rhythm prevails in the production process, worker incentives can no longer be justified. The only possibility is to reduce absenteeism, so that a share of salary should be reduced in case of negligence, not during the working process (which is fully controlled by automation), but outside.

In labor-intensive systems, as in personal service production, it could be difficult to measure workers' productivity: if so, process control by a supervisor becomes necessary.

In capital-intensive systems, automation eliminates this problem because the process is equipped with devices that are able to detect any anomaly in process operations, thus preventing inefficiency induced by negligent workers. In practice automation, by forcing fixed coefficients and full utilization of capital (process), performs itself the role of a working conditions supervisor.

6.3.3 Effects of Automation on Costs Flexibility

The transformation of a labor-intensive process into a capital-intensive one implies the modification of the cost structure of the enterprise by increasing the capital cost (that must be paid in the short term) while reducing labor costs.

Let the total cost C_{T} be defined by the costs of the three factors already considered, namely, intermediate goods, labor, and capital, respectively,

$$C_{\mathrm{T}} = p_{\mathrm{X}}X + wL + c_{\mathrm{K}}K\,, \tag{6.20}$$

where c_{K} denotes the unitary cost of capital.

Referring total cost to the production Q, the cost per production unit c can be stated by substituting the conditions (6.2) and (6.10) into (6.20), and assuming constant capital value in the short term

$$c = C_{\mathrm{T}}/Q = p_{\mathrm{X}}\beta + w/\lambda_{\mathrm{L}} + c_{\mathrm{K}}K/Q\,. \tag{6.21}$$

In labor-intensive systems, condition (6.21) can also be rewritten by using the efficiency wages w^*_{E} allocated in order to obtain optimal productivity $\lambda^*_{\mathrm{L}} = \gamma\lambda_{\mathrm{E}}(w^*_{\mathrm{E}})h^{*\alpha+\delta-1}$, as shown in Sect. 6.3.1,

$$c = p_{\mathrm{X}}\beta + w^*_{\mathrm{E}}/\lambda^*_{\mathrm{L}} + c_{\mathrm{K}}K/Q\,. \tag{6.22}$$

On the contrary, in capital-intensive systems, the presence of large amounts of automation induces the following effects:

1. Labor productivity λ_{A} surely greater than that which could be obtained in labor-intensive systems ($\lambda_{\mathrm{A}} > \lambda_{\mathrm{L}}^{*}$)
2. A salary w_{A} that does not require incentives to obtain optimum efforts from workers, but which implies an additional cost with respect to the minimum salary fixed by the market ($w_{\mathrm{A}} \lesseqgtr w_{\mathrm{E}}^{*}$), in order to select and train personnel
3. A positive correlation between labor productivity and production quantity, owing to the presence of qualified personnel who the enterprise do not like to substitute, even in the presence of temporary reductions of demand from the final product market

$$\lambda_{\mathrm{A}} = \lambda_{\mathrm{A}}(Q),\ \partial\lambda_{\mathrm{A}}/\partial Q > 0,\ \partial^{2}\lambda_{\mathrm{A}}/\partial Q^{2} = 0 \tag{6.23}$$

4. A significantly greater cost of capital, due to the higher cost of automated machinery, than that of a labor-intensive process ($c_{\mathrm{KA}} > c_{\mathrm{K}}$), even for the same useful life and same rate of interest of the loan.

According to these statements, the unitary cost in capital-intensive systems can be stated as

$$c_{\mathrm{A}} = p_{\mathrm{X}}\beta + w_{\mathrm{A}}/\lambda_{\mathrm{A}}(Q) + c_{\mathrm{KA}}K/Q\ . \tag{6.24}$$

Denoting by *profit per product unit* π the difference between sale price and cost

$$\pi = p - c\ , \tag{6.25}$$

the *relative advantage of automation* D, can be evaluated by the following condition, obtained by substituting (6.24) and then (6.22) into (6.25)

$$\begin{aligned} D &= \pi_{\mathrm{A}} - \pi \\ &= w_{\mathrm{E}}^{*}/\lambda_{\mathrm{L}}^{*} - w_{\mathrm{A}}/\lambda_{\mathrm{A}}(Q) - (c_{\mathrm{KA}} - c_{\mathrm{K}})K/Q\ . \end{aligned} \tag{6.26}$$

Except in extreme situations of large underutilization of production capacity (Q should be greater than the critical value Q_{C}), the inequality $w_{\mathrm{E}}^{*}/\lambda_{\mathrm{L}}^{*} > w_{\mathrm{A}}/\lambda_{\mathrm{A}}(Q)$ denotes the necessary condition that assures that automated production techniques can be economically efficient. In this case, the greater cost of capital can be counterbalanced by greater benefits in terms of labor cost per product unit.

In graphical terms, condition (6.26) could be illustrated as a function $D(Q)$ increasing with the production quantity Q, with positive values for production greater than the critical value Q_{C}. This means that large amounts of automation can be adopted for high-quantity (mass) production, because only in this case can the enterprise realize an increase in marginal productivity sufficient to recover the initial cost of capital. This result, however, shows that automation could be more risky than labor-intensive methods, since production variations induced by demand fluctuations could reverse the benefits. This risk, today, is partly reduced by mass-customized production, where automation and process programming can assure process flexibility able to track market evolutions [6.33].

6.4 Mid-Term Effects of Automation

6.4.1 Macroeconomics Effects of Automation: Nominal Prices and Wages

The analysis has been centered so far on microeconomics effects of automation on the firm's costs, assuming product prices are given, since they would be set in the market depending on demand–offer balance in a system with perfect competition.

Real markets however lack a Walrasian auctioneer and are affected by the incapacity of firms to know in advance (rational expectations) the market demand curve under *perfect competition*, and their own demand curve under *imperfect competition*. In the latter case, enterprises cannot maximize their profit on the basis of demand elasticity, as proposed by the economic theory of imperfect competition [6.34–36]. Therefore, they cannot define their price and the related markup on their costs.

Below we suggest an alternative approach, which could be described as *technological–managerial*.

The balance price is not known a priori and price setting necessarily concerns enterprises: they have to submit to the market a price that they consider to be profitable, but not excessive because of the fear that competitors could block selling of all the scheduled production. Firms calculate the sale price p on the basis of a full unit cost c, including a minimum profit, considered as a *normal* capital remuneration.

The full cost is calculated corresponding to a scheduled production quantity Q^{e} that can be allegedly sold on the market, leaving a small share of productive capacity $\bar{Q}$ potentially unused

$$Q^{\mathrm{e}} \leq \bar{Q} = \theta_{\mathrm{K}} \lambda_{\mathrm{K}} \bar{K} = \theta_{\mathrm{K}} \bar{K} / v \,, \qquad (6.27)$$

where $\theta_{\mathrm{K}} = 1$ in the presence of automation, while $v = 1/\lambda_{\mathrm{K}}$ is – as stated above – the capital–product connection defining technology adopted by firms for full productive capacity utilization.

The difference $\bar{Q} - Q^{\mathrm{e}}$ therefore represents the unused capacity that the firm plans to leave available for production demand above the forecast.

To summarize, the sales price is fixed by the enterprise, resorting to connection (6.21), relating the *break-even* point to Q^{e}

$$p = c(Q^{\mathrm{e}}) = p_{\mathrm{X}} \beta + w/\lambda_{\mathrm{L}} + c_{\mathrm{K}} v^{\mathrm{e}} \,, \qquad (6.28)$$

where $v^{\mathrm{e}} = \bar{K}/Q^{\mathrm{e}} \geq v$ (for $Q^{\mathrm{e}} \leq \bar{Q}$) is the programmed capital–product relationship.

In order to transfer this relation to the macroeconomics level, we have to express it in terms of added value (Q is the gross saleable production), as the *gross domestic product* (GDP) results from aggregation of the added values of firms. Therefore we define the added value as

$$PY = pQ - p_{\mathrm{X}} X = (p - p_{\mathrm{X}} \beta) Q \,,$$

where P represents the *prices general level* (the average price of goods that form part of the GDP) and Y the *aggregate supply* (that is, the GDP). From this relation, P is given by

$$P = (p - p_{\mathrm{X}} \beta)/\theta_{\mathrm{Y}} \,, \qquad (6.29)$$

where $\theta_{\mathrm{Y}} = Y/Q$ measures the degree of vertical integration of the economic system, which in the medium/short term we can consider to be steady ($\theta_{\mathrm{Y}} = \bar{\theta}_{\mathrm{Y}}$).

By substituting relation (6.28) into (6.29), the price equation can be rewritten as

$$P = w/\hat{\lambda} + c_{\mathrm{K}} \hat{v} \,, \qquad (6.30)$$

where work productivity and the capital/product ratio are expressed in terms of added value ($\hat{\lambda} = \theta_{\mathrm{Y}} \lambda_{\mathrm{L}} = Y/L$ and $\hat{v} = v^{\mathrm{e}}/\theta_{\mathrm{Y}} = \bar{K}/Y^{\mathrm{e}}$).

In order to evaluate the effects of automation at the macroeconomic level, it is necessary to break up the capital unit cost c_{K} into its components:

- The initial purchase unit price of capital P_{K}^{0}
- The sample gross profit ρ^{*} sought by firms (as a percentage to be applied to the purchase price), which embodies both amortization rate d and the performance r^{*} requested by financiers to remunerate debt (subscribed by bondholders) and risk capital (granted by owners).

So the following definition can be stated

$$c_{\mathrm{K}} = \rho^{*} P_{\mathrm{K}}^{0} = \left[l^{*} P_{\mathrm{K}}^{0} + (1 - l^{*}) P_{\mathrm{K}} \right] / a_{\overline{n}\,|r^{*}} \,. \qquad (6.31)$$

where

- $0 < l^{*} = D^{*}/(P_{\mathrm{K}}^{0} \bar{K}) < 1$ is the *leverage* (debt amount subscribed in capital stock purchase)
- $1 - l^{*}$ is the amount paid by owners
- $P_{\mathrm{K}} > P_{\mathrm{K}}^{0}$ is the *substitution price* of physical capital at the deadline and
- $a_{\overline{n}|r^{*}} = \frac{1-(1+r^{*})^{-n}}{r^{*}}$ is the discounting back factor.

Relation (6.31) implies that the aim of the firm is to maintain unchanged the capital share amount initially brought by owners, while the debt amount is recovered to its face (book) value, as generally obligations are refunded at original monetary value and at a fixed interest rate stated in the contract.

It is also noteworthy that the indebtedness ratio l is fixed at its optimal level l^{*}, and the earning rate depends on it, $r^{*} = r(l^{*})$, because r decreases as the debt-financed share of capital increases due to advantages obtained from the income tax deductibility of stakes [6.37, 38], and increases as a result of failure costs [6.39–41] and agency costs [6.42], which in turn grow as l grows. The optimal level l^{*} is obtained based on the balance between costs and marginal advantages.

The relation (6.31) can be rewritten by using a Taylor series truncated at the first term

$$c_{\mathrm{K}} = (d + r^{*}) \left[l^{*} P_{\mathrm{K}}^{0} + (1 - l^{*}) P_{\mathrm{K}} \right] , \qquad (6.32)$$

which, in the two extreme cases $P_{\mathrm{K}}^{0} = P_{\mathrm{K}}$ and $P_{\mathrm{K}} = P_{\mathrm{K}}^{0}$, can be simplified to

$$c_{\mathrm{K}} = (d + r^{*}) P_{\mathrm{K}} \,, \qquad (6.33a)$$

$$c_{\mathrm{K}} = (d + r^{*}) P_{\mathrm{K}}^{0} \,. \qquad (6.33b)$$

This solution implies the existence of monetary illusion, according to which capital monetary revaluation (following inflation) is completely abandoned, thus impeding owners from keeping their capital intact.

This irrational decision is widely adopted in practice by firms when inflation is low, as it rests upon the accounting procedure codified by European laws that calculated amortization and productivity on the basis of *book value*. Solution (6.33a) embodies two alternatives:

- Enterprises' decision to maintain physical capital undivided [6.43], or to recover the whole capital market value at the deadline, instead of being restricted to the capital value of the stakeholders, in order to guarantee its substitution without reducing existing production capacity; in this case the indebtedness with repayment to nominal value (at fixed rate) involves an extra profit Π for owners (resulting from debt devaluation), which for unity capital corresponds to the difference between relation (6.33a) and (6.32)

$$\Pi = (d+r^*)l^*\left(P_{\mathrm{K}} - P_{\mathrm{K}}^0\right) , \tag{6.34}$$

as clarified by *Cohn* and *Modigliani* [6.44].

- Subscription of debts at variable interest rate, able to be adjusted outright to inflation rate to compensate completely for debt devaluation, according to Fisher's theory of interest; these possibilities should be rules out, as normally firms are insured against debt cost variation since they sign fixed-rate contracts.

Finally the only reason supporting the connection (6.33a) remains the first (accounting for inflation), but generally firms' behavior is intended to calculate c_{K} according to relation (6.33b) (accounting to *historical costs*). However, rational behavior should compel the use of (6.32), thereby avoiding the over- or underestimation of capital cost ex ante.

In summary, the prices equation can be written at a macroeconomics level by substituting (6.32) into (6.30)

$$P = w/\hat{\lambda} + (d+r^*)\hat{v}\left[l^* P_{\mathrm{K}}^0 + (1-l^*)P_{\mathrm{K}}\right] . \tag{6.35a}$$

This relation is simplified according to the different aims of the enterprises:

1. *Keeping physical capital intact*, as suggested by accountancy for inflation, presuming that capital price moves in perfect accordance with product price ($P_{\mathrm{K}}^0 = P_{\mathrm{K}} = p_{\mathrm{k}}P$ over $p_{\mathrm{k}} = P_{\mathrm{K}}/P > 1$ is the capital-related *price* compared with the product one)

$$P_{\mathrm{a}} = \frac{w/\hat{\lambda}}{1-(d+r^*)\hat{v}p_{\mathrm{k}}} = \left(1+\mu_{\mathrm{a}}^*\right)w/\hat{\lambda} . \tag{6.35b}$$

2. *Integrity of capital conferred by owners*, as would be suggested by rational behavior ($P_{\mathrm{K}} = p_{\mathrm{k}}P > P_{\mathrm{K}}^0$)

$$P_{\mathrm{b}} = \frac{w/\hat{\lambda} + l^*(d+r^*)\hat{v}P_{\mathrm{K}}^0}{1-(1-l^*)(d+r^*)\hat{v}p_{\mathrm{k}}} . \tag{6.35c}$$

3. *Recovery of nominal value of capital*, so as only to take account of *historical costs* ($P_{\mathrm{K}} = P_{\mathrm{K}}^0$)

$$P_{\mathrm{c}} = w/\hat{\lambda} + (d+r^*)\hat{v}P_{\mathrm{K}}^0 . \tag{6.35d}$$

Only in the particular case of (6.35b) can the price level be obtained by applying a steady profit-margin factor $(1+\mu_{\mathrm{a}}^*)$ to labor costs per product unit $(w/\hat{\lambda})$.

The *markup* μ^* desired by enterprises (the percentage calculated on variable work costs in order to recover fixed capital cost) results in the following expressions for the three cases above:

1. *Keeping physical capital intact*; in this case, the mark-up results independent of the nominal wage level w

$$\mu_{\mathrm{a}}^* = P_{\mathrm{a}}\hat{\lambda}/w - 1 = \frac{(d+r^*)\hat{v}p_{\mathrm{k}}}{1-(d+r^*)\hat{v}p_{\mathrm{k}}} . \tag{6.36a}$$

2. *Integrity of capital conferred by owners,*

$$\begin{aligned}\mu_{\mathrm{b}}^* &= P_{\mathrm{b}}\hat{\lambda}/w - 1\\ &= \frac{(d+r^*)\hat{v}\left[l^* P_{\mathrm{K}}^0\hat{\lambda}/w + (1-l^*)p_{\mathrm{k}}\right]}{1-(1-l^*)(d+r^*)\hat{v}p_{\mathrm{k}}} .\end{aligned} \tag{6.36b}$$

3. *Recovery of nominal value of capital,*

$$\mu_{\mathrm{c}}^* = P_{\mathrm{c}}\hat{\lambda}/w - 1 = (d+r^*)\hat{v}P_{\mathrm{K}}^0\hat{\lambda}/w . \tag{6.36c}$$

Note that in case 1, enforcing automation generally implies adoption of manufacturing techniques whose relative cost p_{k} increases at a rate greater than proportionally with respect to the capital–product rate reduction $\hat{v}$. The desired markup must then be augmented in order to ensure coverage of capital. In relation (6.35b) this effect is compensated because of productivity $\hat{\lambda}$ growth due to greater automation, so that on the whole the effect of automation on the general price level is beneficial: for given nominal salary, automation reduces price level.

In cases 2 and 3 of rational behavior, referring to (6.35c) in which the enterprise is aware that its debt is to be refunded at its nominal value, and even more so in the particular case (6.35d) in which the firm is enduring monetary illusion, the desired *markup* is variable, a decreasing function of monetary wage.

Therefore the markup theory is a simplification limited to the case of maintaining physical capital intact, and neglecting effects of capital composition (debt refundable at nominal value).

Based on the previous prices equations it follows that an increase of nominal wages or profit rate sought by enterprises involves an increase in prices general level. In comparison with w, the elasticity is only unity in (6.35b) and diminishes increasingly when passing to (6.35c) and (6.35d).

A percentage increase of nominal salaries is therefore transferred on the level of prices in the same proportion – as stated by *markup* theory – only in the particular case of (6.35b). In the other cases the translation results less than proportional, as the sought *markup* decreases as w increases.

Nominal Prices and Wages: Some Conclusions

Elasticity of product price decreases if the term $\hat{v}P_{\mathrm{K}}^{0}\hat{\lambda}/w$ increases, representing the ratio between the nominal value of capital $(P_{\mathrm{K}}^{0}\bar{K})$ and labor cost (wL). Since automation necessarily implies a remarkable increase of this ratio, it results in minor prices sensibility to wages variation. In practice, automation implies beneficial effects on inflation: for increasing nominal wages, a high-capital-intensity economy is less subject to inflation *shocks* caused by wage rises.

6.4.2 Macroeconomics Effects of Automation in the Mid-Term: Actual Wages and Natural Unemployment

In order to analyze effects of automation on macroeconomic balance in the mid term, it is necessary to convey the former equations of prices in terms of real wages, dividing each member by P, in order to take account of $\omega = w/P$, which represents the maximum wage that firms are prepared to pay to employees without giving up their desired profit rate.

1. Keeping physical capital intact $(P_{\mathrm{K}}^{0} = P_{\mathrm{K}} = p_{\mathrm{k}}P)$

$$\omega_{\mathrm{a}} = \hat{\lambda}[1-(d+r^{*})\hat{v}p_{\mathrm{k}}] = \hat{\lambda}/\left(1+\mu_{\mathrm{a}}^{*}\right) \qquad (6.37\mathrm{a})$$

2. Wholeness of capital granted by owners $(P_{\mathrm{K}} = p_{\mathrm{k}}P > P_{\mathrm{K}}^{0})$

$$\omega_{\mathrm{b}} = \hat{\lambda}\left\{1-(d+r^{*})\hat{v}\left[p_{\mathrm{k}} - l^{*}\left(p_{\mathrm{k}} - P_{\mathrm{K}}^{0}/P\right)\right]\right\} \qquad (6.37\mathrm{b})$$

3. Recovery of capital's nominal value $(P_{\mathrm{K}} = P_{\mathrm{K}}^{0})$

$$\omega_{\mathrm{c}} = \hat{\lambda}\left[1-(d+r^{*})\hat{v}P_{\mathrm{K}}^{0}/P\right] \qquad (6.37\mathrm{c})$$

In the borderline case of keeping physical capital intact (6.37a) only one level of real salary ω_{a} exists consistent with a specified level of capital productivity r^{*}, given work productivity $\hat{\lambda}$, amortization rate d, capital/product ratio $\hat{v}$ (corresponding to normal use of plants), and relative price p_{k} of capital with respect to product.

The value of ω_{a} can also be expressed as a link between work productivity and profit margin factor $(1+\mu_{\mathrm{a}}^{*})$ with variable costs, assuming that the desired *markup* is unchanging in comparison with prices.

In the rational case of corporate stock integrity and in the generally adopted case of recovery of capital nominal value, an increasing relation exists between real salary and general price level, with the desired markup being variable, as shown in connections (6.36b) and (6.36c).

The elasticity of ω with respect to P turns out to increase from (6.37a) to (6.37c)

$$\begin{aligned}
&\eta_{\mathrm{a}} = (\partial\omega/\partial P)(P/\omega) = 0\\
&\quad < \eta_{\mathrm{b}} = (\hat{\lambda}/\omega_{\mathrm{b}})l^{*}(d+r^{*})\hat{v}P_{\mathrm{K}}^{0}/P\\
&\quad < \eta_{\mathrm{c}} = (\hat{\lambda}/\omega_{\mathrm{c}})(d+r^{*})\hat{v}P_{\mathrm{K}}^{0}/P\\
&\quad = \hat{\lambda}/\omega_{\mathrm{c}} - 1 \underset{>}{\leq} 1 \text{ with } \omega_{\mathrm{c}} \underset{<}{\geq} \hat{\lambda}/2\,. \qquad (6.37\mathrm{d})
\end{aligned}$$

In cases 2 and 3 growth in the prices general level raises the added value share intended for normal capital remuneration, leaving firms a markup to be used in bargaining in order to grant employees a pay rise in real salary, even while keeping normal profit rate (the calculated level with programmed production) steady.

This markup of real wage bargaining depends on the choice of the capital recovery system: it is higher in the case of fund illusion and lower in the case in which capital stock is intended to be maintained undivided.

Remark: In all three cases above, the level of real salary depends on the degree of production process automation: in economic systems where this is high, productivity of work $(\hat{\lambda})$ and capital $(1/\hat{v})$ are necessarily higher than the related price of capital (p_{k} and P_{K}^{0}/P), so the real wage that the firms are willing to concede in bargaining is higher than the one affecting work-intensive economic systems. In substance, automation weakens firms' resistance in wage bargaining, making them more willing to concede higher real wages.

In order to qualify the positive role of automation we complete the mid-term period macroeconomic model with the wage equation from the workers' side.

Macroeconomics theory believes that, in the mid term, nominal wages w asked for by workers in syndicated or individual bargaining (or imposed by firms in order to select and extract optimal effort in production process) depend on three variables: the unemployment rate of man power u, other factors absorbed in a synthetic variable z, and the expected level of prices P^{e}.

So it is possible to write

$$w = \omega(u,z)P^{\mathrm{e}}\,. \qquad (6.38)$$

Higher unemployment is supposed to weaken workers' contractual strength, compelling them to accept lower wages, and vice versa that a decrease of unemployment rate leads to requests for an increase of real wages ($\partial\omega/\partial u < 0$).

The variable z can express the effects of unemployment increase, which would compel workers to ask for a pay raise, because any termination would appear less risky in terms of *social salary* (the threshold above which an individual is compelled to work and under which he is not prepared to accept, at worst choosing unemployment). Similar effects would be induced by legal imposition of minimum pay and other forms of worker protection, which – making discharge more difficult – would strengthen workers' position in wage bargaining.

Regarding the expected level of prices, it is supposed that

$$\partial w/\partial P^{\mathrm{e}} = w/P^{\mathrm{e}} > 0 \Rightarrow (\partial w/\partial P^{\mathrm{e}})(P^{\mathrm{e}}/w) = 1$$

to point out that rational subjects are interested in real wages (their buying power) and not nominal ones, so an increase in general level of prices would bring about an increase in nominal wages in the same proportion. Wages are however negotiated by firms on nominal terms, on the basis of a price foresight (P^{e}) for the whole length of the contract (generally more than 1 year), during which monetary wages are not corrected if $P \neq P^{\mathrm{e}}$.

To accomplish this analysis, in the mid-term period, wage bargaining is supposed to have real wage as a subject (excluding systematic errors in expected inflation foresight), so that $P = P^{\mathrm{e}}$ and (6.38) can be simplified to

$$\omega = \omega(u, z) \,. \qquad (6.39)$$

Figure 6.2 illustrates this relation with a decreasing curve WS (*wage setting*), on Cartesian coordinates for a given level of z.

Two straight lines, PS (*price setting*), representing price equations (6.37a), considering mainly the borderline case of maintaining physical capital intact, are reported:

- The upper line $\mathrm{PS_A}$ refers to an economic system affected by a high degree of automation, or by technologies where $\theta_{\mathrm{k}} = 1$ and work and capital productivity are higher, being able to contrast the capital's relative higher price; in this case firms are prone to grant higher real wages.

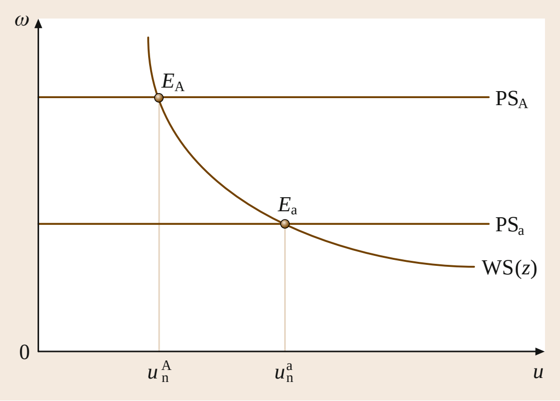

Fig. 6.2 Mid-term equilibrium with high and low automation level

- The lower line $\mathrm{PS_a}$, characterizing an economy with a lower degree of automation, resulting in less willingness to grant high real wages.

The intersection between the curve WS and the line PS indicates one equilibrium point E for each economic system (where workers' plans are consistent with those of firms), corresponding to the case in which only one *natural* unemployment rate exists, obtained by balancing (6.37a) and (6.39)

$$\hat{\lambda}\left[1-(d+r^*)\hat{v}p_{\mathrm{k}}\right] = \omega(u, z) \Rightarrow u_{\mathrm{n}}^{\mathrm{A}} < u_{\mathrm{n}}^{\mathrm{a}} \,, \qquad (6.40a)$$

assuming that $[1-(d+r^*)\hat{v}p_{\mathrm{k}}]d\hat{\lambda} - \hat{\lambda}(d+r^*)p_{\mathrm{k}}d\hat{v} > \hat{\lambda}(d+r^*)\hat{v}dp_{\mathrm{k}}$.

Remark: In the case of a highly automated system, wage bargaining in the mid-term period enables a natural unemployment rate smaller than that affecting a less automated economy: higher productivity makes enterprises more willing to grant higher real wages as a result of bargaining and the search for efficiency in production organizations, so that the economic system can converge towards a lower equilibrium rate of unemployment ($u_{\mathrm{n}}^{\mathrm{A}} < u_{\mathrm{n}}^{\mathrm{a}}$).

The uniqueness of this solution is valid only if enterprises aim to maintain physical capital undivided.

In the case of rational behavior intended to achieve the integrity of capital stock alone (6.37b), or business procedures oriented to recoup the accounting value of capital alone (6.37c), the natural unemployment rate theory is not sustainable. In fact, if we equalize these two relations to (6.39), respectively, we obtain in both cases a relation describing balance couples between unemployment rate and prices general level, indicating that the equilibrium rate is undetermined and therefore that the adjective *natural* is inappropriate

$$\hat{\lambda}\left\{1-(d+r^{*})\hat{v}\left[p_{\mathrm{k}}-l^{*}\left(p_{\mathrm{k}}-P_{\mathrm{K}}^{0}/P\right)\right]\right\}=\omega(u,z)$$
$$\Rightarrow u_{\mathrm{n}}=u_{\mathrm{n}}^{\mathrm{b}}(P)\,, \tag{6.40b}$$
$$\hat{\lambda}\left[1-(d+r^{*})\hat{v}P_{\mathrm{K}}^{0}/P\right]=\omega(u,z)$$
$$\Rightarrow u_{\mathrm{n}}=u_{\mathrm{n}}^{\mathrm{c}}(P)\,, \tag{6.40c}$$

where $\partial u_{\mathrm{n}}/\partial P<0$, since an increase in P increases the margin necessary to recover capital cost and so enterprises can pay out workers a higher real salary ($\partial\omega/\partial P>0$), which in balance is compatible with a lower rate of unemployment.

Summing up, alternative enterprise behavior to that intended to maintain physical capital intact does not allow fixing univocally the natural rate of unemployment. In fact, highly automated economic systems cause a translation of the function $u_{\mathrm{n}}=u_{\mathrm{n}}(P)$ to a lower level: for an identical general level of prices the unemployment balance rate is lower since automation allows increased productivity and real wage that enterprises are prepared to pay.

6.4.3 Macroeconomic Effects of Automation in the Mid Term: Natural Unemployment and Technological Unemployment

The above optimistic conclusion of mid-term equilibrium being more profitable for highly automation economies must be validated in the light of constraints imposed by capital-intensive technologies, where the production rate is higher and yields are constant.

Assume that in the economic system an aggregated demand is guaranteed, such that all production volumes could be sold, either owing to fiscal and monetary politics oriented towards full employment or hoping that, in the mid term, the economy will spontaneously converge through monetary adjustments induced by variation of the price general level.

In a diffused automation context, a problem could result from a potential inconsistency between the unemployment natural rate u_{n} (obtained by imposing equality of expected and actual prices, related to labor market equilibrium) and the unemployment rate imposed by technology $\bar{u}$

$$\bar{u}=1-L^{\mathrm{d}}/L^{\mathrm{s}}=1-(\bar{Y}/\hat{\lambda})/L^{\mathrm{s}}\gtrless u_{\mathrm{n}}\,, \tag{6.41}$$

where $L^{\mathrm{d}}=\bar{Y}/\hat{\lambda}$ is the demand for labor, L^{s} is the labor supply, and $\bar{Y}$ is the potential production rate, compatible with full utilization of production capacity.

A justification of this conclusion can be seen by noting that automation calls for qualified technical personnel, who are still engaged by enterprises even during crisis periods, and of whom overtime work is required in case of expansion. Then, employment variation is not proportional to production variation, as clearly results from the law of *Okun* [6.45], and from papers by *Perry* [6.46] and *Tatom* [6.47].

Remark: From the definition of $\bar{u}$ it follows that economic systems with high automation level, and therefore characterized by high productivity of labor, present higher technological unemployment rates

$$(\partial\bar{u}/\partial\hat{\lambda})(\hat{\lambda}/\bar{u})=(1-\bar{u})/\bar{u}>0\,.$$

On one hand, automation reduces the natural unemployment rate u_{n}, but on the other it forces the technological unemployment rate $\bar{u}$ to increase. If it holds that $\bar{u}\leq u_{\mathrm{n}}$, the market is dominant and the economic system aims to converge in time towards an equilibrium characterized by higher real salary and lower (natural) unemployment rate, as soon as the beneficial effects of automation spread.

In Fig. 6.3, the previous Fig. 6.2 is modified under the hypothesis of a capital-intensive economy, by including two vertical lines corresponding to two potential unemployment rates imposed by technology ($\bar{u}$ and $\bar{u}_{\mathrm{A}}$). Note that $\bar{u}$ has been placed on the left of u_{n} whilst $\bar{u}_{\mathrm{A}}$ has been placed on the right of u_{n}. It can be seen that the labor market equilibrium (point E) dominates when technology implies a degree of automation compatible with a nonconstraining unemployment rate $\bar{u}$. Equilibrium could be obtained, on the contrary, when technology (for a given production capacity of the eco-

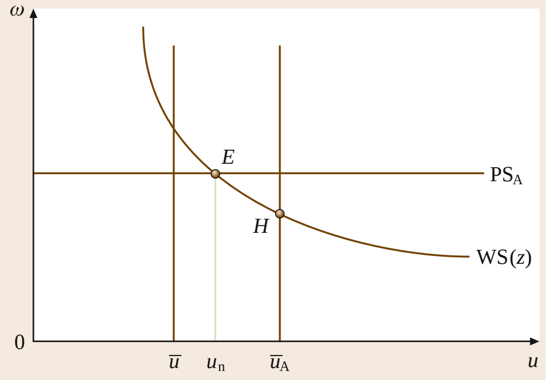

Fig. 6.3 Mid-term equilibrium with high automation level and two different technological unemployment rates

nomic system) cannot assure a low unemployment rate: $\bar{u}_{\mathrm{A}} > u_{\mathrm{n}}$.

The technological unemployment constraint implies a large weakness when wages are negotiated by workers, and it induces a constrained equilibrium (point H) in which the real salary perceived by workers is lower than that which enterprises are willing to pay. The latter can therefore achieve unplanned extra profits, so that automation benefits only generate capital owners' income which, in the share market, gives rise to share value increase.

Only a relevant production increase and equivalent aggregated demand could guarantee a reduction of $\bar{u}_{\mathrm{A}}$, thus transferring automation benefits also to workers.

These conclusions can have a significant impact on the Fisher–Phillips curve (*Fisher* [6.48] and *Phillips* [6.49], first; theoretically supported by *Lipsey* [6.50] and then extended by *Samuelson* and *Solow* [6.51]) describing the trade-off between inflation and unemployment.

Assume that the quality constraint between expected prices and effective prices can, in the mid term, be neglected, in order to analyze the inflation dynamics. Then, substitute (6.38) into (6.35b), by assuming the hypothesis that maintaining capital intact implies constant markup

$$P = (1+\mu^*)\omega(u,z)P^{\mathrm{e}}/\hat{\lambda} \,. \tag{6.42}$$

This relation shows that labor market equilibrium for imperfect information ($P^{\mathrm{e}} \neq P$), implies a positive link between real and expected prices.

By dividing (6.42) by P_{-1}, the following relation results

$$1+\pi = (1+\pi^{\mathrm{e}})(1+\mu^*)\omega(u,z)/\hat{\lambda} \,, \tag{6.43a}$$

where:

- $\pi = P/P_{-1} - 1$ is the current inflation rate
- $\pi^{\mathrm{e}} = P^{\mathrm{e}}/P_{-1} - 1$ is the expected inflation rate.

Assume moderate inflation rates, such that

$$(1+\pi)/(1+\pi^{\mathrm{e}}) \approx 1+\pi-\pi^{\mathrm{e}}$$

and consider a linear relation between productivity and wages, such that it amounts to 100% if

$$z = u = 0 : \omega(u,z)/\hat{\lambda} = 1+\alpha_0 z - \alpha_1 u (\alpha_0, \alpha_1 > 0) \,.$$

Relation (6.43a) can be simplified to

$$\pi = \pi^{\mathrm{e}} + (1+\mu^*)\alpha_0 z - (1+\mu^*)\alpha_1 u \,, \tag{6.43b}$$

which is a linear version of the Phillips curve; according to this form, the current inflation rate depends positively on inflation expectation, markup level, and the variable z, and negatively on the unemployment rate.

For $\pi^{\mathrm{e}} = 0$, the original curve which Phillips and Samuelson–Solow estimated for the UK and USA is obtained.

For $\pi^{\mathrm{e}} = \pi_{-1}$ (i. e., *extrapolative expectations*) a link between the variation of inflation rate and the unemployment rate (accelerated Phillips curve), showing better interpolation of data observed since 1980s, is derived

$$\pi - \pi_{-1} = (1+\mu^*)\alpha_0 z - (1+\mu^*)\alpha_1 u \,. \tag{6.44}$$

Assuming $\pi = \pi^{\mathrm{e}} = \pi_{-1}$ in (6.43b) and (6.44), an estimate of the natural unemployment rate (without systematic errors in mid-term forecasting) can be derived

$$u_{\mathrm{n}} = \alpha_0 z/\alpha_1 \,. \tag{6.45}$$

Now, multiplying and dividing by the α_1 term $(1+\mu^*)\alpha_0 z$ in (6.44), and inserting (6.45) into (6.44), it results that, in the case of *extrapolative expectations*, the inflation rate reduces if the effective unemployment rate is greater than the natural one ($\mathrm{d}\pi < 0$ if $u > u_{\mathrm{n}}$); it increases in the opposite case ($\mathrm{d}\pi > 0$ if $u < u_{\mathrm{n}}$); and it is zero (constant inflation rate) if the effective unemployment rate is equal to the natural one ($\mathrm{d}\pi = 0$ if $u = u_{\mathrm{n}}$)

$$\pi - \pi_{-1} = -(1+\mu^*)\alpha_1(u-u_{\mathrm{n}}) \,. \tag{6.46}$$

Remark: Relation (6.44) does not take into account effects induced by automation diffusion, which imposes on the economic system a technological unemployment $\bar{u}_{\mathrm{A}}$ that increases with increasing automation.

It follows that any econometric estimation based on (6.44) no longer evaluates the natural unemployment rate (6.45) for $\pi - \pi_{-1} = 0$, because the latter varies in time, flattening the interpolating line (increasingly high unemployment rates related to increasingly lower real wages, as shown above). Then, as automation process spreads, the natural unemployment rate (which, without systematic errors, assures compatibility between the real salary paid by enterprises and the real salary either demanded by workers or supplied by enterprises for efficiency motivation) is no longer significant.

In Fig. 6.4a the Phillips curve for the Italian economic system, modified by considering inflation rate variations from 1953 to 2005 and the unemployment rate, is reported; the interpolation line is decreasing but very flat owing to $\bar{u}_{\mathrm{A}}$ movement towards the right.

A natural unemployment rate between 7 and 8% seems to appear, but the intersection of the interpolation line with the abscissa is moved, as shown in the

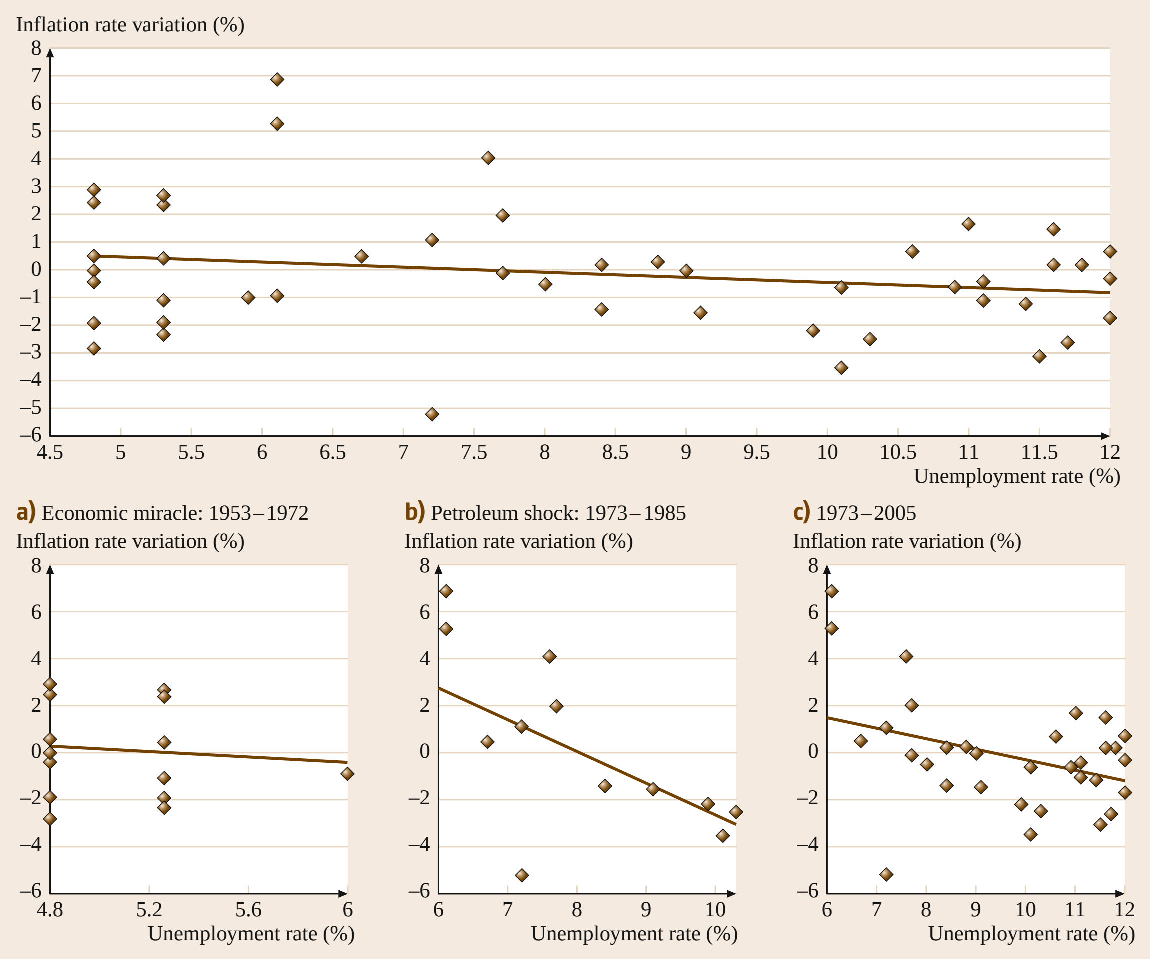

Fig. 6.4a–c Italy: Expectations-augmented Phillips curve (1953–2005). **(a)** Economic miracle: 1953–1972, **(b)** petroleum shock: 1973–1985, **(c)** 1973–2005

three representations where homogeneous data sets of the Italian economic evolution are considered.

Automation has a first significant impact during the oil crisis, moving the intersection from 5.2% for the first post-war 20 years up to 8% in the next period. Extending the time period up to 2005, intersection moves to 9%; the value could be greater, but it has been recently bounded by the introduction of temporary work contracts which opened new labor opportunities but lowered salaries.

Note that Figs. 6.4a–c are partial reproductions of the Fig. 6.4, considering three different intervals of unemployment rate values. This reorganization of data corresponds to the three different periods of the Italian economic growth: (a) the economic miracle (1953–1972), (b) the petroleum shock (1973–1985), and (c) the period from the economic miracle until 2005 (1973–2005).

A more limited but comprehensive analysis, owing to lack of homogeneous historical data over the whole period, has been done also for two other important European countries, namely France (Fig. 6.5a) and Germany (Fig. 6.5b): the period considered ranges from 1977 to 2007.

The unemployment rate values have been recomputed so as to make all the historical series homogeneous. Owing to the limited availability of data for both countries, only two periods have been analyzed: the period 1977–1985, with the effects of the petroleum shock, and the whole period up to 2007, in order to

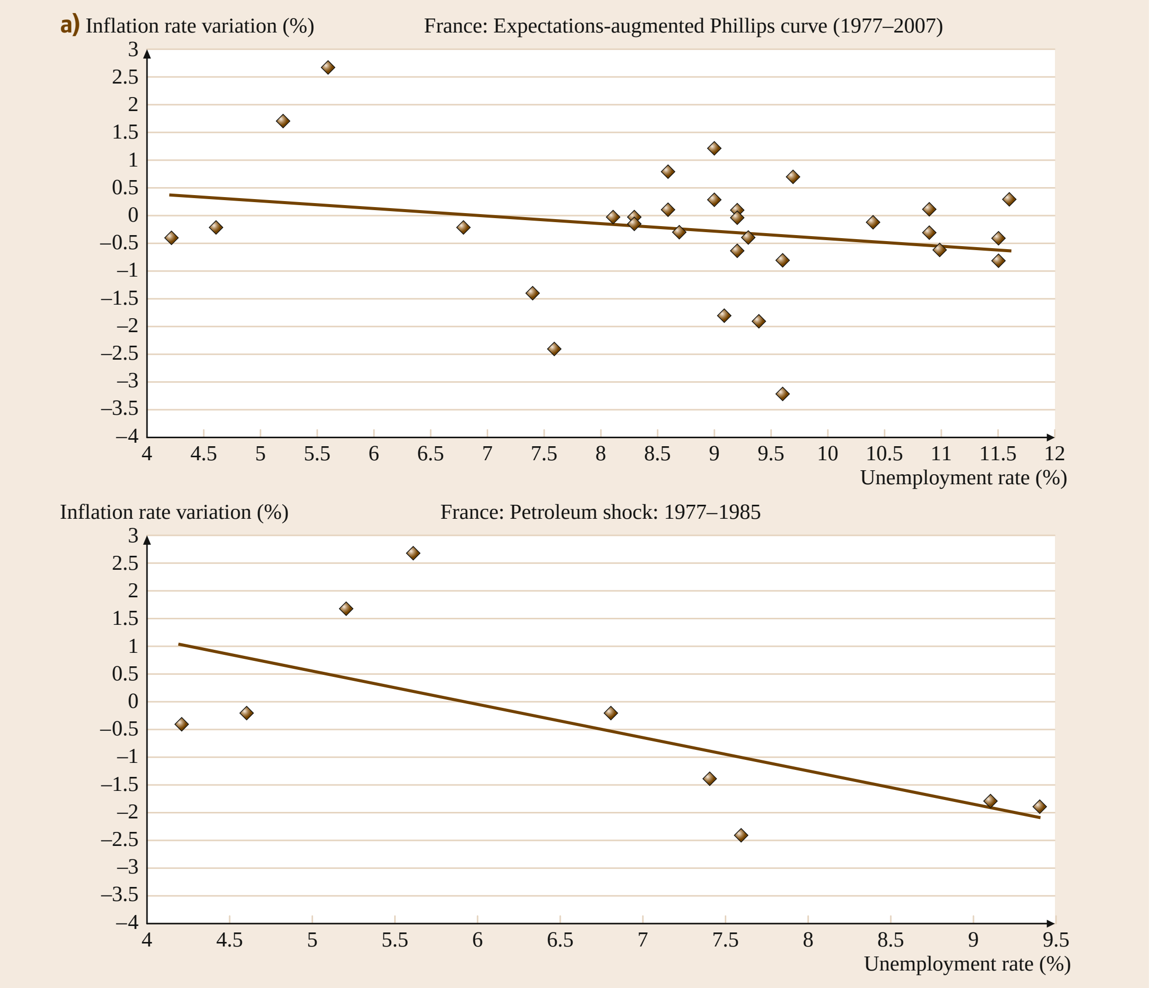

Fig. 6.5 **(a)** France: expectations-augmented Phillips curve (1977–2007) **(b)** ▶ Germany: expectations-augmented Phillips curve (1977–2007)

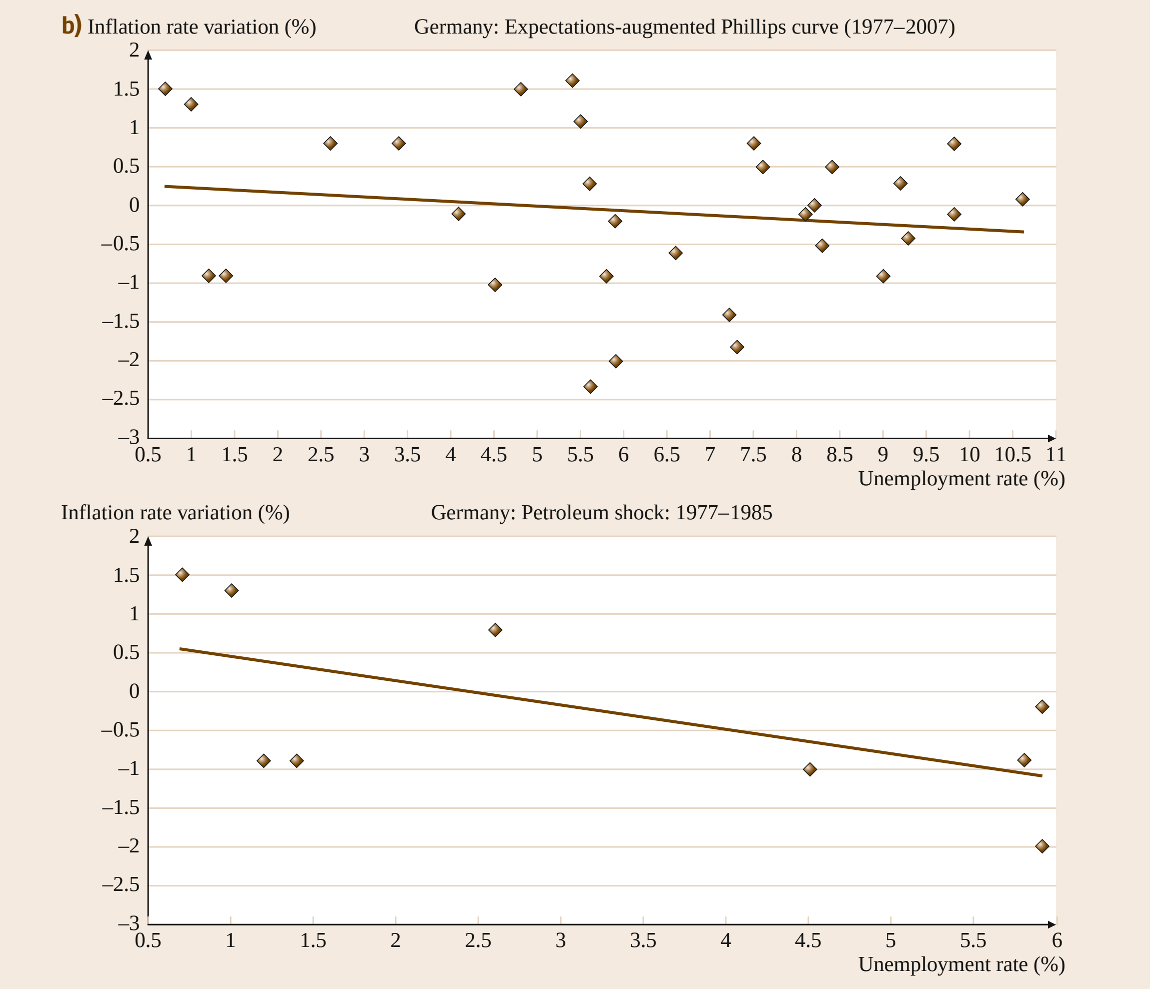
evaluate the increase of the natural unemployment rate from the intersection of the interpolation line with the abscissa.

As far as Fig. 6.5a is concerned, the natural unemployment rate is also increased in France – as in Italy – by more than one percentage point (from less than 6% to more than 7%). In the authors' opinion, this increase should be due to technology automation diffusion and consequent innovation of organization structures.

Referring to Fig. 6.5b, it can be noted that even in Germany the natural unemployment rate increased – more than in France and in Italy – by about three percentage points (from 2.5 to 5.5%). This effect is partly due to application of automated technologies (which should explain about one percentage point, as in the other considered countries), and partly to the reunification of the two parts of German.

A Final Remark: Based on the considerations and data analysis above it follows that the natural unemployment rate, in an industrial system where capital intensive enterprises are largely diffused, is no longer significant, because enterprises do not apply methods to maintain capital intact, and because technological inflation tends to constraint the natural one.

Only structural opposing factors could slow this process, such as labor market reform, to give rise to new work opportunities, and mainly economic politics, which could increase the economy development



trend more than the growth of productivity and labor supply. However, these aspects should be approached in a long-term analysis, and exceed the scope of this chapter.

6.5 Final Comments

Industrial automation is characterized by dominance of capital dynamics over the biological dynamics of human labor, thus increasing the production rate. Therefore automation plays a positive role in reducing costs related to both labor control, sometimes making monetary incentives useless, and supervisors employed to assure the highest possible utilization of personnel. It is automation itself that imposes the production rate and forces workers to correspond to this rate.

In spite of these positive effects on costs, the increased capital intensity implies greater rigidity of the cost structure: a higher capital cost depending on higher investment value, with consequent transformation of some variable costs into fixed costs. This induces a greater variance of profit in relation to production volumes and a higher risk of automation in respect to labor-intensive systems. However, the trade-off between automation yield and risk suggests that enterprises

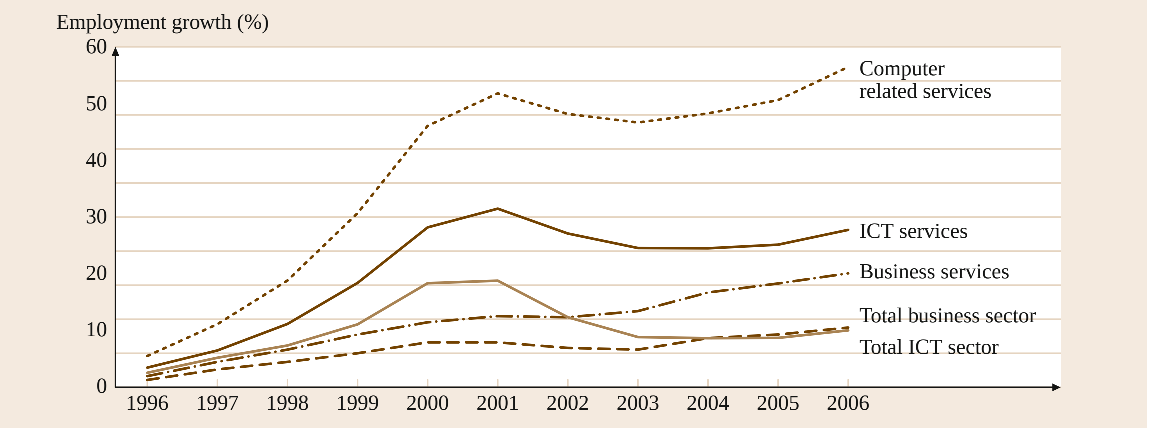


Fig. 6.6 Employment growth by sector with special focus on computer and ICT (source: OECD Information Technology Outlook 2008, based on STAN database)

should increase automation in order to obtain high utilization of production capacity. One positive effort in this direction has been the design and implementation of flexible automation during recent decades (e.g., see Chap. 50 on *Flexible and Precision Assembly*).

Moving from microeconomic to macroeconomic considerations, automation should reduce the effects on short-term inflation caused by nominal salary increases since it forces productivity to augment more than the markup necessary to cover higher fixed costs. In addition, the impact of automation depends on the book-keeping method adopted by the enterprise in order to recover the capital value: this impact is lower if a part of capital can be financed by debts and if the enterprise behavior is motivated by monetary illusion.

Over a mid-term period, automation has been recognized to have beneficial effects (Figs. 6.6–6.8) both on the real salary paid to workers and on the (natural) unemployment trend, if characteristics of automation technologies do not form an obstacle to the market trend towards equilibrium, i. e., negotiation between enterprises and trade unions. If, on the contrary, the system production capacity, for a compatible demand, prevents market convergence, a noncontractual equilibrium only dependent on technology capability could be established, to the advantage of enterprises and the prejudice of workers, thus reducing real wages and increasing the unemployment rate.

Empirical validation seems to show that Italy entered this technology-caused unemployment phase

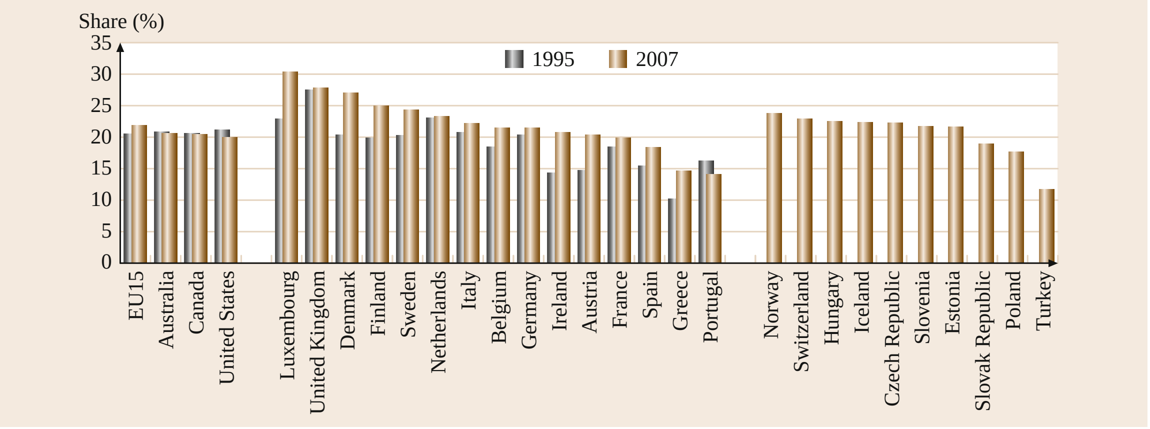

Fig. 6.7 Share of ICT-related occupations in the total economy from 1995 and 2007 (source: OECD IT Outlook 2008, forthcoming)

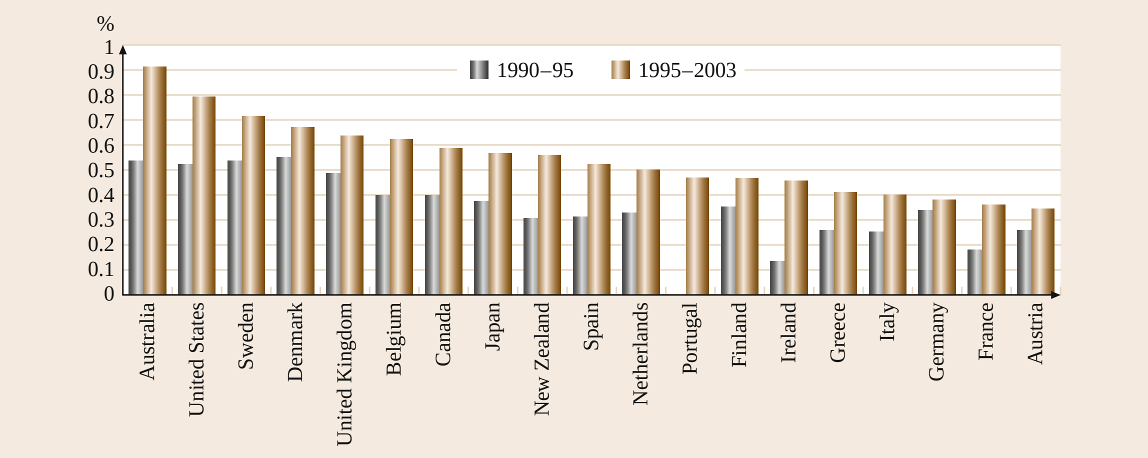

Fig. 6.8 Contributions of ICT investment to GDP growth, 1990–1995 and 1995–2003 in percentage points (source: OECD Productivity Database, September 2005)

during the last 20 years: this corresponds to a flatter Phillips curve because absence of inflation acceleration is related to natural unemployment rates that increase with automation diffusion, even if some structural modification of the labor market restrained this trend.

6.6 Capital/Labor and Capital/Product Ratios in the Most Important Italian Industrial Sectors

A list of the most important industrial sectors in Italy is reported in Table 6.2 (data collected by Mediobanca [6.52] for the year 2005). The following estimations of the model variables and rates have been adopted (as enforced by the available data): capital K is estimated through fixed assets; with reference to production, the added value V_a is considered; labor L is estimated in terms of number of workers.

Some interesting comments can be made based on Table 6.2, by using the production function models presented in the previous sections.

According to the authors' experience (based on their knowledge of the Italian industrial sectors), the following *anomalous sectors* can be considered:

- Sectors concerning *energy production and distribution* and *public services* for the following reasons: they consist of activities applying very high levels of automation; personnel applied in production are extremely scarce, whilst it is involved in organization and control; therefore anomalous values of the capital/labor ratio and of productivity result.
- The *transport* sector, because the very high capital/product ratio depends on the low level of the added value of enterprises that are operating with politically fixed (low) prices.

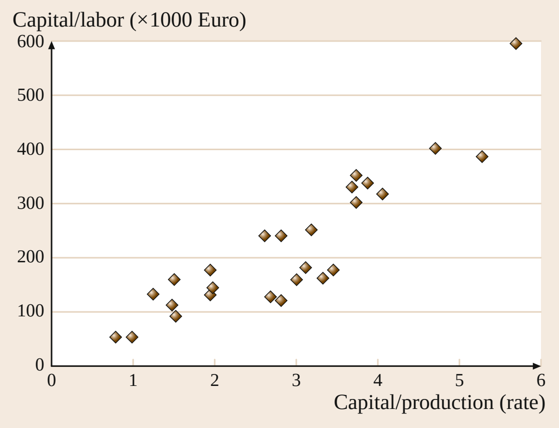

Fig. 6.9 Correlation between capital/labor (× 1000 €) and capital/production (ratios)

Table 6.2 Most important industrial sectors in Italy (after [6.52])

Industrial sector (year 2005)	Fixed assets (million euro) (a)	Added value (million euro) (b)	Number of workers (× 1000) (c)	Capital/ product (a/b)	Capital/ labor (× 1000 euro) (a/c)	Productivity (× 1000 euro) (b/c)
Industrial enterprises	309 689.6	84 373.4	933.8	3.7	331.6	90.4

Glass	2929.3	726.2	9.2	4.0	317.8	78.8

Notation: Labor-intensive sectors Intermediate Anomalous

- The *chemical fibres* sector, because at the time considered it was suffering a deep crisis with a large amount of unused production capacity, which gave rise to an anomalous (too high) capital/product ratio and anomalous (too small) value of productivity.

Sectors with a rate capital/production of 1.5 (such as the clothing industry, pharmaceutics and cosmetics, and hide and leather articles) has been considered as *intermediate sectors*, because automation is highly important in some working phases, whereas other working phases still largely utilize workers. These sectors (and the value 1.5 of the rate capital/production) are used as *separators* between capital-intensive systems (with high degrees of automation) and labor-intensive ones.

Sectors with a capital/production ratio of less than 1.5 have been considered as labor-intensive systems. Among these, note that the graphic sector is capital intensive, but available data for this sector are combined with the editorial sector, which in turn is largely labor intensive.

All other sectors can be viewed as capital-intensive sectors, even though it cannot be excluded that some working phases within their enterprises are still labor intensive.

Two potential correlations, if any, are illustrated in the next two figures: Fig. 6.9 shows the relations between the capital/labor and capital/production ratios, and Fig. 6.10 shows the relations between productivity and capital/labor ratio.

As shown in Fig. 6.9, the capital/labor ratio exhibits a clear positive correlation with the capital/production ratio; therefore they could be considered as alternative measures of capital intensity.

On the contrary, Fig. 6.10 shows that productivity does not present a clear correlation with capital. This could be motivated by the effects of other factors, including the utilization rate of production capacity and the nonuniform flexibility of the workforce, which could have effects on productivity.

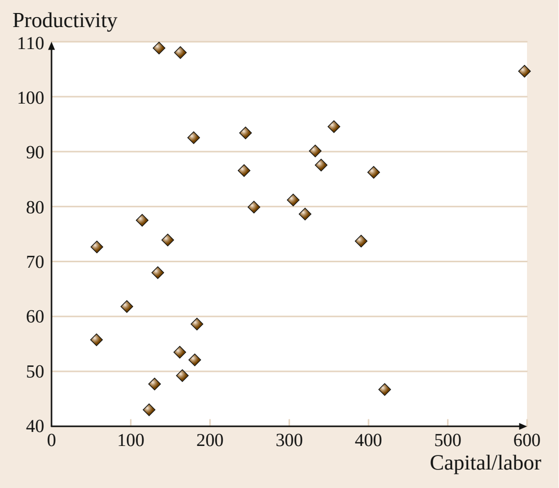

Fig. 6.10 Relation between productivity (× 100 €) and capital/labor (rate)

7. Impacts of Automation on Precision

Alkan Donmez, Johannes A. Soons

Automation has significant impacts on the economy and the development and use of technology. In this chapter, the impacts of automation on precision, which also directly influences science, technology, and the economy, are discussed. As automation enables improved precision, precision also improves automation.

Following the definition of precision and the factors affecting it, the relationship between precision and automation is described. This chapter concludes with specific examples of how automation has improved the precision of manufacturing processes and manufactured products over the last decades.

7.1 What Is Precision?

Precision is the closeness of agreement between a series of individual measurements, values or results. For a manufacturing process, precision describes how well the process is capable of producing products with identical properties. The properties of interest can be the dimensions of the product, its shape, surface finish, color, weight, etc. For a device or instrument, precision describes the invariance of its output when operated with the same set of inputs. Measurement precision is defined by the *International Vocabulary of Metrology* as the [7.1]:

> *... closeness of agreement between indications obtained by replicate measurements on the same or similar objects under specified conditions.*

In this definition, the *specified conditions* describe whether precision is associated with the repeatability or the reproducibility of the measurement process. Repeatability is the closeness of agreement between results of successive measurements of the same quantity carried out under the same conditions. These repeatability conditions include the measurement procedure, observer, instrument, environment, etc. Reproducibility is the closeness of the agreement between results of measurements carried out under changed measurement conditions. In computer science and mathematics, precision is often defined as a measure of the level of detail of a numerical quantity. This is usually expressed as the number of bits or decimal digits used to describe the quantity. In other areas, this aspect of precision is referred to as resolution: the degree to which nearly equal values of a quantity can be discriminated, the smallest measurable change in a quantity or the smallest controlled change in an output.

Precision is a necessary but not sufficient condition for accuracy. Accuracy is defined as the closeness of the agreement between a result and its *true* or intended value. For a manufacturing process, accuracy describes the closeness of agreement between the properties of the manufactured products and the properties defined in the product design. For a measurement, accuracy is the closeness of the agreement between the result of the measurement and a true value of the measurand – the quantity to be measured [7.1]. Accuracy is affected by both precision and bias. An instrument with an incorrect calibration table can be precise, but it would not be accurate. A challenge with the definition of accuracy is that the *true value* is a theoretical concept. In practice, there is a level of uncertainty associated with the true value due to the infinite amount of information required to describe the measurand completely. To the extent that it leaves room for interpretation, the incomplete definition of the measurand introduces uncertainty in the result of a measurement, which may or may not be significant relative to the accuracy required of the measurement; for example, suppose the measurand is the thickness of a sheet of metal. If this thickness is measured using a micrometer caliper, the result of the measurement may be called the best estimate of the *true value* (*true* in the sense that it satisfies the definition of the measurand.) However, had the micrometer caliper been applied to a different part of the sheet of material, the realized quantity would be different, with a different *true value* [7.2]. Thus the lack of information about where the thickness is defined introduces an uncertainty in the *true value*. At some level, every measurand or product design has such an *intrinsic* uncertainty.

7.2 Precision as an Enabler of Automation

Historically, precision is closely linked to automation through the concept of parts interchangeability. In more recent times, it can be seen as a key enabler of lean manufacturing practices. Interchangeable parts are parts that conform to a set of specifications that ensure that they can substitute each other. The concept of interchangeable parts radically changed the manufacturing system used in the first phase of the Industrial Revolution, the English system of manufacturing. The English system of manufacturing was based on the traditional artisan approach to making a product. Typically, a skilled craftsman would manufacture an individual product from start to finish before moving onto the next product. For products consisting of multiple parts, the parts were modeled, hand-fitted, and reworked to fit their counterparts. The craftsmen had to be highly skilled, there was no automation, and production was slow. Moreover, parts were not interchangeable. If a product failed, the entire product had to be sent to an expert craftsman to make custom repairs, including fabrication of replacement parts that would fit their counterparts.

Pioneering work on interchangeable parts occurred in the printing industry (movable precision type), clock and watch industry (toothed gear wheels), and armories (pulley blocks and muskets) [7.3]. In the mid to late 18th century, French General Jean Baptiste Vaquette de Gribeauval promoted the use of standardized parts for key military equipment such as gun carriages and muskets. He realized that interchangeable parts would enable faster and more efficient manufacturing, while facilitating repairs in the field. The development was enabled by the introduction of two-dimensional mechanical drawings, providing a more accurate expression of design intent, and increasingly accurate gauges and templates (jigs), reducing the craftsman's room for deviations while allowing for lower skilled labor. In 1778, master gunsmith Honoré Blanc produced the first set of musket locks completely made from interchangeable parts. He demonstrated that the locks could be assembled from parts selected at random. Blanc understood the need for a hierarchy in measurement standards through the use of working templates for the various pieces of the lock and master copies to enable the reconstruction of the working templates in the case of loss or wear [7.3]. The use of semiskilled labor led to strong resistance from both craftsmen and the government, fearful of the growing independence of manufacturers. In 1806, the French government reverted back to the old system, using the argument that workers who do not function as a whole cannot produce harmonious products.

Thomas Jefferson, a friend of Blanc, promoted the new approach in the USA. Here the ideas led to the American system of manufacturing. The American system of manufacturing is characterized by the sequential application of specialized machinery and templates (jigs) to make large quantities of identical parts manufactured to a tolerance (see, e.g., [7.4]). Interchangeable parts allow the separation of parts production from assembly, enabling the development of the assembly line. The use of standardized parts furthermore facilitated the replacement of skilled labor and hand tools with specialized machinery, resulting in the economical and fast production of accurate parts.

The American system of manufacturing cannot exist without precision and standards. Firstly, the system requires a unified, standardized method of defining nominal part geometry and tolerances. The tolerances describe the maximum allowed deviations in actual part geometry and other properties that ensure proper functioning of the part, including interchangeability. Secondly, the system requires a quality control system, including sampling and acceptance rules, and gauges calibrated to a common standard to ensure that the parts produced are within tolerance. Thirdly, the system requires manufacturing processes capable of realizing parts that conform to tolerance. It is not surprising that the concept of interchangeable parts first came into widespread use in the watchmakers' industry, an area used to a high level of accuracy [7.5].

Precision remains a key requirement for automation. Precision eliminates fitting and rework, enabling automated assembly of parts produced across the globe. Precision improves agility by increasing the range of tasks that unattended manufacturing equipment can accomplish, while reducing the cost and time spent on production trials and incremental process improvements. Modern manufacturing principles such as lean manufacturing, agile manufacturing, just-in-time manufacturing, and zero-defect manufacturing cannot exist without manufacturing processes that are precise and well characterized.

Automated agile manufacturing, for example, is dependent upon the solution of several precision-related technical challenges. Firstly, as production machines become more agile, they also become more complex, yet precision must be maintained or improved for each of the increasing number of tasks that a machine can perform. The design, maintenance, and testing of these machines becomes more difficult as the level of agility increases. Secondly, the practice of trial runs and iterative accuracy improvements is not cost-effective when batch sizes decrease and new products are introduced at increasing speeds. Instead, the first and every part have to be produced on time and within tolerance. Accordingly, the characterization and improvement of the precision of each manufacturing process becomes a key requirement for competitive automated production.

7.3 Automation as an Enabler of Precision

As stated by *Portas*, *random results are the consequence of random procedures* [7.6]. In general, *random results* appear to be random due to a lack of understanding of cause-and-effect relationships and a lack of resources for controlling sources of variability; for example, an instrument may generate a measurement result that fluctuates over time. Closer inspection may reveal that the fluctuations result from environmental temperature variations that cause critical parts of the instrument to expand and deform. The apparent random variations can thus be reduced by tighter environmental temperature control, use of design principles and materials that make the device less sensitive to temperature variations or application of temperature sensors and algorithms to compensate thermal errors in the instrument reading.

Automation has proven to be very effective in eliminating or minimizing variability. Automation reduces variability associated with human operation. Automation furthermore enables control of instruments, processes, and machines with a bandwidth, complexity, and resolution unattainable by human operators. While humans plan and supervise the operation of machines and instruments, the craftsmanship of the operator is no longer a dominant factor in the actual manufacturing or inspection process.

7.4 Cost and Benefits of Precision

Higher precision requires increased efforts to reduce sources of variability or their effect. Parts with tighter tolerances are therefore more difficult to manufacture and more expensive to produce. In general, there is a belief that there exists a nearly exponential relationship between cost and precision, even when new equipment is not needed. However, greater precision does not necessarily imply higher cost when the total manufacturing enterprise, including the final product, is examined [7.7, 8].

The benefits of higher precision can be separated into benefits for product quality and benefits for manufacturing. Higher precision enables new products and new product capabilities. Other benefits are better product performance (e.g., longer life, higher loads, higher efficiency, less noise and wear, and better appearance and customer appeal), greater reliability, easier repair (e.g., improved interchangeability of parts), and opportunities for fewer and smaller parts; for example, the improvements in the reliability and fuel efficiency of automobiles have to a large extent been enabled by increases in the precision of manufacturing processes and equipment. The benefits of higher precision for manufacturing include lower assembly cost (less selective assembly, elimination of *fitting* and rework, automated assembly), better interchangeability of parts sourced from multiple suppliers, lower inventory requirements, less time and cost spend on trial production, fewer rejects, and improved process consistency.

7.5 Measures of Precision

To achieve precision in a process means that the outcome of the process is highly uniform and predictable over a period of time. Since precision is an attribute of a series of entities or process outcomes, statistical methods and tools are used to describe precision. Traditional statistical measures such as mean and standard deviation are used to describe the average and dispersion of the characteristic parameters. International standards and technical reports provide guidance about how such statistical measures are applied for understanding of the short-term and long-term process behavior and for management and continuous improvement of processes [7.9–12].

Statistical process control is based on a comparison of current data with historical data. Historical data is used to build a model for the expected process behavior, including control limits for measurements of the output of the process. Data is then collected from the process and compared with the control limits to determine if the process is still behaving as expected. Process capability compares the output of an in-control process to the specification limits of the requested task. The *process capability index*, C_p, describes the process capability in relation to specified tolerance

$$C_\text{p} = (U - L)/6\sigma \, , \tag{7.1}$$

where U is the upper specification limit, L is the lower specification limit, σ is the standard deviation of the dispersion (note that in the above equation 6σ corresponds to the reference interval of the dispersion for normal distribution; for other types of distribution the reference interval is determined based on the well-established statistical methods).

The *critical process capability index* C_pk also known as the *minimum process capability index*, describes the relationship between the proximity of the mean process parameter of interest to the specified tolerance

$$C_\text{pk} = \min(C_\text{pkL}, C_\text{pkU}) \, , \tag{7.2}$$

where

$$C_\text{pkU} = (U - \mu)/3\sigma \tag{7.3}$$

and

$$C_\text{pkL} = (\mu - L)/3\sigma \, , \tag{7.4}$$

and μ is the mean of the process parameter of interest.

7.6 Factors That Affect Precision

In case of manufacturing processes, there are many factors that affect the precision of the outcome. They are associated with expected and unexpected variations in environment, manufacturing equipment, and process as well as the operator of the equipment; for example, ambient temperature changes over time or temperature gradients in space cause changes in performance of manufacturing equipment, which in turn causes variation in the outcome [7.13, 14]. Similarly, variations in workpiece material such as local hardness variations, residual stresses, deformations due to clamping or process-induced forces contribute to the variations in critical parameters of finished product. Process-induced variations include wear or catastrophic failures of cutting tools used in the process, thermal variations due to the interaction of coolant, workpiece, and the cutting tool, as well as variations in the set locations of tools used in the process (e.g., cutting tool offsets). In the case of manufacturing equipment, performance variations due to thermal deformations, static and dynamic compliances, influences of foundations, and ineffective maintenance are the contributors to the variations in product critical parameters. Finally, variations caused by the operator of the equipment due to insufficient training, motivation, care or information needed constitute the largest source of unexpected variations and therefore impact on the precision of the manufacturing process.

7.7 Specific Examples and Applications in Discrete Part Manufacturing

The effect of automation on improving of precision of discrete part manufacturing can be observed in many applications such as improvements in fabrication, assembly, and inspection of various components for high-value products. In this Section, one specific perspective is presented using the example of machine tools as the primary means of precision part fabrication.

7.7.1 Evolution of Numerical Control and Its Effects on Machine Tools and Precision

The development of numerically controlled machines represents a major revolution of automation in manufacturing industry. Metal-cutting machine tools are used to produce parts by removing material from a part *blank*, a block of raw material, according to the final desired shape of that part. In general, machine tools consist of components that hold the workpiece and the cutting tool. By providing relative motion between these two, a machine tool generates a cutting tool path which in turn generates the desired shape of the workpiece out of a part blank. In early-generation machine tools, the cutting tool motion is controlled manually (by crank wheels rotating the leadscrews), therefore the quality of the workpiece was mostly the result of the competence of the operator of the machine tool. Before the development of numerically controlled machine tools, complex contoured parts were made by drilling closely spaced holes along the desired contour and then manually finishing the resulting surface to obtain a specified surface finish. This process was very time consuming and prone to errors in locating the holes, which utilized cranks and leadscrews to control the orthogonal movements of the work table manually; for example, the best reported accuracy of airfoil shapes using such techniques was ±0.175 mm [7.15]. Later generation of machine tools introduced capabilities to move the cutting tool along a path by tracing a template using mechanical or hydraulic mechanisms, thus reducing reliance on operator competence [7.16]. On the other hand, creating accurate templates was still a main obstacle to achieving cost-effective precision manufacturing.

Around the late 1940s the US Air Force needed more precise parts for its high-performance (faster, highly maneuverable, and heavier) aircraft program (in the late 1940s the target was around ±0.075 mm). There was no simple way to make wing panels to meet the new accuracy specifications. Manufacturing research community and industry had come up with a solution by introducing numerical control automation to general-purpose machine tools. In 1952, the first numerically controlled three-axis milling machine utilizing a paper tape for programmed instructions, vacuum-tube electronics, and relay-based memory was demonstrated by the Servomechanism Laboratory of the MIT [7.17]. This machine was able to move three axes in coordinated fashion with a speed of about 400 mm/min and a control resolution of 1.25 μm. The automation of machine tools was so effective in improving the accuracy and precision of complex-shaped aircraft components that by 1964 nearly 35 000 numerically controlled machine tools were in use in the USA.

Automation of machine tools by numerical control led to reduction of the need for complex fixtures, tooling, masters, and templates and replaced simple clamps, resulting in significant savings by industry. This was most important for complex parts where human error was likely to occur. With numerical control, once the control program was developed and checked for accuracy, the machine would work indefinitely making the same parts without any error.

7.7.2 Enablers to Improve Precision of Motion

Numerically controlled machine tools rely on sensors that detect positions of each machine component and convert them into digital information. Digital position information is used in control units to control actuators to position the cutting tool properly with respect to the workpiece being cut. The precision of such motion is determined by the resolution of the position sensor (feedback device), the digital control algorithm, and the mechanical and thermal behavior of the machine structural elements. Note that, contrary to manual machine tools, operator skill, experience, and dexterity are not part of the determining factors for the precision of motion. With proper design and environmental controls, it has been demonstrated that machine tools with numerical control can achieve levels of precision on the order of 1 μm or less [7.18, 19].

7.7.3 Modeling and Predicting Machine Behavior and Machining

In most material-removal-based manufacturing processes, the workpiece surfaces are generated as a time record of the position of the cutting tool with respect to the workpiece. The instantaneous position of the tool with respect to the workpiece is generated by the multiple axes of the manufacturing equipment moving in a coordinated fashion. Although the introduction of numerical control (NC) and later computer numerical control (CNC) removed the main source of variation in part quality – manual setups and operations – the complex structural nature of machines providing multi-degree-of-freedom motion and the influence of changing thermal conditions within the structures as well as in the production environment still result in undesired variations, leading to reduced precision of products.

Fig. 7.1 Six error components of a machine slide

Specifically, machine tools are composed of multiple slides, rotary tables, and rotary joints, which are usually assembled on top of each other, each designed to move along a single axis of motion, providing either a translational or a rotational degree of freedom. In reality, each moving element of a machine tool has error motions in six degrees of freedom, three translations, and three rotations (Fig. 7.1). Depending on the number of axes of motion, a machine tool can therefore have as many as 30 individual error components. Furthermore, the construction of moving slides and their assemblies with respect to each other introduce additional error components such as squareness and parallelism between axes of motion.

Recognizing the significant benefits of automation provided by numerical control in eliminating random procedures and thus random behavior, in the last five decades many researchers have focused on understanding the fundamental deterministic behavior of error motions of machine tools caused by geometric and thermal influences such that they can be compensated by numerical control functions [7.20–22]. With the advances of robotics research in the 1980s, kinematic modeling of moving structures using homogeneous transformation matrices became a powerful tool for programming and controlling robotic devices [7.23]. Following these developments and assuming rigid-body motions, a general methodology for modeling geometric machine tool errors was introduced using homogeneous transformation matrices to define the relationships between individual error motions and the resulting position and orientation of the cutting tool with respect to the workpiece [7.24]. Kinematic models were further improved to describe the influences of the thermally induced error components of machine tool motions [7.25, 26].

7.7.4 Correcting Machine Errors

Automation of machine tool operation by computer numerical control and the modeling of machine tool systematic errors led to the creation of new hardware and software error compensation technologies enabling improvement of machine tool performance. Machine error compensation in the form of leadscrew pitch errors has been available since the early implementations of CNC. Such leadscrew error compensation is carried out using error tables in the machine controller. When executing motion commands, the controller accesses these tables to adjust target positions used in motion servo algorithms (feedforward control). The leadscrew error compensation tables therefore provide one-dimensional error compensation. Modern machine controllers have more sophisticated compensation tables enabling two- or three-dimensional error compensation based on preprocess measurement of error motions. For more general error compensation capabilities, researchers have developed other means of interfacing with the controllers. One approach for such an interface was through hardware modification of the communication between the controller and the position feedback devices [7.27]. In this case, the position feedback signals are diverted to an external microcomputer, where they are counted to determine the instantaneous positions of the slides, and corresponding corrections were introduced by modifying the feedback signals before they are read by the machine controller. Similarly, the software approaches to error compensation were also implemented by interfacing with the CNC through the controller executive software and regular input/output (I/O) devices (such as parallel I/O) [7.28]. Generic functional diagrams depicting the two approaches are shown in Fig. 7.2a and b.

Real-time error compensation of geometric and thermally induced errors utilizing automated features of machine controllers has been reported in the literature to improve the precision of machine tools by up to an order of magnitude. Today's commercially available CNCs employ some of these technologies and cost-effectively transfer these benefits to the manufacturing end-users.

7.7.5 Closed-Loop Machining (Automation-Enabled Precision)

Beyond just machine tool control through CNC, automation has made significant inroads into manufacturing operations over the last several decades. From automated inspection using dedicated measuring systems (such as go/no-go gauges situated next to the production equipment) to more flexible and general-purpose inspection systems (such as coordinate measuring machines) automation has improved the quality control of manufacturing processes, thereby enabling more precise production.

Automation has even changed the paradigm of traditional quality control functions. Traditionally, the function of quality control in manufacturing has been the prevention of defective products being shipped to the customers. Automation of machining, machine error correction, and part inspection processes have led to new quality control strategies in which real-time control of processes is possible based on real-time information about the machining process and equipment and the resulting part geometries.

In the mid 1990s, the Manufacturing Engineering Laboratory of the National Institute of Standards and Technology demonstrated such an approach in a research project called *Quality In Automation* [7.29]. A quality-control architecture was developed that consisted of three control loops around the machining process: real-time, process-intermittent, and postprocess control loops (Fig. 7.3).

The function of the real-time control loop was to monitor the machine tool and the machining process and to modify the cutting tool path, feed rate, and spindle speed in real time (based on models developed ahead of time) to achieve higher workpiece precision. The function of the process-intermittent con-

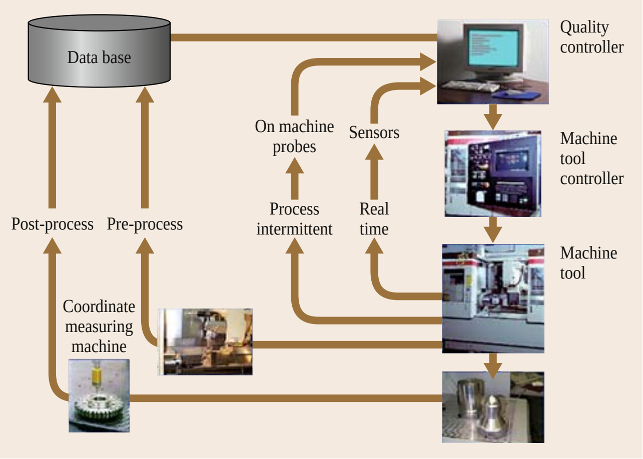

Fig. 7.3 A multilayered quality-control architecture for implementing closed-loop machining

trol loop was to determine the workpiece errors caused by the machining process, such as errors caused by tool deflection during machining, and to correct them by automatically generating a modified NC program for finishing cuts. Finally, the postprocess control loop was used to validate that the machining process was under control and to tune the other two control loops by detecting and correcting the residual systematic errors in the machining system.

7.7.6 Smart Machining

Enabled by automation, the latest developments in machining are leading the technology towards the realization of autonomous, smart machining systems. As described in the paragraphs above, continuous improvements in machining systems through NC and CNC as well as the implementations of various sensing and control technologies have responded to the continuous needs for higher-precision products at lower costs. However, machining systems still require relatively long periods of trial-and-error processing to produce a given new product optimally. Machine tools still operate with NC programs, which provide the design intent of a product to be machined only partially at best. They have no information about the characteristics of the material to be machined. They require costly periodic maintenance to avoid unexpected breakdowns. These deficiencies increase cost and time to market, and reduce productivity.

Smart machining systems are envisioned to be capable of self-recognition, monitoring, and communication of their capabilities; self-optimization of their operations; self-assessment of the quality of their own work; and self-learning for performance improvement over time [7.30]. The underlying technologies are currently being developed by various research and development organizations; for example, a robust optimizer developed at the National Institute of Standards and Technology demonstrated a way to integrate machine tool performance information and process models with their associated uncertainties to determine the optimum operating conditions to achieve a particular set of objectives related to product precision, cycle time, and cost [7.31–33]. New sets of standards are being developed to define the data formats to communicate machine performance information and other machine characteristics [7.34, 35]. New methods to determine material properties under machining conditions (high strain rates and high temperatures) were developed to improve the machining models that are used in machining optimization [7.36]). New signal-processing algorithms are being developed to monitor the condition of machine spindles and predict failures before catastrophic breakdowns. It is expected that in the next 5–10 years smart machining systems will be available in the marketplace, providing manufacturers with cost-effective means of achieving high-precision products reliably.

7.8 Conclusions and Future Trends

Automation is a key enabler to achieve cost-effective, high-quality products and services to drive society's economical engine. The special duality relationship between automation and precision (each driving the other) escalate the effectiveness of automation in many fields. In this chapter this relationship was described from a relatively narrow perspective of discrete part fabrication. Tighter tolerances in product components that lead to high-quality products are only made possible by a high degree of automation of the manufacturing processes. This is one of the reasons for the drive towards more manufacturing automation even in countries with low labor costs. The examples provided in this chapter can easily be extended to other economic and technological fields, demonstrating the significant effects of automation.

Recent trends and competitive pressures indicate that more knowledge has been generated about processes, which leads to the reduction of apparent nonsystematic variations. With increased knowledge and technical capabilities, producers are developing more complex, high-value products with smaller numbers of components and subassemblies. This trend leads to even more automation with less cost.

8. Trends in Automation

Peter Terwiesch, Christopher Ganz

The present chapter addresses automation as a major means for gaining and sustaining productivity advantages. Typical market environment factors for plant and mill operators are identified, and the analysis of current technology trends allows us to derive drivers for the automation industry.

A section on current trends takes a closer look at various aspects of integration and optimization. Integrating process and automation, safety equipment, but also information and engineering processes is analyzed for its benefit for owners during the lifecycle of an installation. Optimizing the operation through advanced control and plant asset monitoring to improve the plant performance is then presented as another trend that is currently being observed. The section covers system integration technologies such as IEC61850, wireless communication, fieldbuses, or plant data management. Apart from runtime system interoperability, the section also covers challenges in engineering integrated systems.

The section on the outlook into future trends addresses the issue of managing increased complexity in automation systems, takes a closer look at future control schemes, and takes an overall view on automation lifecycle planning.

Any work on prediction of the future is based on an extrapolation of current trends, and estimations of their future development. In this chapter we will therefore have a look at the trends that drive the automation industry and identify those developments that are in line with these drivers.

Like in all other areas of the industry, the future of automation is driven by market requirements on one hand and technology capabilities on the other hand. Both have undergone significant changes in recent years, and continue to do so.

In the business environment, globalization has led to increased worldwide competition. It is not only Western companies that use offshore production to lower their cost; it is more and more also companies from upcoming regions such as China and India that go global and increase competition. The constant strive for increased productivity is inherent to all successful players in the market.

In this environment, automation technology benefits from the rapid developments in the information technology (IT) industry. Whereas some 15 years ago automation technology was mostly proprietary, today it builds on technology that is being applied in other fields. Boundaries that have clearly been defined due to the incompatibility of technologies are now fully transparent and allow the integration of various requirements throughout the value chain. Field-level data is distributed throughout the various networks that control a plant, both physically and economically, and can be used for analysis and optimization.

To achieve the desired return, companies need to exploit all possibilities to further improve their production or services. This affects all automation levels from field to enterprise optimization, all lifecycle stages from plant erection to dismantling, and all value chain steps from procurement to service.

In all steps, on all levels, automation may play a prominent role to optimize processes.

8.1 Environment

8.1.1 Market Requirements

Today, even more than in the past, all players in the economy are constantly improving their competitiveness. Inventing and designing differentiating offerings is one key element to achieve this. Once conceived, these offerings need to be brought to market in the most efficient way.

To define the efficiency of a plant or service, we therefore define a measure to rate the various approaches to optimization: The overall equipment effectiveness (OEE). It defines how efficiently the equipment employed is performing its purpose.

Operational Excellence

Looking at the graph in Fig. 8.1, we can clearly see what factors influence a plant owner's return based on the operation of his plant (the graph does not include factors such as market conditions, product differentiation, etc.). The influencing factors are on the cost side, mainly the maintenance cost. Together with plant operation, maintenance quality then determines plant availability, performance, and production quality. From an automation perspective, other factors such as system architecture (redundancy) and system flexibility also have an influence on availability and performance. Operation costs, such as cost of energy/fuel, then have an influence on the product cost.

Future automation system developments must influence these factors positively in order to find wide acceptance in the market.

New Plant Construction

Optimizing plant operations by advanced automation applications is definitely an area where an owner gets most of his operational benefits. An example of the level of automation on plant operations can be seen in Figs. 8.2 and 8.3. When it comes to issues high on the priority list of automation suppliers, delivery costs are as high if not even higher. Although the main benefit of an advanced automation system is with the plant owner (or operator), the automation system is very often not directly sold to that organization, but to an engineering, procurement, and contsruction (EPC) contractor instead. And for these customers, price is one of the top decision criteria.

As automation systems are hardly ever sold off the shelf, but are designed for a specific plant, engineering costs are a major portion of the price of an automation system.

An owner who buys a new automation system looks seriously at the engineering capabilities of the supplier. The effect of efficient engineering on lowering the offer price is one key item that is taken into account. In today's fast developments in the industry, very often the ability to deliver in time is as important as bottom-line price. An owner is in many cases willing to pay a pre-

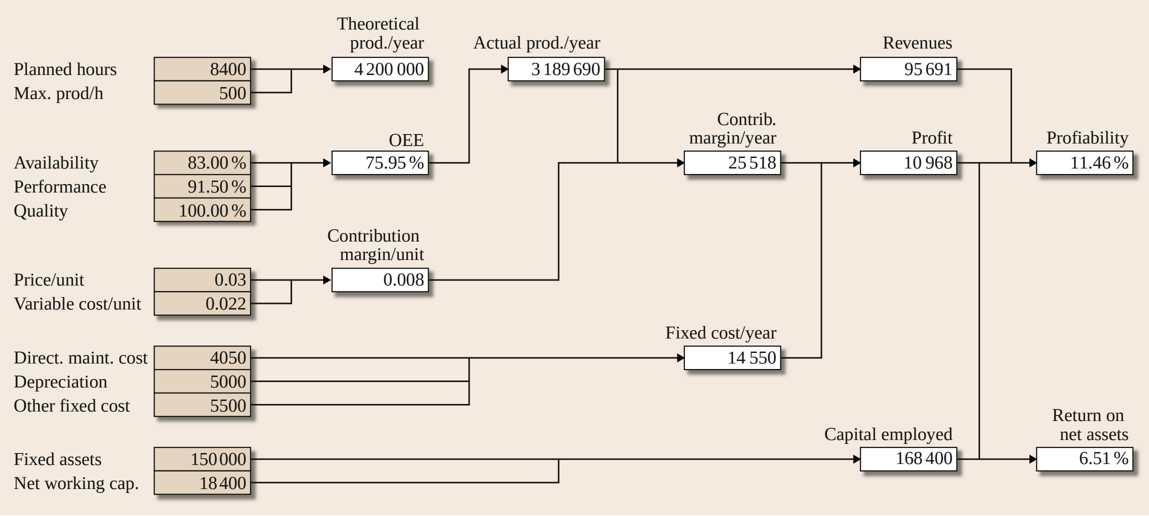

Fig. 8.1 Overall equipment effectiveness

Fig. 8.2 Control of plant operations in the past

mium for a short delivery time, but also for a reduced risk in project execution. Providing expertise from previous projects in an industry is required to keep the execution risk manageable. It also allows the automation company to continuously improve the application design, reuse previous solutions, and therefore increase the quality and reduce the cost of the offering. When talking about the future of automation, engineering will therefore be a major issue to cover.

Plant Upgrades and Extensions

Apart from newly installed greenfield projects, plant upgrades and extensions are becoming increasingly important in the automation business. Depending on the extent of the extension, the business case is similar to the greenfield approach, where an EPC is taking care of all the installations. In many cases however, the owner takes the responsibility of coordinating a plant upgrade. In this case, the focus is mostly on total cost of ownership.

Fig. 8.3 Trend towards fully automated control of plant operations

Furthermore, questions such as compatibility with already installed automation components, upgrade strategies, and integration of old and new components become important to obtain the optimal automation solution for the extended plant.

8.1.2 Technology

Increasingly, automation platforms are driven by information technology. While automation platforms in the past were fully proprietary systems, today they use common IT technology in most areas of the system [8.1]. On the one hand, this development greatly reduces development costs for such systems and eases procurement of off-the-shelf components. On the other hand, the lifecycle of a plant (and its major component the automation system), and IT technology greatly differs. Whereas plants follow investment cycles of 20–30 years, IT technology today at first sight has reached a product lifecycle of less than 1 year, although some underlying technologies may be as old as 10 years or more (e.g., component object model (COM) technology, an interface standard introduced by Microsoft in 1993).

Due to spare parts availability and the lifecycle of software, it is clear that an automation life span of 20 years is not achievable without intermediate updates of the system. A future automation system therefore needs to bridge this wide span of lifecycle expectations and provide means to follow technology in a manner that is safe and efficient for the plant.

Large investments such as field instrumentation, cabling and wiring, engineered control applications, and operational data need to be preserved throughout the lifecycle of the system. Maintaining an automation system as one of the critical assets of a plant needs to be taken into consideration when addressing plant lifecycle issues. In these considerations, striking the right balance between the benefits of standardized products, bringing quality, usability, cost, and training advantages, and customized solutions as the best solution for a given task may become critical.

8.1.3 Economical Trends

In today's economy, globalization is named as the driver for almost everything. However, there are some aspects apart from global price competitiveness that do have an influence on the future of automation.

Communication technology has enabled companies to spread more freely over the globe. While in the past a local company had to be more or less self-supporting (i. e., provide most functions locally), functions can today be distributed worldwide. Front- and back-office organizations no longer need to be under the same roof; development and production can be continents apart. Even within the same project, global organizations can contribute from various locations.

These organizations are interlinked by high-bandwidth communication. These communication links not only connect departments within a company, they also connect companies throughout the value chain. While in earlier days data between suppliers and customers were exchanged on paper in mail (with corresponding time lags), today's interactions between suppliers and customers are almost instant.

In today's business environment, distances as well as time are shorter, resulting in an increase in business interactions.

8.2 Current Trends

8.2.1 Integration

Looking at the trends and requirements listed in the previous Sections, there is one theme which supports these developments, and which is a major driver of the automation industry: integration. This term appears in various aspects of the discussions around requirements, in terms of horizontal, vertical, and temporal integration, among others. In this Section we will look at various trends in integration and analyze their effect on business.

Process Integration

Past approaches to first develop the process and then design the appropriate control strategy for it do not exploit the full advantages of today's advanced control capabilities. If we look at this under the overall umbrella of integration, there is a trend towards integrated design of process and control.

In many cases, more advanced automation solutions are required as constraints become tighter. Figures 8.4–8.6 show examples which highlight the greater degree and complexity of models (i. e., growing number of constraints, reduction in process buffers, and nonlinear dynamic models). There is an ongoing trend towards tighter hard constraints, imposed from regulating authorities. Health, safety, and especially environmental constraints are continuously becoming tighter.

Controllers today not only need to stabilize one control variable, or keep it within a range of the set-point. They also need to make sure that a control action does not violate environmental constraints by producing too much of a by-product (e.g., NO_x). Since many of these boundary conditions are penalized today, these control actions may easily result in significant financial losses or other severe consequences.

In addition to these hard constraints, more and more users want to optimize soft constraints, such as energy consumption (Fig. 8.7), or plant lifecycle. If one ramps up production in the fastest way possible (and maybe meet some market window or production deadline), energy consumed or plant lifecycle consumption due to increased stress on components may compensate these quick gains. An overall optimization problem that takes these soft constraints into account can therefore result in returns that are not obvious even to the experienced operator.

A controller that can keep a process in tighter constraints furthermore allows an owner to optimize process equipment. If the control algorithm can guarantee a tight operational band, process design can reduce buffers and spare capacity. Running the process closer

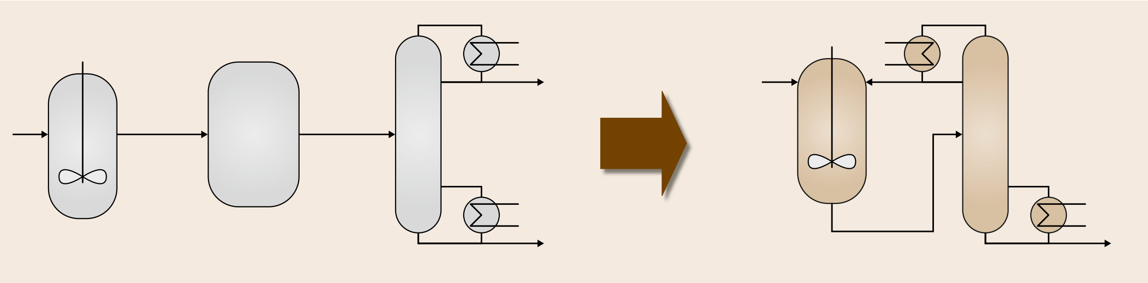

Fig. 8.4 Trend towards reduction of process buffers (e.g., supply chain, company, site, unit)

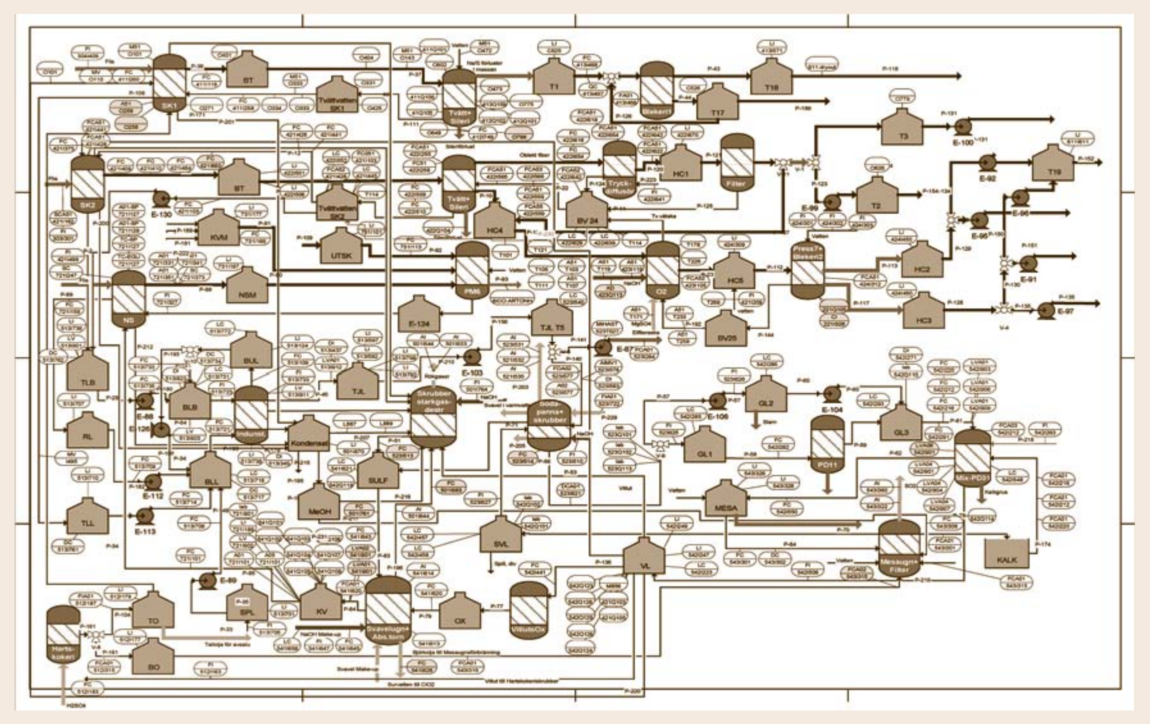

Fig. 8.5 Trend towards broader scope, more complex, and integrated online control, for example, in pulp operations

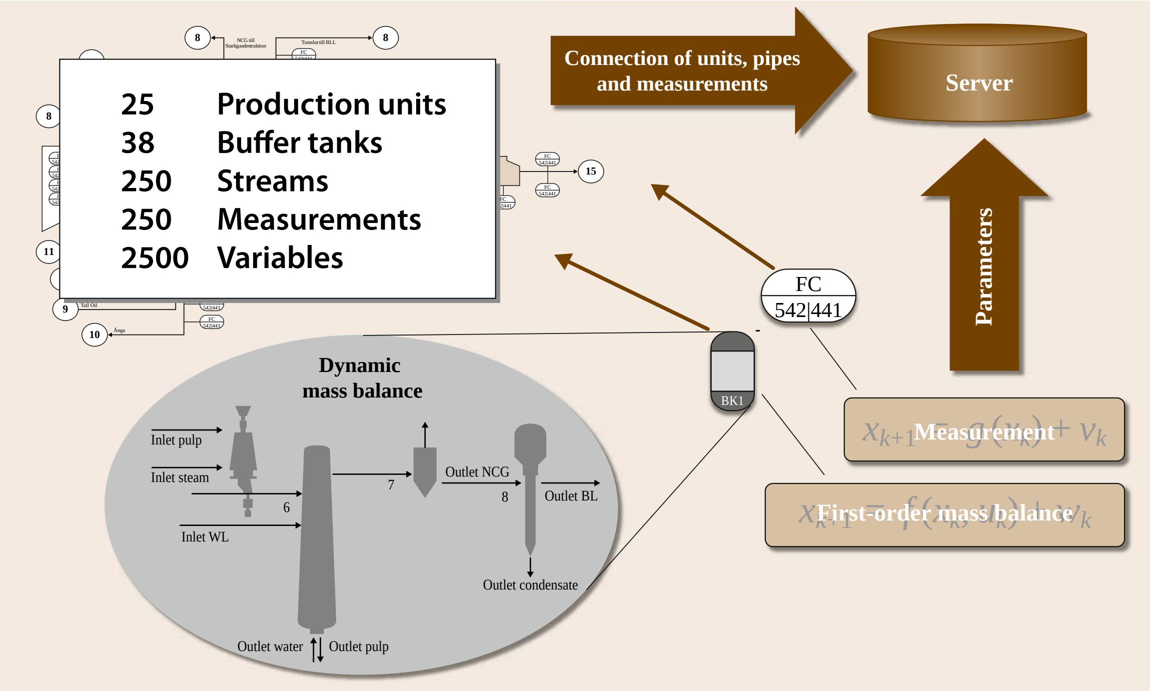

Fig. 8.6 Trend towards a nonlinear dynamic model

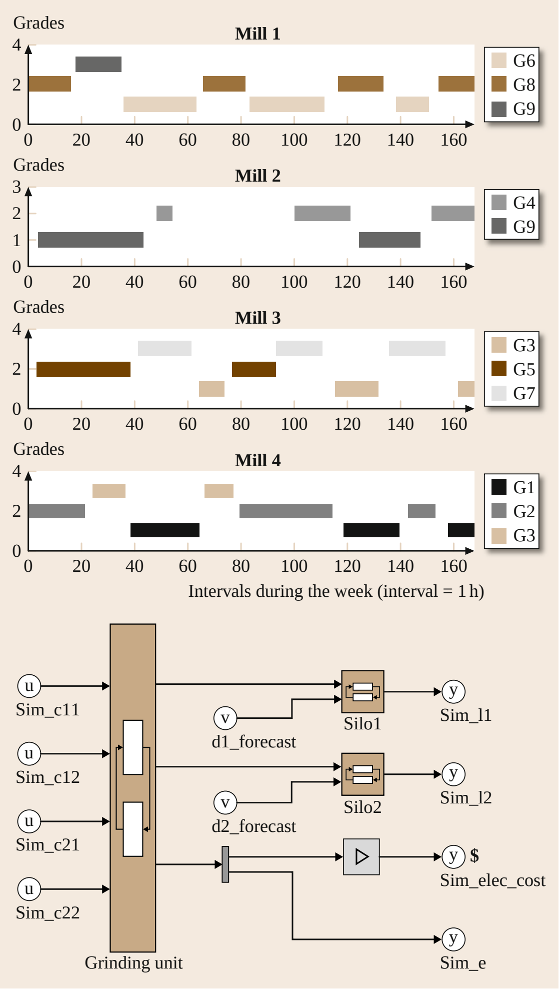

Fig. 8.7 Trend towards automated electrical energy management

to its design limitations results in either higher output, more flexibility, faster reaction or allows to install smaller (and mostly cheaper) components to achieve the same result.

A reduction of process equipment is also possible if advanced production management algorithms are in place. Manual scheduling of a process is hardly ever capable to load all equipment optimally, and the solution to a production bottleneck is frequently solved by installing more capacity. In this case as well, the application of an advanced scheduling algorithm may show that current throughput can be achieved with less equipment, or that current equipment can provide more capacity than expected.

By applying advanced control and scheduling algorithms, not only can an owner increase the productivity of the installed equipment, but he may also be able to reduce installed buffers. Intermediate storage tanks or queues can be omitted if an optimized control scheme considers a larger part of the production facility. In addition to reducing the investment costs by reducing equipment, the reduction of buffers also results in a reduction of work in progress, and in the end allows the owner to run the operation with less working capital.

Looking at the wide impact of more precise control algorithms (which in many cases implies more advanced algorithms) on OEE, we can easily conclude that once these capabilities in control system become more easily available, users will adopt them to their benefit.

Example: Thickness Control in Cold-Rolling Mills Using Adaptive MIMO Controller. In a cold-rolling mill, where a band of metal is rolled off an input coil, run through the mill to change its thickness, and then rolled onto an output coil, the torques of the coilers and the roll position are controlled to achieve a desired output thickness, uncoiler tension, and coiler tension. The past solution was to apply single-loop controllers for each variable together with feedforward strategies.

The approach taken in this case was to design an adaptive multiple-input/multiple-output (MIMO) controller that takes care of all variables. The goal was to improve tolerance over the whole strip length, improve quality during ramp-up/ramp-down, and enable higher speed based on better disturbance rejection. Figure 8.8 shows the results from the plant with a clear improvement by the new control scheme [8.2].

By applying the new control scheme, the operator was able to increase throughput and quality, two inputs of the OEE model shown in Fig. 8.1.

Integrated Safety

The integration of process and automation becomes critical in safety applications. Increasingly, safety-relevant actions are moved from process design into the automation system. With similar motivations as we have seen before, a plant owner may want to reduce installed process equipment in favor of an automation solution, and replace equipment that primarily serves safety purposes by an emergency shutdown system.

Today's automation systems are capable of fulfilling these requirements, and the evolution of the IEC 61508 standard [8.3] has helped to develop a common understanding throughout the world. The many local standards have mostly been replaced by IEC 61508's

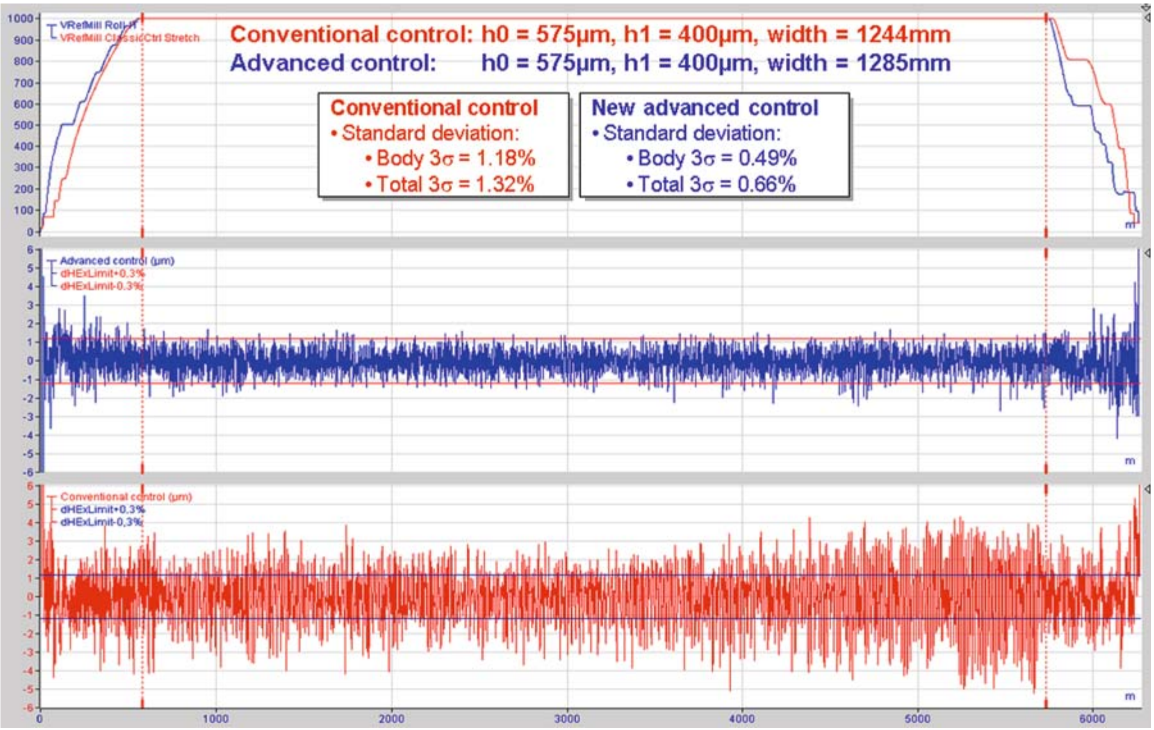

Fig. 8.8 Cold-rolling mill controller comparison

safety integrity level (SIL) requirements. Exceeding the scope of previous standards, ICE61508 not only defines device features that enable them to be used in safety critical applications, it also defines the engineering processes that need to be applied when designing electrical safety systems.

Many automation suppliers today provide a safety-certified variant of their controllers, allowing safety solutions to be tightly integrated into the automation system. Since in many cases these are specially designed and tested variants of the general-purpose controllers, they are perceived having a guaranteed higher quality with longer mean time between failures (MTBF) and/or shorter mean time to repair (MTTR). In some installations where high availability or high quality is required without the explicit need for a certified safety system, plant owners nevertheless choose the safety-certified variant of a system to achieve the desired quality attributes in their system.

A fully integrated safety system furthermore increases planning flexibility. In a fully integrated system, functionality can be moved between the safety controllers and regular controllers, allowing for a fully scalable system that provides the desired safety level. For more information on safety in automation please refer to Chap. 39.

Information Integration

Device and System Integration

Intelligent Field Devices and their Integration. When talking about information integration, some words need to be spent on information sources in an automation system, i. e., on field devices.

Field devices today not only provide a process variable. Field devices today benefit from the huge advancements in miniaturization, which allows manufacturers to move measurement and even analysis functions from the distributed control system (DCS) into the field device. The data transmitted over fieldbuses not only consists of one single value, but of a whole set of information on the measurement. Quality as well as configuration information can be read directly from the device and can be used for advanced asset monitoring. The amount of information available from the field thus greatly increases and calls for extended processing capabilities in the control system.

Miniaturization and increased computing power also allow the integration of ultrafast control loops on the field level, i. e., within the field device, that are not feasible if the information has to traverse controllers and buses.

All these functions call for higher integration capabilities throughout the system. More data needs to be transferred not only from the field to the controller, but since much of the information is not required on the process control level but on the operations or even at the plant management level, information needs to be distributed further. Information management requirements are also increased and call for more and faster data processing.

In addition to the information exchanged online, intelligent field devices also call for an extended reach of engineering tools. Since these devices may include control functionality, planning an automation concept that spreads DCS controllers and field devices requires engineering tools that are capable of drawing the picture across systems and devices.

The increased capabilities of the field devices immediately create the need for standardization. The landscape that was common 20 years ago, where each vendor had his own proprietary integration standard, is gone. In addition to the fieldbus standards already widely in use today, we will look at IEC 61850 [8.4] as one of the industrial Ethernet-based standards that has recently evolved and gained wide market acceptance in short time.

Fieldbus. For some years now, the standard to communicate towards field devices is fieldbus technology [8.5], defined in IEC 61158 [8.6]. All major fieldbus technologies are covered in this standard, and depending on the geographical area and the industry, in most cases one or two of these implementations have evolved to be the most widely used in an area. In process automation, Foundation Fieldbus and Profibus are among the most prominent players.

Fieldbus provides the means for intelligent field devices to communicate their information to each other, or to the controller. It allows remote configuration as well as advanced diagnostics information.

In addition to the IEC 61158 protocols that are based on communication on a serial bus, the HART protocol (highway addressable remote transducer protocol, a master-slave field communication protocol) has evolved to be successful in existing, conventionally wired plants. HART adds serial communication on top of the standard 4–20 mA signal, allowing digital information to be transmitted over conventional wiring.

Fieldbus is the essential technology to further integrate more information from field devices into complex automation systems.

IEC 61850. IEC 61850 is a global standard for *communication networks and systems in substations*. It is a joint International Electrotechnical Commission (IEC) and American National Standards Institute (ANSI) standard, embraced by all major electrical vendors. In addition to just focusing on a communication protocol, IEC 61850 also defines a data model that comprises the context of the transmitted information. It is therefore one of the more successful approaches to achieve true interoperability between devices as well as tools from different vendors [8.7].

IEC 61850 defines all the information that can be provided by a control function through the definition of logical nodes. Substation automation devices can then implement one or several of these functions, and define their capabilities in standardized, extensible markup language (XML)-based data files, which in turn can be read by all IEC 61850-compliant tools [8.8].

System integration therefore becomes much faster than in the past. Engineering is done on an object-oriented level by linking functions together (Fig. 8.9). The configuration of the communication is then derived from these object structures without further manual engineering effort.

Due to the common approach by ANSI and IEC, by users and vendors, this standard was adopted very quickly and is today the common framework in substation automation around the world.

Once an owner has an electrical system that provides IEC 61850 integration, the integration into the plant DCS is an obvious request. To be able to not only communicate to an IEC 61850-based electrical system directly from the DCS, but also to make use of all object-oriented engineering information is a requirement that is becoming increasingly important for major DCS suppliers.

Wireless. When integrating field devices into an automation system, the availability of standard protocols is of great help, as we have seen in *Device and System Integration*. In the past this approach was very often either limited to new plant installations where cable trays were easily accessible, or resulted in very high installation costs. The success of the HART protocol is mainly due to the fact that it can reuse existing wiring [8.9].

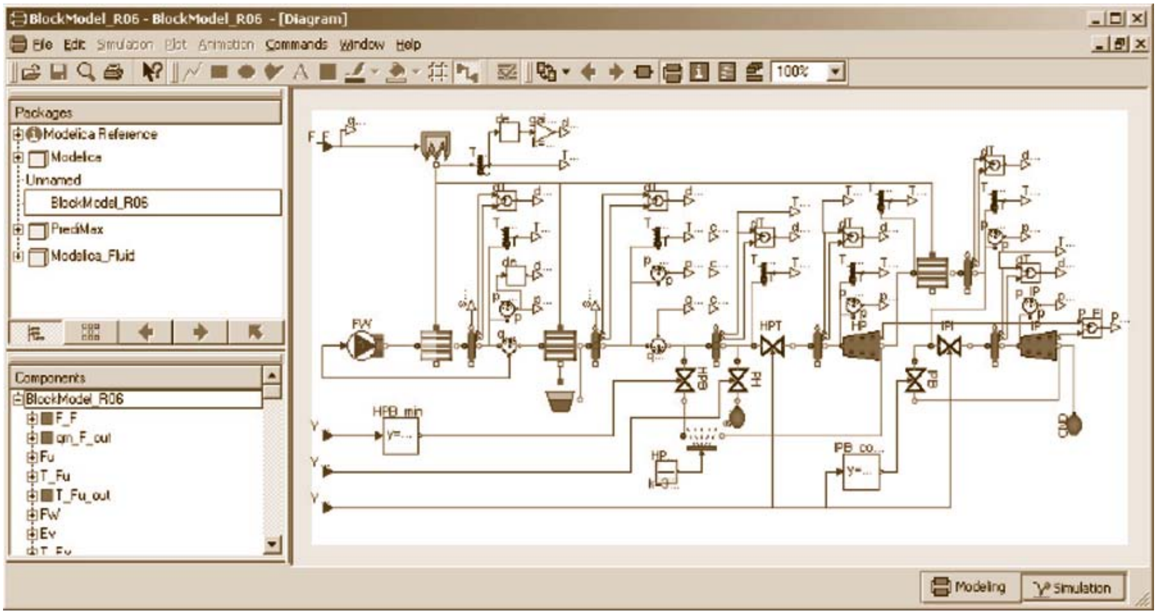

Fig. 8.9 Trend towards object-oriented modeling, e.g., visual flowsheet modeling; combined commodity models with proprietary knowledge; automatic generation of stand-alone executable code

The huge success of wireless technology in other areas of daily life raises the question of whether this technology can also be applied to automation problems. As recent developments have shown, this trend is continuously gaining momentum [8.10]. Different approaches are distinguished as a function of how power is supplied, e.g., by electrical cable, by battery or by power harvesting from their process environment, and by the way the communication is implemented.

As with *wired* communications, also wireless summarizes a variety of technologies which will be discussed in the following sections.

Close Range. In the very close range, serial communication today very often makes use of Bluetooth technology. Originating from mobile phone accessory integration, similar concepts can also be applied in situations in which devices need to communicate over a short distance, e.g., to upgrade firmware, or to read out diagnostics. It merely eliminates the need for a serial cable, and in many cases the requirement to have close-range interaction with a device has been removed completely, since it is connected to the system through other serial buses (such as a fieldbus) that basically allow the user to achieve the same results.

Another upcoming technology under the wireless umbrella is radio frequency identification (RFID). These small chips are powered by the electromagnetic field set up to communicate by the sensing device. RFID chips are used to mark objects (e.g., items in a store), but can also be used to mark plant inventory and keep track of installed components. Chapter 49 discusses RFID technology in more detail.

RFID can not only be used to read out information about a device (such as a serial number or technical data), but to store data dynamically. The last maintenance activity can thus be stored on the device rather than in a plant database. The device keeps this information attached while being stored as spare part, even if it is disconnected from the plant network. When looking for spares, the one with the fewest past operating hours can therefore be chosen. RFID technology today allows for storage of increasing amounts of data, and in some cases is even capable of returning simple measurements from an integrated sensor.

Information stored on RFID chips is normally not accessed in real time through the automation system, but read out by the maintenance engineer walking through the plant or spare parts storage with the corresponding reading device. To display the full information on the device (online health information, data sheet, etc.) a laptop or tablet personal computer (PC) can then retrieve the information online through its wireless communication capability.

Mid-range. Apart from distributing online data to mobile operator terminals throughout the plant, WiFi has made its entrance also on the plant floor.

The aforementioned problem, where sensors cannot easily be wired to the main automation system, is increasingly being solved by the use of wireless communication, reducing the need and cost for additional cabling.

Applications where the installation of wired instruments is difficult are growing, including where:

- The device is in a remote location.
- The device is in an environment that does not allow for electrical signal cables, e.g., measurements on medium- or high-voltage equipment.
- The device is on the move, either rotating, or moving around as part of a production line.
- The device is only installed temporarily, either for commissioning, or for advanced diagnostics and precise fault location.

The wide range of applications has made wireless device communication one of the key topics in automation today.

Long Range. Once we leave the plant environment, wireless communication capabilities through GSM (global system for mobile communication) or more advanced third-generation (3G) communication technologies allow seamless integration of distributed automation systems.

Applications in this range are mostly found in distribution networks (gas, water, electricity), where small stations with low functionality are linked together in a large network with thousands of access points.

However, also operator station functionality can be distributed over long distances, by making thin-client capability available to handheld devices or mobile phones. To receive a plant alarm through SMS (short message service, a part of the GSM standard) and to be able to acknowledge it remotely is common practice in unmanned plants.

Nonautomation Data. In addition to real-time plant information that is conveyed thorough the plant automation system, plant operation requires much more information to run a plant efficiently. In normal operation as well as in abnormal conditions, a plant operator or a maintenance engineer needs to switch quickly between different views on the process. The process display shows the most typical view, and trend displays and event lists are commonly use to obtain the full picture on the state of the process. To navigate quickly between these displays is essential. To call up the process display for a disturbed object directly from the alarm list saves critical time.

Once the device needs further analysis, this normally requires the availability of the plant documentation. Instead of flipping through hundreds of pages in documentation binders, it is much more convenient to directly open the electronic manual on the page where the failed pump is described together with possibilities to initiate the required maintenance actions.

Availability of the information in electronic format is today not an issue. Today, all plant documentation is provided in standard formats. However, the information is normally not linked. It is hardly possible to directly switch between related documents without manual search operations that look for the device's tag or name.

An object-oriented plant model that keeps references to all aspects of a plant object greatly helps in solving this problem. If in one location in the system, all views on the very same object are stored – process display, faceplate, event list, trend display, manufacturer instructions, but also maintenance records and inventory information – a more complete view of the plant state can be achieved.

The reaction to process problems can be much quicker, and personnel in the field can be guided to the source of the problem faster, thus resolving issues more efficiently and keeping the plant availability up. We will see in *Lifecycle Optimization* how maintenance efficiency can even be increased by advanced asset management methods.

Security. A general view on the future of automation systems would not be complete without covering the most prominent threat to the concepts presented so far: system security.

When systems were less integrated, decoupled from other information systems, or interconnected by 4–20 mA or binary input/output (I/O) signals, system security was limited to physical security, i. e., to prevent unauthorized people access the system by physical means (fences, building access, etc.).

Integrating more and more information systems into the automation system, and enabling them to distribute data to wherever it is needed (i. e., also to company headquarters through the Internet), security threats soon become a major concern to all plant owners.

The damage that can be caused to a business by negligence or deliberate intrusion is annoying when web sites are blocked by denial-of-service attacks. It is significant if it affects the financial system by spyware or phishing attacks, but it is devastating when a country's infrastructure is attacked. *Simply* bringing down the electricity system already has quite a high impact, but if a hacker gains access to an automation system, the plant can actually be damaged and be out of service for a significant amount of time. The damage to a modern society would be extremely high.

Security therefore has to be at the top of any list of priorities for any plant operator. Security measures in automation systems of the future need to be continuously increased without giving up some of the advantages of wider information integration.

In addition to technical measures to keep a plant secure, security management needs to be an integral part of any plant staff member's training, as is health and safety management today.

While security concerns for automation systems are valid and need to be addressed by the plant management, technical means and guidance on security-related processes are available today to secure control systems effectively [8.11]. Security concerns should therefore not be the reason for not using the benefits of information integration in plants and enterprises.

Engineering Integration

The increased integration of devices and systems from plant floor to enterprise management poses another challenge for automation engineers: information integration does not happen by itself, it requires significant engineering effort. This increased effort is a contradiction to the requirement for faster and lower-cost project execution. This dilemma can only be resolved by improved engineering environments. Chapter 86, enterprise integration and interoperability, delves deeper into this topic.

Today, all areas of plant engineering, starting at process design and civil engineering, are supported by specialized engineering tools. While their coupling was loose in the past, and results of an engineering phase were handed over on paper and very often typed into other tools again, the trend towards exchanging data in electronic format is obvious. Whoever has tried to exchange data between different types of engineering tools immediately faces the questions:

- What data?
- What format?

The question about what data can only be answered by the two parties exchanging data. The receiver only knows what data he needs, and the provider only knows what data she can provide. If the two parties are within different departments of the same company, an internal standard on data models can be agreed on, but when the exchange is between different business partners, this very often results in a per-project agreement.

In electrical systems, this issue has been addressed by IEC 61850. In addition to being a communication standard, it also covers a data model. Data objects (logical nodes) are defined by the standard, and engineering tools following the standards can easily integrate devices of various vendors without project specific agreements. The standard was even extended beyond electrical systems to cover hydropower plants (and also for wind generators in IEC 61400-25). So far, further extensions into other plant types or industries seem hardly feasible due to the variance and company internal-grown standards.

The discussion on the format today quickly turns into a spreadsheet-based solution. This approach is very common, and most tools provide export and/or import functionality in tabular form. However, this requires separate sheets for each object type, since the data fields may vary between objects. A format that supports a more object-oriented approach is required.

Recently, the most common approach is to go towards XML-based formats. IEC 61850 data is based on XML, and there are standardization tendencies that follow the same path. CAEX (computer aided engineering exchange, an engineering data format) according to IEC 62424 is just one example; PLCOpen XML or AutomationML are others.

The ability to agree on data standards between engineering tools greatly eases interaction between the various disciplines not only in automation engineering, but in plant engineering in general.

Once the data format is defined, there still remains the question of wording or language. Even when using the same language, two different engineering groups may call the same piece of information differently. A semantic approach to information processing may address this issue.

With some of these problems addressed in a nearer future, further optimization is possible by a more parallel approach to engineering. Since information is revised several times during plant design, working with early versions of the information is common. Updates of the information is normally required, and then updating the whole engineering chain is a challenge. To work on a common database is a trend that is evolving in plant design; but also in the design of the automation system, a common database to hold various aspects of automation engineering is an obvious idea. Once these larger engineering environments are in place, data exchange quickly becomes bidirectional. Modifications done in plant design affect the automation system, but also information from the automation database such as cabling or instrumentation details should be fed back into the plant database. This is only possible if the data exchange can be done without loss of information, otherwise data relations cannot be kept consistent.

Even if bidirectional data exchange is solved, more partners in complex projects easily result in multidirectional data exchange. Versioning becomes even more essential than in a single tool. Whether the successful solution of data exchange between two domains can be kept after each of the tools is released in a new version remains to be seen. The challenges in this area are still to be faced.

Customer Value

The overall value of integration for owners is apparent on various levels, as we have shown in the previous Sections.

The pressure to shorten projects and to bring down costs will increase the push for engineering data integration. This will also improve the owner's capability to maintain the plant later by continuously keeping the information up to date, therefore reducing the lifecycle cost of the plant.

The desire to operate the plant efficiently and keep downtimes low and production quality up will drive the urge to have real-time data integrated by connecting interoperable devices and systems on all levels of the automation system [8.12]. The ability to have common event and alarm lists, to operate various type of equipment from one operator workplace, and to obtain consistent asset information combined in one system are key enablers for operational excellence.

Security concerns require a holistic approach on the level of the whole plant, integrating all components into a common security framework, both technically and with regard to processes.

8.2.2 Optimization

The developments described up to now enable one further step in productivity increase that has only been partially exploited in the past. Having more information available at any point in an enterprise allows for a typical control action: to close the loop and to optimize.

Control

Closest to the controlled process, closing the loop is the traditional field of automation. PID controllers (proportional-integral-derivative) mostly govern today's world of automation. Executed by programmable logic controllers (PLC) or DCS controllers, they do a fairly good job at keeping the majority of industrial processes stable.

However, even if much more advanced control schemes are available today, not even the ancient PID loops perform where they could if they were properly tuned. Controller tuning during commissioning is more of an art done by experienced experts than engineering science.

As we have already concluded in *Process Integration*, several advantages favor the application of advanced control algorithms. Their ability to keep processes stable in a narrower band allows either to choose smaller equipment to reach a given limit, or to increase the performance of existing equipment by running the process closer to boundaries.

However, controllers today are mostly designed based on knowledge of a predominantly fixed process, i. e., plant topology and behavior is assumed to be as-designed. This process knowhow is often depicted in a process model which is either used as part of the controller (e.g., model predictive control) or has been used to design the controller.

Once the process deviates from the predefined topology, controllers are soon at their limits. This can easily happen when sensors or communication links fail. This situation is today mostly solved by redundant design, but controllers that consider some amount of missing information may be an approach to increase the reliability of the control system even further. Controllers reacting more flexibly to changing boundary conditions will extend the plant's range of operation, but will also reduce predictability.

Another typical case of a plant deviating from the designed state is ageing or equipment degradation. Controllers that can handle this (e.g., adaptive control) can keep the process in an optimal state even if its components are not. Furthermore, a controller reacting on performance variations of the plant can not only adapt to it, but also convey this information to the maintenance personnel to allow for efficient plant management and optimization.

Plant Optimization

At a plant operation level, all the data generated by intelligent field devices and integrated systems comes together. To have more information available is positive, but to the plant operator it is also confusing. More devices generating more diverse alarms quickly flood a human operator's perception. More information does not per se improve the operation of a plant. Information needs to be turned into knowledge.

This knowledge is buried in large amounts of data, in the form of recorded analog trend signals as well as alarm and event information. Each signal in itself only tells a very small part of the story, but if a larger number of signals are analyzed by using advanced signal processing or model identification algorithms, they reveal information about the device, or the system observed.

This field is today known as asset monitoring. The term denotes anything from very simple use counters up to complex algorithms that derive system lifecycle information from measured data. In some cases, the internal state of a high-value asset can be assessed through the interpretation of signals that are available in the automation system already used in control schemes. If the decision is between applying some analysis software or to shut down the equipment, open it, and visually inspect, the software version can in many cases more directly direct the maintenance personnel towards the true fault of the equipment.

The availability of advanced asset monitoring algorithms allows for optimized operation of the plant. If component ageing can be calculated from measurements, optimizing control algorithms can put the load on less stressed components, or can trade asset lifecycle consumption against the quick return of a fast plant start-up.

The requirement to increase availability and production quality calls for advanced algorithms for asset monitoring and results in an asset optimization scheme that directly influences the plant operator's bottom line. The people operating the plant, be it in the operations department or in maintenance, are supported in their analysis of the situation and in their decisions by more advanced systems than are normally in operation today.

When it comes to discrete manufacturing plants, the optimization potential is as high as in continuous production. Advanced scheduling algorithms are capable of optimizing plant utilization and improving yield. If these algorithms are flexible to allow a rescheduling and production replanning in operation to accommodate urgent orders at runtime, plant efficiency can be optimized dynamically and have an even more positive effect on the bottom line.

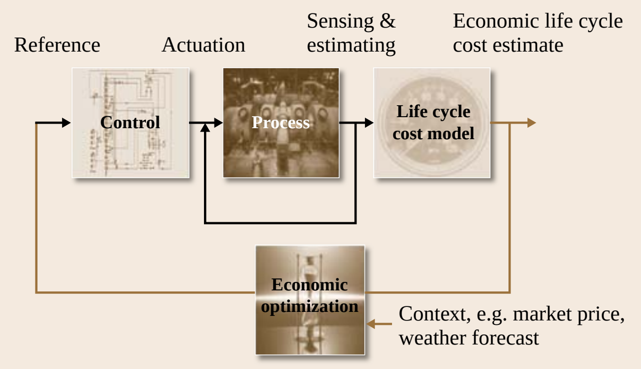

Fig. 8.10 Trend towards lifecycle optimization

Lifecycle Optimization

The optimization concepts presented so far enable a plant owner to optimize OEE on several levels (Fig. 8.10). We have covered online production optimization as well as predictive maintenance through advanced asset optimization tools. If the scope of the optimization can be extended to a whole fleet of plants and over a longer period of time, continuous plant improvement by collecting best practices and statistical information on all equipment and systems becomes feasible.

What does the automation system contribute to this level of optimization? Again, most data originates from the plant automation system's databases. In *Plant Optimization* we have even seen that asset monitoring provides information that goes beyond the raw signals measured by the sensors and can be used to draw conclusions on plant maintenance activities. From a fixed-schedule maintenance scheme where plant equipment is shut down based on statistical experience, asset monitoring can help moving towards a condition-based maintenance scheme. Either equipment operation can be extended towards more realistic schedules, or emergency plant shutdown can be avoided by early detecting equipment degradation and going into planned shutdown.

Interaction with maintenance management systems or enterprise resource planning systems is today evolving, supported by standards such as ISA95. Enterprise-wide information integration is substantial to be continuously on top of production and effectiveness, to track down inefficiencies in processes both technical and organizational.

These concepts have been presented over the years [8.13], but to really close the loop on that level requires significant investments by most industrial companies. Good examples of information integration on that level are airline operators and maintenance companies, where additional minutes used to service deficiencies in equipment become expensive. Failure to address these deficiencies become catastrophic and mission critical.

8.3 Outlook

The current trends presented in the previous Sections do show benefits, in some cases significant. The push to continue the developments along these lines will therefore most probably be sustained.

8.3.1 Complexity Increase

One general countertrend is also clearly visible in many areas: increased complexity to the extent that it becomes a limiting factor. System complexity does not only result in an increase in initial cost (more installed infrastructure, more engineering), but also in increased maintenance (IT support on plant floor). Both factors influence OEE (Fig. 8.1) negatively. To counter the perceived complexity in automation systems it is therefore important to facilitate wider distribution of the advanced concepts presented so far.

Modeling

Many of the solutions available today in either asset monitoring or advanced control rely on plant models. The availability of plant models for applications such as design or training simulation is also essential. However, plant models are highly dependent on the process installation, and need to be designed or at least tuned to every installation. Furthermore, the increased complexity of advanced industrial plants also calls for wider and more complex models. Model building and tuning is today still very expensive and requires highly skilled experts. There is a need common to different areas and industries to keep modeling affordable.

Reuse of models could address this issue in two dimensions:

- To reuse a model designed for one application in another, i. e., to build a controller design model based

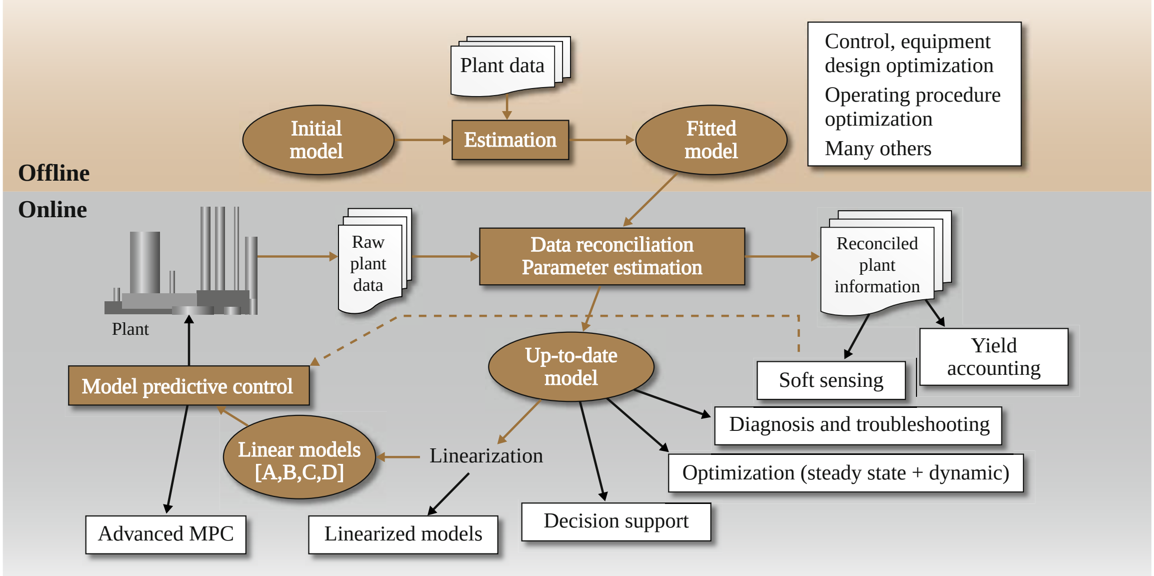

Fig. 8.11 Trend towards automation and control modeling and model reuse

on a model that was used for plant design, or derive the model used in a controller from one that is available for performance monitoring. The plant topology that connects the models can remain the same in all cases.

- To reuse models from project to project, an approach that can also be pursued with engineering solutions to bring down engineering costs (Fig. 8.11).

Operator Interaction

Although modern operator stations are capable of integrating much more information to the operator or maintenance personnel, the operator interaction is not always the most intuitive. In plant diagnostics and maintenance this may be acceptable, but for the operator it is often difficult to quickly perceive a plant situation, whether good or bad, and to act accordingly. This is mostly due to the fact that the operator interface was designed by the engineer who had as inputs the plans of the plant and the automation function, and not the plant environment where the operator needs to navigate.

An operator interface closer to the plant operator's natural environment (and therefore to his intuition) could improve the perception of the plant's current status.

One way of doing this is to display the status in a more intuitive manner. In an aircraft, the artificial horizon combines a large number of measurements in one very simple display, which can be interpreted intuitively by the pilot by just glancing at it. Its movement gives excellent feedback on the plane's dynamics. If we compare this simple display with a current plant operator station with process diagrams, alarm lists, and trend displays, it is obvious that plant dynamics cannot be perceived as easily. Some valuable time early in critical situations is therefore lost by analyzing numbers on a screen. To depict the plant status in more intuitive graphics could exploit humans' capability to interpret moving graphics in a qualitative way more efficiently than from numerical displays.

Automated Engineering

As we have pointed out in *Modeling*, designing and tuning models is a complex task. To design and tune advanced controllers is as complex. Even the effort to tune simple controllers is in reality very often skipped, and controller parameters are left at standard settings of 1.0 for any parameter.

In many cases these settings can be derived from plant parameters without the requirement to tune online on site. Drum sizes or process set-points are documented during plant engineering, and as we have seen in *Engineering Integration*, this data is normally available to the automation engineer. If a control loop's settings are automatically derived from the data found in the plant information, the settings will be much better than the standard values. To the commissioning engineer, this procedure hides some of the complexity of controller fine-tuning.

Whether it is possible to derive control loops automatically from the plant information received from the plant engineering tools remains to be seen. Very simple loops can be chosen based on standard configurations of pumps and valves, but a thorough check of the solution by an experienced automation engineer is still required.

On the other hand, the information contained in engineering data can be used to check the consistency of the manually designed code. If a plant topology model is available that was read out of the process & instrumentation diagram, also piping & instrumentation diagram (P&ID) tool information, automatic measures can be taken to check whether there is an influence of some sort (control logic, interlock logic) between a tank level and the feeding pump.

8.3.2 Controller Scope Extension

Today's control laws are designed on the assumption that the plant behaves as designed. Failed components are not taken into consideration, and deteriorating plant conditions (fouling, drift, etc.) are only to some extent compensated by controller action.

The coverage of nonstandard plant configurations in the design of controllers is rarely seen today. This is the case for advanced control schemes, but also for more advanced scheduling or batch solutions, consideration of these suboptimal plant states in the design of the automation system could improve plant availability. Although this may result in a reduction of quality, the production environment (i. e., the immediate market prices) can still make a lower-quality production useful. To detect whether this is the case, an integration between the business environment, with current cost of material, energy, and maybe even emissions, and the production information in the plant allows to solve optimization problems that optimize the bottom line directly.

8.3.3 Automation Lifecycle Planning

In the past, the automation system was an initial investment like many other installations in a plant.

It was maintained by replacing broken devices by spares, and kept its functionality throughout the years. This option is still available today. In addition to I/O cards, an owner needs to buy spare PCs like other spare parts that may difficult to buy on the market.

The other option an owner has is to continuously follow the technology trend and keep the automation system up to date. This results in much higher lifecycle cost, but against these costs is the benefit of always having the newest technology installed. This in turn requires automation system vendors to continuously provide functionality that improves the plant's performance, justifying the investment.

It is the owner's decision which way to go. It is not an easy decision and shows the importance of keeping total cost of ownership in mind also when purchasing the automation system.

8.4 Summary

Today's business environment as well as technology trends (i. e., robots) are continuously evolving at a fast pace (Fig. 8.12). To improve a plant's competitiveness, a modern automation system must make use of the advancements in technology to react to trends in the business world.

The reaction of the enterprise must be faster, at the lowest level to increase production and reduce downtime, and at higher levels to process customer orders efficiently and react to mid-term trends quickly. The data required for these decisions is mostly buried in the automation system; for dynamic operation it needs to be turned into information, which in turn needs to be processed quickly. To improve the situation with the automation system, different systems on all levels need to be integrated to allow for sophisticated information processing.

The availability of the full picture allows the optimization of single loops, plant operation, and economic performance of the enterprise.

Fig. 8.12 Trend towards more sophisticated robotics

The technologies that allow the automation system to be the core information processing system in a production plant are available today, are evolving quickly, and provide the means to bring the overall equipment effectiveness to new levels.

Automati

Part B Automation Theory and Scientific Foundations

Automation Theory and Scientific Foundations. Part B Automation is based on control theory and intelligent control, although interestingly, automation existed before control theory was developed. The chapters in this part explain the theoretical aspects of automation and its scientific foundations, from the basics to advanced models and techniques; from simple feedback and feedforward automation functioning under certainty to fuzzy logic control, learning control automation, cybernetics, and artificial intelligence. Automation is also based on communication, and in this part this subject is explained from the fundamental communication between sensors and actuators, producers and consumers of signals and information, to automation of and with virtual reality; automation mobility and wireless communication of computers, devices, vehicles, flying objects and other location-based and geography-based automation. The theoretical and scientific knowledge about the human role in automation is covered from the human-oriented and human–centered aspects of automation to be applied and operated by humans, to the human role as supervisor and intelligent controller of automation systems and platforms. This part concludes with analysis and discussion on the limits of automation to the best of our current understanding.

9. Control Theory for Automation: Fundamentals

Alberto Isidori

In this chapter autonomous dynamical systems, stability, asymptotic behavior, dynamical systems with inputs, feedback stabilization of linear systems, feedback stabilization of nonlinear systems, and tracking and regulation are discussed to provide the foundation for control theory for automation.

Modern engineering systems are very complex and comprise a high number of interconnected subcomponents which, thanks to the remarkable development of communications and electronics, can be spread over broad areas and linked through data networks. Each component of this wide interconnected system is a complex system on its own and the good functioning of the overall system relies upon the possibility to efficiently control, estimate or monitor each one of these components. Each component is usually high dimensional, highly nonlinear, and hybrid in nature, and comprises electrical, mechanical or chemical components which interact with computers, decision logics, etc. The behavior of each subsystem is affected by the behavior of part or all of the other components of the system. The control of those complex systems can only be achieved in a decentralized mode, by appropriately designing local controllers for each individual component or small group of components. In this setup, the interactions between components are mostly treated as *commands*, dictated from one particular unit to another one, or as *disturbances*, generated by the operation of other interconnected units. The tasks of the various local controllers are then coordinated by some supervisory unit. Control and computational capabilities being distributed over the system, a steady exchange of data among the components is required, in order for the system to behave properly.

In this setup, each individual component (or small set of components) is viewed as a system whose behavior, in time, is determined or influenced by the behavior of other subsystems. Typically, the physical variables by

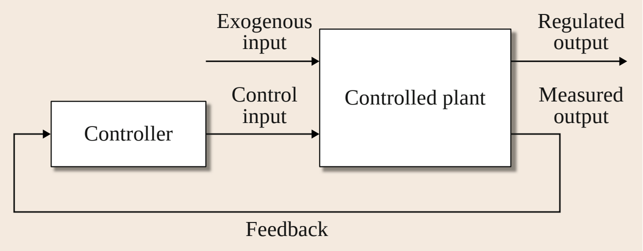

Fig. 9.1 Basic feedback loop

means of which this influence is exerted can be classified into two disjoint sets: one set consisting of all commands and/or disturbances generated by other components (which in this context are usually referred to as *exogenous inputs*) and another set consisting of all variables by means of which the accomplishment of the required tasks is actually imposed (which in this context are usually referred to as *control inputs*). The tasks in question typically comprise the case in which certain variables, called *regulated outputs*, are required to track the behavior of a set of exogenous commands. This leads to the definition, for the variables in question, of a *tracking error*, which should be kept as small as possible, in spite of the possible variation – in time – of the commands and in spite of all exogenous disturbances. The control input, in turn, is provided by a separate subsystem, the *controller*, which processes the information provided by a set of appropriate measurements (the *measured outputs*). The whole control configuration assumes – in this case – the form of a *feedback loop*, as shown in Fig. 9.1.

In any realistic scenario, the control goal has to be achieved in spite of a good number of phenomena which would cause the system to behave differently than expected. As a matter of fact, in addition to the exogenous phenomena already included in the scheme of Fig. 9.1, i. e., the exogenous commands and disturbances, a system may fail to behave as expected also because of endogenous causes, which include the case in which the controlled system responds differently as a consequence of poor knowledge about its behavior due to modeling errors, damages, wear, etc. The ability to handle large uncertainties successfully is one of the main, if not the single most important, reason for choosing the feedback configuration of Fig. 9.1.

To evaluate the overall performances of the system, a number of conventional criteria are chosen. First of all, it must be ensured that the behavior of the variables of the entire system is bounded. In fact, the feedback strategy, which is introduced for the purpose of offsetting exogenous inputs and to attenuate the effect of modeling error, may cause unbounded behaviors, which have to be avoided. Boundedness, and convergence to the desired behavior, are usually analyzed in conventional terms via the concepts of asymptotic *stability* and *steady-state behavior*, discussed in Sects. 9.2–9.3. Since the systems under considerations are systems with inputs (control inputs and exogenous inputs), the influence of such inputs on the behavior of a system also has to be assessed, as discussed in Sect. 9.4. The analytical tools developed in this way are then taken as a basis for the design of a controller, in which – usually – the control structure and free parameters are chosen in such a way as to guarantee that the overall configuration exhibits the desired properties in response to exogenous commands and disturbances and is sufficiently tolerant of any major source of uncertainty. This is discussed in Sects. 9.5–9.8.

9.1 Autonomous Dynamical Systems

In loose terms, a dynamical system is a way to describe how certain physical entities of interest, associated with a natural or artificial process, evolve in time and how their behavior is, or can be, influenced by the evolution of other variables. The most usual point of departure in the analysis of the behavior of a natural or artificial process is the construction of a mathematical model consisting of a set of equations expressing basic physical laws and/or constraints. In the most frequent case, when the study of evolution in time is the issue, the equations in question take the form of an ordinary differential equation, defined on a finite-dimensional Euclidean space. In this chapter, we shall review some fundamental facts underlying the analysis of the solutions of certain ordinary differential equations arising in the study of physical processes.

In this analysis, a convenient point of departure is the case of a mathematical model expressed by means of a first-order differential equation

$$\dot{x} = f(x)\,, \qquad (9.1)$$

in which $\boldsymbol{x} \in \mathbb{R}^n$ is a vector of variables associated with the physical entities of interest, usually referred to as the *state* of the system. A solution of the differential equation (9.1) is a differentiable function $\bar{\boldsymbol{x}} : J \to \mathbb{R}^n$ defined on some interval $J \subset \mathbb{R}$ such that, for all $t \in J$,

$$\frac{\mathrm{d}\bar{\boldsymbol{x}}(t)}{\mathrm{d}t} = f(\bar{\boldsymbol{x}}(t)) .$$

If the map $f : \mathbb{R}^n \to \mathbb{R}^n$ is *locally Lipschitz*, i. e., if for every $\boldsymbol{x} \in \mathbb{R}^n$ there exists a neighborhood U of $\boldsymbol{x}$ and a number $L > 0$ such that, for all $\boldsymbol{x}_1, \boldsymbol{x}_2$ in U,

$$|f(\boldsymbol{x}_1) - f(\boldsymbol{x}_2)| \leq L|\boldsymbol{x}_1 - \boldsymbol{x}_2| ,$$

then, for each $\boldsymbol{x}_0 \in \mathbb{R}^n$ there exists two times $t^- < 0$ and $t^+ > 0$ and a solution $\bar{\boldsymbol{x}}$ of (9.1), defined on the interval $(t^-, t^+) \subset \mathbb{R}$, that satisfies $\bar{\boldsymbol{x}}(0) = \boldsymbol{x}_0$. Moreover, if $\tilde{\boldsymbol{x}}$: $(t^-, t^+) \to \mathbb{R}^n$ is any other solution of (9.1) satisfying $\tilde{\boldsymbol{x}}(0) = \boldsymbol{x}_0$, then necessarily $\tilde{\boldsymbol{x}}(t) = \bar{\boldsymbol{x}}(t)$ for all $t \in (t^-, t^+)$, that is, the solution $\bar{\boldsymbol{x}}$ is unique. In general, the times $t^- < 0$ and $t^+ > 0$ may depend on the point $\boldsymbol{x}_0$. For each $\boldsymbol{x}_0$, there is a maximal open interval $(t_{\mathrm{m}}^-(\boldsymbol{x}_0), t_{\mathrm{m}}^+(\boldsymbol{x}_0))$ containing 0 on which is defined a solution $\bar{\boldsymbol{x}}$ with $\bar{\boldsymbol{x}}(0) = \boldsymbol{x}_0$: this is the union of all open intervals on which there is a solution with $\bar{\boldsymbol{x}}(0) = \boldsymbol{x}_0$ (possibly, but not always, $t_{\mathrm{m}}^-(\boldsymbol{x}_0) = -\infty$ and/or $t_{\mathrm{m}}^+(\boldsymbol{x}_0) = +\infty$).

Given a differential equation of the form (9.1), associated with a locally Lipschitz map f, define a subset W of $\mathbb{R} \times \mathbb{R}^n$ as follows

$$W = \left\{(t, \boldsymbol{x}) : t \in \left(t_{\mathrm{m}}^-(\boldsymbol{x}), t_{\mathrm{m}}^+(\boldsymbol{x})\right), \boldsymbol{x} \in \mathbb{R}^n\right\} .$$

Then define on W a map $\phi : W \to \mathbb{R}^n$ as follows: $\phi(0, \boldsymbol{x}) = \boldsymbol{x}$ and, for each $\boldsymbol{x} \in \mathbb{R}^n$, the function

$$\begin{aligned} \varphi_x : \left(t_{\mathrm{m}}^-(\boldsymbol{x}), t_{\mathrm{m}}^+(\boldsymbol{x})\right) &\to \mathbb{R}^n ,\\ t &\mapsto \phi(t, \boldsymbol{x}) \end{aligned}$$

is a solution of (9.1). This map is called the *flow* of (9.1). In other words, for each fixed $\boldsymbol{x}$, the restriction of $\phi(t, \boldsymbol{x})$ to the subset of W consisting of all pairs $(t, \boldsymbol{x})$ for which $t \in (t_{\mathrm{m}}^-(\boldsymbol{x}), t_{\mathrm{m}}^+(\boldsymbol{x}))$ is the unique (and maximally extended in time) solution of (9.1) passing through $\boldsymbol{x}$ at time $t = 0$.

A dynamical system is said to be *complete* if the set W coincides with the whole of $\mathbb{R} \times \mathbb{R}^n$.

Sometimes, a slightly different notation is used for the flow. This is motivated by the need tom express, within the same context, the flow of a system like (9.1) and the flow of another system, say $\dot{\boldsymbol{y}} = g(\boldsymbol{y})$. In this case, the symbol ϕ, which represents the *map*, must be replaced by two different symbols, one denoting the flow of (9.1) and the other denoting the flow of the other system. The easiest way to achieve this is to use the symbol $\boldsymbol{x}$ to represent the map that characterizes the flow of (9.1) and to use the symbol $\boldsymbol{y}$ to represent the map that characterizes the flow of the other system. In this way, the map characterizing the flow of (9.1) is written $\boldsymbol{x}(t, \boldsymbol{x})$. This notation at first may seem confusing, because the same symbol $\boldsymbol{x}$ is used to represent the map and to represent the second argument of the map itself (the argument representing the initial condition of (9.1)), but this is somewhat inevitable. Once the notation has been understood, though, no further confusion should arise.

In the special case of a *linear* differential equation

$$\dot{\boldsymbol{x}} = \mathbf{A}\boldsymbol{x} \tag{9.2}$$

in which $\mathbf{A}$ is an $n \times n$ matrix of real numbers, the flow is given by

$$\phi(t, \boldsymbol{x}) = \mathrm{e}^{\mathbf{A}t}\boldsymbol{x} ,$$

where the matrix exponential $\mathrm{e}^{\mathbf{A}t}$ is defined as the sum of the series

$$\mathrm{e}^{\mathbf{A}t} = \sum_{i=0}^{\infty} \frac{t^i}{i!}\mathbf{A}^i .$$

Let S be a subset of $\mathbb{R}^n$. The set S is said to be *invariant* for (9.1) if, for all $\boldsymbol{x} \in S$, $\phi(t, \boldsymbol{x})$ is defined for all $t \in (-\infty, +\infty)$ and

$$\phi(t, \boldsymbol{x}) \in S , \quad \text{for all } t \in \mathbb{R} .$$

A set S is *positively* (resp. negatively) *invariant* if for all $\boldsymbol{x} \in S$, $\phi(t, \boldsymbol{x})$ is defined for all $t \geq 0$ (resp. for all $t \leq 0$) and $\phi(t, \boldsymbol{x}) \in S$ for all such t.

Equation (9.1) defines a *dynamical system*. To reflect the fact that the map f does not depend on other independent entities (such as the time t or physical entities originated from *external* processes) the system in question is referred to an *autonomous* system. Complex autonomous systems arising in analysis and design of physical processes are usually obtained as a composition of simpler subsystems, each one modeled by equations of the form

$$\begin{aligned} \dot{\boldsymbol{x}}_i &= f_i(\boldsymbol{x}_i, \boldsymbol{u}_i) ,\\ \boldsymbol{y}_i &= h_i(\boldsymbol{x}_i, \boldsymbol{u}_i) , \end{aligned} \qquad i = 1, \ldots, N ,$$

in which $\boldsymbol{x}_i \in \mathbb{R}^{n_i}$. Here $\boldsymbol{u}_i \in \mathbb{R}^{m_i}$ and, respectively, $\boldsymbol{y}_i \in \mathbb{R}^{p_i}$ are vectors of variables associated with physical entities by means of which the interconnection of various component parts is achieved.

9.2 Stability and Related Concepts

9.2.1 Stability of Equilibria

Consider an autonomous system as (9.1) and suppose that f is locally Lipschitz. A point $\boldsymbol{x}_\mathrm{e} \in \mathbb{R}^n$ is called an *equilibrium* point if $f(\boldsymbol{x}_\mathrm{e}) = 0$. Clearly, the constant function $\boldsymbol{x}(t) = \boldsymbol{x}_\mathrm{e}$ is a solution of (9.1). Since solutions are unique, no other solution of (9.1) exists passing through $\boldsymbol{x}_\mathrm{e}$. The study of equilibria plays a fundamental role in analysis and design of dynamical systems. The most important concept in this respect is that of *stability*, in the sense of *Lyapunov*, specified in the following definition. For $\boldsymbol{x} \in \mathbb{R}^n$, let $|\boldsymbol{x}|$ denote the usual Euclidean norm, that is,

$$|\boldsymbol{x}| = \left(\sum_{i=1}^{n} x_i^2\right)^{1/2} .$$

Definition 9.1

An equilibrium $\boldsymbol{x}_\mathrm{e}$ of (9.1) is *stable* if, for every $\varepsilon > 0$, there exists $\delta > 0$ such that

$$|\boldsymbol{x}(0) - \boldsymbol{x}_\mathrm{e}| \le \delta \Rightarrow |\boldsymbol{x}(t) - \boldsymbol{x}_\mathrm{e}| \le \varepsilon , \quad \text{for all } t \ge 0 .$$

An equilibrium x_e of (9.1) is *asymptotically stable* if it is stable and, moreover, there exists a number $d > 0$ such that

$$|\boldsymbol{x}(0) - \boldsymbol{x}_\mathrm{e}| \le d \Rightarrow \lim_{t\to\infty} |\boldsymbol{x}(t) - \boldsymbol{x}_\mathrm{e}| = 0 .$$

An equilibrium x_e of (9.1) is *globally asymptotically stable* if it is asymptotically stable and, moreover,

$$\lim_{t\to\infty} |\boldsymbol{x}(t) - \boldsymbol{x}_\mathrm{e}| = 0 , \quad \text{for every } \boldsymbol{x}(0) \in \mathbb{R}^n .$$

The most elementary, but rather useful in practice, result in stability analysis is described as follows. Assume that $f(\boldsymbol{x})$ is continuously differentiable and suppose, without loss of generality, that $\boldsymbol{x}_\mathrm{e} = 0$ (if not, change $\boldsymbol{x}$ into $\bar{\boldsymbol{x}} := \boldsymbol{x} - \boldsymbol{x}_\mathrm{e}$ and observe that $\bar{\boldsymbol{x}}$ satisfies the differential equation $\dot{\bar{\boldsymbol{x}}} = f(\bar{\boldsymbol{x}} + \boldsymbol{x}_\mathrm{e})$ in which now $\bar{\boldsymbol{x}} = 0$ is an equilibrium). Expand $f(\boldsymbol{x})$ as follows

$$f(\boldsymbol{x}) = \mathbf{A}\boldsymbol{x} + \tilde{f}(\boldsymbol{x}) , \tag{9.3}$$

in which

$$\mathbf{A} = \frac{\partial f}{\partial \boldsymbol{x}}(0)$$

is the Jacobian matrix of $f(\boldsymbol{x})$, evaluated at $\boldsymbol{x} = 0$, and by construction

$$\lim_{\boldsymbol{x}\to 0} \frac{|\tilde{f}(\boldsymbol{x})|}{|\boldsymbol{x}|} = 0 .$$

The linear system $\dot{\boldsymbol{x}} = \mathbf{A}\boldsymbol{x}$, with the matrix $\mathbf{A}$ defined as indicated, is called the *linear approximation* of the original nonlinear system (9.1) at the equilibrium $\boldsymbol{x} = 0$.

Theorem 9.1

Let $\boldsymbol{x} = 0$ be an equilibrium of (9.1). Suppose every eigenvalue of $\mathbf{A}$ has real part less than $-c$, with $c > 0$. Then, there are numbers $d > 0$ and $M > 0$ such that

$$|\boldsymbol{x}(0)| \le d \Rightarrow |\boldsymbol{x}(t)| \le M \mathrm{e}^{-ct} |\boldsymbol{x}(0)| , \quad \text{for all } t \ge 0 . \tag{9.4}$$

In particular, $\boldsymbol{x} = 0$ is asymptotically stable. If at least one eigenvalue of $\mathbf{A}$ has positive real part, the equilibrium $\boldsymbol{x} = 0$ is not stable.

This property is usually referred to as the *principle of stability in the first approximation*. The equilibrium $\boldsymbol{x} = 0$ is said to be *hyperbolic* if the matrix $\mathbf{A}$ has no eigenvalue with zero real part. Thus, it is seen from the previous Theorem that a hyperbolic equilibrium is either unstable or asymptotically stable.

The inequality on the right-hand side of (9.4) provides a useful bound on the norm of $\boldsymbol{x}(t)$, expressed as a function of the norm of $\boldsymbol{x}(0)$ and of the time t. This bound, though, is very special and restricted to the case of a hyperbolic equilibrium. In general, bounds of this kind can be obtained by means of the so-called *comparison functions*, which are defined as follows.

Definition 9.2

A continuous function $\alpha : [0, a) \to [0, \infty)$ is said to belong to class $\mathcal{K}$ if it is strictly increasing and $\alpha(0) = 0$. If $a = \infty$ and $\lim_{r\to\infty} \alpha(r) = \infty$, the function is said to belong to class $\mathcal{K}_\infty$. A continuous function $\beta : [0, a) \times [0, \infty) \to [0, \infty)$ is said to belong to class $\mathcal{KL}$ if, for each fixed s, the function

$$\alpha : [0, a) \to [0, \infty) , \quad r \mapsto \beta(r, s)$$

belongs to class $\mathcal{K}$ and, for each fixed r, the function

$$\varphi : [0, \infty) \to [0, \infty) , \quad s \mapsto \beta(r, s)$$

is decreasing and $\lim_{s\to\infty} \varphi(s) = 0$.

The composition of two class $\mathcal{K}$ (respectively, class $\mathcal{K}_\infty$) functions $\alpha_1(\cdot)$ and $\alpha_2(\cdot)$, denoted $\alpha_1(\alpha_2(\cdot))$ or $\alpha_1 \circ \alpha_2(\cdot)$, is a class $\mathcal{K}$ (respectively, class $\mathcal{K}_\infty$) function. If $\alpha(\cdot)$ is a class $\mathcal{K}$ function, defined on $[0, a)$ and $b = \lim_{r\to a} \alpha(r)$, there exists a unique *inverse* function, $\alpha^{-1} : [0, b) \to [0, a)$, namely a function satisfying

$$\alpha^{-1}(\alpha(r)) = r, \quad \text{for all } r \in [0, a)$$

and

$$\alpha(\alpha^{-1}(r)) = r, \quad \text{for all } r \in [0, b)\,.$$

Moreover, $\alpha^{-1}(\cdot)$ is a class $\mathcal{K}$ function. If $\alpha(\cdot)$ is a class $\mathcal{K}_\infty$ function, so is also $\alpha^{-1}(\cdot)$.

The properties of stability, asymptotic stability, and global asymptotic stability can be easily expressed in terms of inequalities involving comparison functions. In fact, it turns out that the equilibrium $\boldsymbol{x} = 0$ is *stable* if and only if there exist a class $\mathcal{K}$ function $\alpha(\cdot)$ and a number $d > 0$ such that

$$|\boldsymbol{x}(t)| \le \alpha(|\boldsymbol{x}(0)|)\,,$$
$$\text{for all } \boldsymbol{x}(0) \text{ such that } |\boldsymbol{x}(0)| \le d \text{ and all } t \ge 0\,,$$

the equilibrium $\boldsymbol{x} = 0$ is *asymptotically stable* if and only if there exist a class $\mathcal{KL}$ function $\beta(\cdot,\cdot)$ and a number $d > 0$ such that

$$|\boldsymbol{x}(t)| \le \beta(|\boldsymbol{x}(0)|, t)\,,$$
$$\text{for all } \boldsymbol{x}(0) \text{ such that } |\boldsymbol{x}(0)| \le d \text{ and all } t \ge 0\,,$$

and the equilibrium $\boldsymbol{x} = 0$ is *globally asymptotically stable* if and only if there exist a class $\mathcal{KL}$ function $\beta(\cdot,\cdot)$ such that

$$|\boldsymbol{x}(t)| \le \beta(|\boldsymbol{x}(0)|, t)\,, \quad \text{for all } \boldsymbol{x}(0) \text{ and all } t \ge 0\,.$$

9.2.2 Lyapunov Functions

The most important criterion for the analysis of the stability properties of an equilibrium is the criterion of Lyapunov. We introduce first the special form that this criterion takes in the case of a linear system.

Consider the autonomous linear system

$$\dot{\boldsymbol{x}} = \mathbf{A}\boldsymbol{x}$$

in which $\boldsymbol{x} \in \mathbb{R}^n$. Any symmetric $n \times n$ matrix $\mathbf{P}$ defines a *quadratic form*

$$V(\boldsymbol{x}) = \boldsymbol{x}^\top \mathbf{P}\boldsymbol{x}\,.$$

The matrix $\mathbf{P}$ is said to be *positive definite* (respectively, positive semidefinite) if so is the associated quadratic form $V(\boldsymbol{x})$, i. e., if, for all $\boldsymbol{x} \ne 0$,

$$V(\boldsymbol{x}) > 0\,, \quad \text{respectively } V(\boldsymbol{x}) \ge 0\,.$$

The matrix is said to be *negative definite* (respectively, negative semidefinite) if $-\mathbf{P}$ is positive definite (respectively, positive semidefinite). It is easy to show that a matrix $\mathbf{P}$ is positive definite if (and only if) there exist positive numbers $\underline{a}$ and $\overline{a}$ satisfying

$$\underline{a}|\boldsymbol{x}|^2 \le \boldsymbol{x}^\top \mathbf{P}\boldsymbol{x} \le \overline{a}|\boldsymbol{x}|^2\,, \tag{9.5}$$

for all $\boldsymbol{x} \in \mathbb{R}^n$. The property of a matrix $\mathbf{P}$ to be positive definite is usually expressed with the shortened notation $\mathbf{P} > 0$ (which actually means $\boldsymbol{x}^\top\mathbf{P}\boldsymbol{x} > 0$ for all $\boldsymbol{x} \ne 0$).

In the case of linear systems, the criterion of Lyapunov is expressed as follows.

Theorem 9.2
The linear system $\dot{\boldsymbol{x}} = \mathbf{A}\boldsymbol{x}$ is asymptotically stable (or, what is the same, the eigenvalues of $\mathbf{A}$ have negative real part) if there exists a positive-definite matrix $\mathbf{P}$ such that the matrix

$$\mathbf{Q} := \mathbf{PA} + \mathbf{A}^\top\mathbf{P}$$

is negative definite. Conversely, if the eigenvalues of $\mathbf{A}$ have negative real part, then, for any choice of a negative-definite matrix $\mathbf{Q}$, the linear equation

$$\mathbf{PA} + \mathbf{A}^\top\mathbf{P} = \mathbf{Q}$$

has a unique solution $\mathbf{P}$, which is positive definite.

Note that, if $V(\boldsymbol{x}) = \boldsymbol{x}^\top\mathbf{P}\boldsymbol{x}$,

$$\frac{\partial V}{\partial \boldsymbol{x}} = 2\boldsymbol{x}^\top\mathbf{P}$$

and hence

$$\frac{\partial V}{\partial \boldsymbol{x}}\mathbf{A}\boldsymbol{x} = \boldsymbol{x}^\top(\mathbf{PA} + \mathbf{A}^\top\mathbf{P})\boldsymbol{x}\,.$$

Thus, to say that the matrix $\mathbf{PA} + \mathbf{A}^\top\mathbf{P}$ is negative definite is equivalent to say that the form

$$\frac{\partial V}{\partial \boldsymbol{x}}\mathbf{A}\boldsymbol{x}$$

is negative definite.

The general, nonlinear, version of the criterion of Lyapunov appeals to the existence of a positive definite, but not necessarily quadratic, function of $\boldsymbol{x}$. The quadratic lower and upper bounds of (9.5) are therefore replaced by bounds of the form

$$\underline{\alpha}(|\boldsymbol{x}|) \le V(\boldsymbol{x}) \le \overline{\alpha}(|\boldsymbol{x}|)\,, \tag{9.6}$$

in which $\underline{\alpha}(\cdot)$, $\overline{\alpha}(\cdot)$ are simply class $\mathcal{K}$ functions. The criterion in question is summarized as follows.

Theorem 9.3

Let $V : \mathbb{R}^n \to \mathbb{R}$ be a continuously differentiable function satisfying (9.6) for some pair of class $\mathcal{K}$ functions $\underline{\alpha}(\cdot)$, $\overline{\alpha}(\cdot)$. If, for some $d > 0$,

$$\frac{\partial V}{\partial \boldsymbol{x}} f(\boldsymbol{x}) \le 0 \,, \qquad \text{for all } |\boldsymbol{x}| < d \,, \tag{9.7}$$

the equilibrium $\boldsymbol{x} = 0$ of (9.1) is stable. If, for some class $\mathcal{K}$ function $\alpha(\cdot)$ and some $d > 0$,

$$\frac{\partial V}{\partial \boldsymbol{x}} f(\boldsymbol{x}) \le -\alpha(|\boldsymbol{x}|) \,, \qquad \text{for all } |\boldsymbol{x}| < d \,, \tag{9.8}$$

the equilibrium $\boldsymbol{x} = 0$ of (9.1) is locally asymptotically stable. If $\underline{\alpha}(\cdot)$, $\overline{\alpha}(\cdot)$ are class $\mathcal{K}_\infty$ functions and the inequality in (9.8) holds for all $\boldsymbol{x}$, the equilibrium $\boldsymbol{x} = 0$ of (9.1) is globally asymptotically stable.

A function $V(\boldsymbol{x})$ satisfying (9.6) and either of the subsequent inequalities is called a *Lyapunov function*. The inequality on the left-hand side of (9.6) is instrumental, together with (9.7), in establishing existence and boundedness of $\boldsymbol{x}(t)$. A simple explanation of the arguments behind the criterion of Lyapunov can be obtained in this way. Suppose (9.7) holds. Then, if $\boldsymbol{x}(0)$ is small, the differentiable function of time $V(\boldsymbol{x}(t))$ is defined for all $t \ge 0$ and nonincreasing along the trajectory $\boldsymbol{x}(t)$. Using the inequalities in (9.6) one obtains

$$\underline{\alpha}(|\boldsymbol{x}(t)|) \le V(\boldsymbol{x}(t)) \le V(\boldsymbol{x}(0)) \le \overline{\alpha}(|\boldsymbol{x}(0)|)$$

and hence $|\boldsymbol{x}(t)| \le \underline{\alpha}^{-1} \circ \overline{\alpha}(|\boldsymbol{x}(0)|)$, which establishes the stability of the equilibrium $\boldsymbol{x} = 0$.

Similar arguments are very useful in order to establish the *invariance*, in positive time, of certain bounded subsets of $\mathbb{R}^n$. Specifically, suppose the various inequalities considered in Theorem 9.3 hold for $d = \infty$ and let Ω_c denote the set of all $\boldsymbol{x} \in \mathbb{R}^n$ for which $V(\boldsymbol{x}) \le c$, namely

$$\Omega_c = \{\boldsymbol{x} \in \mathbb{R}^n : V(\boldsymbol{x}) \le c\} \,.$$

A set of this kind is called a *sublevel set* of the function $V(\boldsymbol{x})$. Note that, if $\underline{\alpha}(\cdot)$ is a class $\mathcal{K}_\infty$ function, then Ω_c is a compact set for all $c > 0$. Now, if

$$\frac{\partial V(\boldsymbol{x})}{\partial \boldsymbol{x}} f(\boldsymbol{x}) < 0$$

at each point $\boldsymbol{x}$ of the boundary of Ω_c, it can be concluded that, for any initial condition in the interior of Ω_c, the solution $\boldsymbol{x}(t)$ of (9.1) is defined for all $t \ge 0$ and is such that $\boldsymbol{x}(t) \in \Omega_c$ for all $t \ge 0$, that is, the set Ω_c is invariant in positive time. Indeed, existence and uniqueness are guaranteed by the local Lipschitz property so long as $\boldsymbol{x}(t) \in \Omega_c$, because Ω_c is a compact set. The fact that $\boldsymbol{x}(t)$ remains in Ω_c for all $t \ge 0$ is proved by contradiction. For, suppose that, for some trajectory $\boldsymbol{x}(t)$, there is a time t_1 such that $\boldsymbol{x}(t)$ is in the interior of Ω_c at all $t < t_1$ and $\boldsymbol{x}(t_1)$ is on the boundary of Ω_c. Then,

$$V(\boldsymbol{x}(t)) < c \,, \qquad \text{for all } t < t_1 \quad \text{and} \quad V(\boldsymbol{x}(t_1)) = c \,,$$

and this contradicts the previous inequality, which shows that the derivative of $V(\boldsymbol{x}(t))$ is strictly negative at $t = t_1$.

The criterion for asymptotic stability provided by the previous Theorem has a *converse*, namely, the existence of a function $V(\boldsymbol{x})$ having the properties indicated in Theorem 9.3 is *implied* by the property of asymptotic stability of the equilibrium $\boldsymbol{x} = 0$ of (9.1). In particular, the following result holds.

Theorem 9.4

Suppose the equilibrium $\boldsymbol{x} = 0$ of (9.1) is locally asymptotically stable. Then, there exist $d > 0$, a continuously differentiable function $V : \mathbb{R}^n \to \mathbb{R}$, and class $\mathcal{K}$ functions $\underline{\alpha}(\cdot)$, $\overline{\alpha}(\cdot)$, $\alpha(\cdot)$, such that (9.6) and (9.8) hold. If the equilibrium $\boldsymbol{x} = 0$ of (9.1) is globally asymptotically stable, there exist a continuously differentiable function $V : \mathbb{R}^n \to \mathbb{R}$, and class $\mathcal{K}_\infty$ functions $\underline{\alpha}(\cdot)$, $\overline{\alpha}(\cdot)$, $\alpha(\cdot)$, such that (9.6) and (9.8) hold with $d = \infty$.

To conclude, observe that, if $\boldsymbol{x} = 0$ is a hyperbolic equilibrium and all eigenvalues of $\mathbf{A}$ have negative real part, $|\boldsymbol{x}(t)|$ is bounded, for small $|\boldsymbol{x}(0)|$, by a class $\mathcal{KL}$ function $\beta(\cdot,\cdot)$ of the form

$$\beta(r, t) = M \mathrm{e}^{-\lambda t} r \,.$$

If the equilibrium $\boldsymbol{x} = 0$ of system (9.1) is globally asymptotically stable and, moreover, there exist numbers $d > 0$, $M > 0$, and $\boldsymbol{\lambda} > 0$ such that

$$|\boldsymbol{x}(t)| \le M \mathrm{e}^{-\lambda t} |\boldsymbol{x}(0)| \,, \qquad \begin{aligned} &\text{for all } |\boldsymbol{x}(0)| \le d \\ &\text{and all } t \ge 0 \,, \end{aligned}$$

it is said that this equilibrium is *globally asymptotically and locally exponentially* stable. It can be shown that the equilibrium $\boldsymbol{x} = 0$ of the nonlinear system (9.1) is globally asymptotically and locally exponentially stable if and only if there exists a continuously differentiable function $V(\boldsymbol{x}) : \mathbb{R}^n \to \mathbb{R}$, and class $\mathcal{K}_\infty$ functions $\underline{\alpha}(\cdot)$, $\overline{\alpha}(\cdot)$, $\alpha(\cdot)$, and real numbers $\delta > 0$, $\underline{a} > 0$, $\overline{a} > 0$, $a > 0$, such that

$$\left.\begin{aligned} \underline{\alpha}(|\boldsymbol{x}|) &\le V(\boldsymbol{x}) \le \overline{\alpha}(|\boldsymbol{x}|)\,, \\ \frac{\partial V}{\partial \boldsymbol{x}} f(\boldsymbol{x}) &\le -\alpha(|\boldsymbol{x}|)\,, \end{aligned}\right. \quad \text{for all } \boldsymbol{x} \in \mathbb{R}^n$$

and

$$\underline{\alpha}(s) = \underline{a}\, s^2\,, \quad \alpha(s) = \bar{a}\, s^2\,, \quad \alpha(s) = a\, s^2\,,$$
$$\text{for all } s \in [0, \delta]\,.$$

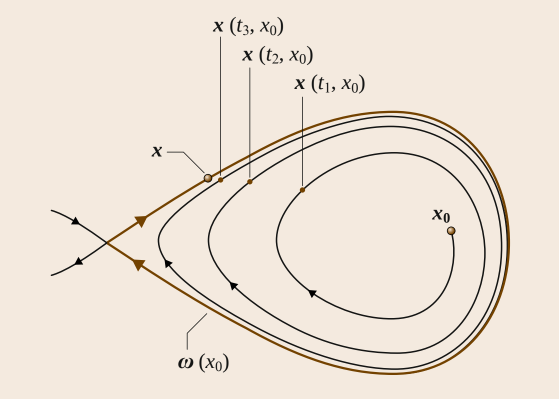
9.3 Asymptotic Behavior

9.3.1 Limit Sets

In the analysis of dynamical systems, it is often important to determine whether or not, as time increases, the variables characterizing the motion asymptotically converge to special motions exhibiting some form of recurrence. This is the case, for instance, when a system possesses an asymptotically stable equilibrium: all motions issued from initial conditions in a neighborhood of this point converge to a special motion in which all variables remain constant. A constant motion, or more generally a periodic motion, is characterized by a property of recurrence that is usually referred to as *steady-state* motion or behavior.

The steady-state behavior of a dynamical system can be viewed as a kind of *limit* behavior, approached either as the *actual* time t tends to $+\infty$ or, alternatively, as the *initial* time t_0 tends to $-\infty$. Relevant in this regard are certain concepts introduced by *Birkhoff* in [9.1]. In particular, a fundamental role is played by the concept of ω-limit set of a given point, defined as follows. Consider an *autonomous* dynamical system such as (9.1) and let $\boldsymbol{x}(t, \boldsymbol{x}_0)$ denote its flow. Assume, in particular, that $\boldsymbol{x}(t, \boldsymbol{x}_0)$ is defined for all $t \ge 0$. A point $\boldsymbol{x}$ is said to be an ω-limit *point* of the motion $\boldsymbol{x}(t, \boldsymbol{x}_0)$ if there exists a sequence of times $\{t_k\}$, with $\lim_{k\to\infty} t_k = \infty$, such that

$$\lim_{k\to\infty} \boldsymbol{x}(t_k, \boldsymbol{x}_0) = \boldsymbol{x}\,.$$



$\boldsymbol{x}\,(t_3, x_0)$
$\boldsymbol{x}\,(t_2, x_0)$
$\boldsymbol{x}\,(t_1, x_0)$
$\boldsymbol{x}$
$\boldsymbol{x}_0$
$\boldsymbol{\omega}\,(x_0)$

Fig. 9.2 The ω-limit set of a point x_0

The ω-limit *set* of a point $\boldsymbol{x}_0$, denoted $\omega(\boldsymbol{x}_0)$, is *the union* of all ω-limit points of the motion $\boldsymbol{x}(t, \boldsymbol{x}_0)$ (Fig. 9.2).

If $\boldsymbol{x}_\mathrm{e}$ is an asymptotically stable equilibrium, then $\boldsymbol{x}_\mathrm{e} = \omega(\boldsymbol{x}_0)$ for all $\boldsymbol{x}_0$ in a neighborhood of $\boldsymbol{x}_\mathrm{e}$. However, in general, an ω-limit point *is not* necessarily a limit of $\boldsymbol{x}(t, \boldsymbol{x}_0)$ as $t \to \infty$, because the function in question may not admit any limit as $t \to \infty$. It happens though, that if the motion $\boldsymbol{x}(t, \boldsymbol{x}_0)$ is *bounded*, then $\boldsymbol{x}(t, \boldsymbol{x}_0)$ asymptotically approaches *the set* $\omega(\boldsymbol{x}_0)$.

Lemma 9.1
Suppose there is a number M such that $|\boldsymbol{x}(t, \boldsymbol{x}_0)| \le M$ for all $t \ge 0$. Then, $\omega(\boldsymbol{x}_0)$ is a nonempty compact connected set, invariant under (9.1). Moreover, the distance of $\boldsymbol{x}(t, \boldsymbol{x}_0)$ from $\omega(\boldsymbol{x}_0)$ tends to 0 as $t \to \infty$.

It is seen from this that the set $\omega(\boldsymbol{x}_0)$ is filled by motions of (9.1) which are *defined, and bounded, for all backward and forward times*. The other remarkable feature is that $\boldsymbol{x}(t, \boldsymbol{x}_0)$ *approaches* $\omega(\boldsymbol{x}_0)$ as $t \to \infty$, in the sense that the distance *of the point* $\boldsymbol{x}(t, \boldsymbol{x}_0)$ (the value at time t of the solution of (9.1) starting in $\boldsymbol{x}_0$ at time $t = 0$) *to the set* $\omega(\boldsymbol{x}_0)$ tends to 0 as $t \to \infty$. A consequence of this property is that, in a system of the form (9.1), if *all* motions issued from a set B are bounded, all such motions asymptotically approach the set

$$\Omega = \bigcup_{x_0 \in B} \omega(\boldsymbol{x}_0)\,.$$

However, the convergence of $\boldsymbol{x}(t, \boldsymbol{x}_0)$ to Ω is not guaranteed to be *uniform* in $\boldsymbol{x}_0$, even if the set B is compact. There is a larger set, though, which does have this property of uniform convergence. This larger set, known as the ω-limit set *of the set* B, is precisely defined as follows.

Consider again system (9.1), let B be a subset of $\mathbb{R}^n$, and suppose $\boldsymbol{x}(t, \boldsymbol{x}_0)$ is defined for all $t \ge 0$ and all

$\boldsymbol{x}_0 \in B$. The ω-limit set of B, denoted $\omega(B)$, is the set of all points $\boldsymbol{x}$ for which there exists a sequence of pairs $\{\boldsymbol{x}_k, t_k\}$, with $\boldsymbol{x}_k \in B$ and $\lim_{k\to\infty} t_k = \infty$ such that

$$\lim_{k\to\infty} \boldsymbol{x}(t_k, \boldsymbol{x}_k) = \boldsymbol{x} .$$

It follows from the definition that, if B consists of only one single point $\boldsymbol{x}_0$, all $\boldsymbol{x}_k$ in the definition above are necessarily equal to $\boldsymbol{x}_0$ and the definition in question reduces to the definition of ω-limit set of a point, given earlier. It also follows that, if for some $\boldsymbol{x}_0 \in B$ the set $\omega(\boldsymbol{x}_0)$ is nonempty, all points of $\omega(\boldsymbol{x}_0)$ are points of $\omega(B)$. Thus, in particular, if all motions with $\boldsymbol{x}_0 \in B$ are bounded in positive time,

$$\bigcup_{\boldsymbol{x}_0\in B} \omega(\boldsymbol{x}_0) \subset \omega(B) .$$

However, the converse inclusion is not true in general.

The relevant properties of the ω-limit set of a set, which extend those presented earlier in Lemma 9.1, can be summarized as follows [9.2].

Lemma 9.2

Let B be a nonempty bounded subset of $\mathbb{R}^n$ and suppose there is a number M such that $|\boldsymbol{x}(t, \boldsymbol{x}_0)| \le M$ for all $t \ge 0$ and all $\boldsymbol{x}_0 \in B$. Then $\omega(B)$ is a nonempty compact set, invariant under (9.1). Moreover, the distance of $\boldsymbol{x}(t, \boldsymbol{x}_0)$ from $\omega(B)$ tends to 0 as $t \to \infty$, uniformly in $\boldsymbol{x}_0 \in B$. If B is connected, so is $\omega(B)$.

Thus, as is the case for the ω-limit set of a point, the ω-limit set of a bounded set B, being compact and invariant, is filled with motions which exist for all $t \in (-\infty, +\infty)$ and are bounded backward and forward in time. But, above all, the set in question is *uniformly* approached by motions with initial state $\boldsymbol{x}_0 \in B$. An important corollary of the property of uniform convergence is that, if $\omega(B)$ is contained in the interior of B, then $\omega(B)$ is also asymptotically stable.

Lemma 9.3

Let B be a nonempty bounded subset of $\mathbb{R}^n$ and suppose there is a number M such that $|\boldsymbol{x}(t, \boldsymbol{x}_0)| \le M$ for all $t \ge 0$ and all $\boldsymbol{x}_0 \in B$. Then $\omega(B)$ is a nonempty compact set, invariant under (9.1). Suppose also that $\omega(B)$ is contained in the interior of B. Then, $\omega(B)$ is asymptotically stable, with a domain of attraction that contains B.

9.3.2 Steady-State Behavior

Consider now again system (9.1), with initial conditions in a closed subset $X \subset \mathbb{R}^n$. Suppose the set X is *positively invariant*, which means that, for any initial condition $\boldsymbol{x}_0 \in X$, the solution $\boldsymbol{x}(t, \boldsymbol{x}_0)$ exists for all $t \ge 0$ and $\boldsymbol{x}(t, \boldsymbol{x}_0) \in X$ for all $t \ge 0$. The motions of this system are said to be *ultimately bounded* if there is a bounded subset B with the property that, for every compact subset X_0 of X, there is a time $T > 0$ such that $\boldsymbol{x}(t, \boldsymbol{x}_0) \in B$ for all $t \ge T$ and all $\boldsymbol{x}_0 \in X_0$. In other words, if the motions of the system are ultimately bounded, every motion eventually enters and remains in the bounded set B.

Suppose the motions of (9.1) are ultimately bounded and let $B' \neq B$ be any other bounded subset with the property that, for every compact subset X_0 of X, there is a time $T > 0$ such that $\boldsymbol{x}(t, \boldsymbol{x}_0) \in B'$ for all $t \ge T$ and all $\boldsymbol{x}_0 \in X_0$. Then, it is easy to check that $\omega(B') = \omega(B)$. Thus, in view of the properties described in Lemma 9.2 above, the following definition can be adopted [9.3].

Definition 9.3

Suppose the motions of system (9.1), with initial conditions in a closed and positively invariant set X, are ultimately bounded. A *steady-state* motion is any motion with initial condition $\boldsymbol{x}(0) \in \omega(B)$. The set $\omega(B)$ is the *steady-state locus* of (9.1) and the *restriction* of (9.1) to $\omega(B)$ is the *steady-state behavior* of (9.1).

9.4 Dynamical Systems with Inputs

9.4.1 Input-to-State Stability (ISS)

In this section we show how to determine the stability properties of an interconnected system, on the basis of the properties of each individual component. The easiest interconnection to be analyzed is a cascade connection of two subsystems, namely a system of the form

$$\begin{aligned} \dot{\boldsymbol{x}} &= f(\boldsymbol{x}, \boldsymbol{z}) , \\ \dot{\boldsymbol{z}} &= g(\boldsymbol{z}) , \end{aligned} \tag{9.9}$$

with $\boldsymbol{x} \in \mathbb{R}^n$, $\boldsymbol{z} \in \mathbb{R}^m$ in which we assume $f(0, 0) = 0$, $g(0) = 0$.

If the equilibrium $\boldsymbol{x}=0$ of $\dot{\boldsymbol{x}}=f(\boldsymbol{x},0)$ is locally asymptotically stable and the equilibrium $\boldsymbol{z}=0$ of the lower subsystem is locally asymptotically stable then the equilibrium $(\boldsymbol{x},\boldsymbol{z})=(0,0)$ of the cascade is locally asymptotically stable. However, in general, *global* asymptotic stability of the equilibrium $\boldsymbol{x}=0$ of $\dot{\boldsymbol{x}}=f(\boldsymbol{x},0)$ and *global* asymptotic stability of the equilibrium $\boldsymbol{z}=0$ of the lower subsystem *do not* imply *global* asymptotic stability of the equilibrium $(\boldsymbol{x},\boldsymbol{z})=(0,0)$ of the cascade. To infer global asymptotic stability of the cascade, a stronger condition is needed, which expresses a property describing how – in the upper subsystem – the response $\boldsymbol{x}(\cdot)$ is influenced by its *input* $\boldsymbol{z}(\cdot)$.

The property in question requires that, when $\boldsymbol{z}(t)$ is bounded over the semi-infinite time interval $[0,+\infty)$, then also $\boldsymbol{x}(t)$ be bounded, and in particular that, if $\boldsymbol{z}(t)$ asymptotically decays to 0, then also $\boldsymbol{x}(t)$ decays to 0. These requirements altogether lead to the notion of *input-to-state stability*, introduced and studied in [9.4, 5]. The notion in question is defined as follows (see also [9.6, Chap. 10] for additional details). Consider a nonlinear system

$$\dot{\boldsymbol{x}}=f(\boldsymbol{x},\boldsymbol{u})\,, \tag{9.10}$$

with state $\boldsymbol{x}\in\mathbb{R}^n$ and input $\boldsymbol{u}\in\mathbb{R}^m$, in which $f(0,0)=0$ and $f(\boldsymbol{x},\boldsymbol{u})$ is locally Lipschitz on $\mathbb{R}^n\times\mathbb{R}^m$. The input function $\boldsymbol{u}:[0,\infty)\to\mathbb{R}^m$ of (9.10) can be any piecewise-continuous bounded function. The set of all such functions, endowed with the supremum norm

$$\|\boldsymbol{u}(\cdot)\|_\infty=\sup_{t\geq 0}|\boldsymbol{u}(t)|$$

is denoted by L_∞^m.

Definition 9.4

System (9.10) is said to be input-to-state stable if there exist a class $\mathcal{KL}$ function $\beta(\cdot,\cdot)$ and a class $\mathcal{K}$ function $\gamma(\cdot)$, called a gain function, such that, for any input $\boldsymbol{u}(\cdot)\in L_\infty^m$ and any $\boldsymbol{x}_0\in\mathbb{R}^n$, the response $\boldsymbol{x}(t)$ of (9.10) in the initial state $\boldsymbol{x}(0)=\boldsymbol{x}_0$ satisfies

$$|\boldsymbol{x}(t)|\leq\beta(|\boldsymbol{x}_0|,t)+\gamma(\|\boldsymbol{u}(\cdot)\|_\infty)\,,\quad \text{for all } t\geq 0\,. \tag{9.11}$$

It is common practice to replace the wording *input-to-state stable* with the acronym ISS. In this way, a system possessing the property expressed by (9.11) is said to be an ISS system. Since, for any pair $\beta>0$, $\gamma>0$, $\max\{\beta,\gamma\}\leq\beta+\gamma\leq\max\{2\beta,2\gamma\}$, an alternative way to say that a system is input-to-state stable is to say that there exists a class $\mathcal{KL}$ function $\beta(\cdot,\cdot)$ and a class $\mathcal{K}$ function $\gamma(\cdot)$ such that, for any input $\boldsymbol{u}(\cdot)\in L_\infty^m$ and any $\boldsymbol{x}_0\in\mathbb{R}^n$, the response $\boldsymbol{x}(t)$ of (9.10) in the initial state $\boldsymbol{x}(0)=\boldsymbol{x}_0$ satisfies

$$|\boldsymbol{x}(t)|\leq\max\{\beta(|\boldsymbol{x}_0|,t),\gamma(\|\boldsymbol{u}(\cdot)\|_\infty)\}\,,\quad \text{for all } t\geq 0\,. \tag{9.12}$$

The property, for a given system, of being input-to-state stable, can be given a characterization which extends the criterion of Lyapunov for asymptotic stability. The key tool for this analysis is the notion of *ISS-Lyapunov function*, defined as follows.

Definition 9.5

A C^1 function $V:\mathbb{R}^n\to\mathbb{R}$ is an ISS-Lyapunov function for system (9.10) if there exist class $\mathcal{K}_\infty$ functions $\underline{\alpha}(\cdot)$, $\overline{\alpha}(\cdot)$, $\alpha(\cdot)$, and a class $\mathcal{K}$ function $\chi(\cdot)$ such that

$$\underline{\alpha}(|\boldsymbol{x}|)\leq V(\boldsymbol{x})\leq\overline{\alpha}(|\boldsymbol{x}|)\,,\quad \text{for all } \boldsymbol{x}\in\mathbb{R}^n \tag{9.13}$$

and

$$|\boldsymbol{x}|\geq\chi(|\boldsymbol{u}|)\Rightarrow\frac{\partial V}{\partial\boldsymbol{x}}f(\boldsymbol{x},\boldsymbol{u})\leq-\alpha(|\boldsymbol{x}|)\,,\quad \text{for all } \boldsymbol{x}\in\mathbb{R}^n \text{and } \boldsymbol{u}\in\mathbb{R}^m\,. \tag{9.14}$$

An alternative, equivalent, definition is the following one.

Definition 9.6

A C^1 function $V:\mathbb{R}^n\to\mathbb{R}$ is an ISS-Lyapunov function for system (9.10) if there exist class $\mathcal{K}_\infty$ functions $\underline{\alpha}(\cdot)$, $\overline{\alpha}(\cdot)$, $\alpha(\cdot)$, and a class $\mathcal{K}$ function $\sigma(\cdot)$ such that (9.13) holds and

$$\frac{\partial V}{\partial\boldsymbol{x}}f(\boldsymbol{x},\boldsymbol{u})\leq-\alpha(|\boldsymbol{x}|)+\sigma(|\boldsymbol{u}|)\,,\quad \text{for all } \boldsymbol{x}\in\mathbb{R}^n \text{and all } \boldsymbol{u}\in\mathbb{R}^m\,. \tag{9.15}$$

The importance of the notion of ISS-Lyapunov function resides in the following criterion, which extends the criterion of Lyapunov for global asymptotic stability to systems with inputs.

Theorem 9.5

System (9.10) is input-to-state stable if and only if there exists an ISS-Lyapunov function.

The comparison functions appearing in the estimates (9.13) and (9.14) are useful to obtain an estimate of the gain function $\gamma(\cdot)$ which characterizes the bound (9.12). In fact, it can be shown that, if system (9.10) possesses an ISS-Lyapunov function $V(\boldsymbol{x})$, the sublevel set

$$\Omega_{\|u(\cdot)\|_\infty} = \{\boldsymbol{x} \in \mathbb{R}^n : V(\boldsymbol{x}) \le \overline{\alpha}(\chi(\|\boldsymbol{u}(\cdot)\|_\infty))\}$$

is invariant in positive time for (9.10). Thus, in view of the estimates (9.13), if the initial state of the system is initially inside this sublevel set, the following estimate holds

$$|\boldsymbol{x}(t)| \le \underline{\alpha}^{-1}\big(\overline{\alpha}(\chi(\|\boldsymbol{u}(\cdot)\|_\infty))\big) , \qquad \text{for all } t \ge 0 ,$$

and one can obtain an estimate of $\gamma(\cdot)$ as

$$\gamma(r) = \underline{\alpha}^{-1} \circ \overline{\alpha} \circ \chi(r) .$$

In other words, establishing the existence of an ISS-Lyapunov function $V(\boldsymbol{x})$ is useful not only to check whether or not the system in question is input-to-state stable, but also to determine an estimate of the gain function $\gamma(\cdot)$. Knowing such estimate is important, as will be shown later, in using the concept of input-to-state stability to determine the stability of interconnected systems.

The following simple examples may help understanding the concept of input-to-state stability and the associated Lyapunov-like theorem.

Example 9.1: Consider a linear system

$$\dot{\boldsymbol{x}} = \mathbf{A}\boldsymbol{x} + \mathbf{B}\boldsymbol{u} ,$$

with $\boldsymbol{x} \in \mathbb{R}^n$ and $\boldsymbol{u} \in \mathbb{R}^m$ and suppose that all the eigenvalues of the matrix $\mathbf{A}$ have negative real part. Let $\mathbf{P} > 0$ denote the unique solution of the Lyapunov equation $\mathbf{PA} + \mathbf{A}^\top\mathbf{P} = -\mathbf{I}$. Observe that the function $V(\boldsymbol{x}) = \boldsymbol{x}^\top\mathbf{P}\boldsymbol{x}$ satisfies

$$\underline{a}|\boldsymbol{x}|^2 \le V(\boldsymbol{x}) \le \overline{a}|\boldsymbol{x}|^2 ,$$

for suitable $\underline{a} > 0$ and $\overline{a} > 0$, and that

$$\frac{\partial V}{\partial \boldsymbol{x}}(\mathbf{A}\boldsymbol{x} + \mathbf{B}\boldsymbol{u}) \le -|\boldsymbol{x}|^2 + 2|\boldsymbol{x}||\mathbf{P}||\mathbf{B}||\boldsymbol{u}| .$$

Pick any $0 < \varepsilon < 1$ and set

$$c = \frac{2}{1-\varepsilon}|\mathbf{P}||\mathbf{B}| , \qquad \chi(r) = cr .$$

Then

$$|\boldsymbol{x}| \ge \chi(|\boldsymbol{u}|) \Rightarrow \frac{\partial V}{\partial \boldsymbol{x}}(\mathbf{A}\boldsymbol{x} + \mathbf{B}\boldsymbol{u}) \le -\varepsilon|\boldsymbol{x}|^2 .$$

Thus, the system is input-to-state stable, with a gain function

$$\gamma(r) = (c\,\overline{a}/\underline{a})\,r$$

which is a *linear* function.

Consider now the simple nonlinear one-dimensional system

$$\dot{\boldsymbol{x}} = -a\boldsymbol{x}^k + \boldsymbol{x}^p\boldsymbol{u} ,$$

in which $k \in \mathbb{N}$ is odd, $p \in \mathbb{N}$ satisfies $p < k$, and $a > 0$. Choose a candidate ISS-Lyapunov function as $V(\boldsymbol{x}) = \frac{1}{2}\boldsymbol{x}^2$, which yields

$$\frac{\partial V}{\partial \boldsymbol{x}} f(\boldsymbol{x}, \boldsymbol{u}) = \\ -a\boldsymbol{x}^{k+1} + \boldsymbol{x}^{p+1}\boldsymbol{u} \le -a|\boldsymbol{x}|^{k+1} + |\boldsymbol{x}|^{p+1}|\boldsymbol{u}| .$$

Set $\nu = k - p$ to obtain

$$\frac{\partial V}{\partial \boldsymbol{x}} f(\boldsymbol{x}, \boldsymbol{u}) \le |\boldsymbol{x}|^{p+1}\Big(-a|\boldsymbol{x}|^\nu + |\boldsymbol{u}|\Big) .$$

Thus, using the class $\mathcal{K}_\infty$ function $\alpha(r) = \varepsilon r^{k+1}$, with $\varepsilon > 0$, it is deduced that

$$\frac{\partial V}{\partial \boldsymbol{x}} f(\boldsymbol{x}, \boldsymbol{u}) \le -\alpha(|\boldsymbol{x}|)$$

provided that

$$(a - \varepsilon)|\boldsymbol{x}|^\nu \ge |\boldsymbol{u}| .$$

Taking, without loss of generality, $\varepsilon < a$, it is concluded that condition (9.14) holds for the class $\mathcal{K}$ function

$$\chi(r) = \left(\frac{r}{a-\varepsilon}\right)^{\frac{1}{\nu}} .$$

Thus, the system is input-to-state stable.

An important feature of the previous example, which made it possible to prove the system is input-to-state stable, is the inequality $p < k$. In fact, if this inequality does not hold, the system may fail to be input-to-state stable. This can be seen, for instance, in the simple example

$$\dot{\boldsymbol{x}} = -\boldsymbol{x} + \boldsymbol{x}\boldsymbol{u} .$$

To this end, suppose $\boldsymbol{u}(t) = 2$ for all $t \ge 0$. The state response of the system, to this input, from the initial state $\boldsymbol{x}(0) = \boldsymbol{x}_0$ coincides with that of the autonomous system $\dot{\boldsymbol{x}} = \boldsymbol{x}$, i. e., $\boldsymbol{x}(t) = \mathrm{e}^t\boldsymbol{x}_0$, which shows that the bound (9.11) cannot hold.

We conclude with an alternative characterization of the property of input-to-state stability, which is useful in many instances [9.7].

Theorem 9.6
System (9.10) is input-to-state stable if and only if there exist class $\mathcal{K}$ functions $\gamma_0(\cdot)$ and $\gamma(\cdot)$ such that, for any input $\boldsymbol{u}(\cdot) \in L_\infty^m$ and any $\boldsymbol{x}_0 \in \mathbb{R}^n$, the response $\boldsymbol{x}(t)$ in the initial state $\boldsymbol{x}(0) = \boldsymbol{x}_0$ satisfies

$$\begin{aligned} \|\boldsymbol{x}(\cdot)\|_\infty &\le \max\{\gamma_0(|\boldsymbol{x}_0|), \gamma(\|\boldsymbol{u}(\cdot)\|_\infty)\} , \\ \limsup_{t\to\infty} |\boldsymbol{x}(t)| &\le \gamma(\limsup_{t\to\infty} |\boldsymbol{u}(t)|) . \end{aligned}$$

9.4.2 Cascade Connections

The property of input-to-state stability is of paramount importance in the analysis of interconnected systems. The first application consists of the analysis of the *cascade connection*. In fact, the cascade connection of two input-to-state stable systems turns out to be input-to-state stable. More precisely, consider a system of the form (Fig. 9.3)

$$\begin{aligned} \dot{\boldsymbol{x}} &= f(\boldsymbol{x}, \boldsymbol{z}) , \\ \dot{\boldsymbol{z}} &= g(\boldsymbol{z}, \boldsymbol{u}) , \end{aligned} \qquad (9.16)$$

in which $\boldsymbol{x} \in \mathbb{R}^n$, $\boldsymbol{z} \in \mathbb{R}^m$, $f(0,0) = 0$, $g(0,0) = 0$, and $f(\boldsymbol{x}, \boldsymbol{z})$, $g(\boldsymbol{z}, \boldsymbol{u})$ are locally Lipschitz.

Theorem 9.7
Suppose that system

$$\dot{\boldsymbol{x}} = f(\boldsymbol{x}, \boldsymbol{z}) , \qquad (9.17)$$

viewed as a system with input $\boldsymbol{z}$ and state $\boldsymbol{x}$, is input-to-state stable and that system

$$\dot{\boldsymbol{z}} = g(\boldsymbol{z}, \boldsymbol{u}) , \qquad (9.18)$$

viewed as a system with input $\boldsymbol{u}$ and state $\boldsymbol{z}$, is input-to-state stable as well. Then, system (9.16) is input-to-state stable.

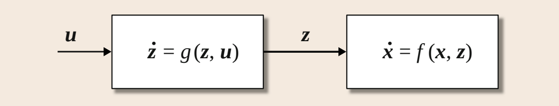
As an immediate corollary of this theorem, it is possible to answer the question of when the cascade connection (9.9) is globally asymptotically stable. In fact, if system

$$\dot{\boldsymbol{x}} = f(\boldsymbol{x}, \boldsymbol{z}) ,$$

viewed as a system with input $\boldsymbol{z}$ and state $\boldsymbol{x}$, is input-to-state stable and the equilibrium $\boldsymbol{z} = 0$ of the lower subsystem is globally asymptotically stable, the equilibrium $(\boldsymbol{x}, \boldsymbol{z}) = (0, 0)$ of system (9.9) is globally asymptotically stable. This is in particular the case if system (9.9) has the special form

$$\begin{aligned} \dot{\boldsymbol{x}} &= \mathbf{A}\boldsymbol{x} + p(\boldsymbol{z}) , \\ \dot{\boldsymbol{z}} &= g(\boldsymbol{z}) , \end{aligned} \qquad (9.19)$$

with $p(0) = 0$ and the matrix $\mathbf{A}$ has all eigenvalues with negative real part. The upper subsystem of the cascade is input-to-state stable and hence, if the equilibrium $\boldsymbol{z} = 0$ of the lower subsystem is globally asymptotically stable, so is the equilibrium $(\boldsymbol{x}, \boldsymbol{z}) = (0, 0)$ of the entire system.



$\boldsymbol{u}$
$\dot{\boldsymbol{z}} = g(\boldsymbol{z}, \boldsymbol{u})$
$\boldsymbol{z}$
$\dot{\boldsymbol{x}} = f(\boldsymbol{x}, \boldsymbol{z})$

Fig. 9.3 Cascade connection

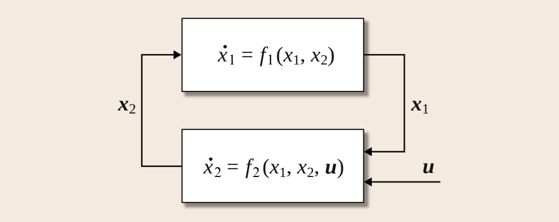
9.4.3 Feedback Connections

In this section we investigate the stability property of nonlinear systems, and we will see that the property of input-to-state stability lends itself to a simple characterization of an important *sufficient condition* under which the feedback interconnection of two globally asymptotically stable systems remains globally asymptotically stable.

Consider the following interconnected system (Fig. 9.3)

$$\begin{aligned} \dot{\boldsymbol{x}}_1 &= f_1(\boldsymbol{x}_1, \boldsymbol{x}_2) , \\ \dot{\boldsymbol{x}}_2 &= f_2(\boldsymbol{x}_1, \boldsymbol{x}_2, u) , \end{aligned} \qquad (9.20)$$

in which $\boldsymbol{x}_1 \in \mathbb{R}^{n_1}$, $\boldsymbol{x}_2 \in \mathbb{R}^{n_2}$, $\boldsymbol{u} \in \mathbb{R}^m$, and $f_1(0,0) = 0$, $f_2(0,0,0) = 0$. Suppose that the first subsystem, viewed as a system with internal state $\boldsymbol{x}_1$ and input $\boldsymbol{x}_2$, is input-to-state stable. Likewise, suppose that the second subsystem, viewed as a system with internal state $\boldsymbol{x}_2$ and inputs $\boldsymbol{x}_1$ and $\boldsymbol{u}$, is input-to-state stable. In view of the results presented earlier, the hypothesis of input-to-state stability of the first subsystem is equivalent to the existence of functions $\beta_1(\cdot,\cdot)$, $\gamma_1(\cdot)$, the first of class $\mathcal{KL}$



$\dot{x}_1 = f_1(x_1, x_2)$
$\boldsymbol{x}_2$
$\boldsymbol{x}_1$
$\dot{x}_2 = f_2(x_1, x_2, \boldsymbol{u})$
$\boldsymbol{u}$

Fig. 9.4 Feedback connection

and the second of class $\mathcal{K}$, such that the response $\boldsymbol{x}_1(\cdot)$ to any input $\boldsymbol{x}_2(\cdot) \in L_\infty^{n_2}$ satisfies

$$|\boldsymbol{x}_1(t)| \le \max\{\beta_1(\|\boldsymbol{x}_1(0)\|, t), \gamma_1(\|\boldsymbol{x}_2(\cdot)\|_\infty)\}\,, \quad \text{for all } t \ge 0\,. \tag{9.21}$$

Likewise the hypothesis of input-to-state stability of the second subsystem is equivalent to the existence of three class functions $\beta_2(\cdot)$, $\gamma_2(\cdot)$, $\gamma_u(\cdot)$ such that the response $\boldsymbol{x}_2(\cdot)$ to any input $\boldsymbol{x}_1(\cdot) \in L_\infty^{n_1}$, $\boldsymbol{u}(\cdot) \in L_\infty^{m}$ satisfies

$$\begin{aligned}&|\boldsymbol{x}_2(t)| \le \\ &\max\{\beta_2(\|\boldsymbol{x}_2(0)\|, t), \gamma_2(\|\boldsymbol{x}_1(\cdot)\|_\infty), \gamma_u(\|\boldsymbol{u}(\cdot)\|_\infty)\}\,, \\ &\text{for all } t \ge 0\,.\end{aligned} \tag{9.22}$$

The important result for the analysis of the stability of the interconnected system (9.20) is that, if the composite function $\gamma_1 \circ \gamma_2(\cdot)$ is a *simple contraction*, i. e., if

$$\gamma_1(\gamma_2(r)) < r\,, \qquad \text{for all } r > 0\,, \tag{9.23}$$

the system in question is input-to-state stable. This result is usually referred to as the *small-gain* theorem.

Theorem 9.8
If the condition (9.23) holds, system (9.20), viewed as a system with state $\boldsymbol{x} = (\boldsymbol{x}_1, \boldsymbol{x}_2)$ and input $\boldsymbol{u}$, is input-to-state stable.

The condition (9.23), i. e., the condition that the composed function $\gamma_1 \circ \gamma_2(\cdot)$ is a contraction, is usually referred to as the *small-gain condition*. It can be written in different alternative ways depending on how the functions $\gamma_1(\cdot)$ and $\gamma_2(\cdot)$ are estimated. For instance, if it is known that $V_1(\boldsymbol{x}_1)$ is an ISS-Lyapunov function for the upper subsystem of (9.20), i. e., a function such

$$\begin{aligned}&\underline{\alpha}_1(|\boldsymbol{x}_1|) \le V_1(\boldsymbol{x}_1) \le \overline{\alpha}_1(|\boldsymbol{x}_1|)\,, \\ &|\boldsymbol{x}_1| \ge \chi_1(|\boldsymbol{x}_2|) \Rightarrow \frac{\partial V_1}{\partial \boldsymbol{x}_1} f_1(\boldsymbol{x}_1, \boldsymbol{x}_2) \le -\alpha(|\boldsymbol{x}_1|)\,,\end{aligned}$$

then $\gamma_1(\cdot)$ can be estimated by

$$\gamma_1(r) = \underline{\alpha}_1^{-1} \circ \overline{\alpha}_1 \circ \chi_1(r)\,.$$

Likewise, if $V_2(\boldsymbol{x}_2)$ is a function such that

$$\begin{aligned}&\underline{\alpha}_2(|\boldsymbol{x}_2|) \le V_2(\boldsymbol{x}_2) \le \overline{\alpha}_2(|\boldsymbol{x}_2|)\,, \\ &|\boldsymbol{x}_2| \ge \max\{\chi_2(|\boldsymbol{x}_1|), \chi_u(|\boldsymbol{u}|)\} \Rightarrow \\ &\quad \frac{\partial V_2}{\partial \boldsymbol{x}_2} f_2(\boldsymbol{x}_1, \boldsymbol{x}_2, \boldsymbol{u}) \le -\alpha(|\boldsymbol{x}_2|)\,,\end{aligned}$$

then $\gamma_2(\cdot)$ can be estimated by

$$\gamma_2(r) = \underline{\alpha}_2^{-1} \circ \overline{\alpha}_2 \circ \chi_2(r)\,.$$

If this is the case, the small-gain condition of the theorem can be written in the form

$$\underline{\alpha}_1^{-1} \circ \overline{\alpha}_1 \circ \chi_1 \circ \underline{\alpha}_2^{-1} \circ \overline{\alpha}_2 \circ \chi_2(r) < r\,.$$

9.4.4 The Steady-State Response

In this subsection we show how the concept of steady state, introduced earlier, and the property of input-to-state stability are useful in the analysis of the *steady-state response* of a system to inputs generated by a separate autonomous dynamical system [9.8].

Example 9.2: Consider an n-dimensional, single-input, *asymptotically stable* linear system

$$\dot{\boldsymbol{z}} = \mathbf{F}\mathbf{z} + \mathbf{G}\mathbf{u} \tag{9.24}$$

forced by the harmonic input $\boldsymbol{u}(t) = u_0 \sin(\omega t + \phi_0)$. A simple method to analyze the asymptotic behavior of (9.24) consists of viewing the forcing input $\boldsymbol{u}(t)$ as provided by an autonomous *signal generator* of the form

$$\begin{aligned}\dot{\boldsymbol{w}} &= \mathbf{S}\boldsymbol{w}\,, \\ \boldsymbol{u} &= \mathbf{Q}\boldsymbol{w}\,,\end{aligned}$$

in which

$$\mathbf{S} = \begin{pmatrix} 0 & \omega \\ -\omega & 0 \end{pmatrix}, \qquad \mathbf{Q} = \begin{pmatrix} 1 & 0 \end{pmatrix},$$

and in analyzing the state-state behavior of the associated *augmented* system

$$\begin{aligned}\dot{\boldsymbol{w}} &= \mathbf{S}\boldsymbol{w}\,, \\ \dot{\boldsymbol{z}} &= \mathbf{F}\mathbf{z} + \mathbf{G}\mathbf{Q}\boldsymbol{w}\,.\end{aligned} \tag{9.25}$$

As a matter of fact, let $\boldsymbol{\Pi}$ be the unique solution of the Sylvester equation $\boldsymbol{\Pi}\mathbf{S} = \mathbf{F}\boldsymbol{\Pi} + \mathbf{G}\mathbf{Q}$ and observe that the graph of the linear map $\boldsymbol{z} = \boldsymbol{\Pi}\boldsymbol{w}$ is an invariant subspace for the system (9.25). Since all trajectories of (9.25) approach this subspace as $t \to \infty$, the limit behavior of (9.25) is determined by the restriction of its motion to this invariant subspace.

Revisiting this analysis from the viewpoint of the more general notion of steady-state introduced earlier, let $W \subset \mathbb{R}^2$ be a set of the form

$$W = \{\boldsymbol{w} \in \mathbb{R}^2 : \|\boldsymbol{w}\| \le c\}\,, \tag{9.26}$$

in which c is a fixed number, and suppose the set of initial conditions for (9.25) is $W \times \mathbb{R}^n$. This is in fact the case when the problem of evaluating the periodic response of (9.24) to harmonic inputs whose amplitude does not exceed a fixed number c is addressed. The set W is compact and invariant for the upper subsystem of (9.25) and, as is easy to check, the ω-limit set of W under the motion of the upper subsystem of (9.25) is the subset W itself.

The set $W \times \mathbb{R}^n$ is closed and positively invariant for the full system (9.25) and, moreover, since the lower subsystem of (9.25) is input-to-state stable, the motions of system of (9.25), for initial conditions taken in $W \times \mathbb{R}^n$, are ultimately bounded. It is easy to check that

$$\omega(\mathbf{B}) = \{(\boldsymbol{w}, \boldsymbol{z}) \in \mathbb{R}^2 \times \mathbb{R}^n : \boldsymbol{w} \in W, \boldsymbol{z} = \boldsymbol{\Pi} \boldsymbol{w}\} ,$$

i. e., that $\omega(\mathbf{B})$ is the graph of the restriction of the map $\boldsymbol{z} = \Pi \boldsymbol{w}$ to the set W. The restriction of (9.25) to the invariant set $\omega(\mathbf{B})$ characterizes the steady-state behavior of (9.24) under the family of all harmonic inputs of fixed angular frequency ω and amplitude not exceeding c.

Example 9.3: A similar result, namely the fact that the *steady-state locus* is the *graph* of a map, can be reached if the *signal generator* is any nonlinear system, with initial conditions chosen in a compact invariant set W. More precisely, consider an augmented system of the form

$$\begin{aligned} \dot{\boldsymbol{w}} &= s(\boldsymbol{w}) , \\ \dot{\boldsymbol{z}} &= \mathbf{F}\mathbf{z} + \mathbf{G}q(\boldsymbol{w}) , \end{aligned} \tag{9.27}$$

in which $\boldsymbol{w} \in W \subset \mathbb{R}^r$, $\boldsymbol{x} \in \mathbb{R}^n$, and assume that: (i) all eigenvalues of F have negative real part, and (ii) the set W is a compact set, invariant for the the upper subsystem of (9.27).

As in the previous example, the ω-limit set of W under the motion of the upper subsystem of (9.27) is the subset W itself. Moreover, since the lower subsystem of (9.27) is input-to-state stable, the motions of system (9.27), for initial conditions taken in $W \times \mathbb{R}^n$, are ultimately bounded. It is easy to check that the steady-state locus of (9.27) is the graph of the map

$$\begin{aligned} \pi : W &\to \mathbb{R}^n , \\ \boldsymbol{w} &\mapsto \pi(\boldsymbol{w}) , \end{aligned}$$

defined by

$$\pi(\boldsymbol{w}) = \lim_{T \to \infty} \int_{-T}^{0} \mathrm{e}^{-F\tau} \mathbf{G} q(\boldsymbol{w}(\tau, \boldsymbol{w})) \, \mathrm{d}\tau . \tag{9.28}$$

There are various ways in which the result discussed in the previous example can be generalized; for instance, it can be extended to describe the steady-state response of a nonlinear system

$$\dot{\boldsymbol{z}} = f(\boldsymbol{z}, \boldsymbol{u}) \tag{9.29}$$

in the neighborhood of a locally exponentially stable equilibrium point. To this end, suppose that $f(0, 0) = 0$ and that the matrix

$$\mathbf{F} = \left[\frac{\partial f}{\partial \boldsymbol{z}}\right](0, 0)$$

has all eigenvalues with negative real part. Then, it is well known (see, e.g., [9.9, p. 275]) that it is always possible to find a compact subset $Z \subset \mathbb{R}^n$, which contains $\boldsymbol{z} = 0$ in its interior and a number $\sigma > 0$ such that, if $|\boldsymbol{z}_0| \in Z$ and $\|\boldsymbol{u}(t)\| \leq \sigma$ for all $t \geq 0$, the solution of (9.29) with initial condition $\boldsymbol{z}(0) = \boldsymbol{z}_0$ satisfies $|\boldsymbol{z}(t)| \in Z$ for all $t \geq 0$. Suppose that the input $\boldsymbol{u}$ to (9.29) is produced, as before, by a signal generator of the form

$$\begin{aligned} \dot{\boldsymbol{w}} &= s(\boldsymbol{w}) , \\ \boldsymbol{u} &= q(\boldsymbol{w}) , \end{aligned} \tag{9.30}$$

with initial conditions chosen in a compact invariant set W and, moreover, suppose that, $\|q(\boldsymbol{w})\| \leq \sigma$ for all $\boldsymbol{w} \in W$. If this is the case, the set $W \times Z$ is positively invariant for

$$\begin{aligned} \dot{\boldsymbol{w}} &= s(\boldsymbol{w}) , \\ \dot{\boldsymbol{z}} &= f(\boldsymbol{z}, q(\boldsymbol{w})) , \end{aligned} \tag{9.31}$$

and the motions of the latter are ultimately bounded, with $\mathbf{B} = W \times Z$. The set $\omega(\mathbf{B})$ may have a complicated structure but it is possible to show, by means of arguments similar to those which are used in the proof of the center manifold theorem, that if Z and $\mathbf{B}$ are small enough, the set in question can still be expressed as the graph of a map $\boldsymbol{z} = \pi(\boldsymbol{w})$. In particular, the graph in question is precisely the center manifold of (9.31) at $(0, 0)$ if $s(0) = 0$, and the matrix

$$S = \left[\frac{\partial s}{\partial \boldsymbol{w}}\right](0)$$

has all eigenvalues on the imaginary axis.

A common feature of the examples discussed above is the fact that the steady-state locus of a system of the form (9.31) can be expressed as the graph of a map $\boldsymbol{z} = \pi(\boldsymbol{w})$. This means that, so long as this is the case, a system of this form has a *unique* well-defined *steady-state response* to the input $\boldsymbol{u}(t) = q(\boldsymbol{w}(t))$. As a matter of fact, the response in question is precisely $\boldsymbol{z}(t) = \pi(\boldsymbol{w}(t))$. Of course, this may not always be the case and *multiple* steady-state responses to a given input may occur. In general, the following property holds.

Lemma 9.4
Let W be a compact set, invariant under the flow of (9.30). Let Z be a closed set and suppose that the motions of (9.31) with initial conditions in $W \times Z$ are ultimately bounded. Then, the steady-state locus of (9.31) is the graph of a set-valued map defined on the whole of W.

9.5 Feedback Stabilization of Linear Systems

9.5.1 Stabilization by Pure State Feedback

Consider a linear system, modeled by equations of the form

$$\begin{aligned} \dot{\boldsymbol{x}} &= \mathbf{A}\boldsymbol{x} + \mathbf{B}\boldsymbol{u} , \\ \boldsymbol{y} &= \mathbf{C}\boldsymbol{x} , \end{aligned} \tag{9.32}$$

in which $\boldsymbol{x} \in \mathbb{R}^n$, $\boldsymbol{u} \in \mathbb{R}^m$, and $\boldsymbol{y} \in \mathbb{R}^p$, and in which $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$ are matrices with real entries.

We begin by analyzing the influence, on the response of the system, of control law of the form

$$\boldsymbol{u} = \mathbf{F}\boldsymbol{x} , \tag{9.33}$$

in which $\mathbf{F}$ is an $n \times m$ matrix with real entries. This type of control is usually referred to as *pure state feedback* or *memoryless state feedback*. The imposition of this control law on the first equation of (9.32) yields the autonomous linear system

$$\dot{\boldsymbol{x}} = (\mathbf{A} + \mathbf{B}\mathbf{F})\boldsymbol{x} .$$

The purpose of the design is to choose $\mathbf{F}$ so as to obtain, if possible, a prescribed asymptotic behavior. In general, two options are sought: (i) the n eigenvalues of $(\mathbf{A} + \mathbf{B}\mathbf{F})$ have negative real part, (ii) the n eigenvalues of $(\mathbf{A} + \mathbf{B}\mathbf{F})$ coincide with the n roots of an arbitrarily fixed polynomial

$$p(\boldsymbol{\lambda}) = \boldsymbol{\lambda}^n + a_{n-1}\boldsymbol{\lambda}^{n-1} + \cdots a_1\boldsymbol{\lambda} + a_0$$

of degree n, with real coefficients. The first option is usually referred to as the *stabilization* problem, while the second is usually referred to as the *eigenvalue assignment* problem.

The conditions for the existence of solutions of these problems can be described as follows. Consider the $n \times (n+m)$ polynomial matrix

$$\mathbf{M}(\boldsymbol{\lambda}) = \big((\mathbf{A} - \boldsymbol{\lambda}\mathbf{I})\ \mathbf{B}\big) . \tag{9.34}$$

Definition 9.7
System (9.32) is said to be *stabilizable* if, for all $\boldsymbol{\lambda}$ which is an eigenvalue of $\mathbf{A}$ and has nonnegative real part, the matrix $\mathbf{M}(\boldsymbol{\lambda})$ has rank n. This system is said to be *controllable* if, for all $\boldsymbol{\lambda}$ which is an eigenvalue of $\mathbf{A}$, the matrix $\mathbf{M}(\boldsymbol{\lambda})$ has rank n.

The two properties thus identified determine the existence of solutions of the problem of stabilization and, respectively, of the problem of eigenvalue assignment. In fact, the following two results hold.

Theorem 9.9
There exists a matrix $\mathbf{F}$ such that $\mathbf{A} + \mathbf{B}\mathbf{F}$ has all eigenvalues with negative real part if and only if system (9.32) is stabilizable.

Theorem 9.10
For any choice of a polynomial $p(\boldsymbol{\lambda})$ of degree n with real coefficients there exists a matrix $\mathbf{F}$ such that the n eigenvalues of $\mathbf{A} + \mathbf{B}\mathbf{F}$ coincide with the n roots of $p(\boldsymbol{\lambda})$ if and only if system (9.32) is controllable.

The actual construction of the matrix $\mathbf{F}$ usually requires a preliminary transformation of the equations describing the system. As an example, we illustrate how this is achieved in the case of a single-input system, for the problem of eigenvalue assignment. If the input of a system is one dimensional, the system is controllable if and only if the $n \times n$ matrix

$$\mathbf{P} = \begin{pmatrix} \mathbf{B} & \mathbf{A}\mathbf{B} & \cdots & \mathbf{A}^{n-1}\mathbf{B} \end{pmatrix} \tag{9.35}$$

is nonsingular. Assuming that this is the case, let γ denote the last row of $\mathbf{P}^{-1}$, that is, the unique solution of the set of equations

$$\gamma \mathbf{B} = \gamma \mathbf{AB} = \cdots = \gamma \mathbf{A}^{n-2}\mathbf{B} = 0,$$
$$\gamma \mathbf{A}^{n-1}\mathbf{B} = 1 .$$

Then, simple manipulations show that the change of coordinates

$$\tilde{\boldsymbol{x}} = \begin{pmatrix} \gamma \\ \gamma \mathbf{A} \\ \cdots \\ \gamma \mathbf{A}^{n-1} \end{pmatrix} \boldsymbol{x}$$

transforms system (9.32) into a system of the form

$$\dot{\tilde{\boldsymbol{x}}} = \tilde{\mathbf{A}}\tilde{\boldsymbol{x}} + \tilde{\mathbf{B}}u ,$$
$$\boldsymbol{y} = \tilde{\mathbf{C}}\tilde{\boldsymbol{x}} \tag{9.36}$$

in which

$$\tilde{\mathbf{A}} = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 & 0 \\ 0 & 0 & 1 & \cdots & 0 & 0 \\ \cdot & \cdot & \cdot & \cdots & \cdot & \cdot \\ 0 & 0 & 0 & \cdots & 0 & 1 \\ d_0 & d_1 & d_2 & \cdots & d_{n-2} & d_{n-1} \end{pmatrix}, \quad \tilde{\mathbf{B}} = \begin{pmatrix} 0 \\ 0 \\ \cdots \\ 0 \\ 1 \end{pmatrix} .$$

This form is known as *controllability canonical form* of the equations describing the system. If a system is written in this form, the solution of the problem of eigenvalue assignment is straightforward. If suffices, in fact, to pick a control law of the form

$$u = -(d_0 + a_0)\tilde{x}_1 - (d_1 + a_1)\tilde{x}_2 - \cdots$$
$$- (d_{n-1} + a_{n-1})\tilde{x}_n := \tilde{\mathbf{F}}\tilde{\boldsymbol{x}} \tag{9.37}$$

to obtain a system

$$\dot{\tilde{\boldsymbol{x}}} = (\tilde{\mathbf{A}} + \tilde{\mathbf{B}}\tilde{\mathbf{F}})\tilde{\boldsymbol{x}}$$

in which

$$\tilde{\mathbf{A}} + \tilde{\mathbf{B}}\tilde{\mathbf{F}} = \begin{pmatrix} 0 & 1 & 0 & \cdots & 0 & 0 \\ 0 & 0 & 1 & \cdots & 0 & 0 \\ \cdot & \cdot & \cdot & \cdots & \cdot & \cdot \\ 0 & 0 & 0 & \cdots & 0 & 1 \\ -a_0 & -a_1 & -a_2 & \cdots & -a_{n-2} & -a_{n-1} \end{pmatrix} .$$

The characteristic polynomial of this matrix coincides with the prescribed polynomial $p(\boldsymbol{\lambda})$ and hence the problem is solved. Rewriting the law (9.37) in the original coordinates, one obtains a formula that directly expresses the matrix $\mathbf{F}$ in terms of the parameters of the system (the $n \times n$ matrix $\mathbf{A}$ and the $1 \times n$ row vector γ) and of the coefficients of the prescribed polynomial $p(\boldsymbol{\lambda})$

$$\boldsymbol{u} = -\gamma\Big[(d_0 + a_0)\mathbf{I} + (d_1 + a_1)\mathbf{A} + \cdots$$
$$+ (d_{n-1} + a_{n-1})\mathbf{A}^{n-1}\Big]\boldsymbol{x}$$
$$= -\gamma\Big[a_0\mathbf{I} + a_1\mathbf{A} + \cdots$$
$$+ a_{n-1}\mathbf{A}^{n-1} + \mathbf{A}^n\Big]\boldsymbol{x} := \mathbf{F}\boldsymbol{x} .$$

The latter is known as Ackermann's formula.

9.5.2 Observers and State Estimation

The imposition of a control law of the form (9.33) requires the availability of all n components of the state $\boldsymbol{x}$ of system (9.32) for measurement, which is seldom the case. Thus, the issue arises of when and how the components in question could be, at least asymptotically, estimated by means of an appropriate auxiliary dynamical system driven by the only variables that are actually accessible for measurement, namely the input $\boldsymbol{u}$ and the output $\boldsymbol{y}$.

To this end, consider a n-dimensional system thus defined

$$\dot{\hat{\boldsymbol{x}}} = \mathbf{A}\hat{\boldsymbol{x}} + \mathbf{B}\boldsymbol{u} + \mathbf{G}(\boldsymbol{y} - \mathbf{C}\hat{\boldsymbol{x}}) , \tag{9.38}$$

viewed as a system with state $\hat{\boldsymbol{x}} \in \mathbb{R}^n$, driven by the *inputs* $\boldsymbol{u}$ and $\boldsymbol{y}$. This system can be interpreted as a *copy* of the original dynamics of (9.32), namely

$$\dot{\hat{\boldsymbol{x}}} = \mathbf{A}\hat{\boldsymbol{x}} + \mathbf{B}\boldsymbol{u}$$

corrected by a term proportional, through the $n \times p$ weighting matrix $\mathbf{G}$, to the *effect* that a possible difference between $\boldsymbol{x}$ and $\hat{\boldsymbol{x}}$ has on the only available measurement. The idea is to determine $\mathbf{G}$ in such a way that $\boldsymbol{x}$ and $\hat{\boldsymbol{x}}$ asymptotically converge. Define the difference

$$\boldsymbol{E} = \boldsymbol{x} - \hat{\boldsymbol{x}} ,$$

which is called *observation error*. Simple algebra shows that

$$\dot{\boldsymbol{e}} = (\mathbf{A} - \mathbf{GC})\boldsymbol{e} .$$

Thus, the observation error obeys an autonomous linear differential equation, and its asymptotic behavior is completely determined by the eigenvalues of $(\mathbf{A} - \mathbf{GC})$. In general, two options are sought: (i) the n eigenvalues of $(\mathbf{A} - \mathbf{GC})$ have negative real part, (ii) the n eigenvalues of $(\mathbf{A} - \mathbf{GC})$ coincide with the n roots of an arbitrarily fixed polynomial of degree n having real coefficients. The first option is usually referred to as the *asymptotic state estimation* problem, while the second does not carry a special name.

Note that, if the eigenvalues of $(\mathbf{A}-\mathbf{GC})$ have negative real part, the state $\hat{\boldsymbol{x}}$ of the auxiliary system (9.38) satisfies

$$\lim_{t\to\infty}[\boldsymbol{x}(t)-\hat{\boldsymbol{x}}(t)]=0\,,$$

i. e., it asymptotically tracks the state $\boldsymbol{x}(t)$ of (9.32) regardless of what the initial states $\boldsymbol{x}(0)$, $\hat{\boldsymbol{x}}(0)$ and the input $u(t)$ are. System (9.38) is called an asymptotic state estimator or a Luenberger *observer*.

The conditions for the existence of solutions of these problems can be described as follows. Consider the $(n+p)\times n$ polynomial matrix

$$\mathbf{N}(\boldsymbol{\lambda})=\begin{pmatrix}(\mathbf{A}-\boldsymbol{\lambda}\mathbf{I})\\ \mathbf{C}\end{pmatrix}\,. \tag{9.39}$$

Definition 9.8

System (9.32) is said to be *detectable* if, for all $\boldsymbol{\lambda}$ which is an eigenvalue of $\mathbf{A}$ and has nonnegative real part, the matrix $\mathbf{N}(\boldsymbol{\lambda})$ has rank n. This system is said to be *observable* if, for all $\boldsymbol{\lambda}$ which is an eigenvalue of $\mathbf{A}$, the matrix $\mathbf{N}(\boldsymbol{\lambda})$ has rank n.

Theorem 9.11

There exists a matrix $\mathbf{G}$ such that $\mathbf{A}-\mathbf{GC}$ has all eigenvalues with negative real part if and only if system (9.32) is detectable.

Theorem 9.12

For any choice of a polynomial $p(\boldsymbol{\lambda})$ of degree n with real coefficients there exists a matrix G such that the n eigenvalues of $\mathbf{A}-\mathbf{GC}$ coincide with the n roots of $p(\boldsymbol{\lambda})$ if and only if system (9.32) is observable.

In this case, also, the actual construction of the matrix $\mathbf{G}$ is made simple by transforming the equations describing the system. If the output of a system is one dimensional, the system is observable if and only if the $n\times n$ matrix

$$\mathbf{Q}=\begin{pmatrix}\mathbf{C}\\ \mathbf{CA}\\ \cdots\\ \mathbf{CA}^{n-1}\end{pmatrix} \tag{9.40}$$

is nonsingular. Let this be the case and let β denote the last column of $\mathbf{Q}^{-1}$, that is, the unique solution of the set of equations

$$\mathbf{C}\beta=\mathbf{CA}\beta=\cdots=\mathbf{CA}^{n-2}\beta=0,\quad \mathbf{CA}^{n-1}\beta=1\,.$$

Then, simple manipulations show that the change of coordinates

$$\tilde{\boldsymbol{x}}=\begin{pmatrix}\mathbf{A}^{n-1}\beta & \cdots & \mathbf{A}\beta & \beta\end{pmatrix}^{-1}\boldsymbol{x}$$

transforms system (9.32) into a system of the form

$$\begin{aligned}\dot{\tilde{x}}&=\tilde{\mathbf{A}}\tilde{\boldsymbol{x}}+\tilde{\mathbf{B}}\boldsymbol{u}\,,\\ \boldsymbol{y}&=\tilde{\mathbf{C}}\tilde{\boldsymbol{x}}\end{aligned} \tag{9.41}$$

in which

$$\tilde{\mathbf{A}}=\begin{pmatrix}d_{n-1} & 1 & 0 & \cdots & 0 & 0\\ d_{n-2} & 0 & 1 & \cdots & 0 & 0\\ \cdot & \cdot & \cdot & \cdots & \cdot & \cdot\\ d_1 & 0 & 0 & \cdots & 0 & 1\\ d_0 & 0 & 0 & \cdots & 0 & 0\end{pmatrix}\,,$$

$$\tilde{\mathbf{C}}=\begin{pmatrix}1 & 0 & \cdots & 0 & 0\end{pmatrix}\,.$$

This form is known as *observability canonical form* of the equations describing the system. If a system is written in this form, it is straightforward to write a matrix $\tilde{\mathbf{G}}$ assigning the eigenvalues to $(\tilde{\mathbf{A}}-\tilde{\mathbf{G}}\tilde{\mathbf{C}})$. If suffices, in fact, to pick a

$$\tilde{\mathbf{G}}=\begin{pmatrix}d_{n-1}+a_{n-1}\\ d_{n-2}+a_{n-2}\\ \cdots\\ d_0+a_0\end{pmatrix} \tag{9.42}$$

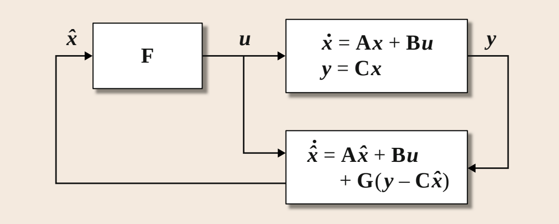
to obtain a matrix

$$\tilde{\mathbf{A}}-\tilde{\mathbf{G}}\tilde{\mathbf{C}}=\begin{pmatrix}-a_{n-1} & 1 & 0 & \cdots & 0 & 0\\ -a_{n-2} & 0 & 1 & \cdots & 0 & 0\\ \cdot & \cdot & \cdot & \cdots & \cdot & 0\\ -a_1 & 0 & 0 & \cdots & 0 & 1\\ -a_0 & 0 & 0 & \cdots & 0 & 0\end{pmatrix}\,,$$

whose characteristic polynomial coincides with the prescribed polynomial $p(\boldsymbol{\lambda})$.

9.5.3 Stabilization via Dynamic Output Feedback

Replacing, in the control law (9.33), the true state $\boldsymbol{x}$ by the estimate $\hat{\boldsymbol{x}}$ provided by the asymptotic observer



$\hat{x}$
F
u
$\dot{x} = \mathbf{A}x + \mathbf{B}u$
$y = \mathbf{C}x$
y
$\dot{\hat{x}} = \mathbf{A}\hat{x} + \mathbf{B}u$
$+ \mathbf{G}(y - \mathbf{C}\hat{x})$

Fig. 9.5 Observer-based control

(9.38) yields a dynamic, output-feedback, control law of the form

$$\begin{aligned} \boldsymbol{u} &= \mathbf{F}\hat{\boldsymbol{x}} \,, \\ \dot{\hat{\boldsymbol{x}}} &= (\mathbf{A}+\mathbf{BF}-\mathbf{GC})\hat{\boldsymbol{x}} + \mathbf{G}\boldsymbol{y} \,. \end{aligned} \tag{9.43}$$

Controlling system (9.32) by means of (9.43) yields the closed-loop system (Fig. 9.5)

$$\begin{pmatrix} \dot{\boldsymbol{x}} \\ \dot{\hat{\boldsymbol{x}}} \end{pmatrix} = \begin{pmatrix} \mathbf{A} & \mathbf{BF} \\ \mathbf{GC} & \mathbf{A}+\mathbf{BF}-\mathbf{GC} \end{pmatrix} \begin{pmatrix} \boldsymbol{x} \\ \hat{\boldsymbol{x}} \end{pmatrix} . \tag{9.44}$$

It is straightforward to check that the eigenvalues of the system thus obtained coincide with those of the two matrices $(\mathbf{A}+\mathbf{BF})$ and $(\mathbf{A}-\mathbf{GC})$. To this end, in fact, it suffices to replace $\hat{\boldsymbol{x}}$ by $\boldsymbol{e} = \boldsymbol{x} - \hat{\boldsymbol{x}}$, which changes system (9.44) into an equivalent system

$$\begin{pmatrix} \dot{\boldsymbol{x}} \\ \dot{\boldsymbol{e}} \end{pmatrix} = \begin{pmatrix} \mathbf{A}+\mathbf{BF} & -\mathbf{BF} \\ 0 & \mathbf{A}-\mathbf{GC} \end{pmatrix} \begin{pmatrix} \boldsymbol{x} \\ \boldsymbol{e} \end{pmatrix} \tag{9.45}$$

in block-triangular form.

From this argument, it can be concluded that the dynamic feedback law (9.43) suffices to yield a closed-loop system whose $2n$ eigenvalues either have negative real part (if system (9.32) is stabilizable and detectable) or even coincide with the roots of a pair of prescribed polynomials of degree n (if (9.32) is controllable and observable). In particular, the result in question can be achieved by means of a *separate* design of **F** and **G**, the former to control the eigenvalues of $(\mathbf{A}+\mathbf{BF})$ and the latter to control the eigenvalues of $(\mathbf{A}-\mathbf{GC})$. This possibility is usually referred to as the *separation principle* for stabilization via (dynamic) output feedback.

It can be concluded from this argument that, if a system is stabilizable and detectable, there exists a dynamic, output feedback, law yielding a closed-loop system with all eigenvalues with negative real part. It is important to observe that also the converse of this property is true, namely the existence of a dynamic, output feedback, law yielding a closed-loop system with all eigenvalues with negative real part requires the controlled system to be *stabilizable and detectable*. The proof of this converse result is achieved by taking any arbitrary dynamic output-feedback law

$$\begin{aligned} \dot{\boldsymbol{\xi}} &= \bar{\mathbf{F}}\boldsymbol{\xi} + \bar{\mathbf{G}}\boldsymbol{y} \,, \\ \boldsymbol{u} &= \bar{\mathbf{H}}\boldsymbol{\xi} + \bar{\mathbf{K}}\boldsymbol{y} \,, \end{aligned}$$

yielding a closed-loop system

$$\begin{pmatrix} \dot{\boldsymbol{x}} \\ \dot{\boldsymbol{\xi}} \end{pmatrix} = \begin{pmatrix} \mathbf{A}+\mathbf{B}\bar{\mathbf{K}}\mathbf{C} & \mathbf{B}\bar{\mathbf{H}} \\ \bar{\mathbf{G}}\mathbf{C} & \bar{\mathbf{F}} \end{pmatrix} \begin{pmatrix} \boldsymbol{x} \\ \boldsymbol{\xi} \end{pmatrix}$$

and proving, via the converse Lyapunov theorem for linear systems, that, if the eigenvalues of the latter have negative real part, *necessarily* there exist two matrices **F** and **G** such that the eigenvalues of $(\mathbf{A}+\mathbf{BF})$ and, respectively, $(\mathbf{A}-\mathbf{GC})$ have negative real part.

9.6 Feedback Stabilization of Nonlinear Systems

9.6.1 Recursive Methods for Global Stability

Stabilization of nonlinear systems is a very difficult task and general methods are not available. Only if the equations of the system exhibit a special structure do there exist systematic methods for the design of pure state feedback (or, if necessary, dynamic, output feedback) laws yielding global asymptotic stability of an equilibrium. In this section we review some of these special design procedures.

We begin by a simple *modular* property which can be recursively used to stabilize systems in *triangular form* (see [9.10, Chap. 9] for further details).

Lemma 9.5
Consider a system described by equations of the form

$$\begin{aligned} \dot{\boldsymbol{z}} &= f(\boldsymbol{z}, \boldsymbol{\xi}) \,, \\ \dot{\boldsymbol{\xi}} &= q(\boldsymbol{z}, \boldsymbol{\xi}) + b(\boldsymbol{z}, \boldsymbol{\xi})\boldsymbol{u} \,, \end{aligned} \tag{9.46}$$

in which $(\boldsymbol{z}, \boldsymbol{\xi}) \in \mathbb{R}^n \times \mathbb{R}$, and the functions $f(\boldsymbol{z}, \boldsymbol{\xi})$, $q(\boldsymbol{z}, \boldsymbol{\xi})$, $b(\boldsymbol{z}, \boldsymbol{\xi})$ are continuously differentiable functions. Suppose that $b(\boldsymbol{z}, \boldsymbol{\xi}) \neq 0$ for all $(\boldsymbol{z}, \boldsymbol{\xi})$ and that $f(0,0) = 0$ and $q(0,0) = 0$. If $\boldsymbol{z} = 0$ is a globally asymptotically stable equilibrium of $\dot{\boldsymbol{z}} = f(\boldsymbol{z}, 0)$, there exists a differentiable function $\boldsymbol{u} = \boldsymbol{u}(\boldsymbol{z}, \boldsymbol{\xi})$ with

$\boldsymbol{u}(0,0)=0$ such that the equilibrium at $(\boldsymbol{z},\xi)=(0,0)$

$$\begin{aligned}\dot{\boldsymbol{z}} &= f(\boldsymbol{z},\xi)\,,\\ \dot{\xi} &= q(\boldsymbol{z},\xi)+b(\boldsymbol{z},\xi)\boldsymbol{u}(\boldsymbol{z},\xi)\,,\end{aligned}$$

is globally asymptotically stable.

The construction of the stabilizing feedback $\boldsymbol{u}(\boldsymbol{z},\xi)$ is achieved as follows. First of all observe that, using the assumption $b(\boldsymbol{z},\xi)\neq 0$, the imposition of the preliminary feedback law

$$\boldsymbol{u}(\boldsymbol{z},\xi)=\frac{1}{b(\boldsymbol{z},\xi)}(-q(\boldsymbol{z},\xi)+v)$$

yields the simpler system

$$\begin{aligned}\dot{\boldsymbol{z}} &= f(\boldsymbol{z},\xi)\,,\\ \dot{\xi} &= v\,.\end{aligned}$$

Then, express $f(\boldsymbol{z},\xi)$ in the form

$$f(\boldsymbol{z},\xi)=f(\boldsymbol{z},0)+p(\boldsymbol{z},\xi)\xi\,,$$

in which $p(\boldsymbol{z},\xi)=[f(\boldsymbol{z},\xi)-f(\boldsymbol{z},0)]/\xi$ is at least continuous.

Since by assumption $\boldsymbol{z}=0$ is a globally asymptotically stable equilibrium of $\dot{\boldsymbol{z}}=f(\boldsymbol{z},0)$, by the converse Lyapunov theorem there exists a smooth real-valued function $V(\boldsymbol{z})$, which is positive definite and proper, satisfying

$$\frac{\partial V}{\partial \boldsymbol{z}}f(\boldsymbol{z},0)<0\,,$$

for all nonzero $\boldsymbol{z}$. Now, consider the positive-definite and proper function

$$W(\boldsymbol{z},\xi)=V(\boldsymbol{z})+\frac{1}{2}\xi^2\,,$$

and observe that

$$\frac{\partial W}{\partial \boldsymbol{z}}\dot{\boldsymbol{z}}+\frac{\partial W}{\partial \xi}\dot{\xi}=\frac{\partial V}{\partial \boldsymbol{z}}f(\boldsymbol{z},0)+\frac{\partial V}{\partial \boldsymbol{z}}p(\boldsymbol{z},\xi)\xi+\xi v\,.$$

Choosing

$$v=-\xi-\frac{\partial V}{\partial \boldsymbol{z}}p(\boldsymbol{z},\xi) \qquad (9.47)$$

yields

$$\frac{\partial W}{\partial \boldsymbol{z}}\dot{\boldsymbol{z}}+\frac{\partial W}{\partial \xi}\dot{\xi}=\frac{\partial V}{\partial \boldsymbol{z}}f(\boldsymbol{z},0)-\xi^2<0\,,$$

for all nonzero $(\boldsymbol{z},\xi)$ and this, by the direct Lyapunov criterion, shows that the feedback law

$$\boldsymbol{u}(\boldsymbol{z},\xi)=\frac{1}{b(\boldsymbol{z},\xi)}\left[-q(\boldsymbol{z},\xi)-\xi-\frac{\partial V}{\partial \boldsymbol{z}}p(\boldsymbol{z},\xi)\right]$$

globally asymptotically stabilizes the equilibrium $(\boldsymbol{z},\xi)=(0,0)$ of the associated closed-loop system.

In the next Lemma (which contains the previous one as a particular case) this result is extended by showing that, for the purpose of stabilizing the equilibrium $(\boldsymbol{z},\xi)=(0,0)$ of system (9.46), it suffices to assume that the equilibrium $\boldsymbol{z}=0$ of

$$\dot{\boldsymbol{z}}=f(\boldsymbol{z},\xi)$$

is *stabilizable* by means of a *virtual* control law $\xi=v^\star(\boldsymbol{z})$.

Lemma 9.6

Consider again the system described by equations of the form (9.46). Suppose there exists a continuously differentiable function

$$\xi=v^\star(\boldsymbol{z})\,,$$

with $v^\star(0)=0$, which globally asymptotically stabilizes the equilibrium $\boldsymbol{z}=0$ of $\dot{\boldsymbol{z}}=f(\boldsymbol{z},v^\star(\boldsymbol{z}))$. Then there exists a differentiable function $\boldsymbol{u}=\boldsymbol{u}(\boldsymbol{z},\xi)$ with $\boldsymbol{u}(0,0)=0$ such that the equilibrium at $(\boldsymbol{z},\xi)=(0,0)$

$$\begin{aligned}\dot{\boldsymbol{z}} &= f(\boldsymbol{z},\xi)\,,\\ \dot{\xi} &= q(\boldsymbol{z},\xi)+b(\boldsymbol{z},\xi)\boldsymbol{u}(\boldsymbol{z},\xi)\end{aligned}$$

is globally asymptotically stable.

To prove the result, and to construct the stabilizing feedback, it suffices to consider the (globally defined) change of variables

$$\boldsymbol{y}=\xi-v^\star(\boldsymbol{z})\,,$$

which transforms (9.46) into a system

$$\begin{aligned}\dot{\boldsymbol{z}} &= f(\boldsymbol{z},v^\star(\boldsymbol{z})+\boldsymbol{y})\,,\\ \dot{\boldsymbol{y}} &= -\frac{\partial v^\star}{\partial \boldsymbol{z}}f(\boldsymbol{z},v^\star(\boldsymbol{z})+\boldsymbol{y})+q(v^\star(\boldsymbol{z})+\boldsymbol{y},\xi)\\ &\quad +b(v^\star(\boldsymbol{z})+\boldsymbol{y},\xi)\boldsymbol{u}\,,\end{aligned} \qquad (9.48)$$

which meets the assumptions of Lemma 9.5, and then follow the construction of a stabilizing feedback as described. Using repeatedly the property indicated in Lemma 9.6 it is straightforward to derive the expression of a globally stabilizing feedback for a system in *triangular* form

$$\begin{aligned}\dot{\boldsymbol{z}} &= f(\boldsymbol{z},\xi_1)\,,\\ \dot{\xi}_1 &= q_1(\boldsymbol{z},\xi_1)+b_1(\boldsymbol{z},\xi_1)\xi_2\,,\\ \dot{\xi}_2 &= q_2(\boldsymbol{z},\xi_1,\xi_2)+b_2(\boldsymbol{z},\xi_1,\xi_2)\xi_3\,,\\ &\cdots\\ \dot{\xi}_r &= q_r(\boldsymbol{z},\xi_1,\xi_2,\ldots,\xi_r)+b_r(\boldsymbol{z},\xi_1,\xi_2,\ldots,\xi_r)\boldsymbol{u}\,.\end{aligned} \qquad (9.49)$$

To this end, in fact, it suffices to assume that the equilibrium $\boldsymbol{z} = 0$ of $\dot{\boldsymbol{z}} = f(\boldsymbol{z}, \boldsymbol{\xi})$ is stabilizable by means of a virtual law $\boldsymbol{\xi} = v^\star(\boldsymbol{z})$, and that $b_1(\boldsymbol{z}, \xi_1), b_2(\boldsymbol{z}, \xi_1, \xi_2), \dots, b_r(\boldsymbol{z}, \xi_1, \xi_2, \dots, \xi_r)$ are nowhere zero.

9.6.2 Semiglobal Stabilization via Pure State Feedback

The global stabilization results presented in the previous section are indeed conceptually appealing but the actual implementation of the feedback law requires the explicit knowledge of a Lyapunov function $V(\boldsymbol{z})$ for the system $\dot{\boldsymbol{z}} = f(\boldsymbol{z}, 0)$ (or for the system $\dot{\boldsymbol{z}} = f(\boldsymbol{z}, v^*(\boldsymbol{z}))$ in the case of Lemma 9.6). This function, in fact, explicitly determines the structure of the feedback law which globally asymptotically stabilizes the system. Moreover, in the case of systems of the form (9.49) with $r > 1$, the computation of the feedback law is somewhat cumbersome, in that it requires to iterate a certain number of times the manipulations described in the proof of Lemmas 9.5 and 9.6. In this section we show how these drawbacks can be overcome, in a certain sense, if a less ambitious design goal is pursued, namely if instead of seeking global stabilization one is interested in a feedback law capable of asymptotically steering to the equilibrium point all trajectories which have origin in a *a priori fixed* (and hence possibly large) *bounded set*.

Consider again a system satisfying the assumptions of Lemma 9.5. Observe that $b(\boldsymbol{z}, \boldsymbol{\xi})$, being continuous and nowhere zero, has a well-defined sign. Choose a simple control law of the form

$$\boldsymbol{u} = -k\ \mathrm{sign}(b)\,\boldsymbol{\xi} \tag{9.50}$$

to obtain the system

$$\begin{aligned} \dot{\boldsymbol{z}} &= f(\boldsymbol{z}, \boldsymbol{\xi})\,, \\ \dot{\boldsymbol{\xi}} &= q(\boldsymbol{z}, \boldsymbol{\xi}) - k|b(\boldsymbol{z}, \boldsymbol{\xi})|\boldsymbol{\xi}\,. \end{aligned} \tag{9.51}$$

Assume that the equilibrium $\boldsymbol{z} = 0$ of $\dot{\boldsymbol{z}} = f(\boldsymbol{z}, 0)$ is globally asymptotically but also *locally exponentially* stable. If this is the case, then the linear approximation of the first equation of (9.51) at the point $(\boldsymbol{z}, \boldsymbol{\xi}) = (0, 0)$ is a system of the form

$$\dot{\boldsymbol{z}} = \mathbf{F}\boldsymbol{z} + \mathbf{G}\boldsymbol{\xi}\,,$$

in which $\mathbf{F}$ is a Hurwitz matrix. Moreover, the linear approximation of the second equation of (9.51) at the point $(\boldsymbol{z}, \boldsymbol{\xi}) = (0, 0)$ is a system of the form

$$\dot{\boldsymbol{\xi}} = \mathbf{Q}\boldsymbol{z} + \mathbf{R}\boldsymbol{\xi} - kb_0\boldsymbol{\xi}\,,$$

in which $b_0 = |b(0, 0)|$. It follows that the linear approximation of system (9.51) at the equilibrium $(\boldsymbol{z}, \boldsymbol{\xi}) = (0, 0)$ is a linear system $\dot{\boldsymbol{x}} = \mathbf{A}\boldsymbol{x}$ in which

$$\mathbf{A} = \begin{pmatrix} \mathbf{F} & \mathbf{G} \\ \mathbf{Q} & (\mathbf{R} - kb_0) \end{pmatrix}\,.$$

Standard arguments show that, if the number k is large enough, the matrix in question has all eigenvalues with negative real part (in particular, as k increases, n eigenvalues approach the n eigenvalues of $\mathbf{F}$ and the remaining one is a real eigenvalue that tends to $-\infty$). It is therefore concluded, from the principle of stability in the first approximation, that if k is sufficiently large the equilibrium $(\boldsymbol{z}, \boldsymbol{\xi}) = (0, 0)$ of the closed-loop system (9.51) is locally asymptotically (actually locally exponentially) stable.

However, a stronger result holds. It can be proven that, for any arbitrary compact subset K of $\mathbb{R}^n \times \mathbb{R}$, there exists a number k^*, such that, for all $k \geq k^*$, the equilibrium $(\boldsymbol{z}, \boldsymbol{\xi}) = (0, 0)$ of the closed-loop system (9.51) is locally asymptotically stable and all initial conditions in K produce a trajectory that asymptotically converges to this equilibrium. In other words, the basin of attraction of the equilibrium $(\boldsymbol{z}, \boldsymbol{\xi}) = (0, 0)$ of the closed-loop system contains the set K. Note that the number k^* depends on the choice of the set K and, in principle, it increases as the size of K increases. The property in question can be summarized as follows (see [9.10, Chap. 9] for further details). A system

$$\dot{\boldsymbol{x}} = f(\boldsymbol{x}, \boldsymbol{u})$$

is said to be *semiglobally stabilizable* (an equivalent, but longer, terminology is *asymptotically stabilizable with guaranteed basin of attraction*) at a given point $\bar{\boldsymbol{x}}$ if, for each *compact* subset $K \subset \mathbb{R}^n$, there exists a feedback law $\boldsymbol{u} = \boldsymbol{u}(\boldsymbol{x})$, *which in general depends on* K, such that in the corresponding closed-loop system

$$\dot{\boldsymbol{x}} = f(\boldsymbol{x}, \boldsymbol{u}(\boldsymbol{x}))$$

the point $\boldsymbol{x} = \bar{\boldsymbol{x}}$ is a locally asymptotically stable equilibrium, and

$$\boldsymbol{x}(0) \in K \Rightarrow \lim_{t \to \infty} \boldsymbol{x}(t) = \bar{x}$$

(i. e., the compact subset K is contained in the basin of attraction of the equilibrium $\boldsymbol{x} = \bar{\boldsymbol{x}}$). The result described above shows that system (9.46), under the said assumptions, is semiglobally stabilizable at $(\boldsymbol{z}, \boldsymbol{\xi}) = (0, 0)$, by means of a feedback law of the form (9.50).

The arguments just shown can be iterated to deal with a system of the form (9.49). In fact, it is easy to realize that, if the equilibrium $\boldsymbol{z} = 0$ of $\dot{\boldsymbol{z}} = f(\boldsymbol{z}, 0)$ is globally asymptotically and also locally exponentially stable, if $q_i(\boldsymbol{z}, \xi_1, \xi_2, \dots, \xi_i)$ vanishes at $(\boldsymbol{z}, \xi_1, \xi_2, \dots, \xi_i) = (0, 0, 0, \dots, 0)$ and $b_i(\boldsymbol{z}, \xi_1, \xi_2, \dots, \xi_i)$ is nowhere zero, for all $i = 1, \dots, r$, system (9.49) is semiglobally stabilizable at the point $(\boldsymbol{z}, \xi_1, \xi_2, \dots, \xi_r) = (0, 0, 0, \dots, 0)$, actually by means of a control law that has the following structure

$$\boldsymbol{u} = \alpha_1 \xi_1 + \alpha_2 \xi_2 + \dots + \alpha_r \xi_r \ .$$

The coefficients $\alpha_1, \dots, \alpha_r$ that characterize this control law can be determined by means of recursive iteration of the arguments described above.

9.6.3 Semiglobal Stabilization via Dynamic Output Feedback

System (9.49) can be semiglobally stabilized, at the equilibrium $(\boldsymbol{z}, \xi_1, \dots, \xi_r) = (0, 0, \dots, 0)$, by means of a simple feedback law, which is a linear function of the *partial state* $(\xi_1, \dots, \xi_r)$. If these variables are not directly available for feedback, one may wish to use instead an estimate – as is possible in the case of linear systems – provided by a dynamical system driven by the measured output. This is actually doable if the output y of (9.49) coincides with the state variable ξ_1. For the purpose of stabilizing system (9.49) by means of dynamic output feedback, it is convenient to reexpress the equations describing this system in a simpler form, known as *normal form*. Set $\eta_1 = \xi_1$ and define

$$\eta_2 = q_1(\boldsymbol{z}, \xi_1) + b_1(\boldsymbol{z}, \xi_1)\xi_2 \ ,$$

by means of which the second equation of (9.49) is changed into $\dot{\eta}_1 = \eta_2$. Set now

$$\begin{aligned} \eta_3 = & \frac{\partial(q_1 + b_1\xi_2)}{\partial \boldsymbol{z}} f(\boldsymbol{z}, \xi_1) \\ & + \frac{\partial(q_1 + b_1\xi_2)}{\partial \xi_1} [q_1 + b_1\xi_2] + b_1[q_2 + b_2\xi_3] \ , \end{aligned}$$

by means of which the third equation of (9.49) is changed into $\dot{\eta}_2 = \eta_3$. Proceeding in this way, it is easy to conclude that the system (9.49) can be changed into a system modeled by

$$\begin{aligned} \dot{\boldsymbol{z}} &= f(\boldsymbol{z}, \eta_1) \ , \\ \dot{\eta}_1 &= \eta_2 \ , \\ \dot{\eta}_2 &= \eta_3 \ , \\ & \dots \\ \dot{\eta}_r &= q(\boldsymbol{z}, \eta_1, \eta_2, \dots, \eta_r) + b(\boldsymbol{z}, \eta_1, \eta_2, \dots, \eta_r)\boldsymbol{u} \ , \\ \boldsymbol{y} &= \eta_1 \ , \end{aligned} \tag{9.52}$$

in which $q(0, 0, 0, \dots, 0) = (0, 0, 0, \dots, 0)$ and $b(\boldsymbol{z}, \eta_1, \eta_2, \dots, \eta_r)$ is nowhere zero.

It has been shown earlier that, if the equilibrium $\boldsymbol{z} = 0$ of $\dot{\boldsymbol{z}} = f(\boldsymbol{z}, 0)$ is globally asymptotically and also locally exponentially stable, this system is semiglobally stabilizable, by means of a feedback law

$$\boldsymbol{u} = h_1\eta_1 + h_2\eta_2 + \dots + h_r\eta_r \ , \tag{9.53}$$

which is a linear function of the states $\eta_1, \eta_2, \dots, \eta_r$. The feedback in question, if the coefficients are appropriately chosen, is able to steer at the equilibrium $(\boldsymbol{z}, \eta_1, \dots, \eta_r) = (0, 0, \dots, 0)$ all trajectories with initial conditions in a given compact set K (whose size influences, as stressed earlier, the actual choice of the parameters $h_1, \dots, h_r$). Note that, since all such trajectories will never exit, in positive time, a (possibly larger) compact set, there exists a number L such that

$$|h_1\eta_1(t) + h_2\eta_2(t) + \dots + h_r\eta_r(t)| \le L \ ,$$

for all $t \ge 0$ whenever the initial condition of the closed loop is in K. Thus, to the extent of achieving asymptotic stability with a basin of attraction including K, the feedback law (9.53) could be replaced with a (nonlinear) law of the form

$$\boldsymbol{u} = \sigma_L(h_1\eta_1 + h_2\eta_2 + \dots + h_r\eta_r) \ , \tag{9.54}$$

in which $\sigma(r)$ is any *bounded* function that coincides with r when $|r| \le L$. The advantage of having a feedback law whose amplitude is guaranteed not to exceed a fixed bound is that, when the partial states η_i will be replaced by approximate estimates, possibly large errors in the estimates will not cause dangerously large control efforts.

Inspection of the equations (9.52) reveals that the state variables used in the control law (9.54) coincide with the measured output $\mathbf{y}$ and its derivatives with respect to time, namely

$$\eta_i = \mathbf{y}^{(i-1)} \ , \quad i = 1, 2, \dots, r \ .$$

It is therefore reasonable to expect that these variables could be asymptotically estimated in some simple way by means of a dynamical system driven by the measured output itself. The system in question is actually of the form

$$\begin{aligned} \dot{\tilde{\eta}}_1 &= \tilde{\eta}_2 - \kappa c_{r-1}(\boldsymbol{y} - \tilde{\eta}_1) \ , \\ \dot{\tilde{\eta}}_2 &= \tilde{\eta}_3 - \kappa^2 c_{r-2}(\boldsymbol{y} - \tilde{\eta}_1) \ , \\ & \dots \\ \dot{\tilde{\eta}}_r &= -\kappa^r c_0(\boldsymbol{y} - \tilde{\eta}_1) \ . \end{aligned} \tag{9.55}$$

It is easy to realize that, if $\tilde{\eta}_1(t) = \boldsymbol{y}(t)$, then all $\tilde{\eta}_i(t)$, for $i = 2, \dots, r$, coincide with $\eta_i(t)$. However, there is no a priori guarantee that this can be achieved and hence system (9.55) cannot be regarded as a true observer of the partial state $\eta_1, \ldots, \eta_r$ of (9.52). It happens, though, that if the reason why this partial state needs to be estimated is only the implementation of the feedback law (9.54), then an *approximate* observer such as (9.55) can be successfully used.

The fact is that, if the coefficients $c_0, \ldots, c_{r-1}$ are coefficients of a Hurwitz polynomial

$$p(\boldsymbol{\lambda}) = \boldsymbol{\lambda}^r + c_{r-1}\boldsymbol{\lambda}^{r-1} + \ldots + c_1\boldsymbol{\lambda} + c_0 \,,$$

and if the parameter κ is sufficiently large, the *rough estimates* $\tilde{\eta}_i$ of η_i provided by (9.55) can be used to replace the true states η_i in the control law (9.54). This results in a controller, which is a dynamical system modeled by equations of the form (Fig. 9.6)

$$\begin{aligned} \dot{\tilde{\boldsymbol{\eta}}} &= \tilde{\mathbf{F}}\tilde{\boldsymbol{\eta}} + \tilde{\mathbf{G}}\boldsymbol{y} \,, \\ \boldsymbol{u} &= \sigma_L(\mathbf{H}\boldsymbol{\eta}) \,, \end{aligned} \tag{9.56}$$

able to solve a problem of semiglobal stabilization for (9.52), if its parameters are appropriately chosen (see [9.6, Chap. 12] and [9.11, 12] for further details).

9.6.4 Observers and Full State Estimation

The design of observers for nonlinear systems modeled by equations of the form

$$\begin{aligned} \dot{\boldsymbol{x}} &= f(\boldsymbol{x}, u) \,, \\ \boldsymbol{y} &= h(\boldsymbol{x}, \boldsymbol{u}) \,, \end{aligned} \tag{9.57}$$

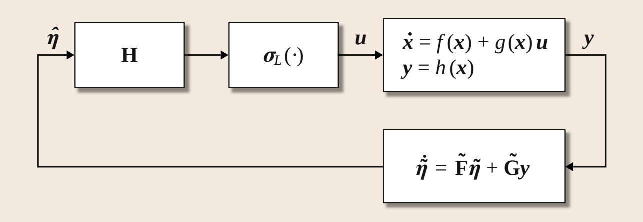
with state $\boldsymbol{x} \in \mathbb{R}^n$, input $\boldsymbol{u} \in \mathbb{R}^m$, and output $\boldsymbol{y} \in \mathbb{R}$ usually requires the preliminary transformation of the equations describing the system, in a form that suitably corresponds to the observability canonical form describe earlier for linear systems. In fact, a key requirement for the existence of observers is the existence of a global changes of coordinates $\tilde{\boldsymbol{x}} = \Phi(\boldsymbol{x})$ carrying system (9.57) into a system of the form

$$\begin{aligned} \dot{\tilde{x}}_1 &= \tilde{f}_1(\tilde{x}_1, \tilde{x}_2, \boldsymbol{u}) \,, \\ \dot{\tilde{x}}_2 &= \tilde{f}_2(\tilde{x}_1, \tilde{x}_2, \tilde{x}_3, \boldsymbol{u}) \,, \\ &\;\cdots \\ \dot{\tilde{x}}_{n-1} &= \tilde{f}_{n-1}(\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_n, \boldsymbol{u}) \,, \\ \dot{\tilde{x}}_n &= \tilde{f}_n(\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_n, \boldsymbol{u}) \,, \\ \boldsymbol{y} &= \tilde{h}(\tilde{x}_1, \boldsymbol{u}) \,, \end{aligned} \tag{9.58}$$

in which the $\tilde{h}(\tilde{x}_1, \boldsymbol{u})$ and $\tilde{f}_i(\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_{i+1}, \boldsymbol{u})$ satisfy

$$\frac{\partial \tilde{h}}{\partial \tilde{x}_1} \neq 0 \,, \quad \text{and} \quad \frac{\partial \tilde{f}_i}{\partial \tilde{x}_{i+1}} \neq 0 \,, \qquad \text{for all} \quad i = 1, \ldots, n-1 \tag{9.59}$$

for all $\tilde{\boldsymbol{x}} \in \mathbb{R}^n$, and all $\boldsymbol{u} \in \mathbb{R}^m$. This form is usually referred to as the *uniform observability canonical form*.



$\hat{\boldsymbol{\eta}}$
H
$\boldsymbol{\sigma}_L(\cdot)$
$\boldsymbol{u}$
$\dot{\boldsymbol{x}} = f(\boldsymbol{x}) + g(\boldsymbol{x})\boldsymbol{u}$
$\boldsymbol{y} = h(\boldsymbol{x})$
$\boldsymbol{y}$
$\dot{\tilde{\boldsymbol{\eta}}} = \tilde{\mathbf{F}}\tilde{\boldsymbol{\eta}} + \tilde{\mathbf{G}}\boldsymbol{y}$

Fig. 9.6 Control via partial-state estimator

The existence of canonical forms of this kind can be obtained as follows [9.13, Chap. 2]. Define – recursively – a sequence of real-valued functions $\varphi_i(\boldsymbol{x}, \boldsymbol{u})$ as follows

$$\begin{aligned} \varphi_1(\boldsymbol{x}, \boldsymbol{u}) &:= h(\boldsymbol{x}, \boldsymbol{u}) \,, \\ &\;\vdots \\ \varphi_i(\boldsymbol{x}, \boldsymbol{u}) &:= \frac{\partial \varphi_{i-1}}{\partial \boldsymbol{x}} f(\boldsymbol{x}, \boldsymbol{u}) \,, \end{aligned}$$

for $i = 1, \ldots, n$. Using these functions, define a sequence of i-vector-valued functions $\Phi_i(\boldsymbol{x}, \boldsymbol{u})$ as follows

$$\Phi_i(\boldsymbol{x}, \boldsymbol{u}) = \begin{pmatrix} \varphi_1(\boldsymbol{x}, \boldsymbol{u}) \\ \vdots \\ \varphi_i(\boldsymbol{x}, \boldsymbol{u}) \end{pmatrix} \,,$$

for $i = 1, \ldots, n$. Finally, for each of the $\Phi_i(\boldsymbol{x}, \boldsymbol{u})$, compute the subspace

$$K_i(\boldsymbol{x}, \boldsymbol{u}) = \ker \left[\frac{\partial \Phi_i}{\partial \boldsymbol{x}} \right]_{(\boldsymbol{x}, \boldsymbol{u})} \,,$$

in which $\ker[M]$ denotes the subspace consisting of all vectors $\boldsymbol{v}$ such that $M\boldsymbol{v} = 0$, that is the so-called null space of the matrix M. Note that, since the entries of the matrix

$$\frac{\partial \Phi_i}{\partial \boldsymbol{x}}$$

are in general dependent on $(\boldsymbol{x}, \boldsymbol{u})$, so is its null space $K_i(\boldsymbol{x}, \boldsymbol{u})$.

The role played by the objects thus defined in the construction of the change of coordinates yielding an observability canonical form is explained in this result.

Lemma 9.7

Consider system (9.57) and the map $\tilde{\boldsymbol{x}} = \Phi(\boldsymbol{x})$ defined by

$$\Phi(\boldsymbol{x}) = \begin{pmatrix} \varphi_1(\boldsymbol{x}, 0) \\ \varphi_2(\boldsymbol{x}, 0) \\ \vdots \\ \varphi_n(\boldsymbol{x}, 0) \end{pmatrix} .$$

Suppose that $\Phi(\boldsymbol{x})$ has a globally defined and continuously differentiable inverse. Suppose also that, for all $i = 1, \ldots, n$,

$$\begin{aligned} &\dim[K_i(\boldsymbol{x}, u)] = n - i \,, \\ &\qquad\qquad \text{for all } \boldsymbol{u} \in \mathbb{R}^m \\ &\qquad\qquad \text{and for all } \boldsymbol{x} \in \mathbb{R}^n \\ &\quad K_i(\boldsymbol{x}, \boldsymbol{u}) = \text{independent of } \boldsymbol{u} \,. \end{aligned}$$

Then, system (9.57) is globally transformed, via $\Phi(\boldsymbol{x})$, into a system in uniform observability canonical form.

Once a system has been changed into its observability canonical form, an asymptotic observer can be built as follows. Take a *copy* of the dynamics of (9.58), corrected by an *innovation* term proportional to the difference between the output of (9.58) and the output of the copy. More precisely, consider a system of the form

$$\begin{aligned} \dot{\hat{x}}_1 &= \tilde{f}_1(\hat{x}_1, \hat{x}_2, \boldsymbol{u}) + \kappa c_{n-1}(\boldsymbol{y} - h(\hat{x}_1, \boldsymbol{u})) \,, \\ \dot{\hat{x}}_2 &= \tilde{f}_2(\hat{x}_1, \hat{x}_2, \hat{x}_3, \boldsymbol{u}) + \kappa^2 c_{n-2}(\boldsymbol{y} - h(\hat{x}_1, \boldsymbol{u})) \,, \\ &\cdots \\ \dot{\hat{x}}_{n-1} &= \tilde{f}_{n-1}(\hat{\boldsymbol{x}}, \boldsymbol{u}) + \kappa^{n-1} c_1(\boldsymbol{y} - h(\hat{x}_1, \boldsymbol{u})) \,, \\ \dot{\hat{x}}_n &= \tilde{f}_n(\hat{\boldsymbol{x}}, \boldsymbol{u}) + \kappa^n c_0(\boldsymbol{y} - h(\hat{x}_1, \boldsymbol{u})) \,, \end{aligned} \tag{9.60}$$

in which κ and $c_{n-1}, c_{n-2}, \ldots, c_0$ are design parameters.

The state of the system thus defined is able to asymptotically track, no matter what the initial conditions $\boldsymbol{x}(0)$, $\tilde{\boldsymbol{x}}(0)$ and the input $\boldsymbol{u}(t)$ are, the state of system (9.58) provided that the two following technical hypotheses hold:

(i) Each of the maps $\tilde{f}_i(\tilde{x}_1, \ldots, \tilde{x}_i, \tilde{x}_{i+1}, \boldsymbol{u})$, for $i = 1, \ldots, n$, is globally Lipschitz with respect to $(\tilde{x}_1, \ldots, \tilde{x}_i)$, uniformly in $\tilde{x}_{i+1}$ and $\boldsymbol{u}$,

(ii) There exist two real numbers α, β, with $0 < \alpha < \beta$, such that

$$\alpha \le \left| \frac{\partial \tilde{h}}{\partial \tilde{x}_1} \right| \le \beta \,, \quad \text{and} \quad \alpha \le \left| \frac{\partial \tilde{f}_i}{\partial \tilde{x}_{i+1}} \right| \le \beta \,,$$
$$\text{for all } i = 1, \ldots, n-1 \,,$$

for all $\tilde{\boldsymbol{x}} \in \mathbb{R}^n$, and all $\boldsymbol{u} \in \mathbb{R}^m$.

Let the *observation error* be defined as

$$e_i = \hat{x}_i - \tilde{x}_i \,, \quad i = 1, 2, \ldots, n \,.$$

The fact is that, if the two assumptions above hold, there is a choice of the coefficients $c_0, c_1, \ldots, c_{n-1}$ and there is a number κ^* such that, if $\kappa \ge \kappa^*$, the observation error asymptotically decays to zero as time tends to infinity, regardless of what the initial states $\tilde{\boldsymbol{x}}(0)$, $\hat{\boldsymbol{x}}(0)$ and the input $\boldsymbol{u}(t)$ are. For this reason the observer in question is called a *high-gain* observer (see [9.13, Chap. 6] for further details).

The availability of such an observer makes it possible to design a dynamic, output feedback, stabilizing control law, thus extending to the case of nonlinear systems the separation principle for stabilization of linear systems. In fact, consider a system in canonical form (9.58), rewritten as

$$\begin{aligned} \dot{\tilde{\boldsymbol{x}}} &= \tilde{f}(\tilde{\boldsymbol{x}}, \boldsymbol{u}) \,, \\ \boldsymbol{y} &= \tilde{h}(\tilde{\boldsymbol{x}}, \boldsymbol{u}) \,. \end{aligned}$$

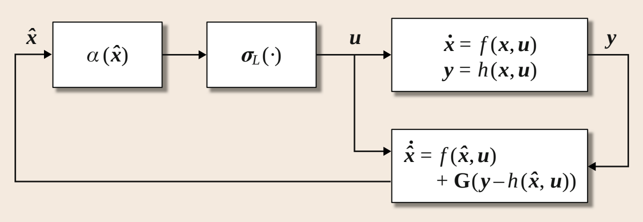
Suppose a feedback law is known $\boldsymbol{u} = \alpha(\tilde{\boldsymbol{x}})$ that globally asymptotic stabilizes the equilibrium point $\tilde{\boldsymbol{x}} = 0$ of the closed-loop system

$$\dot{\tilde{\boldsymbol{x}}} = \tilde{f}(\tilde{\boldsymbol{x}}, \alpha(\tilde{\boldsymbol{x}})) \,.$$

Then, an output feedback controller of the form (Fig. 9.7)

$$\begin{aligned} \dot{\hat{\boldsymbol{x}}} &= \tilde{f}(\hat{\boldsymbol{x}}, \boldsymbol{u}) + \mathbf{G}[\boldsymbol{y} - \tilde{h}(\hat{\boldsymbol{x}}, \boldsymbol{u})] \,, \\ \boldsymbol{u} &= \sigma_L(\alpha(\hat{\boldsymbol{x}})) \,, \end{aligned}$$

whose dynamics are those of system (9.60) and $\sigma_L : \mathbb{R} \to \mathbb{R}$ is a bounded function satisfying $\sigma_L(r) = r$ for all $|r| \le L$, is able to stabilize the equilibrium $(\tilde{\boldsymbol{x}}, \hat{\boldsymbol{x}}) = (0, 0)$ of the closed-loop system, with a basin of attraction that includes any a priori fixed compact set $K \times K$, if its parameters (the coefficients $c_0, c_1, \ldots, c_{n-1}$ and the parameter κ of (9.60) and the parameter L of $\sigma_L(\cdot)$) are appropriately chosen (see [9.13, Chap. 7] for details).



$\hat{\boldsymbol{x}}$
$\alpha(\hat{\boldsymbol{x}})$
$\sigma_L(\cdot)$
$\boldsymbol{u}$
$\dot{\boldsymbol{x}} = f(\boldsymbol{x}, \boldsymbol{u})$
$\boldsymbol{y} = h(\boldsymbol{x}, \boldsymbol{u})$
$\boldsymbol{y}$
$\dot{\hat{\boldsymbol{x}}} = f(\hat{\boldsymbol{x}}, \boldsymbol{u})$
$+ \mathbf{G}(\boldsymbol{y} - h(\hat{\boldsymbol{x}}, \boldsymbol{u}))$

Fig. 9.7 Observer-based control for a nonlinear system

9.7 Tracking and Regulation

9.7.1 The Servomechanism Problem

A central problem in control theory is the design of feedback controllers so as to have certain outputs of a given plant *to track* prescribed reference trajectories. In any realistic scenario, this control goal has to be achieved in spite of a good number of phenomena which would cause the system to behave differently than expected. These phenomena could be endogenous, for instance, parameter variations, or exogenous, such as additional undesired inputs affecting the behavior of the plant. In numerous design problems, the trajectory to be tracked (or the disturbance to be rejected) is not available for measurement, nor is it known ahead of time. Rather, it is only known that this trajectory is simply an (undefined) member in a set of functions, for instance, the set of all possible solutions of an ordinary differential equation. Theses cases include the classical problem of the set-point control, the problem of active suppression of harmonic disturbances of unknown amplitude, phase and even frequency, the synchronization of nonlinear oscillations, and similar others.

In general, a tracking problem of this kind can be cast in the following terms. Consider a finite-dimensional, time-invariant, nonlinear system modeled by equations of the form

$$\begin{aligned} \dot{\boldsymbol{x}} &= f(\boldsymbol{w}, \boldsymbol{x}, \boldsymbol{u}) \,, \\ \boldsymbol{e} &= h(\boldsymbol{w}, \boldsymbol{x}) \,, \\ \boldsymbol{y} &= k(\boldsymbol{w}, \boldsymbol{x}) \,, \end{aligned} \tag{9.61}$$

in which $\boldsymbol{x} \in \mathbb{R}^n$ is a vector of state variables, $\boldsymbol{u} \in \mathbb{R}^m$ is a vector of inputs used for *control* purposes, $\boldsymbol{w} \in \mathbb{R}^s$ is a vector of inputs which cannot be controlled and include *exogenous* commands, exogenous disturbances, and model uncertainties, $\boldsymbol{e} \in \mathbb{R}^p$ is a vector of *regulated* outputs which include tracking errors and any other variable that needs to be steered to 0, and $\boldsymbol{y} \in \mathbb{R}^q$ is a vector of outputs that are available for *measurement* and hence used to feed the device that supplies the control action. The problem is to design a controller, which receives $\boldsymbol{y}(t)$ as input and produces $\boldsymbol{u}(t)$ as output, able to guarantee that, in the resulting closed-loop system, $\boldsymbol{x}(t)$ remains bounded and

$$\lim_{t\to\infty} \boldsymbol{e}(t) = 0 \,, \tag{9.62}$$

regardless of what the exogenous input $\boldsymbol{w}(t)$ actually is.

As observed at the beginning, $\boldsymbol{w}(t)$ is not available for measurement, nor it is known ahead of time, but it is known *to belong to a fixed family* of functions of time, the family of all solutions obtained from a fixed ordinary differential equation of the form

$$\dot{\boldsymbol{w}} = s(\boldsymbol{w}) \tag{9.63}$$

as the corresponding initial condition $\boldsymbol{w}(0)$ is allowed to vary on a prescribed set. This autonomous system is known as *the exosystem*.

The control law is to be provided by a system modeled by equations of the form

$$\begin{aligned} \dot{\boldsymbol{\xi}} &= \varphi(\boldsymbol{\xi}, \boldsymbol{y}) \,, \\ \boldsymbol{u} &= \gamma(\boldsymbol{\xi}, \boldsymbol{y}) \,, \end{aligned} \tag{9.64}$$

with state $\boldsymbol{\xi} \in \mathbb{R}^\nu$. The initial conditions $\boldsymbol{x}(0)$ of the *plant* (9.61), $\boldsymbol{w}(0)$ of the *exosystem* (9.63), and $\boldsymbol{\xi}(0)$ of the *controller* (9.64) are allowed to range over fixed *compact* sets $X \subset \mathbb{R}^n$, $W \subset \mathbb{R}^s$, and $\Xi \subset \mathbb{R}^\nu$, respectively. All maps characterizing the model of the controlled plant, of the exosystem, and of the controller are assumed to be sufficiently differentiable.

The *generalized servomechanism problem* (or *problem of output regulation*) is to design a feedback controller of the form (9.64) so as to obtain a closed-loop system in which all trajectories are bounded and the regulated output $e(t)$ asymptotically decays to 0 as $t \to \infty$. More precisely, it is required that the composition of (9.61), (9.63), and (9.64), that is, the *autonomous* system

$$\begin{aligned} \dot{\boldsymbol{w}} &= s(\boldsymbol{w}) \,, \\ \dot{\boldsymbol{x}} &= f(\boldsymbol{w}, \boldsymbol{x}, \gamma(\boldsymbol{\xi}, k(\boldsymbol{w}, \boldsymbol{x}))) \,, \\ \dot{\boldsymbol{\xi}} &= \varphi(\boldsymbol{\xi}, k(\boldsymbol{w}, \boldsymbol{x})) \,, \end{aligned} \tag{9.65}$$

with output $\boldsymbol{e} = h(\boldsymbol{w}, \boldsymbol{x})$ be such that:

- The positive orbit of $W \times X \times \Xi$ is bounded, i. e., there exists a bounded subset S of $\mathbb{R}^s \times \mathbb{R}^n \times \mathbb{R}^\nu$ such that, for any $(\boldsymbol{w}_0, \boldsymbol{x}_0, \boldsymbol{\xi}_0) \in W \times X \times \boldsymbol{\Xi}$, the integral curve $(\boldsymbol{w}(t), \boldsymbol{x}(t), \boldsymbol{\xi}(t))$ of (9.65) passing through $(\boldsymbol{w}_0, \boldsymbol{x}_0, \boldsymbol{\xi}_0)$ at time $t = 0$ remains in S for all $t \geq 0$.
- $\lim_{t\to\infty} e(t) = 0$, uniformly in the initial condition; i. e., for every $\varepsilon > 0$ there exists a time $\bar{t}$, depending only on ε and *not on* $(\boldsymbol{w}_0, \boldsymbol{x}_0, \boldsymbol{\xi}_0)$ such that the integral curve $(\boldsymbol{w}(t), \boldsymbol{x}(t), \boldsymbol{\xi}(t))$ of (9.65) passing through $(\boldsymbol{w}_0, \boldsymbol{x}_0, \boldsymbol{\xi}_0)$ at time $t = 0$ satisfies $\|\boldsymbol{e}(t)\| \leq \varepsilon$ for all $t \geq \bar{t}$.

9.7.2 Tracking and Regulation for Linear Systems

We show in this section how the servomechanism problem is treated in the case of linear systems. Let system (9.61) and exosystem (9.63) be linear systems, modeled by equations of the form

$$\begin{aligned}\dot{\boldsymbol{w}} &= \mathbf{S}\boldsymbol{w}\,,\\ \dot{\boldsymbol{x}} &= \mathbf{P}\boldsymbol{w}+\mathbf{A}\boldsymbol{x}+\mathbf{B}\boldsymbol{u}\,,\\ \boldsymbol{e} &= \mathbf{Q}\boldsymbol{w}+\mathbf{C}\boldsymbol{x}\,,\end{aligned} \tag{9.66}$$

and suppose that $\boldsymbol{y}=\boldsymbol{e}$, i. e., that regulated and measured variables coincide. We also consider, for simplicity, the case in which $m=1$ and $p=1$. Without loss of generality, it is assumed that all eigenvalues of $\mathbf{S}$ are simple and are on the imaginary axis.

A convenient point of departure for the analysis is the identification of conditions for the existence of a solution of the design problem. To this end, consider a dynamic, output-feedback controller

$$\begin{aligned}\dot{\boldsymbol{\xi}} &= \mathbf{F}\boldsymbol{\xi}+\mathbf{G}\boldsymbol{e}\,,\\ \boldsymbol{u} &= \mathbf{H}\boldsymbol{\xi}\end{aligned} \tag{9.67}$$

and the associated closed-loop system

$$\begin{aligned}\dot{\boldsymbol{w}} &= \mathbf{S}\boldsymbol{w}\,,\\ \begin{pmatrix}\dot{\boldsymbol{x}}\\ \dot{\boldsymbol{\xi}}\end{pmatrix} &= \begin{pmatrix}\mathbf{P}\\ \mathbf{GQ}\end{pmatrix}\boldsymbol{w}+\begin{pmatrix}\mathbf{A} & \mathbf{BH}\\ \mathbf{GC} & \mathbf{F}\end{pmatrix}\begin{pmatrix}\boldsymbol{x}\\ \boldsymbol{\xi}\end{pmatrix}\,.\end{aligned} \tag{9.68}$$

If the controller solves the problem at issue, all trajectories are bounded and $\boldsymbol{e}(t)$ asymptotically decays to zero. Boundedness of all trajectories implies that all eigenvalues of

$$\begin{pmatrix}\mathbf{A} & \mathbf{BH}\\ \mathbf{GC} & \mathbf{F}\end{pmatrix} \tag{9.69}$$

have nonpositive real part. However, if some of the eigenvalues of this matrix were on the imaginary axis, the property of boundedness of trajectories could be lost as a result of infinitesimal variations in the parameters of (9.66) and/or (9.67). Thus, only the case in which the eigenvalues of (9.69) have negative real part is of interest. If the controller is such that this happens, then *necessarily* the pair of matrices $(\mathbf{A},\mathbf{B})$ is stabilizable and the pair of matrices $(\mathbf{A},\mathbf{C})$ is detectable. Observe now that, if the matrix (9.69) has all eigenvalues with negative real part, system (9.68) has a well-defined steady state, which takes place on an invariant subspace (the steady-state locus). The latter, as shown earlier, is necessarily the graph of a linear map, which expresses the $\boldsymbol{x}$ and $\boldsymbol{\xi}$ components of the state vector as functions of the $\boldsymbol{w}$ component. In other terms, the steady-state locus is the set of all triplets $(\boldsymbol{w},\boldsymbol{x},\boldsymbol{\xi})$ in which $\boldsymbol{w}$ is arbitrary, while $\boldsymbol{x}$ and $\boldsymbol{\xi}$ are expressed as

$$\begin{aligned}\boldsymbol{x} &= \Pi\boldsymbol{w}\,,\\ \boldsymbol{\xi} &= \Sigma\boldsymbol{w}\,,\end{aligned}$$

for some Π and Σ. These matrices, in turn, are solutions of the Sylvester equation

$$\begin{pmatrix}\Pi\\ \Sigma\end{pmatrix}\mathbf{S}=\begin{pmatrix}\mathbf{P}\\ \mathbf{GQ}\end{pmatrix}+\begin{pmatrix}\mathbf{A} & \mathbf{BH}\\ \mathbf{GC} & \mathbf{F}\end{pmatrix}\begin{pmatrix}\Pi\\ \Sigma\end{pmatrix}\,. \tag{9.70}$$

All trajectories asymptotically converge to the steady state. Thus, in view of the expression thus found for the steady-state locus, it follows that

$$\begin{aligned}&\lim_{t\to\infty}[\boldsymbol{x}(t)-\Pi\boldsymbol{w}(t)]=0\,,\\ &\lim_{t\to\infty}[\boldsymbol{\xi}(t)-\Sigma\boldsymbol{w}(t)]=0\,.\end{aligned}$$

In particular, it is seen from this that

$$\lim_{t\to\infty}\boldsymbol{e}(t)=\lim_{t\to\infty}[\mathbf{C}\Pi+\mathbf{Q}]\boldsymbol{w}(t)\,.$$

Since $\boldsymbol{w}(t)$ is a persistent function (none of the eigenvalues of $\mathbf{S}$ has negative real part), it is concluded that the regulated variable $\boldsymbol{e}(t)$ converges to 0 as $t\to\infty$ only if the map $e=\mathbf{C}\boldsymbol{x}+\mathbf{Q}\boldsymbol{w}$ is zero on the steady-state locus, i. e., if

$$0=\mathbf{C}\Pi+\mathbf{Q}\,. \tag{9.71}$$

Note that the Sylvester equation (9.70) can be split into two equations, the former of which

$$\Pi\mathbf{S}=\mathbf{P}+\mathbf{A}\Pi+\mathbf{BH}\Sigma\,,$$

having set $\Gamma:=\mathbf{H}\Sigma$, can be rewritten as

$$\Pi\mathbf{S}=\mathbf{A}\Pi+\mathbf{B}\Gamma+\mathbf{P}\,,$$

while the second one, bearing in mind the constraint (9.71), reduces to

$$\Sigma\mathbf{S}=\mathbf{F}\Sigma\,.$$

These arguments have proven – *in particular* – that, if there exists a controller that controller solves the problem, necessarily there exists a pair of matrices Π, Γ such that

$$\begin{aligned}\Pi\mathbf{S} &= \mathbf{A}\Pi+\mathbf{B}\Gamma+\mathbf{P}\\ 0 &= \mathbf{C}\Pi+\mathbf{Q}\,.\end{aligned} \tag{9.72}$$

The (linear) equations thus found are known as the *regulator equations* [9.14]. If, as observed above, the controller is required to solve the problem is spite of arbitrary (small) variations of the parameters of (9.66), the existence of solutions (9.72) is required to hold independently of the specific values of $\mathbf{P}$ and $\mathbf{Q}$. This occurs if and only if none of the eigenvalues of $\mathbf{S}$ is a root of

$$\det\begin{pmatrix}\mathbf{A}-\boldsymbol{\lambda}\mathbf{I} & \mathbf{B}\\ \mathbf{C} & \mathbf{0}\end{pmatrix}=0\,. \tag{9.73}$$

This condition is usually referred to as the *nonresonance* condition.

In summary, it has been shown that, if there exists a controller that solves the servomechanism problem, necessarily the controlled plant (with $\boldsymbol{w}=0$) is *stabilizable and detectable* and *none of the eigenvalues of* $\mathbf{S}$ *is a root of* (9.73). These *necessary* conditions turn out to be also *sufficient* for the existence of a controller that solves the servomechanism problem.

A procedure for the design of a controller is described below. Let

$$\psi(\boldsymbol{\lambda})=\boldsymbol{\lambda}^s+d_{s-1}\boldsymbol{\lambda}^{s-1}+\cdots+d_1\boldsymbol{\lambda}+d_0$$

denote the minimal polynomial of $\mathbf{S}$. Set

$$\varPhi=\begin{pmatrix}0&1&0&\cdots&0&0\\0&0&1&\cdots&0&0\\ \cdot&\cdot&\cdot&\cdots&\cdot&\cdot\\0&0&0&\cdots&0&1\\-d_0&-d_1&-d_2&\cdots&-d_{s-2}&-d_{s-1}\end{pmatrix},$$

$$\boldsymbol{G}=\begin{pmatrix}0\\0\\\cdots\\0\\1\end{pmatrix},$$

$$\boldsymbol{H}=\begin{pmatrix}1&0&0&\cdots&0&0\end{pmatrix}.$$

Let $\varPi$, $\varGamma$ be a solution pair of (9.72) and note that the matrix

$$\varUpsilon=\begin{pmatrix}\varGamma\\ \varGamma\mathbf{S}\\ \cdots\\ \varGamma\mathbf{S}^{s-1}\end{pmatrix}$$

satisfies

$$\varUpsilon\mathbf{S}=\varPhi\varUpsilon,\quad \varGamma=\mathbf{H}\varUpsilon\,. \tag{9.74}$$

Define a controller as follows:

$$\begin{aligned}\dot{\xi}&=\varPhi\xi+\mathbf{G}\boldsymbol{e}\,,\\ \dot{\eta}&=\mathbf{K}\eta+\mathbf{L}\boldsymbol{e}\,,\\ \boldsymbol{u}&=\mathbf{H}\xi+\mathbf{M}\eta\,,\end{aligned} \tag{9.75}$$

in which the matrices $\varPhi$, $\mathbf{G}$, $\mathbf{H}$ are those defined before and $\mathbf{K}$, $\mathbf{L}$, $\mathbf{M}$ are matrices to be determined. Consider now the associated closed-loop system, which can be written in the form

$$\begin{aligned}&\dot{\boldsymbol{w}}=\mathbf{S}\boldsymbol{w}\,,\\ &\begin{pmatrix}\dot{x}\\ \dot{\xi}\\ \dot{\eta}\end{pmatrix}=\begin{pmatrix}\mathbf{P}\\ \mathbf{GQ}\\ \mathbf{LQ}\end{pmatrix}\boldsymbol{w}+\begin{pmatrix}\mathbf{A}&\mathbf{BH}&\mathbf{BM}\\ \mathbf{GC}&\varPhi&0\\ \mathbf{LC}&0&\mathbf{K}\end{pmatrix}\begin{pmatrix}x\\ \xi\\ \eta\end{pmatrix}.\end{aligned} \tag{9.76}$$

By assumption, the pair of matrices $(\mathbf{A},\mathbf{B})$ is stabilizable, the pair of matrices $(\mathbf{A},\mathbf{C})$ is detectable, and none of the eigenvalues of $\mathbf{S}$ is a root of (9.73). As a consequence, in view of the special structure of $\varPhi$, $\mathbf{G}$, $\mathbf{H}$, also the pair

$$\begin{pmatrix}\mathbf{A}&\mathbf{BH}\\ \mathbf{GC}&\varPhi\end{pmatrix},\ \begin{pmatrix}\mathbf{B}\\0\end{pmatrix}$$

is stabilizable and the pair

$$\begin{pmatrix}\mathbf{A}&\mathbf{BH}\\ \mathbf{GC}&\varPhi\end{pmatrix},\ \begin{pmatrix}\mathbf{C}&0\end{pmatrix}$$

is detectable. This being the case, it is possible to pick $\mathbf{K}$, $\mathbf{L}$, $\mathbf{M}$ in such a way that all eigenvalues of

$$\begin{pmatrix}\mathbf{A}&\mathbf{BH}&\mathbf{BM}\\ \mathbf{GC}&\varPhi&0\\ \mathbf{LC}&0&\mathbf{K}\end{pmatrix}$$

have negative real part.

As a result, all trajectories of (9.76) are bounded. Using (9.72) and (9.74) it is easy to check that the graph of the mapping

$$\pi:\boldsymbol{w}\to\begin{pmatrix}\varPi\\ \varUpsilon\\ 0\end{pmatrix}\boldsymbol{w}$$

is invariant for (9.76). This subspace is actually the steady-state locus of (9.76) and $\boldsymbol{e}=\mathbf{C}\boldsymbol{x}+\mathbf{Q}\boldsymbol{w}$ is zero on this subspace. Hence all trajectories of (9.76) are such that $\boldsymbol{e}(t)$ converges to 0 as $t\to\infty$.

The construction described above is insensitive to small arbitrary variations of the parameters, except for the case of parameter variations in the exosystem. The case of parameter variations in the exosystem requires a different design, as explained e.g., in [9.15]. A state-of-the-art discussion of the servomechanism problem for suitable classes of nonlinear systems can be found in [9.16].

9.8 Conclusion

This chapter has reviewed the fundamental methods and models of control theory as applied to automation. The following two chapters address further advancements in this area of automation theory.

10. Control Theory for Automation – Advanced Techniques

István Vajk, Jenő Hetthéssy, Ruth Bars

Analysis and design of control systems is a complex field. In order to develop appropriate concepts and methods to cover this field, mathematical models of the processes to be controlled are needed to apply. In this chapter mainly continuous-time linear systems with multiple input and multiple output (MIMO systems) are considered. Specifically, stability, performance, and robustness issues, as well as optimal control strategies are discussed in detail for MIMO linear systems. As far as system representations are concerned, transfer function matrices, matrix fraction descriptions, and state-space models are applied in the discussions. Several interpretations of all stabilizing controllers are shown for stable and unstable processes. Performance evaluation is supported by applying H_2 and H_∞ norms. As an important class for practical applications, predictive controllers are also discussed. In this case, according to the underlying implementation technique, discrete-time process models are considered. Transformation methods using state variable feedback are discussed, making the operation of nonlinear dynamic systems linear in the complete range of their operation. Finally, the sliding control concept is outlined.

10.1 MIMO Feedback Systems

This chapter on advanced automatic control for automation follows the previous introductory chapter. In this section continuous-time linear systems with multiple input and multiple output (MIMO systems) will be considered. As far as the mathematical models are concerned, transfer functions, matrix fraction descriptions, and state-space models will be used [10.1]. Regarding the notations concerned, transfer functions will always be denoted by explicitly showing the dependence of the complex frequency operator s, while variables in

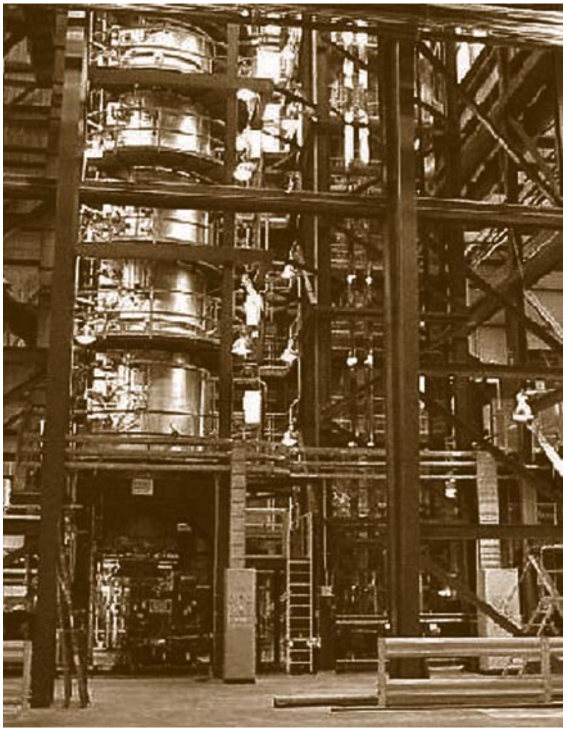

Fig. 10.1 Distillation column in an oil-refinery plant

bold face represent vectors or matrices. Thus, $A(s)$ is a scalar transfer function, $\boldsymbol{A}(s)$ is a transfer function matrix, while $\mathbf{A}$ is a matrix.

Considering the structure of the systems to be discussed, feedback control systems will be studied. Feedback is the most inherent step to create practical control systems, as it allows one to change the dynamical and steady-state behavior of various processes to be controlled to match technical expectations [10.2–7]. In this chapter mainly continuous-time systems such as those in Figs. 10.1–10.3 will be discussed [10.8]. Note that special care should be taken to derive their appropriate discrete-time counterparts [10.9–12]. The well-known advantages of feedback structures, also called closed-loop systems, range from the *servo property* (i. e., to force the process output to follow a prescribed command signal) to effective *disturbance rejection* through *robustness* (the ability to achieve the control goals in spite of incomplete knowledge available on the process) and measurement *noise attenuation*. When designing a control system, however, *stability* should always remain the most important task. Figure 10.4 shows the block diagram of a conventional closed-loop system with negative feedback, where $\boldsymbol{r}$ is the set point, $\boldsymbol{y}$ is the controlled variable (output), $\boldsymbol{u}$ is the process input, $\boldsymbol{d}_{\mathrm{i}}$ and $\boldsymbol{d}_{\mathrm{o}}$ are the input and output disturbances acting on the process, respectively, while $\boldsymbol{d}_{\mathrm{n}}$ represents the additive measurement noise [10.2].

Fig. 10.2 Automated production line

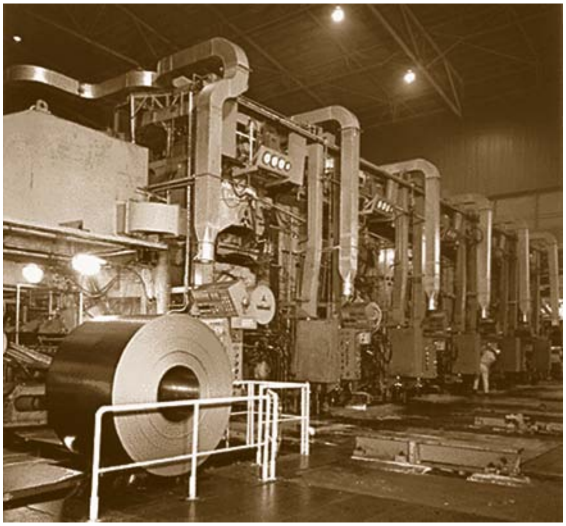

Fig. 10.3 Rolling mill

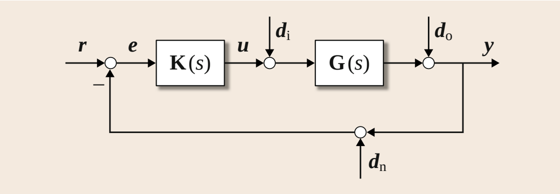

Fig. 10.4 Multivariable feedback system

In the figure $\mathbf{G}(s)$ denotes the transfer function matrix of the process and $\mathbf{K}(s)$ stands for the controller. For the designer of the closed-loop system, $\mathbf{G}(s)$ is given, while $\mathbf{K}(s)$ is the result of the design procedure. Note that $\mathbf{G}(s)$ is only a model of the process and serves here as the basis to design an appropriate $\mathbf{K}(s)$. In practice the signals driving the control system are delivered by a given process or technology and the control input is in fact applied to the given process.

The main design objectives are [10.2, 6, 13]:

- Closed-loop and internal stability (just as it will be addressed in this section)
- Good command following (servo property)
- Good disturbance rejection
- Good measurement noise attenuation.

In addition, to keep operational costs low, small process input values are preferred over large excursions in the control signal. Also, as the controller design is based on a model of the process, which always implies uncertainties, design procedures aiming at stability and desirable performance based on the nominal plant model should be extended to tolerate modeling uncertainties as well. Thus the list of the design objectives is to be completed by:

- Achieve reduced input signals
- Achieve robust stability
- Achieve robust performance.

Some of the above design objectives could be conflicting; however, the performance-related issues typically emerge in separable frequency ranges.

In this section linear multivariable feedback systems will be discussed with the following representations.

10.1.1 Transfer Function Models

Consider a linear process with n_u control inputs arranged into a $\boldsymbol{u} \in \mathbb{R}^{n_u}$ input vector and n_y outputs arranged into a $\boldsymbol{y} \in \mathbb{R}^{n_y}$ output vector. Then the transfer function matrix contains all possible transfer functions between any of the inputs and any of the outputs

$$\boldsymbol{y}(s) = \begin{pmatrix} y_1(s) \\ \vdots \\ y_{n_y-1}(s) \\ y_{n_y}(s) \end{pmatrix} = \mathbf{G}(s)\boldsymbol{u}(s)$$

$$= \begin{pmatrix} G_{1,1}(s) & G_{1,2}(s) & \dots & G_{1,n_u}(s) \\ \vdots & \vdots & \ddots & \vdots \\ G_{n_y-1,1}(s) & G_{n_y-1,2}(s) & \dots & G_{n_y-1,n_u}(s) \\ G_{n_y,1}(s) & G_{n_y,2}(s) & \dots & G_{n_y,n_u}(s) \end{pmatrix} \begin{pmatrix} u_1(s) \\ \vdots \\ u_{n_u-1}(s) \\ u_{n_u}(s) \end{pmatrix} ,$$

where s is the Laplace operator and $G_{k,l}(s)$ denotes the transfer function from the l-th component of the input $\boldsymbol{u}$ to the k-th component of the output $\boldsymbol{y}$. The transfer function approach has always been an emphasized modeling tool for control practice. One of the reasons is that the $G_{k,l}(s)$ transfer functions deliver the magnitude and phase frequency functions via a formal substitution of $G_{k,l}(s)\big|_{s=\mathrm{i}\omega} = A_{k,l}(\omega)\,\mathrm{e}^{\mathrm{i}\phi_{k,l}(\omega)}$. Note that for real physical processes $\lim_{\omega\to\infty} A_{k,l}(\omega) = 0$. The transfer function matrix $\mathbf{G}(s)$ is stable if each of its elements is a stable transfer function. Also, the transfer function matrix $\mathbf{G}(s)$ will be called proper if each of its elements is a proper transfer function.

10.1.2 State-Space Models

Introducing n_x state variables arranged into an $\boldsymbol{x} \in \mathbb{R}^{n_x}$ state vector, the state-space model of a MIMO system is given by the following equations

$$\begin{aligned} \dot{\boldsymbol{x}}(t) &= \mathbf{A}\boldsymbol{x}(t) + \mathbf{B}\boldsymbol{u}(t) \, , \\ \boldsymbol{y}(t) &= \mathbf{C}\boldsymbol{x}(t) + \mathbf{D}\boldsymbol{u}(t) \, , \end{aligned}$$

where $\mathbf{A} \in \mathbb{R}^{n_x \times n_x}$, $\mathbf{B} \in \mathbb{R}^{n_x \times n_u}$,$\mathbf{C} \in \mathbb{R}^{n_y \times n_x}$, and $\mathbf{D} \in \mathbb{R}^{n_y \times n_u}$ are the system parameters [10.14, 15].

Important notions (state variable feedback, controllability, stabilizability, observability and detectability) have been introduced to support the deep analysis of state-space models [10.1, 2]. Roughly speaking a state-space representation is *controllable* if an arbitrary initial state can be moved to any desired state by suitable choice of control signals. In terms of state-space realizations, feedback means *state variable feedback* realized by a control law of $\boldsymbol{u} = -\mathbf{K}\boldsymbol{x}$, $\mathbf{K} \in \mathbb{R}^{n_u \times n_x}$. Regarding controllable systems, state variable feedback can relocate all the poles of the closed-loop system to arbitrary locations. If a system is not controllable, but the modes (eigenvalues) attached to the uncontrollable states are stable, the complete system is still *stabilizable*. A state-space realization is said to be *observable* if the initial state $\boldsymbol{x}(0)$ can be determined from the output function $\boldsymbol{y}(t)$, $0 \leq t \leq t_{\text{final}}$. A system is said to be *detectable* if the modes (eigenvalues) attached to the unobservable states are stable.

Using the Laplace transforms in the state-space model equations the relation between the state-space model and the transfer function matrix can easily be derived as

$$\mathbf{G}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D}\ .$$

As far as the above relation is concerned the condition $\lim_{\omega\to\infty} A_{k,l}(\omega) = 0$ raised for real physical processes leads to $\mathbf{D} = \mathbf{0}$. Note that the $\mathbf{G}(s)$ transfer function contains only the controllable *and* observable subsystem represented by the state-space model $\{\mathbf{A}, \mathbf{B}, \mathbf{C}, \mathbf{D}\}$.

10.1.3 Matrix Fraction Description

Transfer functions can be factorized in several ways. As matrices, in general, do not commute, the matrix fraction description (MFD) form exists as a result of right and left factorization, respectively [10.2, 6, 13]

$$\mathbf{G}(s) = \mathbf{B}_\mathrm{R}(s)\mathbf{A}_\mathrm{R}^{-1}(s) = \mathbf{A}_\mathrm{L}^{-1}(s)\mathbf{B}_\mathrm{L}(s)\ ,$$

where $\mathbf{A}_\mathrm{R}(s)$, $\mathbf{B}_\mathrm{R}(s)$, $\mathbf{A}_\mathrm{L}(s)$, and $\mathbf{B}_\mathrm{L}(s)$ are all stable transfer function matrices. In [10.2] it is shown that the right and left MFDs can be related to stabilizable and detectable state-space models, respectively. To outline the procedure consider first the right matrix fraction description (RMFD) $\mathbf{G}(s) = \mathbf{B}_\mathrm{R}(s)\mathbf{A}_\mathrm{R}^{-1}(s)$. For the sake of simplicity the practical case of $\mathbf{D} = \mathbf{0}$ will be considered. Assuming that $\{\mathbf{A}, \mathbf{B}\}$ is stabilizable, apply a state feedback to stabilize the closed-loop system using a gain matrix $\mathbf{K} \in \mathbb{R}^{n_u \times n_x}$

$$\boldsymbol{u}(t) = -\mathbf{K}\boldsymbol{x}(t)\ ,$$

then the RMFD components can be derived in a straightforward way as

$$\mathbf{B}_\mathrm{R}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A} + \mathbf{B}\mathbf{K})^{-1}\mathbf{B}\ ,$$
$$\mathbf{A}_\mathrm{R}(s) = \mathbf{I} - \mathbf{K}(s\mathbf{I} - \mathbf{A} + \mathbf{B}\mathbf{K})^{-1}\mathbf{B}\ .$$

It can be shown that $\mathbf{G}(s) = \mathbf{B}_\mathrm{R}(s)\mathbf{A}_\mathrm{R}^{-1}(s)$ will not be a function of the stabilizing gain matrix $\mathbf{K}$, however, the proof is rather involved [10.2]. Also, following the above procedure, both $\mathbf{B}_\mathrm{R}(s)$ and $\mathbf{A}_\mathrm{R}(s)$ will be stable transfer function matrices.

In a similar way, assuming that $\{\mathbf{A}, \mathbf{C}\}$ is detectable, apply a state observer to detect the closed-loop system using a gain matrix $\mathbf{L}$. Then the left matrix fraction description (LMFD) components can be obtained as

$$\mathbf{B}_\mathrm{L}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A} + \mathbf{L}\mathbf{C})^{-1}\mathbf{B}\ ,$$
$$\mathbf{A}_\mathrm{L}(s) = \mathbf{I} - \mathbf{C}(s\mathbf{I} - \mathbf{A} + \mathbf{L}\mathbf{C})^{-1}\mathbf{L}\ ,$$

being stable transfer function matrices. Again, $\mathbf{G}(s) = \mathbf{A}_\mathrm{L}^{-1}(s)\mathbf{B}_\mathrm{L}(s)$ will be independent of $\mathbf{L}$.

Concerning the coprime factorization, an important relation, the *Bezout identity*, will be used, which holds for the components of the RMFD and LMFD coprime factorization

$$\begin{pmatrix} \mathbf{X}_\mathrm{L}(s) & \mathbf{Y}_\mathrm{L}(s) \\ -\mathbf{B}_\mathrm{L}(s) & \mathbf{A}_\mathrm{L}(s) \end{pmatrix} \begin{pmatrix} \mathbf{A}_\mathrm{R}(s) & -\mathbf{Y}_\mathrm{R}(s) \\ \mathbf{B}_\mathrm{R}(s) & \mathbf{X}_\mathrm{R}(s) \end{pmatrix}$$
$$= \begin{pmatrix} \mathbf{A}_\mathrm{R}(s) & -\mathbf{Y}_\mathrm{R}(s) \\ \mathbf{B}_\mathrm{R}(s) & \mathbf{X}_\mathrm{R}(s) \end{pmatrix} \begin{pmatrix} \mathbf{X}_\mathrm{L}(s) & \mathbf{Y}_\mathrm{L}(s) \\ -\mathbf{B}_\mathrm{L}(s) & \mathbf{A}_\mathrm{L}(s) \end{pmatrix} = \mathbf{I}\ ,$$

where

$$\mathbf{Y}_\mathrm{R}(s) = \mathbf{K}(s\mathbf{I} - \mathbf{A} + \mathbf{B}\mathbf{K})^{-1}\mathbf{L}\ ,$$
$$\mathbf{X}_\mathrm{R}(s) = \mathbf{I} + \mathbf{C}(s\mathbf{I} - \mathbf{A} + \mathbf{B}\mathbf{K})^{-1}\mathbf{L}\ ,$$
$$\mathbf{Y}_\mathrm{L}(s) = \mathbf{K}(s\mathbf{I} - \mathbf{A} + \mathbf{L}\mathbf{C})^{-1}\mathbf{L}\ ,$$
$$\mathbf{X}_\mathrm{L}(s) = \mathbf{I} + \mathbf{K}(s\mathbf{I} - \mathbf{A} + \mathbf{L}\mathbf{C})^{-1}\mathbf{B}\ .$$

Note that the Bezout identity plays an important role in control design. A good review on this can be found in [10.1]. Also note that a MFD factorization can be accomplished by using the Smith–McMillan form of $\mathbf{G}(s)$ [10.1]. As a result of this procedure, however, $\mathbf{A}_\mathrm{R}(s)$, $\mathbf{B}_\mathrm{R}(s)$, $\mathbf{A}_\mathrm{L}(s)$, and $\mathbf{B}_\mathrm{L}(s)$ will be polynomial matrices. Moreover, both $\mathbf{A}_\mathrm{R}(s)$ and $\mathbf{A}_\mathrm{L}(s)$ will be diagonal matrices.

10.2 All Stabilizing Controllers

In general, a feedback control system follows the structure shown in Fig. 10.5, where the control configuration consists of two subsystems. In this general setup any of the subsystems $\mathbf{S}_1(s)$ or $\mathbf{S}_2(s)$ may play the role of the process or the controller [10.3]. Here $\{\boldsymbol{u}_1, \boldsymbol{u}_2\}$ and $\{\boldsymbol{y}_1, \boldsymbol{y}_2\}$ are multivariable external input and output signals in general sense, respectively. Moreover, $\mathbf{S}_1(s)$ and $\mathbf{S}_2(s)$ represent transfer function matrices according to

$$\boldsymbol{y}_1(s) = \mathbf{S}_1(s)[\boldsymbol{u}_1(s) + \boldsymbol{y}_2(s)]\ ,$$
$$\boldsymbol{y}_2(s) = \mathbf{S}_2(s)[\boldsymbol{u}_2(s) + \boldsymbol{y}_1(s)]\ .$$

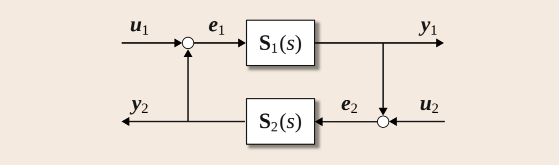

Fig. 10.5 A general feedback configuration

Being restricted to linear systems the closed-loop system is *internally stable* if and only if *all* the four entries of the transfer function matrix

$$\begin{pmatrix} \mathbf{H}_{11}(s) & \mathbf{H}_{12}(s) \\ \mathbf{H}_{21}(s) & \mathbf{H}_{22}(s) \end{pmatrix}$$

are asymptotically stable, where

$$\begin{aligned} \begin{pmatrix} \boldsymbol{e}_1(s) \\ \boldsymbol{e}_2(s) \end{pmatrix} &= \begin{pmatrix} \boldsymbol{u}_1(s) + \boldsymbol{y}_2(s) \\ \boldsymbol{u}_2(s) + \boldsymbol{y}_1(s) \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{H}_{11}(s) & \mathbf{H}_{12}(s) \\ \mathbf{H}_{21}(s) & \mathbf{H}_{22}(s) \end{pmatrix} \begin{pmatrix} \boldsymbol{u}_1(s) \\ \boldsymbol{u}_2(s) \end{pmatrix} \\ &= \begin{pmatrix} [\mathbf{I} - \mathbf{S}_2(s)\mathbf{S}_1(s)]^{-1} & [\mathbf{I} - \mathbf{S}_2(s)\mathbf{S}_1(s)]^{-1}\mathbf{S}_2(s) \\ [\mathbf{I} - \mathbf{S}_1(s)\mathbf{S}_2(s)]^{-1}\mathbf{S}_1(s) & [\mathbf{I} - \mathbf{S}_1(s)\mathbf{S}_2(s)]^{-1} \end{pmatrix} \\ &\quad \times \begin{pmatrix} \boldsymbol{u}_1(s) \\ \boldsymbol{u}_2(s) \end{pmatrix} . \end{aligned}$$

Also, from

$$\begin{aligned} \boldsymbol{e}_1(s) &= \boldsymbol{u}_1(s) + \boldsymbol{y}_2(s) = \boldsymbol{u}_1(s) + \mathbf{S}_2(s)\boldsymbol{e}_2(s) , \\ \boldsymbol{e}_2(s) &= \boldsymbol{u}_2(s) + \boldsymbol{y}_1(s) = \boldsymbol{u}_2(s) + \mathbf{S}_1(s)\boldsymbol{e}_1(s) , \end{aligned}$$

we have

$$\begin{aligned} \begin{pmatrix} \boldsymbol{e}_1 \\ \boldsymbol{e}_2 \end{pmatrix} &= \begin{pmatrix} \mathbf{H}_{11}(s) & \mathbf{H}_{12}(s) \\ \mathbf{H}_{21}(s) & \mathbf{H}_{22}(s) \end{pmatrix} \begin{pmatrix} \boldsymbol{u}_1(s) \\ \boldsymbol{u}_2(s) \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{I} & -\mathbf{S}_2(s) \\ -\mathbf{S}_1(s) & \mathbf{I} \end{pmatrix}^{-1} \begin{pmatrix} \boldsymbol{u}_1 \\ \boldsymbol{u}_2 \end{pmatrix} , \end{aligned}$$

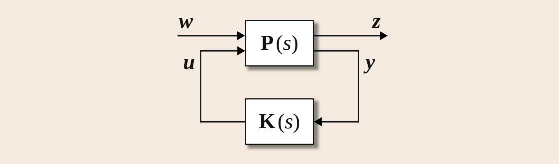

Fig. 10.6 General control system configuration

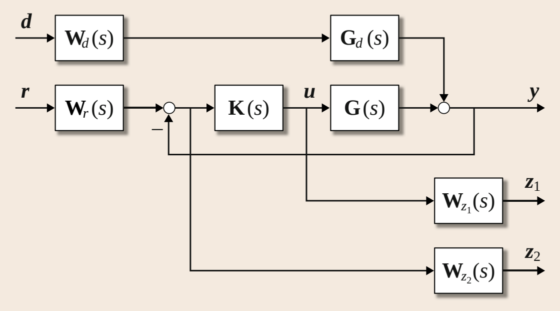

Fig. 10.7 A sample closed-loop control system

so for internal stability we need the transfer function matrix

$$\begin{aligned} &\begin{pmatrix} [\mathbf{I} - \mathbf{S}_2(s)\mathbf{S}_1(s)]^{-1} & [\mathbf{I} - \mathbf{S}_2(s)\mathbf{S}_1(s)]^{-1}\mathbf{S}_2(s) \\ [\mathbf{I} - \mathbf{S}_1(s)\mathbf{S}_2(s)]^{-1}\mathbf{S}_1(s) & [\mathbf{I} - \mathbf{S}_1(s)\mathbf{S}_2(s)]^{-1} \end{pmatrix} \\ &= \begin{pmatrix} \mathbf{I} & -\mathbf{S}_2(s) \\ -\mathbf{S}_1(s) & \mathbf{I} \end{pmatrix}^{-1} \end{aligned}$$

to be asymptotically stable [10.13].

In the control system literature a more practical, but still general closed-loop control scheme is considered, as shown in Fig. 10.6 with a generalized plant $\mathbf{P}(s)$ and controller $\mathbf{K}(s)$ [10.6,13,14]. In this configuration $\boldsymbol{u}$ and $\boldsymbol{y}$ represent the process input and output, respectively, $\boldsymbol{w}$ denotes external inputs (command signal, disturbance or noise), $\boldsymbol{z}$ is a set of signals representing the closed-loop performance in general sense. The controller $\mathbf{K}(s)$ is to be adjusted to ensure a stable closed-loop system with appropriate performance.

As an example Fig. 10.7 shows a possible control loop for tracking and disturbance rejection. Once the disturbance signal $\boldsymbol{d}$ and the command signal (or set point) signal $\boldsymbol{r}$ are combined to a vector-valued signal $\boldsymbol{w}$, the block diagram can easily be redrawn to match the general scheme in Fig. 10.6. Note the $\mathbf{W}_d(s)$, $\mathbf{W}_r(s)$, and $\mathbf{W}_z(s)$ filters introduced just to shape the system performance. Since any closed-loop system can be redrawn to the general configuration shown in Fig. 10.5,

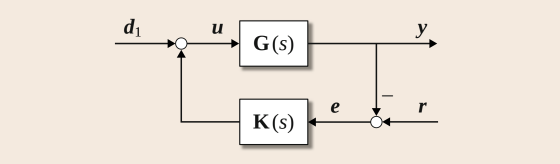

Fig. 10.8 Control system configuration including set point and input disturbance

the block diagram in Fig. 10.8 will be considered in the sequel.

Adopting the condition earlier developed for internal stability with $\mathbf{S}_1(s) = \mathbf{G}(s)$ and $\mathbf{S}_2(s) = -\mathbf{K}(s)$ it is seen that now we need asymptotic stability for the following four transfer functions

$$\begin{pmatrix} [\mathbf{I}+\mathbf{K}(s)\mathbf{G}(s)]^{-1} & [\mathbf{I}+\mathbf{K}(s)\mathbf{G}(s)]^{-1}\mathbf{K}(s) \\ -[\mathbf{I}+\mathbf{G}(s)\mathbf{K}(s)]^{-1}\mathbf{G}(s) & [\mathbf{I}+\mathbf{G}(s)\mathbf{K}(s)]^{-1} \end{pmatrix} .$$

At the same time the block diagram of Fig. 10.8 suggests

$$\begin{aligned} \boldsymbol{e}(s) &= \boldsymbol{r}(s) - \boldsymbol{y}(s) = \boldsymbol{r}(s) - \mathbf{G}(s)\mathbf{K}(s)\boldsymbol{e}(s) \\ &\Rightarrow \boldsymbol{e}(s) = [\mathbf{I}+\mathbf{G}(s)\mathbf{K}(s)]^{-1}\boldsymbol{r}(s) , \end{aligned}$$

which leads to

$$\begin{aligned} \boldsymbol{u}(s) &= \mathbf{K}(s)\boldsymbol{e}(s) = \mathbf{K}(s)[\mathbf{I}+\mathbf{G}(s)\mathbf{K}(s)]^{-1}\boldsymbol{r}(s) \\ &= \mathbf{Q}(s)\boldsymbol{r}(s) , \end{aligned}$$

where

$$\mathbf{Q}(s) = \mathbf{K}(s)[\mathbf{I}+\mathbf{G}(s)\mathbf{K}(s)]^{-1} .$$

It can easily be shown that, *in the case of a stable* $\mathbf{G}(s)$ *plant*, any stable $\mathbf{Q}(s)$ transfer function, in other words *Q parameter*, results in internal stability. Rearranging the above equation $\mathbf{K}(s)$ parameterized by $\mathbf{Q}(s)$ exhibits *all stabilizing controllers*

$$\mathbf{K}(s) = [\mathbf{I} - \mathbf{Q}(s)\mathbf{G}(s)]^{-1}\mathbf{Q}(s) .$$

This result is known as the *Youla parameterization* [10.13, 16]. Recalling $\boldsymbol{u}(s) = \mathbf{Q}(s)\boldsymbol{r}(s)$ and $\boldsymbol{y}(s) = \mathbf{G}(s)\boldsymbol{u}(s) = \mathbf{G}(s)\mathbf{Q}(s)\boldsymbol{r}(s)$ allows one to draw the block diagram of the closed-loop system explicitly using $\mathbf{Q}(s)$ (Fig. 10.9). The control scheme shown in Fig. 10.9 satisfies $\boldsymbol{u}(s) = \mathbf{Q}(s)\boldsymbol{r}(s)$ and $\boldsymbol{y}(s) = \mathbf{G}(s)\mathbf{Q}(s)\boldsymbol{r}(s)$, moreover the process modeling uncertainties ($\mathbf{G}(s)$ of the physical process and $\mathbf{G}(s)$ of the model, as part of the controller are different) are also taken into account. This is the well-known internal model controller (IMC) scheme [10.17, 18].

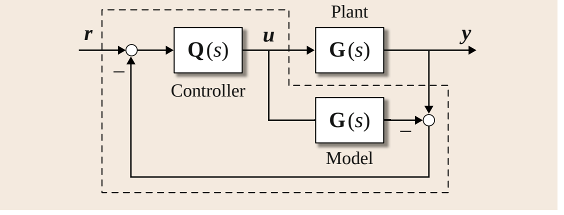

Fig. 10.9 Internal model controller

A quick evaluation for the Youla parameterization should point out a fundamental difference between designing an overall transfer function $\mathbf{T}(s)$ from the $\boldsymbol{r}(s)$ reference signal to the $\boldsymbol{y}(s)$ output signal using a nonlinear parameterization by $\mathbf{K}(s)$

$$\boldsymbol{y}(s) = \mathbf{T}(s)\boldsymbol{r}(s) = \mathbf{G}(s)\mathbf{K}(s)[\mathbf{I}+\mathbf{G}(s)\mathbf{K}(s)]^{-1}\boldsymbol{r}(s)$$

versus a design by

$$\boldsymbol{y}(s) = \mathbf{T}(s)\boldsymbol{r}(s) = \mathbf{G}(s)\mathbf{Q}(s)\boldsymbol{r}(s)$$

linear in $\mathbf{Q}(s)$.

Further analysis of the relation by $\boldsymbol{y}(s) = \mathbf{T}(s)\boldsymbol{r}(s) = \mathbf{G}(s)\mathbf{Q}(s)\boldsymbol{r}(s)$ indicates that $\mathbf{Q}(s) = \mathbf{G}^{-1}(s)$ is a reasonable choice to achieve an ideal servo controller to ensure $\boldsymbol{y}(s) = \boldsymbol{r}(s)$. However, to intend to set $\mathbf{Q}(s) = \mathbf{G}^{-1}(s)$ is not a practical goal for several reasons [10.2]:

- Non-minimum-phase processes would exhibit unstable $\mathbf{Q}(s)$ controllers and closed-loop systems
- Problems concerning the realization of $\mathbf{G}^{-1}(s)$ are immediately seen regarding processes with positive relative degree or time delay
- The ideal servo property would destroy the disturbance rejection capability of the closed-loop system
- $\mathbf{Q}(s) = \mathbf{G}^{-1}(s)$ would lead to large control effort
- Effects of errors in modeling the real process by $\mathbf{G}(s)$ need further analysis.

Replacing the exact inverse $\mathbf{G}^{-1}(s)$ by an approximated inverse is in harmony with practical demands.

To discuss the concept of handling processes with time delay consider single-input single-output (SISO) systems and assume that

$$G(s) = G_{\mathrm{p}}(s)\,\mathrm{e}^{-sT_{\mathrm{d}}} ,$$

where $G_{\mathrm{p}}(s) = B(s)/A(s)$ is a proper transfer function with no time delay and $T_{\mathrm{d}} > 0$ is the time delay. Recognizing that the time delay characteristics is not invertible

$$y(s) = T_{\mathrm{p}}(s)\,\mathrm{e}^{-sT_{\mathrm{d}}}r(s) = G_{\mathrm{p}}(s)Q(s)\,\mathrm{e}^{-sT_{\mathrm{d}}}r(s)$$

can be assigned as the overall transfer function to be achieved. Updating Fig. 10.9 for $G(s) = B(s)/A(s)\mathrm{e}^{-sT_{\mathrm{d}}}$, Fig. 10.10 illustrates the control scheme. A key point is here, however, that the parameterization by $Q(s)$ should consider only $G_{\mathrm{p}}(s)$ to achieve $G_{\mathrm{p}}(s)Q(s)$ specified by the designer. Note that, in the model shown in Fig. 10.10, uncertainties in $G_{\mathrm{p}}(s)$ and in the time delay should both be taken into account when studying the closed-loop system.

Fig. 10.11 Controller using Smith predictor

The control scheme in Fig. 10.10 has been immediately derived by applying the Youla parameterization concept for processes with time delay. The idea, however, of letting the time delay appear in the overall transfer function and restricting the design procedure to a process with no time delay is more than 50 years old and comes from *Smith* [10.19].

The fundamental concept of the design procedure called the *Smith predictor* is to set up a closed-loop system to control the output signal predicted ahead by the time delay. Then, to meet the causality requirement, the predicted output is delayed to derive the real system output. All these conceptional steps can be summarized in a control scheme; just redraw Fig. 10.10 to Fig. 10.11 with

$$Q(s) = K(s)[I + G_\mathrm{p}(s)K(s)]^{-1}\,.$$

The fact that the output of the internal loop can be considered as the predicted value of the process output explains the name of the controller. Note that the Smith predictor is applicable for unstable processes as well.

In the case of *unstable plants*, stabilization of the closed-loop system needs a more involved discussion. In order to separate the unstable (in a more general sense, the undesired) poles both the plant and the controller transfer function matrices will be factorized to (right or left) coprime transfer functions

$$\mathbf{G}(s) = \mathbf{B}_\mathrm{R}(s)\mathbf{A}_\mathrm{R}^{-1}(s) = \mathbf{A}_\mathrm{L}^{-1}(s)\mathbf{B}_\mathrm{L}(s)\,,$$
$$\mathbf{K}(s) = \mathbf{Y}_\mathrm{R}(s)\mathbf{X}_\mathrm{R}^{-1}(s) = \mathbf{X}_\mathrm{L}^{-1}(s)\mathbf{Y}_\mathrm{L}(s)\,,$$

where $\mathbf{B}_\mathrm{R}(s)$, $\mathbf{A}_\mathrm{R}(s)$, $\mathbf{B}_\mathrm{L}(s)$, $\mathbf{A}_\mathrm{L}(s)$, $\mathbf{Y}_\mathrm{R}(s)$, $\mathbf{X}_\mathrm{R}(s)$, $\mathbf{Y}_\mathrm{L}(s)$, and $\mathbf{X}_\mathrm{L}(s)$ are all stable coprime transfer functions. Stability implies that $\mathbf{B}_\mathrm{R}(s)$ should contain all the right half plane (RHP)-zeros of $\mathbf{G}(s)$, and $\mathbf{A}_\mathrm{R}(s)$ should contain as RHP-zeros all the RHP-poles of $\mathbf{G}(s)$. Similar statements are valid for the left coprime pairs. As far as the internal stability analysis is concerned, assuming that $\mathbf{G}(s)$ is strictly proper and $\mathbf{K}(s)$ is proper, the coprime factorization offers the stability analysis via checking the stability of

$$\begin{pmatrix} \mathbf{A}_\mathrm{R}(s) & -\mathbf{Y}_\mathrm{R}(s) \\ \mathbf{B}_\mathrm{R}(s) & \mathbf{X}_\mathrm{R}(s) \end{pmatrix}^{-1} \quad \text{and} \quad \begin{pmatrix} \mathbf{X}_\mathrm{L}(s) & \mathbf{Y}_\mathrm{L}(s) \\ -\mathbf{B}_\mathrm{L}(s) & \mathbf{A}_\mathrm{L}(s) \end{pmatrix}^{-1}\,,$$

respectively. According to the Bezout identity [10.6, 13, 20] there exist $\mathbf{X}_\mathrm{L}(s)$ and $\mathbf{Y}_\mathrm{L}(s)$ as stable transfer function matrices satisfying

$$\mathbf{X}_\mathrm{L}(s)\mathbf{A}_\mathrm{R}(s) + \mathbf{Y}_\mathrm{L}(s)\mathbf{B}_\mathrm{R}(s) = \mathbf{I}\,.$$

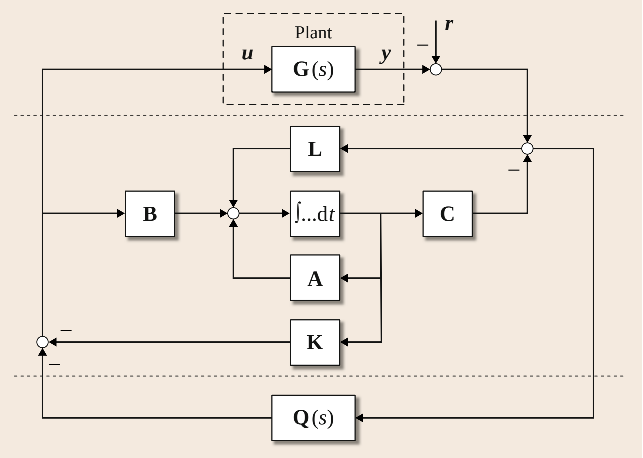

Fig. 10.15 State-space realization of all stabilizing controllers

In a similar way, a left coprime pair of transfer function matrices $\mathbf{X}_\mathrm{R}(s)$ and $\mathbf{Y}_\mathrm{R}(s)$ can be found by

$$\mathbf{B}_\mathrm{L}(s)\mathbf{Y}_\mathrm{R}(s)+\mathbf{A}_\mathrm{L}(s)\mathbf{X}_\mathrm{R}(s)=\mathbf{I}\,.$$

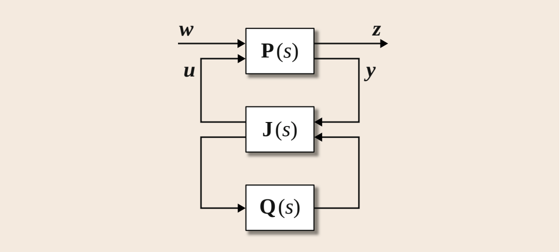

Fig. 10.16 General control system using Youla parameterization

The stabilizing $\mathbf{K}(s)=\mathbf{Y}_\mathrm{R}(s)\mathbf{X}_\mathrm{R}^{-1}(s)=\mathbf{X}_\mathrm{L}^{-1}(s)\mathbf{Y}_\mathrm{L}(s)$ controllers can be parameterized as follows. Assume that the Bezout identity results in a given stabilizing controller $\mathbf{K}=\mathbf{Y}_\mathrm{R}^0(s)\mathbf{X}_\mathrm{R}^{0\;-1}(s)=\mathbf{X}_\mathrm{L}^{0\;-1}(s)\mathbf{Y}_\mathrm{L}^0(s)$, then

$$\begin{aligned}
\mathbf{X}_\mathrm{R}(s)&=\mathbf{X}_\mathrm{R}^0(s)-\mathbf{B}_\mathrm{R}(s)\mathbf{Q}(s)\,,\\
\mathbf{Y}_\mathrm{R}(s)&=\mathbf{Y}_\mathrm{R}^0(s)+\mathbf{A}_\mathrm{R}(s)\mathbf{Q}(s)\,,\\
\mathbf{X}_\mathrm{L}(s)&=\mathbf{X}_\mathrm{L}^0(s)-\mathbf{Q}(s)\mathbf{B}_\mathrm{L}(s)\,,\\
\mathbf{Y}_\mathrm{L}(s)&=\mathbf{Y}_\mathrm{L}^0(s)+\mathbf{Q}(s)\mathbf{A}_\mathrm{L}(s)\,,
\end{aligned}$$

delivers all stabilizing controllers parameterized by any stable proper $\mathbf{Q}(s)$ transfer function matrix with appropriate size.

Though the algebra of the controller design procedure may seem rather involved, in terms of block diagrams it can be interpreted in several ways. In Fig. 10.12 two possible realizations are shown to support the reader in comparing the results obtained for unstable processes with those shown earlier in Fig. 10.9 to control stable processes.

Another obvious interpretation of the general design procedure can also be read out from the realizations of Fig. 10.12. Namely, the immediate loops around $\mathbf{G}(s)$ along $\mathbf{Y}_\mathrm{L}^0(s)$ and $\mathbf{X}_\mathrm{L}^{0\;-1}(s)$ or along $\mathbf{X}_\mathrm{R}^{0\;-1}(s)$ and $\mathbf{Y}_\mathrm{R}^0(s)$, respectively, stabilize the unstable plant, then $\mathbf{Q}(s)$ serves the parameterization in a similar way as originally introduced for stable processes.

Having the general control structure developed using LMFD or RMFD components (Fig. 10.12 gives the complete review), respectively, we are in the position to show how the control of the state-space model introduced earlier in Sect. 10.1 can be parameterized with $\mathbf{Q}(s)$. To visualize this capability recall $\mathbf{K}(s)=\mathbf{X}_\mathrm{L}^{-1}(s)\mathbf{Y}_\mathrm{L}^0(s)$ and

$$\begin{aligned}
\mathbf{B}_\mathrm{L}(s)&=\mathbf{C}(s\mathbf{I}-\mathbf{A}+\mathbf{LC})^{-1}\mathbf{B}\,,\\
\mathbf{A}_\mathrm{L}(s)&=\mathbf{I}-\mathbf{C}(s\mathbf{I}-\mathbf{A}+\mathbf{LC})^{-1}\mathbf{L}\,,
\end{aligned}$$

and apply these relations in the control scheme of Fig. 10.12 using LMFD components.

Similarly, recall $\mathbf{K}(s) = \mathbf{Y}_{\mathrm{R}}^{0}(s)\mathbf{X}_{\mathrm{R}}^{0\,-1}(s)$ and

$$\mathbf{B}_{\mathrm{R}}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A} + \mathbf{B}\mathbf{K})^{-1}\mathbf{B}\,,$$
$$\mathbf{A}_{\mathrm{R}}(s) = \mathbf{I} - \mathbf{K}(s\mathbf{I} - \mathbf{A} + \mathbf{B}\mathbf{K})^{-1}\mathbf{B}\,,$$

and apply these relations in the control scheme of Fig. 10.12 using RMFD components.

To complete the discussion on the various interpretations of the all stabilizing controllers, observe that the control schemes in Figs. 10.13 and 10.14 both use $4\times n$ state variables to realize the controller dynamics beyond $\mathbf{Q}(s)$. As Fig. 10.15 illustrates, equivalent reduction of the block diagrams of Figs. 10.13 and 10.14, respectively, both lead to the realization of the all stabilizing controllers. Observe that the application of the LMFD and RMFD components lead to identical control scheme.

In addition, any of the realizations shown in Figs. 10.12–10.15 can directly be redrawn to form the general control system scheme most frequently used in the literature to summarize the structure of the Youla parameterization. This general control scheme is shown in Fig. 10.16. In fact, the state-space realization by Fig. 10.15 follows the general control scheme shown in Fig. 10.16, assuming $\boldsymbol{z} = \mathbf{0}$ and $\boldsymbol{w} = \boldsymbol{r}$. The transfer function $\mathbf{J}(s)$ itself is realized by the state estimator and state feedback using the gain matrices $\mathbf{L}$ and $\mathbf{K}$, as shown in Fig. 10.15. Note that Fig. 10.16 can also be derived from Fig. 10.6 by interpreting $\mathbf{J}(s)$ as a controller stabilizing $\mathbf{P}(s)$, thus allowing one to apply an additional all stabilizing $\mathbf{Q}(s)$ controller.

10.3 Control Performances

So far we have derived various closed-loop structures and parameterizations attached to them only to ensure internal stability. Stability, however, is not the only issue for the control system designer. To achieve goals in terms of the closed-loop performance needs further considerations [10.2, 6, 13, 17]. Just to see an example: in control design it is a widely posed requirement to ensure zero steady-state error while compensating step-like changes in the command or disturbance signals. The practical solution suggests one to insert an integrator into the loop. The same goal can be achieved while using the Youla parameterization, as well. To illustrate this action SISO systems will be considered. Apply stable $Q_1(s)$ and $Q_2(s)$ transfer functions to form

$$Q(s) = sQ_1(s) + Q_2(s)\,.$$

Then Fig. 10.9 suggests the transfer function between r and $r - y$ to be

$$1 - Q(s)G(s)\,.$$

To ensure

$$1 - [Q(s)G(s)]_{s=0} = 0$$

we need

$$Q_2(s)(0) = [G(0)]^{-1}\,.$$

Alternatively, using state models the selection according to

$$Q(0) = 1/[\mathbf{C}(-\mathbf{A} + \mathbf{B}\mathbf{K} + \mathbf{L}\mathbf{C})^{-1}\mathbf{B}]$$

will insert an integrator to the loop.

Several criteria exist to describe the required performances for the closed-loop performance. To be able to design closed-loop systems with various performance specifications, appropriate norms for the signals and systems involved should be introduced [10.13, 17].

10.3.1 Signal Norms

One possibility to characterize the closed-loop performance is to integrate various functions derived from the error signal. Assume that a generalized error signal $\boldsymbol{z}(t)$ has been constructed. Then

$$\|\boldsymbol{z}(t)\|_v = \left(\int_0^\infty |\mathbf{z}|^v \,\mathrm{d}t\right)^{1/v}$$

defines the L_v norm of $\boldsymbol{z}(t)$ with v as a positive integer.

The relatively easy calculations required for the evaluations made the L_2 norm the most widely used criterion in control. A further advantage of the quadratic function is that energy represented by a given signal can also be taken into account in this way in many cases. Moreover, applying the Parseval’s theorem the L_2

norm can be evaluated using the signal described in the frequency domain. Namely having $\boldsymbol{z}(s)$ as the Laplace transform of $\boldsymbol{z}(t)$

$$\boldsymbol{z}(s) = \int\limits_0^\infty \boldsymbol{z}(t)\,\mathrm{e}^{-st}\,\mathrm{d}t$$

the Parseval's theorem offers the following closed form to calculate the L_2 norm as

$$\begin{aligned}\|\boldsymbol{z}(t)\|_2 &= \|\boldsymbol{z}(s)|_{s=\mathrm{i}\omega}\|_2 = \|\boldsymbol{z}(\mathrm{i}\omega)\|_2\\ &\widehat{=}\left(\frac{1}{2\pi}\int\limits_{-\infty}^{\infty}|\boldsymbol{z}(\mathrm{i}\omega)|^2\,\mathrm{d}\omega\right)^{1/2}.\end{aligned}$$

Another important selection for v takes $v \to \infty$, which results in

$$\|\boldsymbol{z}(t)\|_\infty = \sup_t |\boldsymbol{z}(t)|$$

and is interpreted as the largest or worst-case error.

10.3.2 System Norms

Frequency functions are extremely useful tools to analyze and design SISO closed-loop control systems. MIMO systems, however, exhibit an input-dependent, variable gain at a given frequency. Consider a MIMO system given by a transfer function matrix $\mathbf{G}(s)$ and driven by an input signal $\boldsymbol{w}$ and delivering an output signal $\boldsymbol{z}$. The norm $\|\boldsymbol{z}(\mathrm{i}\omega)\| = \|\mathbf{G}(\mathrm{i}\omega)\boldsymbol{w}(\mathrm{i}\omega)\|$ of the system output $\boldsymbol{z}$ depends on both the magnitude and direction of the input vector $\boldsymbol{w}(\mathrm{i}\omega)$, where $\|\ldots\|$ denotes Euclidean norm. The associated norms are therefore called *induced norms*. Bounds for $\|\boldsymbol{z}(\mathrm{i}\omega)\|$ are given by

$$\underline{\sigma}(\mathbf{G}(\mathrm{i}\omega)) \le \frac{\|\mathbf{G}(\mathrm{i}\omega)\boldsymbol{w}(\mathrm{i}\omega)\|}{\|\boldsymbol{w}(\mathrm{i}\omega)\|} \le \overline{\sigma}(\mathbf{G}(\mathrm{i}\omega))\,,$$

where $\underline{\sigma}(\mathbf{G}(\mathrm{i}\omega))$ and $\overline{\sigma}(\mathbf{G}(\mathrm{i}\omega))$ denote the minimum and maximum values of the singular values of $\mathbf{G}(\mathrm{i}\omega)$, respectively. The most frequently used system norms are the H_2 and H_∞ norms defined as follows

$$\|\mathbf{G}\|_2 = \left(\frac{1}{2\pi}\int\limits_{-\infty}^{\infty}\mathrm{trace}[\mathbf{G}^\top(-\mathrm{i}\omega)\mathbf{G}(\mathrm{i}\omega)]\,\mathrm{d}\omega\right)^{1/2}$$

and

$$\|\mathbf{G}\|_\infty = \sup_\omega \overline{\sigma}(\mathbf{G}(\mathrm{i}\omega))\,.$$

It is clear that the system norms – as induced norms – can be expressed by using signal norms. Introducing $\boldsymbol{g}(t)$ as the unit impulse response of $\mathbf{G}(s)$ the Parseval's theorem suggests expressing the H_2 system norm by the L_2 signal norm

$$\|\mathbf{G}\|_2^2 = \int\limits_0^\infty \mathrm{trace}[\boldsymbol{g}^\top(t)\boldsymbol{g}(t)]\,\mathrm{d}t\,.$$

Further on, the H_∞ norm can also be expressed as

$$\begin{aligned}\|\mathbf{G}\|_\infty = \sup_\omega \max_w \Bigg(&\frac{\|\mathbf{G}(\mathrm{i}\omega)\boldsymbol{w}\|}{\|\boldsymbol{w}\|}\ \text{where } \boldsymbol{w} \ne 0\\ &\text{and } \boldsymbol{w} \in \mathbb{C}^{n_w}\Bigg)\,,\end{aligned}$$

where $\boldsymbol{w}$ denotes a complex-valued vector. For a dynamic system the above expression leads to

$$\|\mathbf{G}\|_\infty = \sup_w\left(\frac{\|\boldsymbol{z}(t)\|_2}{\|\boldsymbol{w}(t)\|_2}\ \text{where } \|\boldsymbol{w}(t)\|_2 \ne 0\right),$$

if $\mathbf{G}(s)$ is stable and proper. The above expression means that the H_∞ norm can be expressed by L_2 signal norm.

Assume a linear system given by a state model $\{\mathbf{A}, \mathbf{B}, \mathbf{C}\}$ and calculate its H_2 and H_∞ norms. Transforming the state model to a transfer function matrix

$$\mathbf{G}(s) = \mathbf{C}(s\mathbf{I} - \mathbf{A})^{-1}\mathbf{B}$$

the H_2 norm is obtained by

$$\|\mathbf{G}\|_2^2 = \mathrm{trace}(\mathbf{C}\mathbf{P}_0\mathbf{C}^\top) = \mathrm{trace}(\mathbf{B}^\top\mathbf{P}_\mathrm{c}\mathbf{B})\,,$$

where $\mathbf{P}_\mathrm{c}$ and $\mathbf{P}_0$ are delivered by the solution of the Lyapunov equations

$$\begin{aligned}&\mathbf{A}\mathbf{P}_0 + \mathbf{P}_0\mathbf{A}^\top + \mathbf{B}\mathbf{B}^\top = \mathbf{0}\,,\\ &\mathbf{P}_\mathrm{c}\mathbf{A} + \mathbf{A}^\top\mathbf{P}_\mathrm{c} + \mathbf{C}^\top\mathbf{C} = \mathbf{0}\,.\end{aligned}$$

The calculation of the H_∞ norm can be performed via an iterative procedure, where in each step an H_2 norm is to be minimized. Assuming a stable system, construct the Hamiltonian matrix

$$\mathbf{H} = \begin{pmatrix}\mathbf{A} & \frac{1}{\gamma^2}\mathbf{B}\mathbf{B}^\top\\ -\mathbf{C}^\top\mathbf{C} & -\mathbf{A}^\top\end{pmatrix}.$$

For large γ the matrix $\mathbf{H}$ has n_x eigenvalues with negative real part and n_x eigenvalues with positive real part. As γ decreases these eigenvalues eventually hit the imaginary axis. Thus

$$\begin{aligned}\|\mathbf{G}\|_\infty = \inf_{\gamma>0}(&\gamma \in \mathbb{R}\colon \mathbf{H}\ \text{has no eigenvalues}\\ &\text{with zero real part})\,.\end{aligned}$$

Note that each step within the γ-iteration procedure is after all equivalent to solve an underlying Riccati equation. The solution of the Riccati equation will be detailed later on in Sect. 10.4.

So far stability issues have been discussed and signal and system norms, as performance measures, have been introduced to evaluate the overall operation of the closed-loop system. In the sequel the focus will be turned on design procedures resulting in both stable operation and expected performance. Controller design techniques to achieve appropriate performance measures via optimization procedures related to the H_2 and H_∞ norms will be discussed, respectively [10.6, 21].

10.4 H_2 Optimal Control

To start the discussion consider the general control system configuration shown in Fig. 10.6 describe the plant by the transfer function

$$\begin{pmatrix} \boldsymbol{z} \\ \boldsymbol{y} \end{pmatrix} = \begin{pmatrix} \mathbf{G}_{11} & \mathbf{G}_{12} \\ \mathbf{G}_{21} & \mathbf{G}_{22} \end{pmatrix} \begin{pmatrix} \boldsymbol{w} \\ \boldsymbol{u} \end{pmatrix}$$

or equivalently, by a state model

$$\begin{pmatrix} \dot{\boldsymbol{x}} \\ \boldsymbol{z} \\ \boldsymbol{y} \end{pmatrix} = \begin{pmatrix} \mathbf{A} & \mathbf{B}_1 & \mathbf{B}_2 \\ \mathbf{C}_1 & \mathbf{0} & \mathbf{D}_{12} \\ \mathbf{C}_2 & \mathbf{D}_{21} & \mathbf{0} \end{pmatrix} \begin{pmatrix} \boldsymbol{x} \\ \boldsymbol{w} \\ \boldsymbol{u} \end{pmatrix} .$$

Assume that $(\mathbf{A}, \mathbf{B}_1)$ is controllable, $(\mathbf{A}, \mathbf{B}_2)$ is stabilizable, $(\mathbf{C}_1, \mathbf{A})$ is observable, and $(\mathbf{C}_2, \mathbf{A})$ is detectable. For the sake of simplicity nonsingular $\mathbf{D}_{12}^\top \mathbf{D}_{12}$ and $\mathbf{D}_{21}\mathbf{D}_{21}^\top$ matrices, as well as $\mathbf{D}_{12}^\top \mathbf{C}_1 = \mathbf{0}$ and $\mathbf{D}_{21}\mathbf{B}_1^\top = \mathbf{0}$ will be considered.

Using a feedback via $\mathbf{K}(s)$

$$\boldsymbol{u} = -\mathbf{K}(s)\boldsymbol{y} ,$$

the closed-loop system becomes

$$\boldsymbol{z} = \mathbf{F}[\mathbf{G}(s), \mathbf{K}(s)]\boldsymbol{w} ,$$

where

$$\mathbf{F}[\mathbf{G}(s), \mathbf{K}(s)] = \mathbf{G}_{11}(s) - \mathbf{G}_{12}(s)[\mathbf{I} + \mathbf{K}(s)\mathbf{G}_{22}(s)]^{-1} \mathbf{K}(s)\mathbf{G}_{21}(s) .$$

Aiming at designing optimal control in H_2 sense the $J_2 = \|\mathbf{F}(\mathbf{G}(\mathrm{i}\omega), \mathbf{K}(\mathrm{i}\omega))\|_2^2$ norm is to be minimized by a realizable $\mathbf{K}(s)$. Note that this control policy can be interpreted as a special case of the linear quadratic (LQ) control problem formulation. To show this relation assume a weighting matrix $\mathbf{Q}_x$ assigned for the state variables and a weighting matrix $\mathbf{R}_u$ assigned for the input variables. Choosing

$$\mathbf{C}_1 = \begin{pmatrix} \mathbf{Q}_x^{1/2} \\ \mathbf{0} \end{pmatrix} \quad \text{and} \quad \mathbf{D}_{12} = \begin{pmatrix} \mathbf{0} \\ \mathbf{R}_u^{1/2} \end{pmatrix}$$

and

$$\boldsymbol{z} = \mathbf{C}_1\boldsymbol{x} + \mathbf{D}_{12}\boldsymbol{u}$$

as an auxiliary variable the well-known LQ loss function can be reproduced with

$$\mathbf{Q}_x = \left(\mathbf{Q}_x^{1/2}\right)^\top \mathbf{Q}_x^{1/2} \quad \text{and} \quad \mathbf{R}_u = \left(\mathbf{R}_u^{1/2}\right)^\top \mathbf{R}_u^{1/2} .$$

Up to this point the feedback loop has been set up and the design problem has been formulated to find $\mathbf{K}(s)$ minimizing $J_2 = \|\mathbf{F}(\mathbf{G}(\mathrm{i}\omega), \mathbf{K}(\mathrm{i}\omega))\|_2^2$. Note that the optimal controller will be derived as a solution of the state-feedback problem. The optimization procedure is discussed below.

10.4.1 State-Feedback Problem

If all the state variables are available then the state variable feedback

$$\boldsymbol{u}(t) = -\mathbf{K}_2\boldsymbol{x}(t)$$

is used with the gain

$$\mathbf{K}_2 = (\mathbf{D}_{12}^\top \mathbf{D}_{12})^{-1}\mathbf{B}_2^\top \mathbf{P}_\mathrm{c} ,$$

where $\mathbf{P}_\mathrm{c}$ represents the positive-definite or positive-semidefinite solution of the

$$\mathbf{A}^\top \mathbf{P}_\mathrm{c} + \mathbf{P}_\mathrm{c}\mathbf{A} - \mathbf{P}_\mathrm{c}\mathbf{B}_2\left(\mathbf{D}_{12}^\top \mathbf{D}_{12}\right)^{-1}\mathbf{B}_2^\top \mathbf{P}_\mathrm{c} + \mathbf{C}_1^\top \mathbf{C}_1 = \mathbf{0}$$

Riccati equation. According to this control law the

$$\mathbf{A} - \mathbf{B}_2\mathbf{K}_2$$

matrix will determine the closed-loop stability.

As far as the solution of the Riccati equation is concerned, an augmented problem setup can turn this task to an equivalent eigenvalue–eigenvector decomposition (EVD). In details, the EVD decomposition of the Hamiltonian matrix

$$\mathbf{H} = \begin{pmatrix} \mathbf{A} & -\mathbf{B}_2\left(\mathbf{D}_{12}^\top \mathbf{D}_{12}\right)^{-1}\mathbf{B}_2^\top \\ -\mathbf{C}_1^\top \mathbf{C}_1 & -\mathbf{A}^\top \end{pmatrix}$$

will separate the eigenvectors belonging to stable and unstable eigenvalues, then the positive-definite $\mathbf{P}_\mathrm{c}$ matrix can be calculated from the eigenvectors belonging to the stable eigenvalues. Denote $\mathbf{\Lambda}$ the diagonal matrix containing the stable eigenvalues and collect the associated eigenvectors to a block matrix

$$\begin{pmatrix}\mathbf{F}\\ \mathbf{G}\end{pmatrix} ,$$

i. e.,

$$\mathbf{H}\begin{pmatrix}\mathbf{F}\\ \mathbf{G}\end{pmatrix} = \begin{pmatrix}\mathbf{F}\\ \mathbf{G}\end{pmatrix}\mathbf{\Lambda} .$$

Then it can be shown that the solution of the Riccati equation is obtained by

$$\mathbf{P}_\mathrm{c} = \mathbf{G}\mathbf{F}^{-1} .$$

At the same time it should be noted that there exist further, numerically advanced procedures to find $\mathbf{P}_\mathrm{c}$.

10.4.2 State-Estimation Problem

The optimal state estimation (state reconstruction) is the dual of the optimal control task [10.1, 4]. The estimated states are derived as the solution of the following differential equation:

$$\dot{\hat{\boldsymbol{x}}}(t) = \mathbf{A}\hat{\boldsymbol{x}}(t) + \mathbf{B}_2\boldsymbol{u}(t) + \mathbf{L}_2[\boldsymbol{y}(t) - \mathbf{C}_2\hat{\boldsymbol{x}}(t)] ,$$

where

$$\mathbf{L}_2 = \mathbf{P}_0\mathbf{C}_2^\top(\mathbf{D}_{21}\mathbf{D}_{21}^\top)^{-1}$$

and the $\mathbf{P}_0$ matrix is the positive-definite or positive-semidefinite solution of the Riccati equation

$$\mathbf{P}_0\mathbf{A}^\top + \mathbf{A}\mathbf{P}_0 - \mathbf{P}_0\mathbf{C}_2^\top(\mathbf{D}_{21}\mathbf{D}_{21}^\top)^{-1}\mathbf{C}_2\mathbf{P}_0 + \mathbf{B}_1\mathbf{B}_1^\top = \mathbf{0} .$$

Note that the

$$\mathbf{A} - \mathbf{P}_0\mathbf{C}_2^\top(\mathbf{D}_{21}\mathbf{D}_{21}^\top)^{-1}\mathbf{C}_2$$

matrix characterizing the closed-loop system is stable, i. e., all its eigenvalues are on the left-hand half plane.

Remark 1: Putting the problem just discussed so far into a stochastic environment the above state estimation is also called a *Kalman filter*.

Remark 2: The gains $\mathbf{L}_2 \in \mathbb{R}^{n_x \times n_y}$ and $\mathbf{K}_2 \in \mathbb{R}^{n_u \times n_x}$ have been introduced and applied in earlier stages in this chapter to create the LMFD and RMFD descriptions, respectively. Here their optimal values have been derived in H_2 sense.

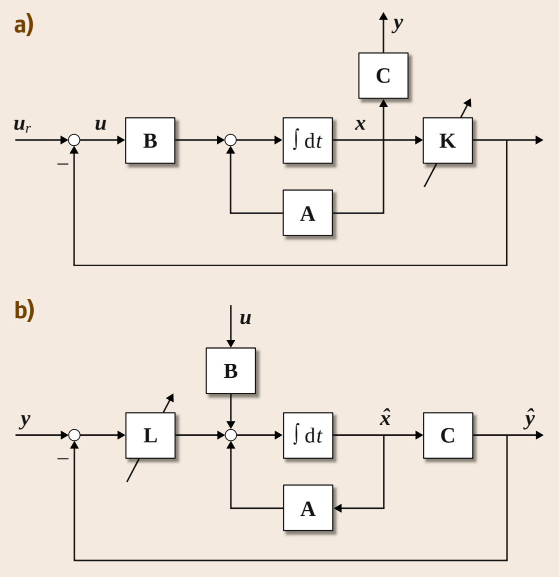

Fig. 10.17 Duality of state control and state estimation

Remark 3: State control and state estimation exhibit dual properties and share some common structural features. Comparing Fig. 10.17a and b it is seen that the structure of the state feedback control and that of the full order observer resemble each other to a large extent. The output signal, as well as the $\mathbf{L}$ and $\mathbf{C}$ matrices in the observer, play identical role as the control signal, as do the $\mathbf{B}$ and $\mathbf{K}$ matrices in state feedback control. Parameters in the matrices $\mathbf{L}$ and $\mathbf{K}$ are to be freely adjusted for the observer and for the state feedback control, respectively. In a sense, calculating the controller and observer feedback gain matrices represent dual problems. In this case duality means that any of the structures shown in Fig. 10.17a,b can be turned to its dual form by reversing the direction of the signal propagation, interchanging the input and output signals ($\boldsymbol{u} \leftrightarrow \boldsymbol{y}$), and transforming the summation points to signal nodes and vice versa.

10.4.3 Output-Feedback Problem

If the state variables are not available for feedback the optimal control law utilizes the reconstructed states. In case of designing optimal control in H_2 sense the control law $\boldsymbol{u}(t) = -\mathbf{K}_2\boldsymbol{x}(t)$ is replaced by $\boldsymbol{u}(t) = -\mathbf{K}_2\hat{\boldsymbol{x}}(t)$.

It is important to prove that the joint state estimation and control lead to stable closed-loop control. The proof is based on observing that the complete system satisfies the following state equations

$$\begin{pmatrix} \dot{\boldsymbol{x}} \\ \dot{\boldsymbol{x}} - \dot{\hat{\boldsymbol{x}}} \end{pmatrix} = \begin{pmatrix} \mathbf{A} - \mathbf{B}_2\mathbf{K}_2 & \mathbf{B}_2\mathbf{K}_2 \\ \mathbf{0} & \mathbf{A} - \mathbf{L}_2\mathbf{C}_2 \end{pmatrix} \begin{pmatrix} \boldsymbol{x} \\ \boldsymbol{x} - \hat{\boldsymbol{x}} \end{pmatrix} + \begin{pmatrix} \mathbf{B}_1 \\ \mathbf{B}_1 - \mathbf{L}_2\mathbf{D}_{21} \end{pmatrix} \boldsymbol{w} \,.$$

This form clearly shows that the poles introduced by the controller and those introduced by the observer are separated from each other. The concept is therefore called the *separation principle*. The importance of this observation lies in the fact that, in the course of the design procedure the controller poles and the observer poles can be assigned independently from each other. Note that the control law $\boldsymbol{u}(t) = -\mathbf{K}_2\hat{\boldsymbol{x}}(t)$ still exhibits an optimal controller in the sense that $\|\mathbf{F}(\mathbf{G}(\mathrm{i}\omega), \mathbf{K}(\mathrm{i}\omega))\|_2$ is minimized.

10.5 H_∞ Optimal Control

Herewith below the optimal control in H_∞ sense will be discussed. The H_∞ optimal control minimizes the H_∞ norm of the overall transfer function of the closed-loop system

$$J_\infty = \|\mathbf{F}(\mathbf{G}(\mathrm{i}\omega), \mathbf{K}(\mathrm{i}\omega))\|_\infty$$

using a state variable feedback with a constant gain, where $\mathbf{F}[\mathbf{G}(s), \mathbf{K}(s)]$ denotes the overall transfer function matrix of the closed-loop system [10.2, 6, 6, 13]. To minimize J_∞ requires rather involved procedures. As one option, γ-iteration has already been discussed earlier. In short, as earlier discussions on the norms pointed out, the H_∞ norm can be calculated using L_2 norms by

$$J_\infty \widehat{=} \sup\left(\frac{\|\boldsymbol{z}\|_2}{\|\boldsymbol{w}\|_2} : \|\boldsymbol{w}\|_2 \neq 0 \right) .$$

10.5.1 State-Feedback Problem

If all the state variables are available then the state variable feedback

$$\boldsymbol{u}(t) = -\mathbf{K}_\infty \boldsymbol{x}(t)$$

is used with the gain $\mathbf{K}_\infty$ minimizing J_∞. Similarly to the H_2 optimal control discussed earlier, in each step of the γ-iteration $\mathbf{K}_\infty$ can be obtained via $\mathbf{P}_\mathrm{c}$ as the symmetrical positive-definite or positive-semidefinite solution of the

$$\mathbf{A}^\top\mathbf{P}_\mathrm{c} + \mathbf{P}_\mathrm{c}\mathbf{A} - \mathbf{P}_\mathrm{c}\mathbf{B}_2\left(\mathbf{D}_{12}^\top\mathbf{D}_{12}\right)^{-1}\mathbf{B}_2^\top\mathbf{P}_\mathrm{c} + \gamma^{-2}\mathbf{P}_\mathrm{c}\mathbf{B}_1\mathbf{B}_1^\top\mathbf{P}_\mathrm{c} + \mathbf{C}_1^\top\mathbf{C}_1 = \mathbf{0}$$

Riccati equation, provided that the matrix

$$\mathbf{A} - \mathbf{B}_2\left(\mathbf{D}_{12}^\top\mathbf{D}_{12}\right)^{-1}\mathbf{B}_2^\top\mathbf{P}_\mathrm{c} + \gamma^{-2}\mathbf{B}_1\mathbf{B}_1^\top\mathbf{P}_\mathrm{c}$$

represents a stable system (i. e., all the eigenvalues are on the left-hand half plane). Once $\mathbf{P}_\mathrm{c}$ belonging to the minimal γ value has been found the state variable feedback is realized by using the feedback gain matrix of

$$\mathbf{K}_\infty = (\mathbf{D}_{12}^\top\mathbf{D}_{12})^{-1}\mathbf{B}_2^\top\mathbf{P}_\mathrm{c} \,.$$

10.5.2 State-Estimation Problem

The optimal state estimation in H_∞ sense requires to minimize

$$J_\infty^0 \widehat{=} \sup\left(\frac{\|\boldsymbol{z} - \hat{\boldsymbol{z}}\|_2}{\|\boldsymbol{w}\|_2} : \|\boldsymbol{w}\|_2 \neq 0 \right)$$

as a function of $\mathbf{L}$. Again, minimization can be performed by γ-iteration. Specifically, γ_min is looked for to satisfy $J_\infty^0 < \gamma$ with $\gamma > 0$ for all $\boldsymbol{w}$. To find the optimal $\mathbf{L}_\infty$ gain the symmetrical positive-definite or positive-semidefinite solution of the following Riccati equation is required

$$\mathbf{P}_0\mathbf{A}^\top + \mathbf{A}\mathbf{P}_0 - \mathbf{P}_0\mathbf{C}_2^\top\left(\mathbf{D}_{12}\mathbf{D}_{12}^\top\right)^{-1}\mathbf{C}_2\mathbf{P}_0 + \gamma^{-2}\mathbf{P}_0\mathbf{C}_1^\top\mathbf{C}_1\mathbf{P}_0 + \mathbf{B}_1\mathbf{B}_1^\top = \mathbf{0}$$

provided that

$$\mathbf{A} - \mathbf{P}_0\mathbf{C}_2^\top\left(\mathbf{D}_{12}\mathbf{D}_{12}^\top\right)^{-1}\mathbf{C}_2 + \gamma^{-2}\mathbf{P}_0\mathbf{C}_1^\top\mathbf{C}_1$$

represents a stable system, i. e., it has all its eigenvalues on the left-hand half plane. Finding the solution $\mathbf{P}_0$ belonging to the minimal γ value, the optimal feedback gain matrix is obtained by

$$\mathbf{L}_\infty = \mathbf{P}_0\mathbf{C}_2^\top\left(\mathbf{D}_{21}\mathbf{D}_{21}^\top\right)^{-1} .$$

Then

$$\dot{\hat{\boldsymbol{x}}}(t) = \mathbf{A}\hat{\boldsymbol{x}}(t) + \mathbf{B}_2\boldsymbol{u}(t) + \mathbf{L}_\infty[\boldsymbol{y}(t) - \mathbf{C}_2\hat{\boldsymbol{x}}(t)]$$

is in complete harmony with the filtering procedure obtained earlier for the state reconstruction in H_2 sense.

10.5.3 Output-Feedback Problem

If the state variables are not available for feedback then a $\mathbf{K}(s)$ controller satisfying $J_\infty < \gamma$ is looked for. This controller, similarly to the procedure followed by the H_2 optimal control design, can be determined in two phases: first the unavailable states are to be estimated, then state feedback driven by the estimated states is to be realized. As far as the state feedback is concerned, similarly to the H_2 optimal control law, the H_∞ optimal control is accomplished by

$$\boldsymbol{u}(t) = -\mathbf{K}_\infty \hat{\boldsymbol{x}}(t) \, .$$

However, the H_∞ optimal state estimation is more involved than the H_2 optimal state estimation. Namely the H_∞ optimal state estimation includes the worst-case estimation of the exogenous $\boldsymbol{w}$ input, and the feedback matrix $\mathbf{L}_\infty$ needs to be modified, too. The $\mathbf{L}^*_\infty$ modified feedback matrix takes the following form

$$\begin{aligned}\mathbf{L}^*_\infty &= \left(\mathbf{I} - \gamma^{-2}\mathbf{P}_0\mathbf{P}_\mathrm{c}\right)^{-1}\mathbf{L}_\infty \\ &= \left(\mathbf{I} - \gamma^{-2}\mathbf{P}_0\mathbf{P}_\mathrm{c}\right)^{-1}\mathbf{P}_0\mathbf{C}_2^\top(\mathbf{D}_{21}\mathbf{D}_{21}^\top)^{-1} \, ,\end{aligned}$$

then the state estimation applies the above gain according to

$$\begin{aligned}\dot{\hat{\boldsymbol{x}}}(t) = {} & (\mathbf{A} + \mathbf{B}_1\gamma^{-2}\mathbf{B}_1^\top\mathbf{P}_\mathrm{c})\hat{\boldsymbol{x}}(t) + \mathbf{B}_2\boldsymbol{u}(t) \\ & + \mathbf{L}^*_\infty[\boldsymbol{y}(t) - \mathbf{C}_2\hat{\boldsymbol{x}}(t)] \, .\end{aligned}$$

Reformulating the above results into a transfer function form gives

$$\begin{aligned}\mathbf{K}(s) = \mathbf{K}_\infty\big(& s\mathbf{I} - \mathbf{A} - \mathbf{B}_1\gamma^{-2}\mathbf{B}_1^\top\mathbf{P}_\mathrm{c} + \mathbf{B}_2\mathbf{K}_\infty \\ & + \mathbf{L}^*_\infty\mathbf{C}_2\big)^{-1}\mathbf{L}^*_\infty \, .\end{aligned}$$

The above $\mathbf{K}(s)$ controller satisfies the norm inequality $\|\mathbf{F}(\mathbf{G}(\mathrm{i}\omega), \mathbf{K}(\mathrm{i}\omega))\|_\infty < \gamma$ and it results in a stable control strategy if the following three conditions are satisfied [10.6]:

- $\mathbf{P}_\mathrm{c}$ is a symmetrical positive-semidefinite solution of the algebraic Riccati equation
$$\begin{aligned}& \mathbf{A}^\top\mathbf{P}_\mathrm{c} + \mathbf{P}_\mathrm{c}\mathbf{A} - \mathbf{P}_\mathrm{c}\mathbf{B}_2\left(\mathbf{D}_{12}^\top\mathbf{D}_{12}\right)^{-1}\mathbf{B}_2^\top\mathbf{P}_\mathrm{c} \\ & + \gamma^{-2}\mathbf{P}_\mathrm{c}\mathbf{B}_1\mathbf{B}_1^\top\mathbf{P}_\mathrm{c} + \mathbf{C}_1^\top\mathbf{C}_1 = \mathbf{0} \, ,\end{aligned}$$
provided that
$$\mathbf{A} - \mathbf{B}_2(\mathbf{D}_{12}^\top\mathbf{D}_{12})^{-1}\mathbf{B}_2^\top\mathbf{P}_\mathrm{c} + \gamma^{-2}\mathbf{B}_1\mathbf{B}_1^\top\mathbf{P}_\mathrm{c}$$
is stable.
- $\mathbf{P}_0$ is a symmetrical positive-semidefinite solution of the algebraic Riccati equation
$$\begin{aligned}& \mathbf{P}_0\mathbf{A}^\top + \mathbf{A}\mathbf{P}_0 - \mathbf{P}_0\mathbf{C}_2^\top\left(\mathbf{D}_{21}\mathbf{D}_{21}^\top\right)^{-1}\mathbf{C}_2\mathbf{P}_0 \\ & + \gamma^{-2}\mathbf{P}_0\mathbf{C}_1^\top\mathbf{C}_1\mathbf{P}_0 + \mathbf{B}_1\mathbf{B}_1^\top = \mathbf{0} \, ,\end{aligned}$$
provided that
$$\mathbf{A} - \mathbf{P}_0\mathbf{C}_2^\top\left(\mathbf{D}_{21}\mathbf{D}_{21}^\top\right)^{-1}\mathbf{C}_2 + \gamma^{-2}\mathbf{P}_0\mathbf{C}_1^\top\mathbf{C}_1$$
is stable.
- The largest eigenvalue of $\mathbf{P}_\mathrm{c}\mathbf{P}_0$ is smaller than γ^2
$$\rho(\mathbf{P}_\mathrm{c}\mathbf{P}_0) < \gamma^2 \, .$$

The H_∞ optimal output feedback control design procedure minimizes the $\|\mathbf{F}(\mathbf{G}(\mathrm{i}\omega), \mathbf{K}(\mathrm{i}\omega))\|_\infty$ norm via γ-iteration and while γ_min is looked for all the three conditions above should be satisfied. The optimal control in H_∞ sense is accomplished by $\mathbf{K}(s)$ belonging to γ_min.

Remark: Now that we are ready to design optimal controllers in H_2 or H_∞ sense, respectively, it is worth devoting a minute to analyze what can be expected from these procedures. To compare the nature of the H_2 versus H_∞ norms a relation for $\|\mathbf{G}\|_2$ should be found, where the $\|\mathbf{G}\|_2$ norm is expressed by the singular values. It can be shown that

$$\|\mathbf{G}\|_2 = \left(\frac{1}{2\pi}\int_{-\infty}^{\infty}\sum_i \sigma_i^2(\mathbf{G}(\mathrm{i}\omega))\,\mathrm{d}\omega\right)^{1/2} \, .$$

Comparing now the above expression with

$$\|\mathbf{G}\|_\infty = \sup_\omega \overline{\sigma}(\mathbf{G}(\mathrm{i}\omega))$$

it is seen that $\|\mathbf{G}\|_\infty$ represents the largest possible singular value, while $\|\mathbf{G}\|_2$ represents the sum of all the singular values over all frequencies [10.6].

10.6 Robust Stability and Performance

When designing control systems, the design procedure needs a model of the process to be controlled. So far it has been assumed that the design procedure is based on a perfect model of the process. Stability analysis based on the nominal process model can be qualified as *nominal stability* (NS) analysis. Similarly, closed-loop performance analysis based on the nominal process model can be qualified as *nominal performance* (NP) analysis. It is evident, however, that some uncertainty is always present in the model. Moreover, an important purpose of using feedback is even to reduce the effects of uncertainty involved in the model. The classical approach introduced the notions of the phase margin and gain margin as measures to handle uncertainty. However, these measures are rather crude and contradictory [10.13, 22]. Though they work fine in a number of practical applications, they are not capable of supporting the design for processes exhibiting unusual frequency behavior (e.g., slightly damped poles). The postmodern era of control theory places special emphasis on modeling of uncertainties. Specifically, wide classes of structured, as well as additively or multiplicatively unstructured uncertainties have been introduced and taken into account in the design procedure. Modeling, analysis, and synthesis methods have been developed under the name *robust control* [10.17, 23, 24]. Note that the linear quadratic regulator (LQR) design method inherits some measures of robustness, however, in general the pure structure of the LQR regulators does not guarantee stability margins [10.1, 6].

As far as the unstructured uncertainties are concerned, let $\mathbf{G}_0(s)$ denote the nominal transfer function matrix of the process. Then the true plant behavior can be expressed by

$$\begin{aligned}\mathbf{G}(s) &= \mathbf{G}_0(s) + \boldsymbol{\Delta}_\mathrm{a}(s)\,,\\ \mathbf{G}(s) &= \mathbf{G}_0(s)[\mathbf{I} + \boldsymbol{\Delta}_\mathrm{i}(s)]\,,\\ \mathbf{G}(s) &= [\mathbf{I} + \boldsymbol{\Delta}_\mathrm{o}(s)]\mathbf{G}_0(s)\,,\end{aligned}$$

where $\boldsymbol{\Delta}_\mathrm{a}(s)$ represents an additive perturbation, $\boldsymbol{\Delta}_\mathrm{i}(s)$ an input multiplicative perturbation, and $\boldsymbol{\Delta}_\mathrm{o}(s)$ an output multiplicative perturbation. These perturbations are assumed to be frequency independent with bounded $\|\boldsymbol{\Delta}_\bullet(s)\|_\infty$ norms concerning their size. Frequency dependence can easily be added to the perturbations by using appropriate pre- and post-filters.

All the above three perturbation models can be transformed to a common form

$$\mathbf{G}(s) = \mathbf{G}_0(s) + \mathbf{W}_1(s)\boldsymbol{\Delta}(s)\mathbf{W}_2(s)\,,$$

where $\|\boldsymbol{\Delta}(s)\|_\infty \leq 1$. Uncertainties extend the general control system configuration outlined earlier in Fig. 10.6. The nominal plant now is extended by a block representing the uncertainties and the feedback is still applied in parallel as Fig. 10.18 shows. This standard model *removes* $\boldsymbol{\Delta}(s)$, as well as the $\mathbf{K}(s)$ controller from the closed-loop system and lets $\mathbf{P}(s)$ represent the rest of the components. It may involve additional output signals ($\boldsymbol{z}$) and a set of external signals ($\boldsymbol{w}$) including the set point.

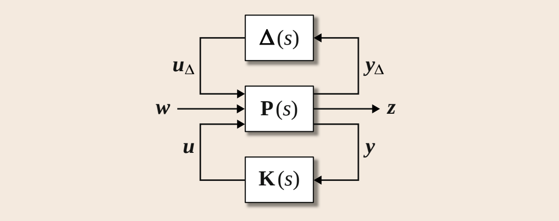

Fig. 10.18 Standard model of control system extended by uncertainties

Using a priori knowledge on the plant the concept of the uncertainty modeling can further be improved. Separating identical and independent technological components into groups the perturbations can be expressed as *structured uncertainties*

$$\begin{aligned}\boldsymbol{\Delta}(s) = \mathrm{diag}\,[\boldsymbol{\Delta}_1(s), \boldsymbol{\Delta}_2(s), \ldots, \boldsymbol{\Delta}_r(s)]\,, \quad \text{where}\\ \|\boldsymbol{\Delta}_i(s)\|_\infty \leq 1 \quad i = 1\ldots r\,.\end{aligned}$$

Structured uncertainties clearly lead to less conservative design as the unstructured uncertainties may want to take care of perturbations never occurring in practice.

Consider the following control system (Fig. 10.19) as one possible realization of the standard model shown in Fig. 10.18. As a matter of fact here the common form of the perturbations is used. Derivation is also straightforward from the standard form of Fig. 10.18 with $\boldsymbol{z} = \mathbf{0}$ and $\boldsymbol{w} = \boldsymbol{r}$. Handling the nominal plant and the feedback as one single unit described by $\mathbf{R}(s) = [\mathbf{I} + \mathbf{K}(s)\mathbf{G}_0(s)]^{-1}\mathbf{K}(s)$, condition for the robust stability can easily be derived by applying the *small gain theorem* (Fig. 10.20). The small gain theorem is the most fundamental result in robust stabilization under unstructured perturbations. According to the small gain theorem any closed-loop system consisting of two stable subsystems $\mathbf{G}_1(s)$ and $\mathbf{G}_2(s)$ results in stable closed-loop system provided that

$$\|\mathbf{G}_1(\mathrm{i}\omega)\|_\infty \|\mathbf{G}_2(\mathrm{i}\omega)\|_\infty < 1\,.$$

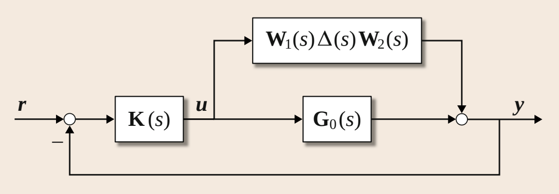

Fig. 10.19 Control system with uncertainties

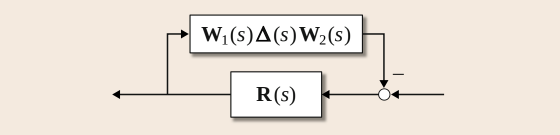

Fig. 10.20 Reduced control system with uncertainties

Applying the small gain theorem to the stability analysis of the system shown in Fig. 10.20, the condition

$$\|\mathbf{W}_2(\mathrm{i}\omega)\mathbf{R}(\mathrm{i}\omega)\mathbf{W}_1(\mathrm{i}\omega)\mathbf{\Delta}(\mathrm{i}\omega)\|_\infty < 1$$

guarantees closed-loop stability. As

$$\begin{aligned}&\|\mathbf{W}_2(\mathrm{i}\omega)\mathbf{R}(\mathrm{i}\omega)\mathbf{W}_1(\mathrm{i}\omega)\mathbf{\Delta}(\mathrm{i}\omega)\|_\infty \leq\\ &\|\mathbf{W}_2(\mathrm{i}\omega)\mathbf{R}(\mathrm{i}\omega)\mathbf{W}_1(\mathrm{i}\omega)\|_\infty\|\mathbf{\Delta}\|_\infty \text{ and}\\ &\|\mathbf{\Delta}(\mathrm{i}\omega)\|_\infty \leq 1\,,\end{aligned}$$

thus the stability condition reduces to

$$\|\mathbf{W}_2(\mathrm{i}\omega)\mathbf{R}(\mathrm{i}\omega)\mathbf{W}_1(\mathrm{i}\omega)\|_\infty < 1\,.$$

To support the closed-loop design procedure for robust stability introduce the γ-norm $\|\mathbf{W}_2(\mathrm{i}\omega)\mathbf{R}(\mathrm{i}\omega)$ $\mathbf{W}_1(\mathrm{i}\omega)$ $\mathbf{\Delta}(\mathrm{i}\omega)\|_\infty = \gamma < 1$. Finding $\mathbf{K}(s)$ such that the γ-norm is kept at its minimum the *maximally stable robust controller* can be constructed.

The performance of a closed-loop system can be rather conservative in case of having structural information on the uncertainties. To avoid this drawback in the design procedure the so-called *structural singular value* is used instead of the H_∞ norm (being equal to the maximum of the singular value). The structured singular value of a matrix $\mathbf{M}$ is defined as

$$\begin{aligned}\mu_\Delta(\mathbf{M}) \widehat{=} \Big[&\min(k|\det(\mathbf{I}-k\mathbf{M}\Delta)=0\\ &\text{for structured } \Delta,\ \overline{\sigma}(\Delta)\leq 1)\Big]^{-1}\,,\end{aligned}$$

where Δ has a block-diagonal form of $\Delta = \mathrm{diag}(\ldots \Delta_i \ldots)$ and $\overline{\sigma}(\Delta) \leq 1$. This definition suggests the following interpretation: a large value of $\mu_\Delta(\mathbf{M})$ indicates that even a small perturbation can make the $\mathbf{I}-\mathbf{M}\Delta$ matrix singular. On the other hand a small value of $\mu_\Delta(\mathbf{M})$ represents favorable conditions in this sense. The structured singular value can be considered as the generalization of the maximal singular value [10.6, 13].

Using the notion of the structured singular value the condition for *robust stability* (RS) can be formulated as follows. Robust stability of the closed-loop system is guaranteed if the maximum of the structured singular value of $\mathbf{W}_2(\mathrm{i}\omega)\mathbf{R}(\mathrm{i}\omega)\mathbf{W}_1(\mathrm{i}\omega)$ lies within the unity uncertainty radius

$$\sup_\omega \mu_\Delta(\mathbf{W}_2(\mathrm{i}\omega)\mathbf{R}(\mathrm{i}\omega)\mathbf{W}_1(\mathrm{i}\omega)) < 1\,.$$

Designing robust control systems is a far more involved task than testing robust stability. The design procedure minimizing the supremum of the structured singular value is called *structured singular value synthesis* or *μ-synthesis*. At this moment there is no direct method to synthesize a μ-optimal controller. Related algorithms to perform the minimization are discussed in the literature under the term DK-iteration [10.6]. In [10.6] not only a detailed discussion is presented, but also a MATLAB program is shown to provide better understanding of the iterations to improve the robust performance conditions.

So far the robust stability issue has been discussed in this section. It has been shown that the closed-loop system remains stable, i. e., it is robustly stable, if stability is guaranteed for all possible uncertainties. In a similar way, the notion of robust performance (RP) is to be worked out. The closed-loop system exhibits robust performance if the performance measures are kept within a prescribed limit even for all possible uncertainties, including the worst case, as well. Design considerations for the robust performance have been illustrated in Fig. 10.18.

As the system performance is represented by the signal $\boldsymbol{z}$, robust performance analysis is based on investigating the relation between the external input signal $\boldsymbol{w}$ and the performance output $\boldsymbol{z}$

$$\boldsymbol{z} = \mathbf{F}[\mathbf{G}(s), \mathbf{K}(s), \Delta(s)]\boldsymbol{w}\,.$$

Defining a performance measure on the transfer function matrix $\mathbf{F}[\mathbf{G}(s), \mathbf{K}(s), \Delta(s)]$ by

$$J[\mathbf{F}(\mathbf{G}, \mathbf{K}, \Delta)]$$

the performance of the transfer function from the exogenous inputs $\boldsymbol{w}$ and to outputs $\boldsymbol{z}$ can be calculated. The maximum of the performance – even in the worst case possibly delivered by the uncertainties – can be evaluated by

$$\sup_\Delta\{J[\mathbf{F}(\mathbf{G}, \mathbf{K}, \Delta)]:\ \|\Delta\|_\infty < 1\}\,.$$

Based on this value the robust performance of the system can be judged. If the robust performance analysis is to be performed in H_∞ sense, the measure to be applied is

$$J_\infty = \|\mathbf{F}[\mathbf{G}(\mathrm{i}\omega), \mathbf{K}(\mathrm{i}\omega), \Delta(\mathrm{i}\omega)]\|_\infty\,.$$

In this case the prespecified performance can be normalized and the limit can be selected as 1. So equivalently, the robust performance requirement can be formulated

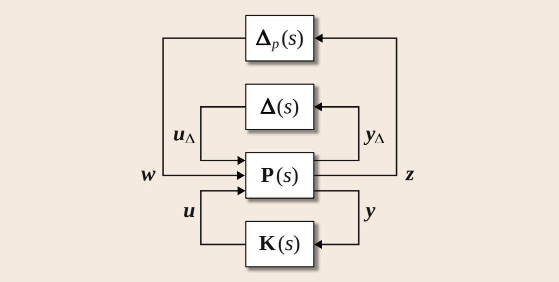

Fig. 10.21 Design for robust performance traced back to robust stability

as

$$\|\mathbf{F}[\mathbf{G}(\mathrm{i}\omega),\mathbf{K}(\mathrm{i}\omega),\Delta(\mathrm{i}\omega)]\|_\infty < 1\,,\quad \forall\|\Delta(\mathrm{i}\omega)\|_\infty \le 1\,.$$

Robust performance analysis can formally be traced back to robust stability analysis. In this case a fictitious Δ_p uncertainty block representing the nominal performance requirements should be inserted across $\boldsymbol{w}$ and $\boldsymbol{z}$ (Fig. 10.21). Then introducing the

$$\begin{pmatrix}\Delta_\mathrm{p} & \mathbf{0}\\ \mathbf{0} & \Delta\end{pmatrix}$$

matrix of the uncertainties gives a pleasant way to trace back the robust performance problem to the robust stability problem.

If robust performance synthesis is used the performance measure must be minimized. In this case μ-optimal design problem can be solved as an extended robust stability design problem.

10.7 General Optimal Control Theory

In the previous sections design techniques have been presented to control linear or linearized plants. Minimization of L_2, H_2 or H_∞ loss functions all resulted in linear control strategies. In practice, however, both the processes and the control actions are mostly nonlinear, e.g., control inputs are typically constrained or saturated in various technologies, and time-optimal control needs to alter the control input instantaneously.

To cover a wider class of control problems the control tasks minimizing loss functions can be formulated in a more general framework [10.25–31]. Restricted to deterministic problems consider the following process to be controlled

$$\dot{\boldsymbol{x}}(t) = \boldsymbol{f}(\boldsymbol{x}(t),\boldsymbol{u}(t),t)\,,\quad 0\le t\le T\,,\qquad \boldsymbol{x}(0):\ \text{given}\,,$$

where $\boldsymbol{x}(t)$ denotes the state variables available for state feedback, and $\boldsymbol{u}(t)$ is the control input. The control performance is expressed via the loss function constructed by penalizing terms V_T and V

$$J = V_T(\boldsymbol{x}(T),T) + \int_0^T V[\boldsymbol{x}(t),\boldsymbol{u}(t),t]\,\mathrm{d}t\,.$$

Designing an optimal controller is equivalent to minimize the above loss function.

Denote by $J^*(\boldsymbol{x}(t),t)$ the optimal value of the loss function while the system is governed from an initial state $\boldsymbol{x}(0)$ to a final state $\boldsymbol{x}(T)$. The principle of *dynamic programming* [10.32] determines the optimal control law by

$$\min_{u\in U}\left\{V[\mathbf{x}(t),\boldsymbol{u}(t),t] + \frac{\partial J^*[\mathbf{x}(t),t]}{\partial \mathbf{x}^\top} f[\mathbf{x}(t),\boldsymbol{u}(t),t]\right\} = -\frac{\partial J^*[\mathbf{x}(t),t]}{\partial t}\,,$$

where the optimal loss function satisfies

$$J^*[\mathbf{x}(T),T] = V_T[\mathbf{x}(T),T]\,.$$

The equation of the optimal control law is called the Hamilton–Jacobi–Bellman (HJB) equation in the control literature.

Note that the L_2 and H_2 optimal control policies discussed earlier can be regarded as the special case of the dynamic programming, where the process is linear and the loss function is quadratic, and moreover the control horizon is infinitely large and the control input is not restricted. Thus the linear system

$$\dot{\mathbf{x}}(t) = \mathbf{A}\boldsymbol{x}(t) + \mathbf{B}\boldsymbol{u}(t)$$

with the loss function

$$J = \frac{1}{2}\int_0^\infty \left(\mathbf{x}^\top \mathbf{Q}_x \boldsymbol{x} + \boldsymbol{u}^\top \mathbf{R}_u \boldsymbol{u}\right)\mathrm{d}t$$

requires the optimal control via state-variable feedback

$$\boldsymbol{u}(t) = -\mathbf{R}_u^{-1}\mathbf{B}^\top \mathbf{P}\boldsymbol{x}(t)\,,$$

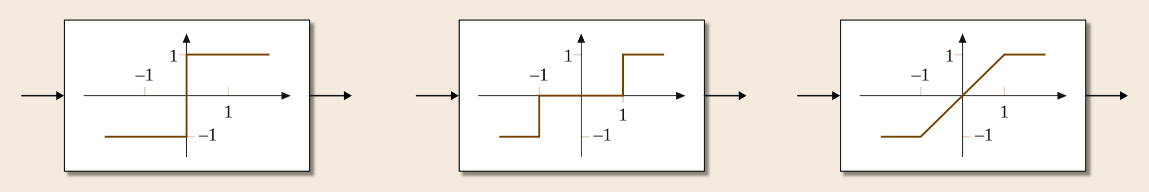

Fig. 10.22 Relay, relay with dead zone, and saturation function to be applied for each vector entry

where $\mathbf{Q}_x \geq \mathbf{0}$ and $\mathbf{R}_u > \mathbf{0}$, and finally the $\mathbf{P}$ matrix is derived as the solution of the following algebraic Riccati equation

$$\mathbf{A}^\top \mathbf{P} + \mathbf{P}\mathbf{A} - \mathbf{P}\mathbf{B}\mathbf{R}_u^{-1}\mathbf{B}^\top \mathbf{P} + \mathbf{Q}_x = \mathbf{0} .$$

At this point it is important to restate the importance of stabilizability and detectability conditions. Without satisfying these conditions, an optimizing controller merely optimizes the cost function and may not stabilize the closed-loop system. In particular, for the LQR problem just discussed, it is important to state that $\{\mathbf{A}, \mathbf{B}\}$ is stabilizable and $\{\mathbf{A}, \mathbf{Q}_x^{1/2}\}$ is detectable.

The HJB equation can be reformulated. To do so, introduce the auxiliary variable $\boldsymbol{\lambda}(t)$ along the optimal trajectory by

$$\boldsymbol{\lambda}(t) \widehat{=} \frac{\partial J[\mathbf{x}(t), t]}{\partial \boldsymbol{x}} .$$

Apply $\boldsymbol{\lambda}(t)$ to define the following Hamiltonian function

$$H(\boldsymbol{x}, \boldsymbol{u}, t) \widehat{=} V(\boldsymbol{x}, \boldsymbol{u}, t) + \boldsymbol{\lambda}^\top f(\boldsymbol{x}, \boldsymbol{u}, t) .$$

Then according to the Pontryagin *minimum principle*

$$\frac{\partial H}{\partial \boldsymbol{\lambda}} = \dot{\boldsymbol{x}}(t) ,$$
$$\frac{\partial H}{\partial \boldsymbol{x}} = -\dot{\boldsymbol{\lambda}}(t) ,$$

as well as

$$\boldsymbol{u}^*(t) = \arg \min_{u \in U} H$$

hold. (Note that if the control input is not restricted then the last equation can be written as $\partial H / \partial \boldsymbol{u} = 0$.)

Applying the minimum principle for time-invariant linear dynamic systems with constrained input ($|u_i| \leq 1$, $i = 1 \ldots n_u$), various loss functions will lead to special optimal control laws. Having the Hamiltonian function in a general form of

$$H(\boldsymbol{x}, \boldsymbol{u}) = V(\boldsymbol{x}, \boldsymbol{u}) + \boldsymbol{\lambda}^\top (\mathbf{A}\boldsymbol{x} + \mathbf{B}\boldsymbol{u}) ,$$

various optimal control strategies can be formulated by assigning suitable $V(\boldsymbol{x}(t), t)$ loss functions:

- If the goal is to achieve minimal transfer time, then assign $V(\boldsymbol{x}, \boldsymbol{u}) = 1$.
- If the goal is to minimize fuel consumption, then assign $V(\boldsymbol{x}, \boldsymbol{u}) = \boldsymbol{u}^\top \operatorname{sign}(\boldsymbol{u})$.
- If the goal is to minimize energy consumption, then assign $V(\boldsymbol{x}, \boldsymbol{u}) = \frac{1}{2}\boldsymbol{u}^\top \boldsymbol{u}$.

Then the application of the minimum principle provides closed forms for the optimal control, namely:

- Minimal transfer time requires $\boldsymbol{u}^0(t) = -\operatorname{sign}(\mathbf{B}^\top \boldsymbol{\lambda})$ (relay control)
- Minimal fuel consumption requires $\boldsymbol{u}^0(t) = -\operatorname{sgzm}(\mathbf{B}^\top \boldsymbol{\lambda})$ (relay with dead zone)
- Minimal energy consumption requires $\boldsymbol{u}^0(t) = -\operatorname{sat}(\mathbf{B}^\top \boldsymbol{\lambda})$ (saturation).

These examples clarify that even for linear systems the optimal control policies can be (and typically are) nonlinear. The nonlinear relations participating in the above control laws are shown in Fig. 10.22.

Dynamic programming is a general concept allowing the exact mathematical handling of various control strategies. Apart from the simplest cases, however, the optimal control law needs demanding computer-aided calculations. In the next section a special class of optimal controllers will be considered. These controllers are called predictive controllers and they require restricted calculation complexity, however, result in good performance.

10.8 Model-Based Predictive Control

As we have seen so far most control system design methods assume a mathematical model of the process to be controlled. Given a process model and knowledge on the external system inputs the process output can be predicted to some extent. To characterize the behavior of the closed-loop system a combined loss function can be constructed from the values of the predicted process outputs and that of the associated control inputs. Control strategies minimizing this loss function are called *model-based predictive control* (MPC). Related algorithms using special loss functions can be interpreted as an LQ (linear quadratic) problem with finite horizon. The performance of well-tuned predictive control algorithms is outstanding for processes with dead time. Specific model-based predictive control algorithms are also known as dynamic matrix control (DMC), generalized predictive control (GPC), and receding horizon control (RHC) [10.33–41]. Due to the nature of the model-based control algorithms the discrete-time (sampled-data) version of the control algorithms will be discussed in the sequel. Also, most of the detailed discussion is reduced for SISO systems in this section.

The fundamental idea of predictive control can be demonstrated through the DMC algorithm [10.40], where the process output sample $y(k+1)$ is predicted by using all the available process input samples up to the discrete time instant k $(k = 0, 1, 2 \ldots)$ via a linear function *func*

$$\begin{aligned}\hat{y}(k+1) = func[&u(k), u(k-1), u(k-2),\\ &u(k-3), \ldots] .\end{aligned}$$

Repeating the above one-step-ahead prediction for further time instants as

$$\begin{aligned}\hat{y}(k+2) = func[&u(k+1), u(k), u(k-1),\\ &u(k-2), \ldots] ,\\ \hat{y}(k+3) = func[&u(k+2), u(k+1), u(k),\\ &u(k-1), \ldots] ,\\ &\vdots\end{aligned}$$

requires the knowledge of future control actions $u(k+1), u(k+2), u(k+3), \ldots$, as well. Introduce the *free response* involving the future values of the process input obtained provided no change occurs in the control input at time k

$$\begin{aligned}y^*(k+1) = func[&u(k) = u(k-1), u(k-1),\\ &u(k-2), u(k-3), \ldots] ,\\ y^*(k+2) = func[&u(k+1) = u(k-1), u(k) =\\ &u(k-1), u(k-1), u(k-2), \ldots] ,\\ y^*(k+3) = func[&u(k+2) = u(k-1), u(k+1) =\\ &u(k-1), u(k) = u(k-1), u(k-1), \ldots] ,\\ &\vdots\end{aligned}$$

Using the free response just introduced above the predicted process outputs can be expressed by

$$\begin{aligned}\hat{y}(k+1) &= s_1\Delta u(k) + y^*(k+1)\\ \hat{y}(k+2) &= s_1\Delta u(k+1) + s_2\Delta u(k) + y^*(k+2)\\ \hat{y}(k+3) &= s_1\Delta u(k+2) + s_2\Delta u(k+1) + s_3\Delta u(k)\\ &\quad + y^*(k+3) ,\\ &\vdots\end{aligned}$$

where

$$\Delta u(k+i) = u(k+i) - u(k+i-1) ,$$

and s_i denotes the i-th sample of the discrete-time-step response of the process. Now a more compact form of

$$\textit{Predicted value} = \textit{Forced response} + \textit{Free response}$$

is looked for in vector/matrix form

$$\begin{pmatrix}\hat{y}(k+1)\\ \hat{y}(k+2)\\ \hat{y}(k+3)\\ \vdots\end{pmatrix} = \begin{pmatrix}s_1 & 0 & 0 & \ldots\\ s_2 & s_1 & 0 & \ldots\\ s_3 & s_2 & s_1 & \ldots\\ \vdots & \vdots & \vdots & \ddots\end{pmatrix}\begin{pmatrix}\Delta u(k)\\ \Delta u(k+1)\\ \Delta u(k+2)\\ \vdots\end{pmatrix} + \begin{pmatrix}y^*(k+1)\\ y^*(k+2)\\ y^*(k+3)\\ \vdots\end{pmatrix} .$$

Apply here the following notations

$$\mathbf{S} = \begin{pmatrix} s_1 & 0 & 0 & \dots \\ s_2 & s_1 & 0 & \dots \\ s_3 & s_2 & s_1 & \dots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix} ,$$

$$\hat{\boldsymbol{Y}} = [\hat{y}(k+1), \hat{y}(k+2), \hat{y}(k+3), \dots]^\top ,$$

$$\Delta \boldsymbol{U} = [\Delta u(k), \Delta u(k+1), \Delta u(k+2), \dots]^\top ,$$

$$\boldsymbol{Y}^* = [y^*(k+1), y^*(k+2), y^*(k+3), \dots]^\top .$$

Utilizing these notations

$$\hat{\boldsymbol{Y}} = \mathbf{S}\Delta \boldsymbol{U} + \boldsymbol{Y}^*$$

holds. Assuming that the reference signal (set point) $y_{\text{ref}}(k)$ is available for the future time instants, define the loss function to be minimized by

$$\sum_{i=1}^{N_y} \left[y_{\text{ref}}(k+i) - \hat{y}(k+i)\right]^2 .$$

If no restriction for the control signal is taken into account the minimization leads to

$$\Delta \boldsymbol{U}_{\text{opt}} = \mathbf{S}^{-1}\left(\boldsymbol{Y}_{\text{ref}} - \boldsymbol{Y}^*\right) ,$$

where $\boldsymbol{Y}_{\text{ref}}$ has been constructed from the samples of the future set points.

The receding horizon control concept utilizes only the very first element of the $\Delta \boldsymbol{U}_{\text{opt}}$ vector according to

$$\Delta u(k) = \mathbf{1}\Delta \boldsymbol{U}_{\text{opt}} ,$$

where $\mathbf{1} = (1, 0, 0, \dots)$. Observe that RHC needs to recalculate $\boldsymbol{Y}^*$ and to update $\Delta \boldsymbol{U}_{\text{opt}}$ in each step. The application of the RHC algorithm results in zero steady-state error; however, it requires considerable control effort while minimizing the related loss function.

Smoothing in the control input can be achieved:

- By extending the loss function with another component penalizing the control signal or its change
- By reducing the control horizon as follows

$$\Delta \boldsymbol{U} = [\Delta u(k), \Delta u(k+1), \Delta u(k+2), \dots,$$
$$\Delta u(k+N_u-1), 0, 0, \dots, 0]^\top .$$

Accordingly, define the loss function by

$$\sum_{i=1}^{N_y} \left[y_{\text{ref}}(k+i) - \hat{y}(k+i)\right]^2$$
$$+ \lambda \sum_{i=1}^{N_u} [u(k+i) - u(k+i-1)]^2 ,$$

then the control signal becomes

$$\Delta u(k) = \mathbf{1}(\mathbf{S}^\top \mathbf{S} + \lambda \boldsymbol{I})^{-1}\mathbf{S}^\top \left(\boldsymbol{Y}_{\text{ref}} - \boldsymbol{Y}^*\right) ,$$

where

$$\mathbf{S} = \begin{pmatrix} s_1 & 0 & \dots & 0 & 0 \\ s_2 & s_1 & \dots & 0 & 0 \\ s_3 & s_2 & \dots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ s_{N_y-1} & s_{N_y-2} & \dots & s_{N_y-N_u+1} & s_{N_y-N_u} \\ s_{N_y} & s_{N_y-1} & \dots & s_{N_y-N_u+2} & s_{N_y-N_u+1} \end{pmatrix} .$$

All the above relations can easily be modified to cover the control of processes with known time delay. Simply replace $y(k+1)$ by $y(k+d+1)$ to consider $y(k+d+1)$ as the earliest sample of the process output effected by the control action taken at time k, where $d > 0$ represents the discrete time delay.

As the idea of the model-based predictive control is quite flexible, a number of variants of the above discussed algorithms exist. The tuning parameters of the algorithm are the prediction horizon N_y, the control horizon N_u, and the λ penalizing factor. Predictions related to disturbances can also be included. Just as an example, a loss function

$$\left(\hat{\boldsymbol{Y}} - \boldsymbol{Y}_{\text{ref}}\right)^\top \mathbf{W}_y \left(\hat{\boldsymbol{Y}} - \boldsymbol{Y}_{\text{ref}}\right) + \boldsymbol{U}_{\text{c}}^\top \mathbf{W}_u \boldsymbol{U}_{\text{c}}$$

can be assigned to incorporate weighting matrices $\mathbf{W}_u$ and $\mathbf{W}_y$, respectively, and a reduced version of the control signals can be applied according to

$$\boldsymbol{U} = \mathbf{T}_{\text{c}} \boldsymbol{U}_{\text{c}} ,$$

where $\mathbf{T}_{\text{c}}$ is an a priori defined matrix typically containing zeros and ones. Then minimization of the loss function results in

$$\Delta u(k) = \mathbf{1}\mathbf{T}_{\text{c}}\left(\mathbf{T}_{\text{c}}^\top \mathbf{S}^\top \mathbf{W}_y \mathbf{S}\mathbf{T}_{\text{c}} + \mathbf{W}_u\right)^{-1} \mathbf{T}_{\text{c}}^\top \mathbf{S}^\top \mathbf{W}_y$$
$$(\boldsymbol{Y}_{\text{ref}} - \boldsymbol{Y}^*) .$$

Constraints existing for the control input open a new class for the control algorithms. In this case a quadratic programming problem (conditional minimization of a quadratic loss function to satisfy control constraints represented by inequalities) should be solved in each step. In detail, the loss function

$$\left(\hat{\boldsymbol{Y}} - \boldsymbol{Y}_{\text{ref}}\right)^\top \mathbf{W}_y \left(\hat{\boldsymbol{Y}} - \boldsymbol{Y}_{\text{ref}}\right) + \boldsymbol{U}_{\text{c}}^\top \mathbf{W}_u \boldsymbol{U}_{\text{c}}$$

is to be minimized again by $\boldsymbol{U}_{\text{c}}$, where

$$\hat{\boldsymbol{Y}} = \mathbf{S}\mathbf{T}_{\text{c}} \boldsymbol{U}_{\text{c}} + \boldsymbol{Y}^*$$

under the constraint

$$\Delta u_{\min} \le \Delta u(j) \le \Delta u_{\max} \quad \text{or}$$
$$u_{\min} \le u(j) \le u_{\max} \,.$$

The classical DMC approach is based on the samples of the step response of the process. Obviously, the process model can also be represented by a unit impulse response, a state-space model or a transfer function. Consequently, beyond the control input, the process output prediction can utilize the process output, the state variables or the estimated state variables, as well. Note that the original DMC is an open-loop design method in nature, which should be extended by a closed-loop aspect or be combined with an IMC-compatible concept to utilize the advantages offered by the feedback concept.

A further remark relates to stochastic process models. As an example, the generalized predictive control concept [10.38, 39] applies the model

$$A(q^{-1})y(k) = B(q^{-1})u(k-d) + \frac{C(q^{-1})}{\Delta}\zeta_k \,.$$

where $A(q^{-1})$, $B(q^{-1})$, and $C(q^{-1})$ are polynomials of the backward shift operator q^{-1}, and $\Delta = 1 - q^{-1}$. Moreover, ζ_k is a discrete-time white-noise sequence. Then the conditional expected value of the loss function

$$E\left[(\hat{\boldsymbol{Y}} - \boldsymbol{Y}_{\text{ref}})^{\top}\mathbf{W}_y(\hat{\boldsymbol{Y}} - \boldsymbol{Y}_{\text{ref}}) + \boldsymbol{U}_{\text{c}}^{\top}\mathbf{W}_u\boldsymbol{U}_{\text{c}}|k\right]$$

is to be minimized by $\boldsymbol{U}_{\text{c}}$. Note that model-based predictive control algorithms can be extended for MIMO and nonlinear systems.

While LQ design supposing infinite horizon provides stable performance, predictive control with finite horizon using receding horizon strategy lacks stability guarantees. Introduction of terminal penalty in the cost function including the quadratic deviations of the states from their final values is one way to ensure stable performance. Other methods leading to stable performance with detailed stability analysis, as well as proper handling of constraints, are discussed in [10.35, 36, 42], where mainly sufficient conditions have been derived for stability.

For real-time applications fast solutions are required. Effective numerical methods to solve optimization problems with reduced computational demand and suboptimal solutions have been developed [10.33].

MPC with linear constraints and uncertainties can be formulated as a multiparametric programming problem, which is a technique to obtain the solution of an optimization problem as a function of the uncertain parameters (generally the states). For the different ranges of the states the calculation can be executed offline [10.33,43]. Different predictive control approaches for robust constrained predictive control of nonlinear systems are also in the forefront of interest [10.33, 44].

10.9 Control of Nonlinear Systems

In this section results available for linear control systems will be extended for a special class of nonlinear systems. For the sake of simplicity only SISO systems will be considered.

In practice all control systems exhibit nonlinear behavior to some extent [10.45, 46]. To avoid facing problems caused by nonlinear effects linear models around a nominal operating point are considered. In fact, most systems work in a linear region for small changes. However, at various operating points the linearized models are different from each other according to the nonlinear nature. In this section transformation methods will be discussed making the operation of nonlinear dynamic systems linear over the complete range of their operation. Clearly, this treatment, even though the original process to be controlled remains nonlinear, will allow us to apply all the design techniques developed for linear systems. As a common feature the transformation methods developed for a special class of nonlinear systems all apply *state-variable feedback*. In the past decades a special tool, called Lie algebra, was developed by mathematicians to extend notions such as controllability or observability for nonlinear systems [10.45]. The formalism offered by the Lie algebra will not be discussed here; however, considerations behind the application of this methodology will be presented.

10.9.1 Feedback Linearization

Define the state vector $\boldsymbol{x} \in \mathbb{R}^n$ and the mappings $\{\boldsymbol{f}(\boldsymbol{x}), \boldsymbol{g}(\boldsymbol{x}) : \mathbb{R}^n \to \mathbb{R}^n\}$ as functions of the state vector. Then the Lie derivative of $\boldsymbol{g}(\boldsymbol{x})$ is defined by

$$L_f\boldsymbol{g}(\boldsymbol{x}) \widehat{=} \frac{\partial \boldsymbol{g}(\boldsymbol{x})}{\partial \boldsymbol{x}^{\top}}\boldsymbol{f}(\boldsymbol{x})$$

and the Lie product of $\boldsymbol{g}(\boldsymbol{x})$ and $\boldsymbol{f}(\boldsymbol{x})$ is defined by

$$\begin{aligned}\mathrm{ad}_f\boldsymbol{g}(\boldsymbol{x}) &\mathrel{\widehat{=}} \frac{\partial \boldsymbol{g}(\boldsymbol{x})}{\partial \boldsymbol{x}^\top}\boldsymbol{f}(\boldsymbol{x}) - \frac{\partial \boldsymbol{f}(\boldsymbol{x})}{\partial \boldsymbol{x}^\top}\boldsymbol{g}(\boldsymbol{x})\\ &= L_f\boldsymbol{g}(\boldsymbol{x}) - \frac{\partial \boldsymbol{g}(\boldsymbol{x})}{\partial \boldsymbol{x}^\top}\boldsymbol{f}(\boldsymbol{x})\,.\end{aligned}$$

Consider now a SISO nonlinear dynamic system given by

$$\begin{aligned}\dot{\boldsymbol{x}} &= \boldsymbol{f}(\boldsymbol{x}) + \boldsymbol{g}(\boldsymbol{x})u\,,\\ y &= h(\boldsymbol{x})\,,\end{aligned}$$

where $\boldsymbol{x} = (x_1, x_2, \dots, x_n)^\top$ is the state vector, u is the input, and y is the output, while $\boldsymbol{f}$, $\boldsymbol{g}$, and h are unknown smooth nonlinear functions with $\{\boldsymbol{f}(\boldsymbol{x}), \boldsymbol{g}(\boldsymbol{x}) \colon \mathbb{R}^n \to \mathbb{R}^n\}$, $\{h(\boldsymbol{x}) \colon \mathbb{R}^n \to \mathbb{R}\}$, and $\boldsymbol{f}(\boldsymbol{0}) = \boldsymbol{0}$. The above SISO system has relative degree r at a point $\boldsymbol{x}_0$ if:

- $L_g L_f^k\, h(\boldsymbol{x}) = 0$ for all $\boldsymbol{x}$ in a neighborhood of $\boldsymbol{x}_0$ and for all $k < r - 1$
- $L_g L_f^{r-1} h(\boldsymbol{x}_0) \neq 0$.

It can be shown that the above system equation can be transformed to a form having identical structure for the first r entries

$$\begin{aligned}\dot{z}_1 &= z_2\,,\\ \dot{z}_2 &= z_3\,,\\ &\vdots\\ \dot{z}_{r-1} &= z_r\,,\\ \dot{z}_r &= a(\boldsymbol{z}) + b(\boldsymbol{z})u\,,\\ \dot{z}_{r+1} &= q_{r+1}(\boldsymbol{z})\,,\\ &\vdots\\ \dot{z}_n &= q_n(\boldsymbol{z})\,,\end{aligned}$$

and

$$y = z_1\,,$$

where the last $n - r$ equations are called the zero dynamics. The above equation will be referred to later on as canonical form, where the new state vector is $\boldsymbol{z} = (z_1, z_2, \dots, z_n)^\top$. Using the Lie derivatives, $a(\boldsymbol{z})$ and $b(\boldsymbol{z})$ can be found by

$$\begin{aligned}a(\boldsymbol{z}) &= L_g L_f^{r-1} h(\boldsymbol{x})\,,\\ b(\boldsymbol{z}) &= L_f^r h(\boldsymbol{x})\,.\end{aligned}$$

The normal form related to the original system equations can be defined by the diffeomorphism T as follows

$$\begin{aligned}z_1 &= T_1(\boldsymbol{x}) = y = h(\boldsymbol{x})\,,\\ z_2 &= T_2(\boldsymbol{x}) = \dot{y} = \frac{\partial h}{\partial \boldsymbol{x}^\top}\dot{\boldsymbol{x}} = L_f h(\boldsymbol{x})\,,\\ &\vdots\\ z_r &= T_r(\boldsymbol{x}) = y^{(r)} = \frac{\partial L_f^{r-2} h(\boldsymbol{x})}{\partial \boldsymbol{x}^\top}\dot{\boldsymbol{x}} = L_f^{r-1} h(\boldsymbol{x})\,.\end{aligned}$$

Assuming that

$$\begin{aligned}L_g h(\boldsymbol{x}) &= 0\,,\\ L_g L_f h(\boldsymbol{x}) &= 0\,,\\ &\vdots\\ L_g L_f^{r-2} h(\boldsymbol{x}) &= 0\,,\end{aligned}$$

all the remaining

$$T_{r+1}(\boldsymbol{x}), \dots, T_n(\boldsymbol{x})$$

elements of the transformation matrix can be determined in a similar way. The geometric conditions for the existence of such a global normal form have been studied in [10.45].

Now, concerning the feedback linearization, the following result serves as a starting point for further analysis: a nonlinear system with the above assumptions can be locally transformed into a controllable linear system by state feedback. The transformation of coordinates can be achieved if and only if

$$\operatorname{rank}\left\{\boldsymbol{g}(\boldsymbol{x}_0),\ \mathrm{ad}_f\boldsymbol{g}(\boldsymbol{x}_0), \dots,\ \mathrm{ad}_f^{n-1}\boldsymbol{g}(\boldsymbol{x}_0)\right\} = n$$

at a given $\boldsymbol{x}_0$ point and

$$\left\{\boldsymbol{g},\ \mathrm{ad}_f\boldsymbol{g}, \dots,\ \mathrm{ad}_f^{n-2}\boldsymbol{g}\right\}$$

is involutive near $\boldsymbol{x}_0$. Introducing

$$v = \dot{z}_r$$

and using the canonical form it is seen that the feedback according to $u = [v - a(\boldsymbol{z})]/b(\boldsymbol{z})$ results in a linear relationship between v and y in such a way that v is simply the r-th derivative of y. In other words the linearizing feedback establishes a relation from v to y equivalent to r cascaded integrators. Note that the outputs of the integrators determine r states, while the remaining $(n - r)$ states correspond to the zero dynamics.

The importance of the feedback linearization lies in the fact that the linearized structure allows us to apply the wide selection in the control design methods available for linear systems. Before going into the details of such applications an engineering interpretation of the design aspects of the feedback linearization will be given. Specifically, the feedback linearization technique developed for nonlinear systems will be applied for linear plants.

10.9.2 Feedback Linearization Versus Linear Controller Design

Assume a single-input single-output *linear system* given by the following state-space representation

$$\dot{\boldsymbol{x}} = \mathbf{A}\boldsymbol{x} + \mathbf{B}u\ ,$$
$$y = \mathbf{C}\boldsymbol{x}\ .$$

The derivatives of the output can sequentially be generated as

$$\begin{aligned}
y &= \mathbf{C}\boldsymbol{x}\ ,\\
\dot{y} &= \mathbf{C}\dot{\boldsymbol{x}} = \mathbf{CA}\boldsymbol{x}\ ,\\
\ddot{y} &= \mathbf{CA}\dot{\boldsymbol{x}} = \mathbf{CA}^2\boldsymbol{x}\ ,\\
&\vdots\\
y^{(r)} &= \mathbf{CA}^{r-1}\dot{\boldsymbol{x}} = \mathbf{CA}^{r}\boldsymbol{x} + \mathbf{CA}^{r-1}\mathbf{B}u\ ,
\end{aligned}$$

where $\mathbf{CA}^i\mathbf{B} = 0$ for $i < r-1$ and $\mathbf{CA}^{r-1}\mathbf{B} \neq 0$ with r being the relative degree. Note that r is invariant to similarity transformations. Observe that this derivation is in close harmony with the canonical form derived earlier. The conditions of the exact state control ($r = n$) are that:

- The system is controllable: $\operatorname{rank}(\mathbf{B}, \mathbf{AB}, \mathbf{A}^2\mathbf{B}, \ldots) = n$
- The relative degree is equal to the system order ($r = n$), which could be interpreted as the involutive condition for the linear case.

A more direct relation between the feedback linearization and the linear control design is seen if the linear system is assumed to be given by an input–output (transfer function) representation

$$\frac{y}{u} = \frac{B_{n-r}(s)}{A_n(s)}\ ,$$

where the transfer function of the process has appropriate $B_{n-r}(s)$ and $A_n(s)$ polynomials of the complex frequency operator s. The subindices refer to the degree of the polynomials. If the system has a relative degree of r, the feedback generates

$$y^{(r)} = v\ ,$$

which is formally equivalent to a series compensator of

$$C(s) = \frac{A_n(s)}{B_{n-r}(s)}\frac{1}{s^r}\ .$$

The above compensator is realizable in the sense that the numerator and the denominator polynomials are of identical order n. To satisfy practical needs when realizing a controller in a stable manner it is required that the zeros of the process must be in the left half plane. This condition is equivalent to the requirement that the zero dynamics remains exponentially stable as the feedback linearization has been performed.

10.9.3 Sliding-Mode Control

Coming back to the nonlinear case, now a solution is looked for to transform nonlinear dynamic systems via state-variable feedback to dynamic systems with relative degree of 1. Achieving this goal the nonlinear dynamic system with n state variables could be handled as one single integrator, which is evidently easy to control [10.47]. The key point of the solution is to create a fictitious system with relative degree of 1. Additionally, it will be explained that the internal dynamics of the closed-loop system can be defined by the designer.

For the sake of simplicity assume that the nonlinear system is given in controllable form by

$$y^{(n)} = f(\boldsymbol{x}) + g(\boldsymbol{x})u\ ,$$

where the state variables are

$$\boldsymbol{x} = (y, \dot{y}, \ddot{y}, \ldots, y^{(n-1)})\ .$$

Create the fictitious output signal as the linear combination of these state variables

$$z = \boldsymbol{h}^{\top}\boldsymbol{x} = h_0 y + h_1\dot{y} + h_2\ddot{y} + \ldots + y^{(n-1)}\ .$$

Now use the method elaborated earlier for the feedback linearization. Consider the derivative of the fictitious output signal and, taking $y^{(n)} = f(\boldsymbol{x}) + g(\boldsymbol{x})u$ into account,

$$\dot{z} = \boldsymbol{h}^{\top}\dot{\boldsymbol{x}} = h_0\dot{y} + h_1\ddot{y} + h_2\dddot{y} + \ldots + f(\boldsymbol{x}) + g(\boldsymbol{x})u$$

is obtained. Observe that $\dot{z}$ appears to be a function of the input u, meaning that the relative degree of the fictitious system is 1. Now expressing u, and just as before, introducing the new input signal v,

$$u = \frac{1}{g(\boldsymbol{x})}\big[v - h_0\dot{y} - h_1\ddot{y} - h_2\dddot{y} - \ldots - h_{n-2}y^{(n-1)} - f(\boldsymbol{x})\big]$$

is obtained. Consequently, the complete system can become realized as one single integrator by $\dot{z} = v$.

The internal dynamics of the closed-loop system is governed by the h_i coefficients. Using Laplace transforms and defining

$$H(s) = h_0 + h_1 s + \ldots + h_{n-2} s^{n-2} + s^{n-1} ,$$

$z(s)$ can be expressed by

$$z(s) = H(s) y(s) .$$

Introduce the z_{ref} reference signal for z

$$\begin{aligned}\tilde{z}(s) = z(s) - z_{\text{ref}}(s) &= H(s)[y(s) - y_{\text{ref}}(s)]\\ &= H(s)\tilde{y}(s) ,\end{aligned}$$

where

$$z_{\text{ref}}(s) = H(s) y_{\text{ref}}(s) .$$

The question is, what happens to $\tilde{y}(t) = L^{-1}[\tilde{y}(s)]$ if $\tilde{z}(t) = L^{-1}[\tilde{z}(s)]$ tends to zero in steady state. Clearly, having all the roots of $H(s)$ on the left half plane, $\tilde{y}(t)$ will tend to zero together with $\tilde{z}(t)$ according to

$$\tilde{y}(s) = \frac{1}{H(s)} \tilde{z}(s) .$$

Both $y(t) \to y_{\text{ref}}(t)$ and $\tilde{z}(t) \to 0$ is highly expected from a well-designed control loop. In addition, the dynamic behavior of the $y(t) \to y_{\text{ref}}(t)$ transient response depends on the location of the roots of $H(s)$. One possible setting for $H(s)$ is $H(s) = (s + \lambda)^{n-1}$.

Note that in practice, taking model uncertainties into account, the relation between v and z becomes $\dot{z} \approx v$. To see how to control an approximated integrator effectively recall the Lyapunov stability theory with the Lyapunov function

$$V(\tilde{z}(t)) = \frac{1}{2} \tilde{z}(t)^2 .$$

Then $\tilde{z}(t) \to 0$ if $\dot{V}(\tilde{z}) = \dot{\tilde{z}}\tilde{z} < 0$; moreover, $\tilde{z}(t) = 0$ can be reached in finite time, if the above Lyapunov function satisfies

$$\dot{V}(\tilde{z}) < -\eta |\tilde{z}(t)| ,$$

where η is some positive constant. By differentiating $V(\tilde{z})$ the above stability condition reduces to

$$\dot{\tilde{z}}(t) \leq -\eta \, \text{sign}[\tilde{z}(t)] .$$

The above control technique is called the *reaching law*. Here η is to be tuned by the control engineer to compensate the knowledge about the uncertainties involved.

According to the above considerations the control loop discussed earlier should be extended with a discontinuous component given by

$$v(t) = -K_s \text{sign}[\tilde{z}(t)] ,$$

where $K_s > \eta$. To reduce the switching gain and to increase the speed of convergence, the discontinuous part of the controller can be extended by a proportional feedback

$$v(t) = -K_s \text{sign}[\tilde{z}(t)] - K_p \tilde{z}(t) .$$

Note that the application of the above control law may lead to chattering in the control signal. To avoid this undesired phenomenon the saturation function is used instead of the signum function in practice.

To conclude the discussion on sliding control it has been shown that this concept consists of two phases. In the first phase the sliding surface is to be reached (reaching mode), while in the second the system is controlled to move along the sliding surface (sliding mode). In fact, these two phases can be designed independently from each other. Reaching the sliding surface can be realized by appropriate switching elements. The way to reach the sliding surface can be modified via the parameters in the discontinuous part of the controller. Forcing the system to move along the sliding surface can be effected by assigning various parameters in the $H(s)$. The algorithm shown here can be regarded as a special version of the *variable-structure controller design*.

10.10 Summary

In this chapter advanced control system design methods have been discussed. Advanced methods reflect the current state of the art of the related applied research activity in the field and a number of advanced methods are available today for demanding control applications. One of the driving forces behind browsing among various advanced techniques has been the applicability of the control algorithms for practical applications. Starting with the stability issues, then covering performance and robustness issues, MIMO techniques, optimal control strategies, and predictive control algorithms have been discussed. The concept of feedback linearization for certain nonlinear systems has also been shown. Sliding control as a representative of the class of variable-structure controllers has been outlined. To check the detailed operation of the presented control techniques in numerical examples the reader is kindly asked to use the various toolboxes [10.48].

11. Control of Uncertain Systems

Jianming Lian, Stanislaw H. Żak

Novel direct adaptive robust state and output feedback controllers are presented for the output tracking control of a class of nonlinear systems with unknown system dynamics and disturbances. Both controllers employ a variable-structure radial basis function (RBF) network that can determine its structure dynamically to approximate unknown system dynamics. Radial basis functions are added or removed online in order to achieve the desired tracking accuracy and prevent to network redundancy. The raised-cosine RBF is employed to enable fast and efficient training and output evaluation of the RBF network. The direct adaptive robust output feedback controller is constructed by utilizing a high-gain observer to estimate the tracking error for the controller implementation. The closed-loop systems driven by the variable neural direct adaptive robust controllers are actually switched systems.

Automation is commonly understood as the replacement of manual operations by computer-based methods. Automation is also defined as the condition of being automatically controlled or operated. Thus control is an essential ingredient of automation. The goal of control is to specify the controlled system inputs that force the system outputs to behave in a prespecified manner. This specification of the appropriate system inputs is realized by a controller being developed by a control engineer. In any controller design problem, the first step is to construct the so-called *truth model* of the dynamics of the process to be controlled, where the process is often referred to as the plant. Because the truth model contains all the relevant characteristics of the plant, it is too complicated to be used for the controller design and is mainly used as a simulation model to test the performance of the developed controller [11.1]. Thus, a simplified model that contains the essential features of the plant has to be derived to be used as design model for the controller design. However, it is often infeasible in real applications to obtain a quality mathematical model because the underlying dynamics of the plant may not be understood well enough. Thus, the derived mathematical model may contain uncertainties, which may come from lack of parameter values, either constant or time varying, or result from imperfect knowledge of system inputs. In addition, the inaccurate modeling can introduce uncertainties to the mathematical model as well. Examples of uncertain systems are robotic manipulators or chemical reactors [11.2]. In robotic manipulators, inertias as seen by the drive motors vary with the end-effector position and the load mass so that the robot's dynamical model varies with the robot's attitude. For chemical reactors, their transfer functions vary according to the mix of reagents and catalysts in the vessel and change as the reaction progresses [11.2]. Hence, effective approaches to the control of uncertain systems with high performance are in demand.

11.1 Background and Overview

One approach to the control of uncertain systems is so-called deterministic robust control. Deterministic robust controllers use fixed nonlinear feedback control to ensure the stability of the closed-loop system over a specified range of a class of parametric variations [11.3]. Deterministic control includes variable-structure control and Lyapunov min–max control. Variable structure control was first introduced by Emel'yanov et al. in the early 1960s. It is a nonlinear switching feedback control, which has discontinuity on one or more manifolds in the state space [11.4]. A particular type of variable-structure control is sliding mode control [11.5,6]. Under sliding mode control, the system states are driven to and are then constrained within a neighborhood of the intersection of all the switching manifolds. The Lyapunov min–max control was proposed in [11.7], where nonlinear controllers are developed based on Lyapunov functions and uncertainty bounds. Deterministic robust controllers can guarantee transient performance and final tracking accuracy by compensating for parametric uncertainties and input disturbances with robustifying components. However, they usually involve high-gain feedback or switching, which, in turn, results in high-frequency chattering in the responses of the controlled systems. On the other hand, high-frequency chattering may also excite the unmodeled high-frequency dynamics. Smoothing techniques to eliminate high-frequency chattering were proposed in [11.8]. The resulting controllers are continuous within a boundary layer in the neighborhood of the switching manifold so that the high-frequency chattering can be prevented. However, this is achieved at the price of degraded control performance.

Another effective approach to the control of uncertain systems is adaptive control [11.9–11]. Adaptive controllers are different from deterministic robust controllers because they have a learning mechanism that adjusts the controller's parameters automatically by adaptation laws in order to reduce the effect of the uncertainties. There are two kinds of adaptive controllers: indirect and direct adaptive controllers. In indirect adaptive control strategies, the plant's parameters are estimated online and the controller's parameters are adjusted based on these estimates, see [11.12, p. 14] and [11.13, p. 14]. In contrast, in direct adaptive control strategies, the controller's parameters are directly adjusted to improve a given performance index without the effort to identify the plant's parameters [11.12, p. 14]. Several adaptive controller design methodologies for uncertain systems have been introduced such as adaptive feedback linearization [11.14, 15], adaptive backstepping [11.11, 16–18], nonlinear damping and swapping [11.19] and switching adaptive control [11.20–22]. Adaptive controllers are capable of achieving asymptotic stabilization or tracking for systems subject to only parametric uncertainties without high-gain feedback. However, the adaptation laws of adaptive controllers may lead to instability even when small disturbances appears [11.23]. When adaptive controllers utilize function approximators to approximate unknown system dynamics, the robustness of the adaptation laws to approximation errors needs to be considered as well. The robustness issues make the applicability of adaptive controllers questionable, because there are always disturbances, internal or external, in real systems. To address this problem, robust adaptive controllers were developed to ensure the stability of adaptive controllers [11.23–26]. However, there is a disadvantage shared by adaptive controllers and robust adaptive controllers: their transient performance cannot be guaranteed and the final tracking accuracy usually depends on the approximation errors and disturbances. Thus, adaptive robust controllers, which effectively combine the design techniques of adaptive control and deterministic robust control, were proposed [11.27–33].

In particular, various adaptive (robust) control strategies for feedback linearizable uncertain systems have been proposed. A feedback linearizable system model can be transformed into equivalent linear models by a change of coordinates and a static-state feedback so that linear control design methods can be applied to achieve the desired performance. This approach has been successfully applied to the control of both single-input single-output (SISO) systems [11.10, 27–29, 32–40] and multi-input multi-output (MIMO) systems [11.41–46]. The above adaptive (robust) control strategies have been developed under the assumption that all system states are available in the controller implementation. However, in practical applications, only the system outputs are usually available. To overcome

the problem of inaccessibility of the system states, output feedback controllers that employ state observers in feedback implementation were developed. In particular, a high-gain observer has been employed in the design of output feedback-based control strategies for nonlinear systems [11.38, 46–51]. The advantage of using a high-gain observer is that the control problem can be formulated in a standard singular perturbation format and then the singular perturbation theory can be applied to analyze the closed-loop system stability. The performance of the output feedback controller utilizing a high-gain observer would asymptotically approach the performance of the state feedback controller [11.49].

To deal with dynamical uncertainties, adaptive (robust) control strategies often involve certain types of function approximators to approximate unknown system dynamics. The use of fuzzy-logic systems for function approximation has been introduced [11.28, 29, 32, 33, 36, 39, 40, 42–44, 46]. However, the fuzzy rules required by the fuzzy-logic systems may not be available. On the other hand, one-layer neural-network-based adaptive (robust) control approaches have been reported [11.26, 27, 34, 38] that use radial basis function (RBF) networks to approximate unknown system dynamics. However, fixed-structure RBF networks require offline determination of the appropriate network structure, which is not suitable for the online operation. In [11.10, 35, 41], multilayer neural-network-based adaptive robust control strategies were proposed to avoid some limitations associated with one-layer neural network such as defining a basis function set or choosing some centers and variations of radial basis type of activation functions [11.35]. Although it is not required to define a basis function set for multilayer neural network, it is still necessary to predetermine the number of hidden neurons. Moreover, compared with multilayer neural networks, RBF networks are characterized by simpler structures, faster computation time, and superior adaptive performance. Variable-structure neural-network-based adaptive (robust) controllers have recently been proposed for SISO feedback linearizable uncertain systems. In [11.52], a constructive wavelet-network-based adaptive state feedback controller was developed. In [11.53–56], variable-structure RBF networks are employed in the adaptive (robust) controller design. Variable-structure RBF networks preserve the advantages of the RBF network and, at the same time, overcome the limitations of fuzzy-logic systems and the fixed-structure RBF network. In [11.53], a growing RBF network was utilized for function approximation, and in [11.54–57] self-organizing RBF networks that can both grow and shrink were used. However, all these variable-structure RBF networks are subject to the problem of infinitely fast switching between different structures because there is no time constraint on two consecutive switchings. To overcome this problem, a dwelling-time requirement is introduced into the structure variation of the RBF network in [11.58].

In this chapter, the problem of output tracking control is considered for a class of SISO feedback linearizable uncertain systems modeled by

$$\begin{cases} \dot{x}_i = x_{i+1}\,, & i = 1, \ldots, n-1 \\ \dot{x}_n = f(\boldsymbol{x}) + g(\boldsymbol{x})u + d & \\ y = x_1\,, & \end{cases} \qquad (11.1)$$

where $\boldsymbol{x} = (x_1, \ldots, x_n)^\top \in \mathbb{R}^n$ is the state vector, $u \in \mathbb{R}$ is the input, $y \in \mathbb{R}$ is the output, d models the disturbance, and $f(\boldsymbol{x})$ and $g(\boldsymbol{x})$ are unknown functions with $g(\boldsymbol{x})$ bounded away from zero. A number of adaptive (robust) tracking control strategies have been reported in the literature. In this chapter, novel direct adaptive robust state and output feedback controllers are presented. Both controllers employ the variable-structure RBF network presented in [11.58], which is an improved version of the network considered in [11.56, 57], for

function approximation. This variable-structure RBF network avoids selecting basis functions offline by determining its structure online dynamically. It can add or remove RBFs according to the tracking performance in order to ensure tracking accuracy and prevent network redundancy simultaneously. Moreover, a dwelling-time requirement is imposed on the structure variation to avoid the problem of infinitely fast switching between different structures as in [11.52, 59]. The raised-cosine RBF presented in [11.60] is employed instead of the commonly used Gaussian RBF because the raised-cosine RBF has compact support, which can significantly reduce computations for the RBF network's training and output evaluation [11.61]. The direct adaptive robust output feedback controller is constructed by incorporating a high-gain observer to estimate the tracking error for the controller implementation. The closed-loop systems driven by the direct adaptive robust controllers are characterized by guaranteed transient performance and final tracking accuracy. The lists of limitations and advantages of different tracking control strategies found in the recent literature are given in Tables 11.1 and 11.2, respectively. In Table 11.3, different types of tracking control strategies are listed. In Table 11.4, these tracking control strategies are compared with each other. The control strategy in this chapter shares the same disadvantages and advantages as that in [11.56, 57].

11.2 Plant Model and Notation

The system dynamics (11.1) can be represented in a canonical controllable form as

$$\begin{cases} \dot{\boldsymbol{x}} = \mathbf{A}\boldsymbol{x} + \boldsymbol{b}\big(f(\boldsymbol{x}) + g(\boldsymbol{x})u + d\big) \,, \\ y = \boldsymbol{c}\boldsymbol{x} \,, \end{cases} \tag{11.2}$$

where

$$\mathbf{A} = \begin{pmatrix} \mathbf{0}_{n-1} & \boldsymbol{I}_{n-1} \\ 0 & \mathbf{0}_{n-1}^{\top} \end{pmatrix} \,, \quad \boldsymbol{b} = \begin{pmatrix} \mathbf{0}_{n-1} \\ 1 \end{pmatrix} \,,$$

$$\boldsymbol{c}^{\top} = \begin{pmatrix} 1 \\ \mathbf{0}_{n-1} \end{pmatrix} \,,$$

and $\mathbf{0}_{n-1}$ denotes the $(n-1)$-dimensional zero vector. For the above system model, it is assumed in this chapter that $f(\boldsymbol{x})$ and $g(\boldsymbol{x})$ are unknown Lipschitz continuous functions. Without loss of generality, $g(\boldsymbol{x})$ is assumed to be strictly positive such that $0 < \underline{g} \leq g(\boldsymbol{x}) \leq \overline{g}$, where $\underline{g}$ and $\overline{g}$ are lower and upper bounds of $g(\boldsymbol{x})$. The disturbance d could be in the form of $d(t)$, $d(\boldsymbol{x})$ or $d(\boldsymbol{x}, t)$. It is assumed that d is Lipschitz-continuous in $\boldsymbol{x}$ and piecewise-continuous in t. It is also assumed that $|d| \leq d_0$, where d_0 is a known constant. The control objective is to develop a tracking control strategy such that the system output y tracks a reference signal y_{d} as accurately as possible. It is assumed that the desired trajectory y_{d} has bounded derivatives up to the n-th order, that is, $y_{\mathrm{d}}^{(n)} \in \boldsymbol{\Omega}_{y_{\mathrm{d}}}$, where $\boldsymbol{\Omega}_{y_{\mathrm{d}}}$ is a compact subset of $\mathbb{R}$. The desired system state vector $\boldsymbol{x}_{\mathrm{d}}$ is then defined as

$$\boldsymbol{x}_{\mathrm{d}} = \left(y_{\mathrm{d}}, \dot{y}_{\mathrm{d}}, \ldots, y_{\mathrm{d}}^{(n-1)}\right)^{\top} \,.$$

We have $\boldsymbol{x}_{\mathrm{d}} \in \boldsymbol{\Omega}_{x_{\mathrm{d}}}$, where $\boldsymbol{\Omega}_{x_{\mathrm{d}}}$ is a compact subset of $\mathbb{R}^n$. Let

$$e = y - y_{\mathrm{d}} \tag{11.3}$$

denote the output tracking error and let

$$\boldsymbol{e} = \boldsymbol{x} - \boldsymbol{x}_{\mathrm{d}} = \left(e, \dot{e}, \ldots, e^{(n-1)}\right)^{\top} \tag{11.4}$$

denote the system tracking error. Then the tracking error dynamics can be described as

$$\dot{\boldsymbol{e}} = \mathbf{A}\boldsymbol{e} + \boldsymbol{b}\left[y^{(n)} - y_{\mathrm{d}}^{(n)}\right] \tag{11.5}$$

$$= \mathbf{A}\boldsymbol{e} + \boldsymbol{b}\left[f(\boldsymbol{x}) + g(\boldsymbol{x})u - y_{\mathrm{d}}^{(n)} + d\right] . \tag{11.6}$$

Consider the following controller,

$$u_{\mathrm{a}} = \frac{1}{\hat{g}(\boldsymbol{x})}\left[-\hat{f}(\boldsymbol{x}) + y_{\mathrm{d}}^{(n)} - \boldsymbol{k}\boldsymbol{e}\right] , \tag{11.7}$$

where $\hat{f}(\boldsymbol{x})$ and $\hat{g}(\boldsymbol{x})$ are approximations of $f(\boldsymbol{x})$ and $g(\boldsymbol{x})$, respectively, and $\boldsymbol{k}$ is selected such that $\mathbf{A}_m = \mathbf{A} - \boldsymbol{b}\boldsymbol{k}$ is Hurwitz. The controller u_{a} in (11.7) consists of a feedforward term $-\hat{f}(\boldsymbol{x}) + y_{\mathrm{d}}^{(n)}$ for model compensation and a linear feedback term $-\boldsymbol{k}\boldsymbol{e}$ for stabilization. Substituting (11.7) into (11.6), the tracking error dynamics become

$$\dot{\boldsymbol{e}} = \mathbf{A}_m\boldsymbol{e} + \boldsymbol{b}\tilde{d} \,, \tag{11.8}$$

where

$$\tilde{d} = \left[f(\boldsymbol{x}) - \hat{f}(\boldsymbol{x})\right] + \left[g(\boldsymbol{x}) - \hat{g}(\boldsymbol{x})\right]u_{\mathrm{a}} + d \,. \tag{11.9}$$

It follows from (11.8) that, if only u_{a} is applied to the plant, the tracking error does not converge to zero if $\tilde{d}$ is present. Therefore, an additional robustifying component is required to ensure the tracking performance in the presence of approximation errors and disturbances.

11.3 Variable-Structure Neural Component

In this section, the variable-structure RBF network employed to approximate $f(\boldsymbol{x})$ and $g(\boldsymbol{x})$ over a compact set $\boldsymbol{\Omega}_x \subset \mathbb{R}^n$ is first introduced. This variable-structure RBF network is an improved version of the self-organizing RBF network considered in [11.56], which in turn was adapted from [11.61]. The RBF adding and removing operations are improved and a dwelling time T_{d} is introduced into the structure variation of the network to prevent fast switching between different structures.

The employed self-organizing RBF network has N different admissible structures, where N is determined by the design parameters discussed later. For each admissible structure illustrated in Fig. 11.1, the self-organizing RBF network consists of n input neurons, M_v hidden neurons, where $v \in \{1, \ldots, N\}$

Part B | 11.3

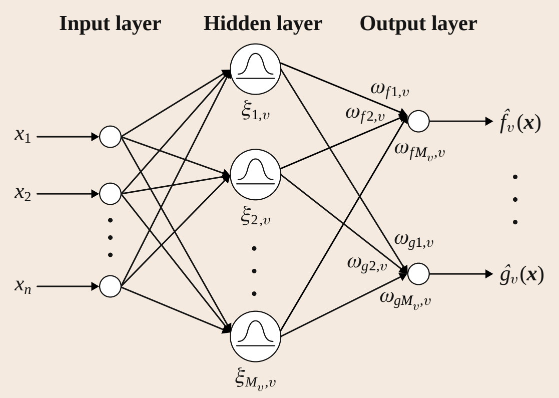

Fig. 11.1 Self-organizing radial basis function network

denotes the scalar index, and two output neurons corresponding to $\hat{f}_v(\boldsymbol{x})$ and $\hat{g}_v(\boldsymbol{x})$. For a given input $\boldsymbol{x} = (x_1, x_2, \ldots, x_n)^\top$, the output $\hat{f}_v(\boldsymbol{x})$ is represented as

$$\hat{f}_v(\boldsymbol{x}) = \sum_{j=1}^{M_v} \omega_{fj,v} \xi_{j,v}(\boldsymbol{x}) \tag{11.10}$$

$$= \sum_{j=1}^{M_v} \omega_{fj,v} \prod_{i=1}^{n} \psi\left(\frac{|x_i - c_{ij,v}|}{\delta_{ij,v}}\right) , \tag{11.11}$$

where $\omega_{fj,v}$ is the adjustable weight from the j-th hidden neuron to the output neuron and $\xi_{j,v}(\boldsymbol{x})$ is the radial basis function for the j-th hidden neuron. The parameter $c_{ij,v}$ is the i-th coordinate of the center of $\xi_{j,v}(\boldsymbol{x})$, $\delta_{ij,v}$ is the radius of $\xi_{j,v}(\boldsymbol{x})$ in the i-th coordinate, and $\psi : [0, \infty) \to \mathbb{R}^+$ is the activation function. In the above, the symbol $\mathbb{R}^+$ denotes the set of nonnegative real numbers. Usually, the activation function ψ is constructed so that it is radially symmetric with respect to its center. The largest value of ψ is obtained when $x_i = c_{ij,v}$, and the value of ψ vanishes or becomes very small for large $|x_i - c_{ij,v}|$. Let

$$\boldsymbol{\omega}_{f,v} = \left(\omega_{f1,v}, \omega_{f2,v}, \ldots, \omega_{fM_v,v}\right)^\top \tag{11.12}$$

be the weight vector and let

$$\boldsymbol{\xi}_v(\boldsymbol{x}) = \left(\xi_{1,v}(\boldsymbol{x}), \xi_{2,v}(\boldsymbol{x}), \ldots, \xi_{M_v,v}(\boldsymbol{x})\right)^\top . \tag{11.13}$$

Then (11.11) can be rewritten as $\hat{f}_v(\boldsymbol{x}) = \boldsymbol{\omega}_{f,v}^\top \boldsymbol{\xi}_v(\boldsymbol{x})$, and the output $\hat{g}_v(\boldsymbol{x})$ can be similarly represented as $\hat{g}_v(\boldsymbol{x}) = \boldsymbol{\omega}_{g,v}^\top \boldsymbol{\xi}_v(\boldsymbol{x})$.

One of the most popular types of radial basis functions is the Gaussian RBF (GRBF) that has the form

$$\xi(x) = \exp\left(-\frac{(x-c)^2}{2\delta^2}\right) . \tag{11.14}$$

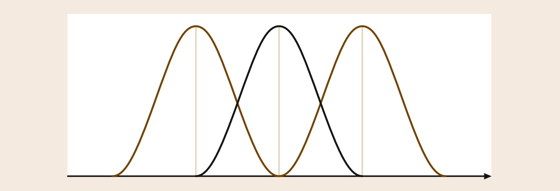

Fig. 11.2 Plot of one-dimensional (1-D) raised-cosine radial basis functions

The support of the GRBF is unbounded. The compact support of the RBF plays an important role in achieving fast and efficient training and output evaluation of the RBF network, especially as the size of the network and the dimensionality of the input space increase. Therefore, the raised-cosine RBF (RCRBF) presented in [11.60] which has compact support is employed herein. The one-dimensional raised-cosine RBF shown in Fig. 11.2 is described as

$$\xi(x) = \begin{cases} \frac{1}{2}\left[1 + \cos\left(\frac{\pi(x-c)}{\delta}\right)\right] & \text{if } |x-c| \leq \delta \\ 0 & \text{if } |x-c| > \delta , \end{cases} \tag{11.15}$$

whose support is the compact set $[c-\delta, c+\delta]$. In the n-dimensional space, the raised-cosine RBF centered at $\boldsymbol{c} = [c_1, c_2, \ldots, c_n]$ with $\boldsymbol{\delta} = [\delta_1, \delta_2, \ldots, \delta_n]$ can be represented as the product of n one-dimensional raised-cosine RBFs

$$\xi(\boldsymbol{x}) = \prod_{i=1}^{n} \xi(x_i) \tag{11.16}$$

$$= \begin{cases} \prod_{i=1}^{n} \frac{1}{2}\left[1 + \cos\left(\frac{\pi(x_i - c_i)}{\delta_i}\right)\right] \\ \qquad \text{if } |x_i - c_i| \leq \delta_i \text{ for all } i , \\ 0 \qquad \text{if } |x_i - c_i| > \delta_i \text{ for some } i . \end{cases} \tag{11.17}$$

A plot of a two-dimensional raised-cosine RBF is shown in Fig. 11.3.

Unlike fixed-structure RBF networks that require offline determination of the network structure, the employed self-organizing RBF network is capable of determining the parameters M_v, $c_{ij,v}$, and $\delta_{ij,v}$ dynamically according to the tracking performance. Detailed descriptions are given in the following subsections.

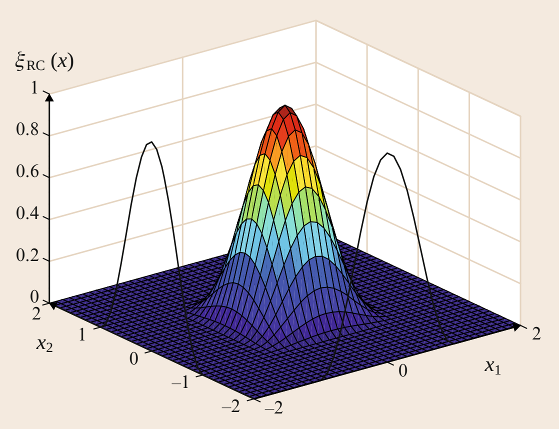

Fig. 11.3 Plot of a two-dimensional (2-D) raised-cosine radial basis function

11.3.1 Center Grid

Recall that the unknown functions are approximated over a compact set $\boldsymbol{\Omega}_x \subset \mathbb{R}^n$. It is assumed that $\boldsymbol{\Omega}_x$ can be represented as

$$\boldsymbol{\Omega}_x = \left\{\boldsymbol{x} \in \mathbb{R}^n : \boldsymbol{x}_\mathrm{l} \le \boldsymbol{x} \le \boldsymbol{x}_\mathrm{u}\right\} \quad (11.18)$$

$$= \left\{\boldsymbol{x} \in \mathbb{R}^n : x_{\mathrm{l}i} \le x_i \le x_{\mathrm{u}i},\ 1 \le i \le n\right\}, \quad (11.19)$$

where the n-dimensional vectors $\boldsymbol{x}_\mathrm{l}$ and $\boldsymbol{x}_\mathrm{u}$ denote lower and upper bounds of $\boldsymbol{x}$, respectively. To locate the centers of RBFs inside the approximation region $\boldsymbol{\Omega}_x$, an n-dimensional center grid with layer hierarchy is utilized, where each grid node corresponds to the center of one RBF. The center grid is initialized with its nodes located at $(x_{\mathrm{l}1}, x_{\mathrm{u}1}) \times (x_{\mathrm{l}2}, x_{\mathrm{u}2}) \times \cdots \times (x_{\mathrm{l}n}, x_{\mathrm{u}n})$, where × denotes the Cartesian product. The 2^n grid nodes of the initial center grid are referred to as boundary grid nodes and cannot be removed. Additional grid nodes will be added and then can be removed within this initial grid as the controlled system evolves in time. The centers of new RBFs can only be placed at the potential locations. The potential grid nodes are determined coordinate-wise. In each coordinate, the potential grid nodes of the first layer are the two fixed boundary grid nodes. The second layer has only one potential grid node in the middle of the boundary grid nodes. Then the potential grid nodes of the subsequent layers are in the middle of the adjacent potential grid nodes of all the previous layers. The determination of potential grid nodes in one coordinate is illustrated in Fig. 11.4.

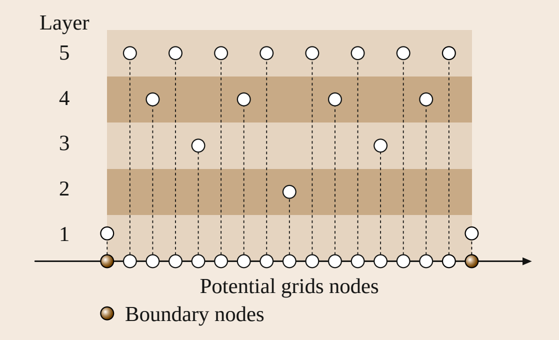

Fig. 11.4 Example of determining potential grid nodes in one coordinate

11.3.2 Adding RBFs

As the controlled system evolves in time, the output tracking error e is measured. If the magnitude of e exceeds a predetermined threshold e_max, and if the dwelling time of the current network structure has been greater than the prescribed T_d, the network tries to add new RBFs at potential grid nodes, that is, add new grid nodes. First, the nearest-neighboring grid node, denoted $\boldsymbol{c}_{(\mathrm{nearest})}$, to the current input $\boldsymbol{x}$ is located among existing grid nodes. Then the nearer-neighboring grid node denoted $\boldsymbol{c}_{(\mathrm{nearer})}$ is located, where $c_{i(\mathrm{nearer})}$ is determined such that x_i is between $c_{i(\mathrm{nearest})}$ and $c_{i(\mathrm{nearer})}$. Next, the adding operation is performed for each coordinate independently.

In the i-th coordinate, if the distance between x_i and $c_{i(\mathrm{nearest})}$ is smaller than a prescribed threshold $d_{i(\mathrm{threshold})}$ or smaller than a quarter of the distance between $c_{i(\mathrm{nearest})}$ and $c_{i(\mathrm{nearer})}$, no new grid node is added in the i-th coordinate. Otherwise, a new grid node located at half of the sum of $c_{i(\mathrm{nearest})}$ and $c_{i(\mathrm{nearer})}$ is added in the i-th coordinate. The design parameter $d_{i(\mathrm{threshold})}$ specifies the minimum grid distance in the i-th coordinate. The above procedures for adding RBFs are illustrated with two-dimensional examples shown in Fig. 11.5. In case 1, no RBFs are added. In case 2, new grid nodes are added out of the first coordinate. In case 3, new grid nodes are added out of both coordinates. In summary, a new grid node is added in the i-th coordinate if the following conditions are satisfied:

1. $|e| > e_\mathrm{max}$.
2. The elapsed time since last operation, adding or removing, is greater than T_d.
3. $\left|x_i - c_{i(\mathrm{nearest})}\right|$ $> \max\left\{\left|c_{i(\mathrm{nearest})} - c_{i(\mathrm{nearer})}\right|/4,\ d_{i(\mathrm{threshold})}\right\}$.

Fig. 11.5 Two-dimensional examples of adding RBFs

The layer of the i-th coordinate assigned to the newly added grid node is one level higher than the highest layer of the two adjacent existing grid nodes in the same coordinate. A possible scenario of formation of the layer hierarchy in one coordinate is shown in Fig. 11.6. The white circles denote potential grid nodes, and the black circles stand for existing grid nodes. The number in the black circles shows the order in which the corresponding grid node is added. The two black circles with number 1 are the initial grid nodes in this coordinate, so they are in the first layer. Suppose the adding operation is being implemented in this coordinate after the grid initialization. Then a new grid node is added in the middle of two boundary nodes 1 – see the black circle with number 2 in Fig. 11.6. This new grid node is assigned to the second layer because of the resulting resolution it yields. Then all the following grid nodes are added one by one. Note that nodes 3 and 4 belong to the same third layer because they yield the same resolution. On the other hand, node 5 belongs to the fourth layer because it yields higher resolution than nodes 2 and 3.

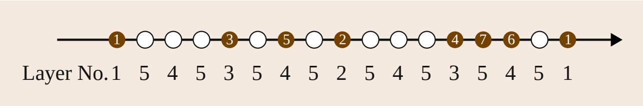

Fig. 11.6 Example of formation of the layer hierarchy in one coordinate

Nodes 6 and 7 are assigned to their layers in a similar fashion.

11.3.3 Removing RBFs

When the magnitude of the output tracking error e falls within the predetermined threshold $e_{\max}$ and the dwelling-time requirement has been satisfied, the network attempts to remove some of the existing RBFs, that is, some of the existing grid nodes, in order to avoid network redundancy. The RBF removing operation is also implemented for each coordinate independently. If $c_{i(\text{nearest})}$ is equal to $x_{\text{l}i}$ or $x_{\text{u}i}$, then no grid node is removed from the i-th coordinate. Otherwise, the grid node located at $c_{i(\text{nearest})}$ is removed from the i-th coordinate if this grid node is in the higher than or in the same layer as the highest layer of the two neighboring grid nodes in the same coordinate, and the distance between x_i and $c_{i(\text{nearest})}$ is smaller than a fraction τ of the distance between $c_{i(\text{nearest})}$ and $c_{i(\text{nearer})}$, where

Case 3: The fourth condition is not satisfied for the second coordinate

Fig. 11.7 Two-dimensional examples of removing RBFs

the fraction τ is a design parameter between 0 and 0.5. The above conditions for the removing operation to take place in the i-th coordinate can be summarized as:

1. $|e| \le e_{\max}$.
2. The elapsed time since last operation, adding or removing, is greater than T_d.
3. $c_{i(\text{nearest})} \notin \left(x_{\text{l}i}, x_{\text{u}i}\right)$.
4. The grid node in the i-th coordinate with its coordinate equal to $c_{i(\text{nearest})}$ is in a higher than or in the same layer as the highest layer of the two neighboring grid nodes in the same coordinate.
5. $\left|x_i - c_{i(\text{nearest})}\right| < \tau\left|c_{i(\text{nearest})} - c_{i(\text{nearer})}\right|$, $\tau \in (0, 0.5)$.

Two-dimensional examples of removing RBFs are illustrated in Fig. 11.7, where the conditions (1), (2), and (5) are assumed to be satisfied for both coordinates.

11.3.4 Uniform Grid Transformation

The determination of the radius of the RBF is much easier in a uniform grid than in a nonuniform grid because the RBF is radially symmetric with respect to its center. Unfortunately, the center grid used to locate RBFs is usually nonuniform. Moreover, the structure of the center grid changes after each adding or removing operation, which further complicates the problem. In order to simplify the determination of the radius, the one-to-one mapping $\boldsymbol{z}(\boldsymbol{x}) = [z_1(x_1), z_2(x_2), \dots, z_n(x_n)]^\top$, proposed in [11.60], is used to transform the center grid into a uniform grid. Suppose that the self-organizing RBF network is now with the v-th admissible structure after the adding or removing operation and there are $M_{i,v}$ distinct elements in S_i, ordered as $c_{i(1)} < c_{i(2)} < \dots < c_{i(M_{i,v})}$, where $c_{i(k)}$ is the k-th element with $c_{i(1)} = x_{\text{l}i}$ and $c_{i(M_{i,v})} = x_{\text{u}i}$. Then the mapping function $z_i(x_i) : [x_{\text{l}i}, x_{\text{u}i}] \to [1, M_{i,v}]$ takes the following form:

$$z_i(x_i) = k + \frac{x_i - c_{i(k)}}{c_{i(k+1)} - c_{i(k)}}, \qquad c_{i(k)} \le x_i < c_{i(k+1)}\,, \tag{11.20}$$

which maps $c_{i(k)}$ into the integer k. Thus, the transformation $\boldsymbol{z}(\boldsymbol{x}) : \boldsymbol{\Omega}_x \to \mathbb{R}^n$ maps the center grid into a grid with unit spacing between adjacent grid nodes such that the radius of the RBF can be easily chosen. For the raised-cosine RBF, the radius in every coordinate is selected to be equal to one unit, that is, the radius will touch but not extend beyond the neighboring grid nodes in the uniform grid. This particular choice of the radius guarantees that for a given input $\boldsymbol{x}$, the number of nonzero raised-cosine RBFs in the uniform grid is at most 2^n.

To simplify the implementation, it is helpful to reorder the M_v grid nodes into a one-dimensional array of points using a scalar index j. Let the vector $\boldsymbol{q}_v \in \mathbb{R}^n$ be the index vector of the grid nodes, where $\boldsymbol{q}_v = (q_{1,v}, \dots, q_{n,v})^\top$ with $1 \le q_{i,v} \le M_{i,v}$. Then the scalar index j can be uniquely determined by the index vector $\boldsymbol{q}_v$, where

$$\begin{aligned} j = {} & (q_{n,v} - 1)M_{n-1,v} \cdots M_{2,v}M_{1,v} + \cdots \\ & + (q_{3,v} - 1)M_{2,v}M_{1,v} + (q_{2,v} - 1)M_{1,v} + q_{1,v}\,. \end{aligned} \tag{11.21}$$

Let $\boldsymbol{c}_{j,v} = (c_{1j,v}, \dots, c_{nj,v})^\top$ denote the location of the $\boldsymbol{q}_v$-th grid node in the original grid. Then the corresponding grid node in the uniform grid is located at $\boldsymbol{z}_{j,v} = \boldsymbol{z}(\boldsymbol{c}_{j,v}) = (q_{1,v}, \dots, q_{n,v})^\top$. Using the scalar index j in (11.21), the output $\hat{f}_{i,v}(\boldsymbol{x})$ of the self-organizing raised-cosine RBF network implemented in the uniform grid can be expressed as

$$\begin{aligned} \hat{f}_v(\boldsymbol{x}) &= \sum_{j=1}^{M_v} \omega_{fj,v}\xi_{j,v}(\boldsymbol{x}) \\ &= \sum_{j=1}^{M_v} \omega_{fj,v} \prod_{i=1}^{n} \psi\left(\left|z_i(x_i) - q_{i,v}\right|\right)\,, \end{aligned} \tag{11.22}$$

where the radius is one unit in each coordinate.

When implementing the output feedback controller, the state vector estimate $\hat{\boldsymbol{x}}$ is used rather than the actual state vector $\boldsymbol{x}$. It may happen that $\hat{\boldsymbol{x}} \notin \boldsymbol{\Omega}_x$. In such a case, the definition of the transformation (11.20) is extended as

$$\begin{cases} z_i(\hat{x}_i) = 1 & \text{if } \hat{x}_i < c_{i(1)} \\ z_i(\hat{x}_i) = M_{i,v} & \text{if } \hat{x}_i > c_{i(M_{i,v})}\,, \end{cases} \tag{11.23}$$

for $i = 1, 2, \dots, n$. If $\hat{\boldsymbol{x}} \in \boldsymbol{\Omega}_x$, the transformation (11.20) is used. Therefore, it follows from (11.20) and (11.23) that the function $\boldsymbol{z}(\boldsymbol{x})$ maps the whole n-dimensional space $\mathbb{R}^n$ into the compact set $[1, M_{1,v}] \times [1, M_{2,v}] \times \dots \times [1, M_{n,v}]$.

11.3.5 Remarks

1. The internal structure of the self-organizing RBF network varies as the output tracking error trajectory evolves. When the output tracking error is large, the network adds RBFs in order to achieve better model compensation so that the large output tracking error

can be reduced. When, on the other hand, the output tracking error is small, the network removes RBFs in order to avoid a redundant structure. If the design parameter $e_{\max}$ is too large, the network may stop adding RBFs prematurely or even never adjust its structure at all. Thus, $e_{\max}$ should be at least smaller than $|e(t_0)|$. However, if $e_{\max}$ is too small, the network may keep adding and removing RBFs all the time and cannot approach a steady structure even though the output tracking error is already within the acceptable bound. In the worst case, the network will try to add RBFs forever. This, of course, leads to an unnecessary large network size and, at the same time, undesirable high computational cost. An appropriate $e_{\max}$ may be chosen by trial and error through numerical simulations.

2. The advantage of the raised-cosine RBF over the Gaussian RBF is the property of the compact support associated with the raised-cosine RBF. The number of terms in (11.22) grows rapidly with the increase of both the number of grid nodes M_i in each coordinate and the dimensionality n of the input space. For the GRBF network, all the terms will be nonzero due to the unbounded support, even though most of them are quite small. Thus, a lot of computations are required for the network's output evaluation, which is impractical for real-time applications, especially for higher-order systems. However, for the RCRBF network, most of the terms in (11.22) are zero and therefore do not have to be evaluated. Specifically, for a given input $\boldsymbol{x}$, the number of nonzero raised-cosine RBFs in each coordinate is either one or two. Consequently, the number of nonzero terms in (11.22) is at most 2^n. This feature allows one to speed up the output evaluation of the network in comparison with a direct computation of (11.22) for the GRBF network. To illustrate the above discussion, suppose $M_i = 10$ and $n = 4$. Then the GRBF network will require 10^4 function evaluations, whereas the RCRBF network will only require 2^4 function evaluations, which is almost three orders of magnitude less than that required by the GRBF network. For a larger value of n and a finer grid, the saving of computations is even more dramatic. The same saving is also achieved for the network's training. When the weights of the RCRBF network are updated, there are also only 2^n weights to be updated for each output neuron, whereas $n \times M$ weights has to be updated for the GRBF network. Similar observations were also reported in [11.60, p. 6].

11.4 State Feedback Controller Development

The direct adaptive robust state feedback controller presented in this chapter has the form

$$\begin{aligned} u &= u_{a,v} + u_{s,v} \\ &= \frac{1}{\hat{g}_v(\boldsymbol{x})}\left(-\hat{f}_v(\boldsymbol{x}) + y_{\mathrm{d}}^{(n)} - \boldsymbol{k}\boldsymbol{e}\right) + u_{s,v} \,, \end{aligned} \tag{11.24}$$

where $\hat{f}_v(\boldsymbol{x}) = \boldsymbol{\omega}_{f,v}^{\top}\boldsymbol{\xi}_v(\boldsymbol{x})$, $\hat{g}_v(\boldsymbol{x}) = \boldsymbol{\omega}_{g,v}^{\top}\boldsymbol{\xi}_v(\boldsymbol{x})$ and $u_{s,v}$ is the robustifying component to be described later. To proceed, let $\boldsymbol{\Omega}_{e_0}$ denote the compact set including all the possible initial tracking errors and let

$$c_{e_0} = \max_{\boldsymbol{e}\in\boldsymbol{\Omega}_{e_0}} \frac{1}{2}\boldsymbol{e}^{\top}\mathbf{P}_m\boldsymbol{e} \,, \tag{11.25}$$

where $\mathbf{P}_m$ is the positive-definite solution to the continuous Lyapunov matrix equation $\mathbf{A}_m^{\top}\mathbf{P}_m + \mathbf{P}_m\mathbf{A}_m = -2\mathbf{Q}_m$ for $\mathbf{Q}_m = \mathbf{Q}_m^{\top} > 0$. Choose $c_e > c_{e_0}$ and let

$$\boldsymbol{\Omega}_e = \left\{\boldsymbol{e} : \frac{1}{2}\boldsymbol{e}^{\top}\mathbf{P}_m\boldsymbol{e} \le c_e\right\} \,. \tag{11.26}$$

Then the compact set $\boldsymbol{\Omega}_x$ is defined as

$$\boldsymbol{\Omega}_x = \left\{\boldsymbol{x} : \boldsymbol{x} = \boldsymbol{e} + \boldsymbol{x}_{\mathrm{d}},\, \boldsymbol{e} \in \boldsymbol{\Omega}_e,\, \boldsymbol{x}_{\mathrm{d}} \in \boldsymbol{\Omega}_{x_{\mathrm{d}}}\right\} ,$$

over which the unknown functions $f(\boldsymbol{x})$ and $g(\boldsymbol{x})$ are approximated.

For practical implementation, $\boldsymbol{\omega}_{f,v}$ and $\boldsymbol{\omega}_{g,v}$ are constrained, respectively, to reside inside compact sets $\boldsymbol{\Omega}_{f,v}$ and $\boldsymbol{\Omega}_{g,v}$ defined as

$$\boldsymbol{\Omega}_{f,v} = \left\{\boldsymbol{\omega}_{f,v} : \underline{\omega}_f \le \omega_{fj,v} \le \overline{\omega}_f,\, 1 \le j \le M_v\right\} \tag{11.27}$$

and

$$\boldsymbol{\Omega}_{g,v} = \left\{\boldsymbol{\omega}_{g,v} : 0 < \underline{\omega}_g \le \omega_{gj,v} \le \overline{\omega}_g \,,\, 1 \le j \le M_v\right\} , \tag{11.28}$$

where $\underline{\omega}_f$, $\overline{\omega}_f$, $\underline{\omega}_g$ and $\overline{\omega}_g$ are design parameters. Let $\boldsymbol{\omega}_{f,v}^{*}$ and $\boldsymbol{\omega}_{g,v}^{*}$ denote the *optimal* constant weight vectors corresponding to each admissible network structure, which are used only in the analytical analysis and defined, respectively, as

$$\boldsymbol{\omega}^*_{f,v} = \underset{\boldsymbol{\omega}_{f,v}\in\boldsymbol{\Omega}_{f,v}}{\operatorname{argmin}} \; \max_{\boldsymbol{x}\in\boldsymbol{\Omega}_x} \left| f(\boldsymbol{x}) - \boldsymbol{\omega}_{f,v}^{\top}\boldsymbol{\xi}_v(\boldsymbol{x}) \right| \tag{11.29}$$

and

$$\boldsymbol{\omega}^*_{g,v} = \underset{\boldsymbol{\omega}_{g,v}\in\boldsymbol{\Omega}_{g,v}}{\operatorname{argmin}} \; \max_{\boldsymbol{x}\in\boldsymbol{\Omega}_x} \left| g(\boldsymbol{x}) - \boldsymbol{\omega}_{g,v}^{\top}\boldsymbol{\xi}_v(\boldsymbol{x}) \right| . \tag{11.30}$$

For the controller implementation, let

$$d_f = \max_v \left(\max_{\boldsymbol{x}\in\boldsymbol{\Omega}_x} \left| f(\boldsymbol{x}) - \boldsymbol{\omega}^{*\,\top}_{f,v}\boldsymbol{\xi}_v(\boldsymbol{x}) \right| \right) \tag{11.31}$$

and

$$d_g = \max_v \left(\max_{\boldsymbol{x}\in\boldsymbol{\Omega}_x} \left| g(\boldsymbol{x}) - \boldsymbol{\omega}^{*\,\top}_{g,v}\boldsymbol{\xi}_v(\boldsymbol{x}) \right| \right) , \tag{11.32}$$

where $\max_v(\cdot)$ denotes the maximization taken over all admissible structures of the self-organizing RBF networks. Let $\boldsymbol{\phi}_{f,v} = \boldsymbol{\omega}_{f,v} - \boldsymbol{\omega}^*_{f,v}$ and $\boldsymbol{\phi}_{g,v} = \boldsymbol{\omega}_{g,v} - \boldsymbol{\omega}^*_{g,v}$, and let

$$c_f = \max_v \left(\max_{\boldsymbol{\omega}_{f,v},\boldsymbol{\omega}^*_{f,v}\in\boldsymbol{\Omega}_{f,v}} \frac{1}{2\eta_f}\boldsymbol{\phi}_{f,v}^{\top}\boldsymbol{\phi}_{f,v} \right) \tag{11.33}$$

and

$$c_g = \max_v \left(\max_{\boldsymbol{\omega}_{g,v},\boldsymbol{\omega}^*_{g,v}\in\boldsymbol{\Omega}_{g,v}} \frac{1}{2\eta_g}\boldsymbol{\phi}_{g,v}^{\top}\boldsymbol{\phi}_{g,v} \right) , \tag{11.34}$$

where η_f and η_g are positive design parameters often referred to as learning rates. It is obvious that c_f (or c_g) will decrease as η_f (or η_g) increases. Let $\sigma = \boldsymbol{b}^{\top}\mathbf{P}_m\boldsymbol{e}$. The following weight vector adaptation laws are employed, respectively, for the weight vectors $\boldsymbol{\omega}_f$ and $\boldsymbol{\omega}_g$,

$$\dot{\boldsymbol{\omega}}_{f,v} = \operatorname{Proj}\left[\boldsymbol{\omega}_{f,v}, \eta_f\sigma\boldsymbol{\xi}_v(\boldsymbol{x})\right] \tag{11.35}$$

and

$$\dot{\boldsymbol{\omega}}_{g,v} = \operatorname{Proj}\left[\boldsymbol{\omega}_{g,v}, \eta_g\sigma\boldsymbol{\xi}_v(\boldsymbol{x})u_{a,v}\right] , \tag{11.36}$$

where $\operatorname{Proj}(\boldsymbol{\omega}_v, \boldsymbol{\theta}_v)$ denotes $\operatorname{Proj}(\omega_{j,v}, \boldsymbol{\theta}_{j,v})$ for $j = 1, \ldots, M_v$ and

$$\operatorname{Proj}(\omega_{j,v}, \boldsymbol{\theta}_{j,v}) = \begin{cases} 0 & \text{if } \omega_{j,v} = \underline{\omega} \text{ and } \boldsymbol{\theta}_{j,v} < 0 , \\ 0 & \text{if } \omega_{j,v} = \overline{\omega} \text{ and } \boldsymbol{\theta}_{j,v} > 0 , \\ \boldsymbol{\theta}_{j,v} & \text{otherwise} , \end{cases} \tag{11.37}$$

is a discontinuous projection operator proposed in [11.65]. The robustifying component $u_{s,v}$ is designed as

$$u_{s,v} = -\frac{1}{\underline{g}}k_{s,v}\,\operatorname{sat}\left(\frac{\sigma}{\nu}\right) , \tag{11.38}$$

where $k_{s,v} = d_f + d_g|u_{a,v}| + d_0$ and $\operatorname{sat}(\cdot)$ is the saturation function with small $\nu > 0$. Let

$$k_s = d_f + d_g \max_v\left(\max |u_{a,v}|\right) + d_0 , \tag{11.39}$$

where the inner maximization is taken over $\boldsymbol{e} \in \boldsymbol{\Omega}_e$, $\boldsymbol{x}_{\mathrm{d}} \in \boldsymbol{\Omega}_{x_{\mathrm{d}}}$, $y_{\mathrm{d}}^{(n)} \in \boldsymbol{\Omega}_{y_{\mathrm{d}}}$, $\boldsymbol{\omega}_{f,v} \in \boldsymbol{\Omega}_{f,v}$, and $\boldsymbol{\omega}_{g,v} \in \boldsymbol{\Omega}_{g,v}$.

It can be shown [11.58] that, for the plant (11.2) driven by the proposed direct adaptive robust state feedback controller (DARSFC) (11.24) with the robustifying component (11.38) and the adaptation laws (11.35) and (11.36), if one of the following conditions is satisfied:

- The dwelling time T_{d} of the self-organizing RBF network is selected such that

$$T_{\mathrm{d}} \geq \frac{1}{\mu}\ln\left(\frac{3}{2}\right) , \tag{11.40}$$

- The constants c_f, c_g, and ν satisfy the inequality

$$0 < c_f + c_g < \frac{\exp(\mu T_{\mathrm{d}}) - 1}{3 - 2\exp(\mu T_{\mathrm{d}})}\frac{k_s\nu}{4\mu} , \tag{11.41}$$

where μ is the ratio of the minimal eigenvalve of $\mathbf{Q}_{\mathrm{m}}$ to the maximal eigenvalue of $\mathbf{P}_{\mathrm{m}}$. If η_f, η_g, and ν are selected such that

$$c_e \geq \max\left\{ c_{e_0} + c_f + c_g,\, 2\left(c_f + c_g + \frac{k_s\nu}{8\mu}\right) + c_f + c_g \right\} , \tag{11.42}$$

then $\boldsymbol{e}(t) \in \boldsymbol{\Omega}_e$ and $\boldsymbol{x}(t) \in \boldsymbol{\Omega}_x$ for $t \geq t_0$. Moreover, there exists a finite time $T \geq t_0$ such that

$$\frac{1}{2}\boldsymbol{e}^{\top}(t)\mathbf{P}_m\boldsymbol{e}(t) \leq 2\left(c_f + c_g + \frac{k_s\nu}{8\mu}\right) + c_f + c_g \tag{11.43}$$

for $t \geq T$. If, in addition, there exists a finite time $T_{\mathrm{s}} \geq t_0$ such that $v = v_{\mathrm{s}}$ for $t \geq T_{\mathrm{s}}$, then there exists a finite time $T \geq T_{\mathrm{s}}$ such that

$$\frac{1}{2}\boldsymbol{e}^{\top}(t)\mathbf{P}_m\boldsymbol{e}(t) \leq 2\left(c_f + c_g + \frac{k_s\nu}{8\mu}\right) \tag{11.44}$$

for $t \geq T$. It can be seen from (11.43) and (11.44) that the tracking performance is inversely proportional to η_f

and η_g, and proportional to ν. Therefore, larger learning rates and smaller saturation boundary imply better tracking performance.

11.4.1 Remarks

1. For the above direct adaptive robust controller, the weight vector adaptation laws are synthesized together with the controller design. This is done for the purpose of reducing the output tracking error only. However, the adaptation laws are limited to be of gradient type with ceratin tracking errors as driving signals, which may not have as good convergence properties as other types of adaptation laws such as the ones based on the least-squares method [11.66]. Although this design methodology can achieve excellent output tracking performance, it may not achieve the convergence of the weight vectors. When good convergence of the weight vectors is a secondary goal to be achieved, an indirect adaptive robust controller [11.66] or an integrated direct/indirect adaptive robust control [11.65] have been proposed to overcome the problem of poor convergence associated with the direct adaptive robust controllers.
2. It seems to be desirable to select large learning rates and small saturation boundary based on (11.43) and (11.44). However, it is not desirable in practice to choose excessively large η_f and η_g. If η_f and η_g are too large, fast adaptation could excite the unmodeled high-frequency dynamics that are neglected in the modeling. On the other hand, the selection of ν cannot be too small either. Otherwise, the robustifying component exhibits high-frequency chattering, which may also excite the unmodeled dynamics. Moreover, smaller ν requires higher bandwidth to implement the controller for small tracking error. To see this more clearly, consider the following first-order dynamics,

$$\dot{e} = ae + \left(f + gu - \dot{y}_{\mathrm{d}} + d\right)\,, \tag{11.45}$$

which is a special case of (11.6). Applying the following controller,

$$u = \frac{1}{\hat{g}}\left(-\hat{f} + \dot{y}_{\mathrm{d}} - ke\right) - \frac{1}{\underline{g}}k_s \operatorname{sat}\left(\frac{\sigma}{\nu}\right)\,, \tag{11.46}$$

where $\sigma = e$, one obtains

$$\dot{e} = -a_m e + \tilde{d} - \frac{g}{\underline{g}}k_s \operatorname{sat}\left(\frac{e}{\nu}\right)\,, \tag{11.47}$$

where $-a_m = a - k < 0$. When $|e| \le \nu$, (11.47) becomes

$$\dot{e} = -\left(a_m + \frac{g}{\underline{g}}\frac{k_s}{\nu}\right)e + \tilde{d}\,, \tag{11.48}$$

which implies that smaller ν results in higher controller bandwidth.

11.5 Output Feedback Controller Construction

The direct adaptive robust state feedback controller presented in the previous section requires the availability of the plant states. However, often in practice only the plant outputs are available. Thus, it is desirable to develop a direct adaptive robust output feedback controller (DAROFC) architecture. To overcome the problem of inaccessibility of the system states, the following high-gain observer [11.38, 49],

$$\dot{\hat{\boldsymbol{e}}} = \mathbf{A}\hat{\boldsymbol{e}} + \boldsymbol{l}\left(e - \boldsymbol{c}\hat{\boldsymbol{e}}\right)\,, \tag{11.49}$$

is applied to estimate the tracking error $\boldsymbol{e}$. The observer gain $\boldsymbol{l}$ is chosen as

$$\boldsymbol{l} = \left(\frac{\alpha_1}{\epsilon}, \frac{\alpha_2}{\epsilon^2}, \dots, \frac{\alpha_n}{\epsilon^n}\right)^{\top}\,, \tag{11.50}$$

where $\epsilon \in (0, 1)$ is a design parameter and α_i, $i = 1, 2, \dots, n$, are selected so that the roots of the polynomial equation, $s^n + \alpha_1 s^{n-1} + \dots + \alpha_{n-1}s + \alpha_n = 0$, have negative real parts. The structure of the above high-gain tracking error observer is shown in Fig. 11.8. Substituting $\boldsymbol{e}$ with $\hat{\boldsymbol{e}}$ in the controller u defined in (11.24) with (11.38) gives

$$\hat{u} = \hat{u}_{a,v} + \hat{u}_{s,v}\,, \tag{11.51}$$

where

$$\hat{u}_{a,v} = \frac{1}{\hat{g}_v(\hat{\boldsymbol{x}})}\left[-\hat{f}_v(\hat{\boldsymbol{x}}) + y_{\mathrm{d}}^{(n)} - \boldsymbol{k}\hat{\boldsymbol{e}}\right] \tag{11.52}$$

and

$$\hat{u}_{s,v} = -\frac{1}{\underline{g}}\hat{k}_{s,v} \operatorname{sat}\left(\frac{\hat{\sigma}}{\nu}\right)\,, \tag{11.53}$$

with $\hat{\boldsymbol{x}} = \boldsymbol{x}_{\mathrm{d}} + \hat{\boldsymbol{e}}$, $\hat{k}_{s,v} = d_f + d_g|\hat{u}_{a,v}| + d_0$ and $\hat{\sigma} = \boldsymbol{b}^{\top}\mathbf{P}_m\hat{\boldsymbol{e}}$. Let

$$\hat{k}_s = d_f + d_g \max_{v}\left(\max|\hat{u}_{a,v}|\right) + d_0\,,$$

and the inner maximization is taken over $\hat{\boldsymbol{e}} \in \boldsymbol{\Omega}_{\hat{e}}$, $\boldsymbol{x}_\mathrm{d} \in \boldsymbol{\Omega}_{x_\mathrm{d}}$, $\boldsymbol{y}_\mathrm{d}^{(n)} \in \boldsymbol{\Omega}_{y_\mathrm{d}}$, $\boldsymbol{\omega}_{f,v} \in \boldsymbol{\Omega}_{f,v}$, and $\boldsymbol{\omega}_{g,v} \in \boldsymbol{\Omega}_{g,v}$. For the high-gain observer described by (11.49), there exist peaking phenomena [11.67]. Hence, the controller $\hat{u}$ defined in (11.51) cannot be applied to the plant directly. To eliminate the peaking phenomena, the saturation is introduced into the control input $\hat{u}$ in (11.51). Let

$$\boldsymbol{\Omega}_{\hat{e}} = \left\{ \boldsymbol{e} : \frac{1}{2} \boldsymbol{e}^{\top} \mathbf{P}_m \boldsymbol{e} \le c_{\hat{e}} \right\} , \qquad (11.54)$$

where $c_{\hat{e}} > c_e$. Let

$$S \ge \max_{v} \left[\max \left| u\left(\boldsymbol{e}, \boldsymbol{x}_\mathrm{d}, y_\mathrm{d}^{(n)}, \boldsymbol{\omega}_{f,v}, \boldsymbol{\omega}_{g,v} \right) \right| \right] , \qquad (11.55)$$

where u is defined in (11.24) and the inner maximization is taken over $\boldsymbol{e} \in \boldsymbol{\Omega}_{\hat{e}}$, $\boldsymbol{x}_\mathrm{d} \in \boldsymbol{\Omega}_{x_\mathrm{d}}$, $y_\mathrm{d}^{(n)} \in \boldsymbol{\Omega}_{y_\mathrm{d}}$, $\boldsymbol{\omega}_{f,v} \in \boldsymbol{\Omega}_{f,v}$, and $\boldsymbol{\omega}_{g,v} \in \boldsymbol{\Omega}_{g,v}$. Then the proposed direct adaptive robust output feedback controller takes the form

$$u^s = S\,\mathrm{sat}\left(\frac{\hat{u}_{a,v} + \hat{u}_{s,v}}{S} \right) . \qquad (11.56)$$

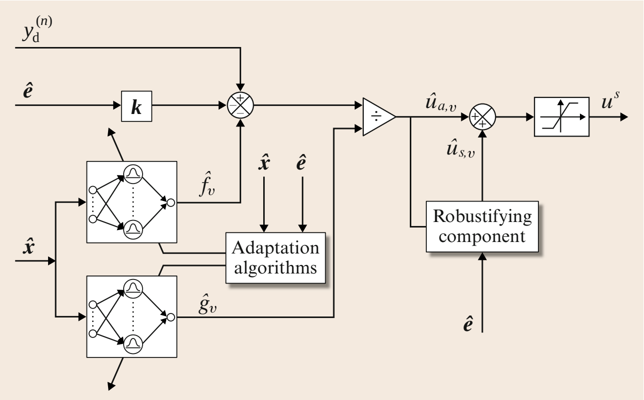

Fig. 11.9 Diagram of the direct adaptive robust output feedback controller (DAROFC)

The adaptation laws for the weight vectors $\boldsymbol{\omega}_{f,v}$ and $\boldsymbol{\omega}_{g,v}$ change correspondingly and take the following new form, respectively

$$\dot{\boldsymbol{\omega}}_{f,v} = \mathrm{Proj}\left[\boldsymbol{\omega}_{f,v}, \eta_f \hat{\sigma} \boldsymbol{\xi}_v(\hat{\boldsymbol{x}}) \right] \qquad (11.57)$$

and

$$\dot{\boldsymbol{\omega}}_{g,v} = \mathrm{Proj}\left[\boldsymbol{\omega}_{g,v}, \eta_g \hat{\sigma} \boldsymbol{\xi}_v(\hat{\boldsymbol{x}}) \hat{u}_{a,v} \right] . \qquad (11.58)$$

A block diagram of the above direct adaptive robust output feedback controller is shown in Fig. 11.9, while a block diagram of the closed-loop system is given in Fig. 11.10.

For the high-gain tracking error observer (11.49), it is shown in [11.68] that there exists a constant $\epsilon_1^* \in (0, 1)$ such that, if $\epsilon \in (0, \epsilon_1^*)$, then $\|\boldsymbol{e}(t) - \hat{\boldsymbol{e}}(t)\| \le \beta\epsilon$ with $\beta > 0$ for $t \in [t_0 + T_1(\epsilon), t_0 + T_3)$, where $T_1(\epsilon)$ is a finite time and $t_0 + T_3$ is the moment when the tracking error $\boldsymbol{e}(t)$ leaves the compact set $\boldsymbol{\Omega}_e$ for the first time. Moreover, we have $\lim_{\epsilon \to 0^+} T_1(\epsilon) = 0$ and $c_{e_1} = \frac{1}{2} \boldsymbol{e}(t_0 + T_1(\epsilon))^{\top} \mathbf{P}_m \boldsymbol{e}(t_0 + T_1(\epsilon)) < c_e$. For the plant (11.2) driven by the direct adaptive robust output feedback controller given by (11.56) with the adaptation laws (11.57) and (11.58), if one of the following conditions is satisfied:

$$c_e \ge c_{e_1} + c_f + c_g \tag{11.61}$$

and

$$c_e > 2\left(c_f + c_g + \frac{\hat{k}_s \nu}{8\mu} \right) + c_f + c_g , \tag{11.62}$$

there exists a constant $\epsilon^* \in (0,\, 1)$ such that, if $\epsilon \in (0,\, \epsilon^*)$, then $\boldsymbol{e}(t) \in \boldsymbol{\Omega}_e$ and $\mathbf{x}(t) \in \boldsymbol{\Omega}_x$ for $t \ge t_0$. Moreover, there exists a finite time $T \ge t_0 + T_1(\epsilon)$ such that

$$\frac{1}{2} \boldsymbol{e}(t)^{\top} \mathbf{P}_m \boldsymbol{e}(t) \le 2\left(c_f + c_g + \frac{\hat{k}_s \nu}{8\mu} \right) + r\epsilon + c_f + c_g \tag{11.63}$$

with some $r > 0$ for $t \ge T$. In addition, suppose that there exists a finite time $T_s \ge t_0 + T_1(\epsilon)$ such that $\upsilon = \upsilon_s$ for $t \ge T_s$. Then there exists a finite time $T \ge T_s$ such that

$$\frac{1}{2} \boldsymbol{e}^{\top}(t) \mathbf{P}_m \boldsymbol{e}(t) \le 2\left(c_f + c_g + \frac{\hat{k}_s \nu}{8\mu} \right) + r\epsilon \tag{11.64}$$

for $t \ge T$. A proof of the above statement can be found in [11.58]. It can be seen that the performance of the output feedback controller approaches that of the state feedback controller as ϵ approaches zero.

11.6 Examples

In this section, two example systems are used to illustrate the features of the proposed direct adaptive robust controllers. In Example 11.1, a benchmark problem from the literature is used to illustrate the controller performance under different situations. Especially, the reference signal changes during the operation in order to demonstrate the advantage of the self-organizing RBF network. In Example 11.2, the Duffing forced oscillation system is employed to test the controller performance for time-varying systems.

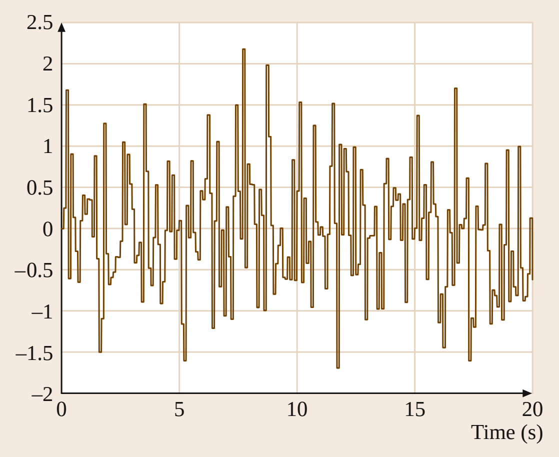

Fig. 11.11 Disturbance d in example 11.1

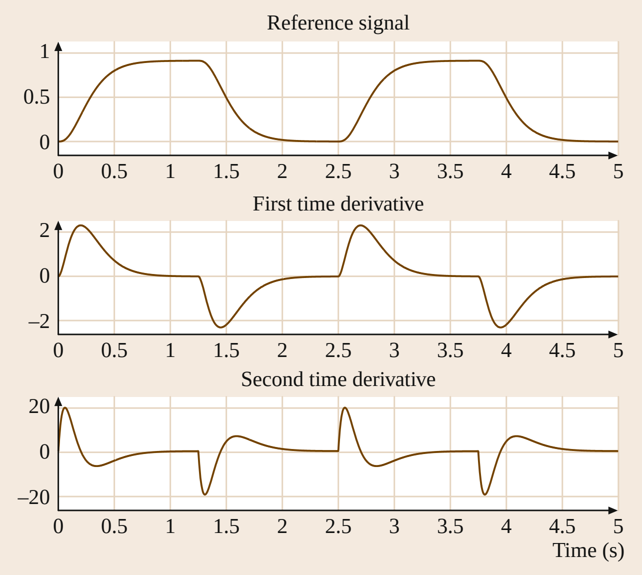

Fig. 11.12 Reference signal and its time derivatives

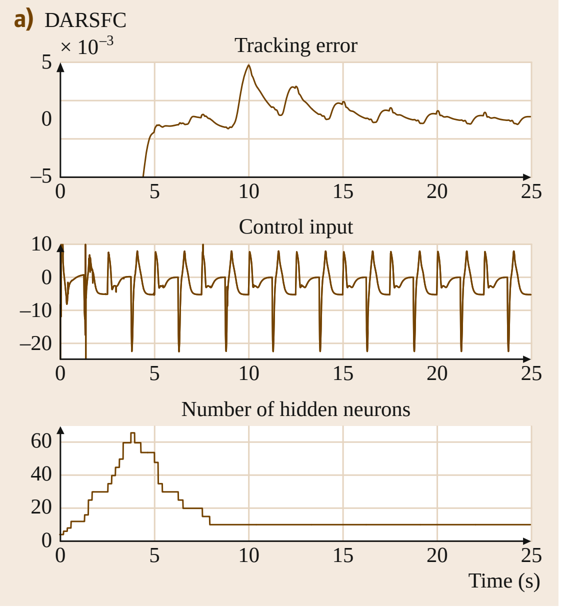

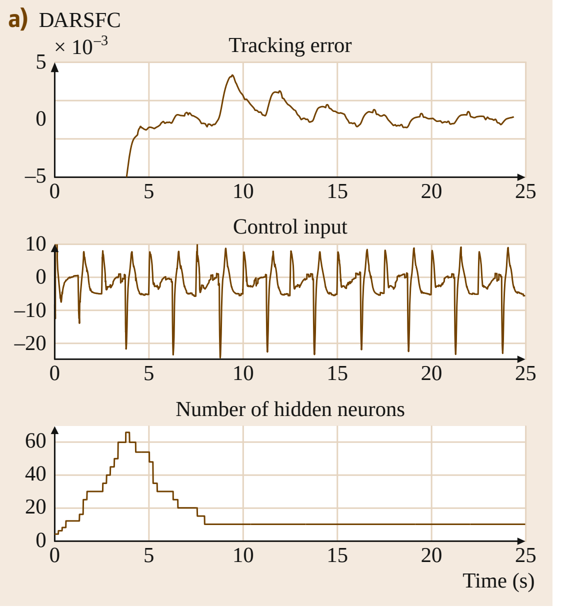

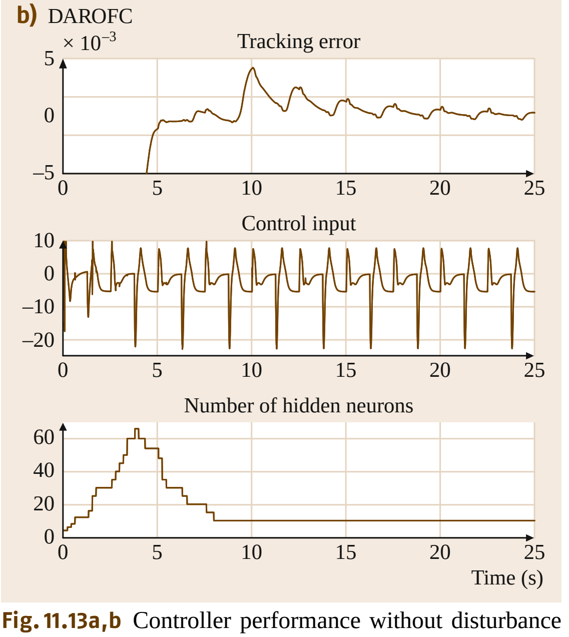

Fig. 11.13a,b Controller performance without disturbance in example 11.1. **(a)** State feedback controller, **(b)** output feedback controller

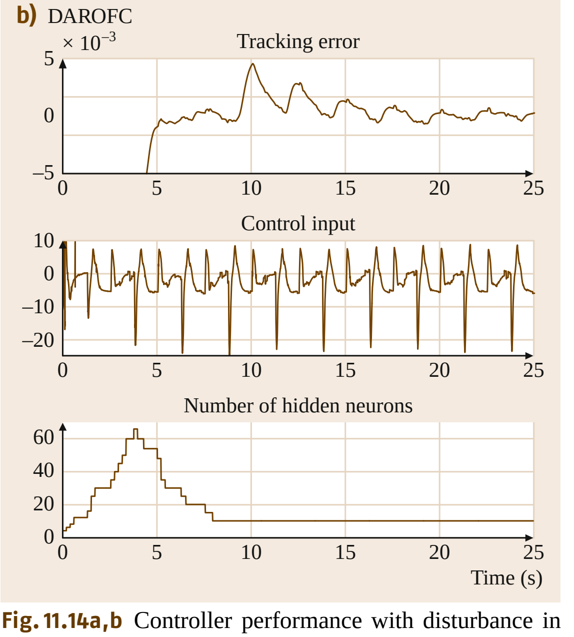

Fig. 11.14a,b Controller performance with disturbance in Example 11.1. **(a)** State feedback controller, **(b)** output feedback controller

*Example 11.1:*The nonlinear plant model used in this example is given by

$$\begin{aligned}\ddot{y} &= f(y,\dot{y})+g(y)u+d\\ &= 16\frac{\sin(4\pi y)}{4\pi y}\left(\frac{\sin(\pi\dot{y})}{\pi\dot{y}}\right)^2\\ &\quad+\{2+\sin[3\pi(y-0.5)]\}u+d\,,\end{aligned}$$

which, if $d=0$, is the same plant model as in [11.27, 34, 38], used as a testbed for proposed controllers. It is easy to check that the above uncertain system dynamics are in the form of (11.2) with $\boldsymbol{x}=[y,\dot{y}]^\top$. For the simulation, the disturbance d is selected to be band-limited white noise generated using SIMULINK (version 6.6) with noise power 0.05, sample time 0.1 s, and seed value 23 341, which is shown in Fig. 11.11.

The reference signal is the same as in [11.38], which is the output of a low-pass filter with the transfer function $(1+0.1s)^{-3}$, driven by a unity amplitude square-wave input with frequency 0.4 Hz and a time average of 0.5 s. The reference signal y_d and its derivatives $\dot{y}_\text{d}$ and $\ddot{y}_\text{d}$ are shown in Fig. 11.12. The grid boundaries for y and $\dot{y}$, respectively, are selected to be $(-1.5, 1.5)$ and $(-3.5, 3.5)$, that is, $\boldsymbol{x}_\text{l}=(-1.5,-3.5)^\top$ and $\boldsymbol{x}_\text{u}=(1.5,3.5)^\top$. The rest of the network's parameters are $\boldsymbol{d}_\text{threshold}=(0.2,0.3)$, $e_\text{max}=0.005$, $T_\text{d}=0.2$ s, $\overline{\omega}_f=25$, $\underline{\omega}_f=-25$, $\overline{\omega}_g=5$, $\underline{\omega}_g=0.1$, and $\eta_f=\eta_g=1000$. The controller's parameters are $\boldsymbol{k}=(1,2)$, $\mathbf{Q}_m=0.5\mathbf{I}_2$, $d_f=5$, $d_g=2$, $d_0=3$, $\nu=0.01$, and $S=50$. The observer's parameters are $\epsilon=0.001$, $\alpha_1=10$, and $\alpha_2=25$. The initial conditions are $y(0)=-0.5$ and $\dot{y}(0)=2.0$. The controller performance without disturbance is shown in Fig. 11.13, whereas the controller performance in the presence of disturbance is illustrated in Fig. 11.14.

In order to demonstrate the advantages of the self-organizing RBF network in the proposed controller architectures, a different reference signal, $y_\text{d}(t)=\sin(2t)$, is applied at $t=25$ s. It can be seen from Fig. 11.15 that the self-organizing RCRBF network-based direct adaptive robust output feedback controller performs very well for both reference signals. There is no need to adjust the network's or the controller's parameters offline when the new reference signal is applied. The self-organizing RBF network determines its structure dynamically by itself as the reference signal changes.

*Example 11.2:*In this example, the direct adaptive robust output feedback controller is tested on a time-varying system. The plant is the Duffing forced oscillation system [11.28] modeled by

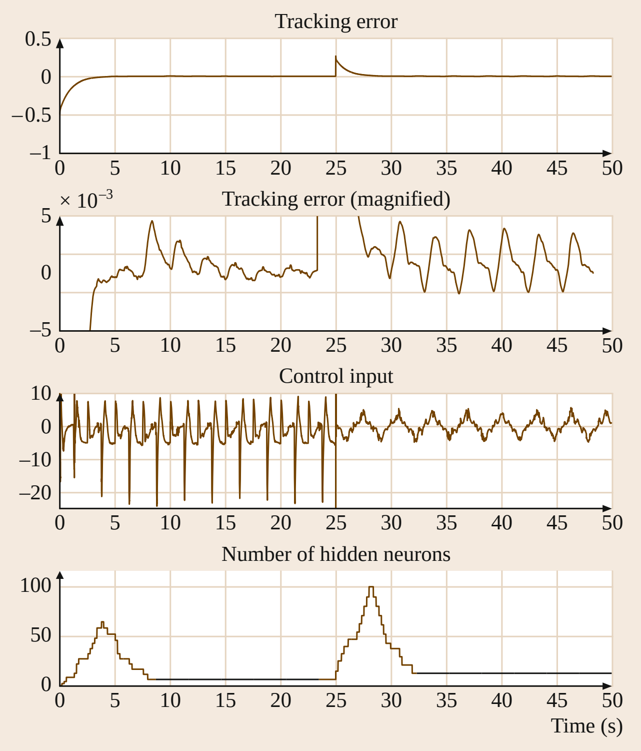

Fig. 11.15 Output feedback controller performance with varying reference signals in Example 11.1

$$\begin{aligned}\dot{x}_1 &= x_2\\ \dot{x}_2 &= -0.1x_2-x_1^3+12\cos(t)+u\,.\end{aligned}$$

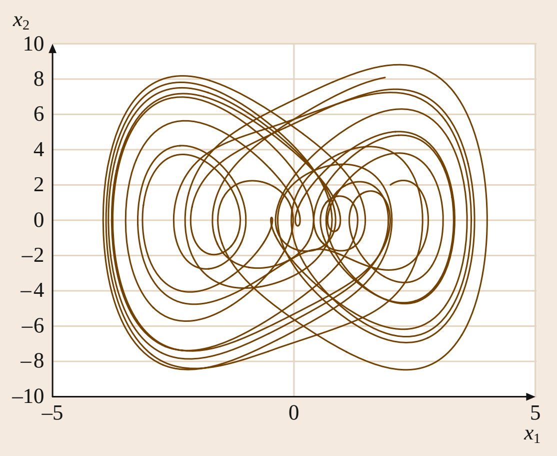

Fig. 11.16 Phase portrait of the uncontrolled system in Example 11.2

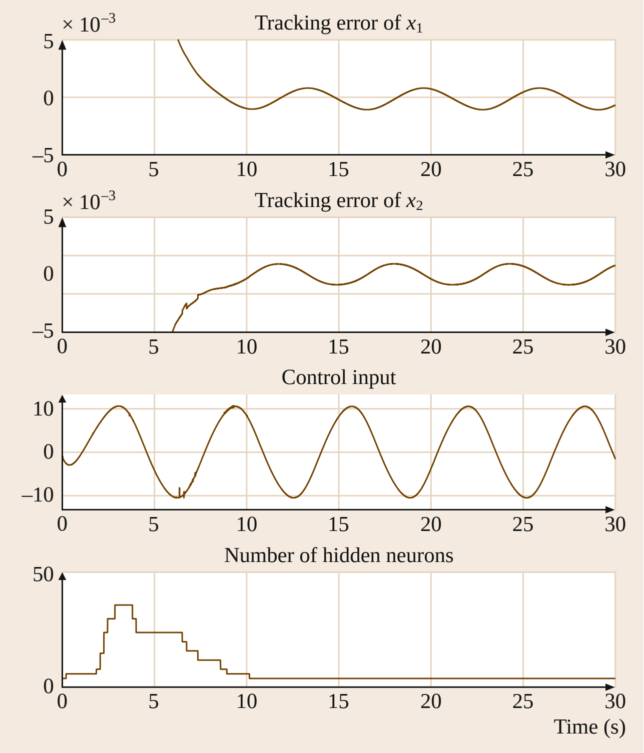

Fig. 11.18 Output feedback controller performance in Example 11.2

The phase portrait of the uncontrolled system is shown in Fig. 11.16 for $x_1(0) = x_2(0) = 2$, $t_0 = 0$, and $t_f = 50$. The disturbance d is set to be zero.

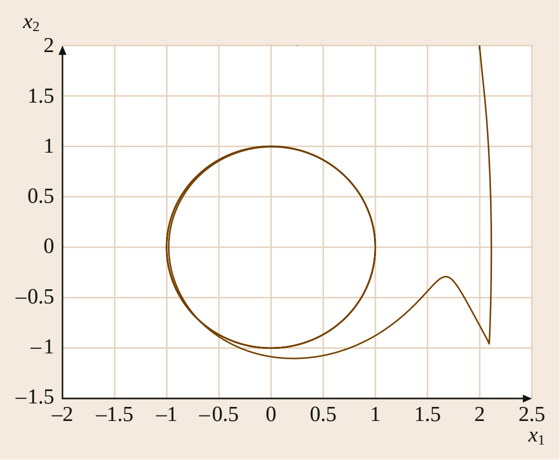

Fig. 11.17 Phase portrait of the closed-loop system driven by the output feedback controller in Example 11.2

The reference signal, $y_d(t) = \sin(t)$, is used, which is the unit circle in the phase plane. The grid boundaries for y and $\dot{y}$, respectively, are $[-2.5, 2.5]$ and $[-2.5, 2.5]$. The design parameters are chosen to be the same as in example 11.1except that $e_{\max} = 0.05$, $d_f = 15$, and $\nu = 0.001$. The phase portrait of the closed-loop system is shown in Fig. 11.17. It follows from Fig. 11.18 that the controller performs very well for this time-varying system.

11.7 Summary

Novel direct adaptive robust state and output feedback controllers have been presented for the output tracking control of a class of nonlinear systems with unknown system dynamics. The presented techniques incorporate a variable-structure RBF network to approximate the unknown system dynamics. The network structure varies as the output tracking error trajectory evolves in order to ensure tracking accuracy and, at the same time, avoid redundant network structure. The Gaussian RBF and the raised-cosine RBF are compared in the simulations. The property of compact support associated with the raised-cosine RBF results in significant reduction of computations required for the network's training and output evaluation [11.61]. This feature becomes especially important when the center grid becomes finer and the dimension of the network input becomes higher.

The effectiveness of the presented direct adaptive robust controllers are illustrated with two examples.

In order to evaluate and compare different proposed control strategies for the uncertain system given in (11.1), it is necessary to use performance measures. In the following, a list of possible performance indices [11.69] is given.

- Transient performance

$$e_M = \max_{t_0 \le t \le t_f} \{|e(t)|\}$$

- Final tracking accuracy

$$e_F = \max_{t \in [t_f - 2, t_f]} \{|e(t)|\}$$

- Average tracking performance

$$L_2(e) = \sqrt{\frac{1}{t_f}\int_{t_0}^{t_f} |e(\tau)|^2\,\mathrm{d}\tau}$$

- Average control input

$$L_2(u) = \sqrt{\frac{1}{t_f}\int_{t_0}^{t_f} |u(\tau)|^2\,\mathrm{d}\tau}$$

- Degree of control chattering

$$c_u = \frac{L_2(\Delta u)}{L_2(u)}\,,$$

where

$$L_2(\Delta u) = \sqrt{\frac{1}{N}\sum_{j=1}^{N} \big|u(j\Delta T) - u[(j-1)\Delta T]\big|^2}$$

The approach presented in this chapter has been used as a starting point towards the development of direct adaptive robust controllers for a class of MIMO uncertain systems in [11.58]. The MIMO uncertain system considered in [11.58] can be modeled by the following set of equations

$$\begin{cases} y_1^{(n_1)} &= f_1(\boldsymbol{x}) + \sum\limits_{j=1}^{p} g_{1j}(\boldsymbol{x})u_j + d_1 \\ y_2^{(n_2)} &= f_2(\boldsymbol{x}) + \sum\limits_{j=1}^{p} g_{2j}(\boldsymbol{x})u_j + d_2 \\ & \vdots \\ y_p^{(n_p)} &= f_p(\boldsymbol{x}) + \sum\limits_{j=1}^{p} g_{pj}(\boldsymbol{x})u_j + d_p\,, \end{cases} \tag{11.65}$$

where $\boldsymbol{u} = \left(u_1, u_2, \dots, u_p\right)^\top$ is the system input vector, $\boldsymbol{y} = \left(y_1, y_2, \dots, y_p\right)^\top$ is the system output vector, $\boldsymbol{d} = \left(d_1, d_2, \dots, d_p\right)^\top$ models the bounded disturbance, $\boldsymbol{x} = \left(\boldsymbol{x}_1^\top, \boldsymbol{x}_2^\top, \dots, \boldsymbol{x}_p^\top\right)^\top \in \mathbb{R}^n$ is the system state vector with $\boldsymbol{x}_i = \left(y_i, \dot{y}_i, \dots, y_i^{(n_i-1)}\right)^\top$ and $n = \sum_{i=1}^{p} n_i$, and $f_i(\boldsymbol{x})$ and $g_{ij}(\boldsymbol{x})$ are unknown Lipschitz-continuous functions.

12. Cybernetics and Learning Automata

John Oommen, Sudip Misra

Stochastic learning automata are probabilistic finite state machines which have been used to model how biological systems can learn. The structure of such a machine can be fixed or can be changing with time. A learning automaton can also be implemented using action (choosing) probability updating rules which may or may not depend on estimates from the environment being investigated. This chapter presents an overview of the field of learning automata, perceived as a completely new paradigm for learning, and explains how it is related to the area of *cybernetics*.

12.1 Basics

What is a *learning automaton*? What is *learning* all about? what are the different types of learning automata (LA) available? How are LA related to the general field of *cybernetics*? These are some of the fundamental issues that this chapter attempts to describe, so that we can understand the potential of the mechanisms, and their capabilities as primary tools which can be used to solve a host of very complex problems.

The Webster's dictionary defines *cybernetics* as:

> ... *the science of communication and control theory that is concerned especially with the comparative study of automatic control systems (as the nervous system, the brain and mechanical–electrical communication systems).*

The word *cybernetics* itself has its etymological origins in the Greek root *kybernan*, meaning *to steer* or *to govern*. Typically, as explained in the *Encyclopaedia Britannica*:

> *Cybernetics is associated with models in which a monitor compares what is happening to a system at various sampling times with some standard of what should be happening, and a controller adjusts the system's behaviour accordingly.*

Of course, the goal of the exercise is to design the *controller* so as to appropriately adjust the system's behavior. Modern cybernetics is an interdisciplinary field, which philosophically encompasses an ensemble of areas including neuroscience, computer science, cognition, control systems, and electrical networks.

The linguistic meaning of *automaton* is a self-operating machine or a mechanism that responds to a sequence of instructions in a certain way, so as to achieve a certain goal. The automaton either responds to a predetermined set of rules, or adapts to the environmental dynamics in which it operates. The latter types of automata are pertinent to this chapter, and are termed as *adaptive automata*. The term *learning* in psychology means the act of acquiring knowledge and modifying one's behavior based on the experience gained. Thus, in our case, the adaptive automaton we study in this chapter adapts to the responses from the environment through a series of interactions with it. It then attempts to learn the best action from a set of possible actions that are offered to it by the random stationary or nonstationary environment in which it operates. The automaton thus acts as a decision maker to arrive at the best action.

Well then, what do *learning automata* have to do with *cybernetics*? The answer to this probably lies in the results of the Russian pioneer *Tsetlin* [12.1, 2]. Indeed, when Tsetlin first proposed his theory of learning, his aim was to use the principles of automata theory to model how biological systems could learn. Little did he guess that his seminal results would lead to a completely new paradigm for learning, and a subfield of cybernetics.

The operations of the LA can be best described through the words of the pioneers *Narendra* and *Thathachar* [12.3, p. 3]:

> *... a decision maker operates in the random environment and updates its strategy for choosing actions on the basis of the elicited response. The decision maker, in such a feedback configuration of decision maker (or automaton) and environment, is referred to as the learning automaton. The automaton has a finite set of actions, and corresponding to each action, the response of the environment can be either favorable or unfavorable with a certain probability.*

LA, thus, find applications in optimization problems in which an optimal action needs to be determined from a set of actions. It should be noted that, in this context, learning might be of best help only when there are high levels of *uncertainty* in the system in which the automaton operates. In systems with low levels of uncertainty, LA-based learning may not be a suitable tool of choice [12.3].

The first studies with LA models date back to the studies by mathematical psychologists such as *Bush* and *Mosteller* [12.4], and *Atkinson* et al. [12.5]. In 1961, the Russian mathematician, *Tsetlin* [12.1, 2] studied deterministic LA in detail. *Varshavskii* and *Vorontsova* [12.6] introduced the stochastic variable structure versions of the LA. *Tsetlin*'s deterministic automata [12.1, 2] and *Varshavskii* and *Vorontsova*'s stochastic automata [12.6] were the major initial motivators of further studies in this area. Following them, several theoretical and experimental studies have been conducted by several researchers: Narendra, Thathachar, Lakshmivarahan, Obaidat, Najim, Poznyak, Baba, Mason, Papadimitriou, and Oommen, to mention a few. A comprehensive overview of research in the field of LA can be found in the classic text by *Narendra* and *Thathachar* [12.3], and in the recent special issue of *IEEE Transactions* [12.7].

It should be noted that none of the work described in this chapter is original. Most of the discussions, terminologies, and all the algorithms that are explained in this chapter are taken from the corresponding existing pieces of literature. Thus, the notation and terminology can be considered to be *off the shelf*, and fairly standard.

With regard to applications, the entire field of LA and stochastic learning, has had a myriad of applications [12.3, 8–11], which (apart from the many applications listed in these books) include solutions for problems in network and communications [12.12–15], network call admission, traffic control, quality-of-service routing, [12.16–18], distributed scheduling [12.19], training hidden Markov models [12.20], neural network adaptation [12.21], intelligent vehicle control [12.22], and even fairly theoretical problems such as graph partitioning [12.23].

We conclude this introductory section by emphasizing that this brief chapter should not be considered a comprehensive survey of the field of LA. In particular, we have not addressed the concept of LA which possess an infinite number of actions [12.24], systems which deal with *teachers* and *liars* [12.25], nor with any of the myriad issues that arise when we deal with networks of LA [12.11]. Also, the reader should not expect a mathematically deep exegesis of the field. Due to space limitations, the results available are merely cited. Additionally, while the results that are reported in the acclaimed books are merely alluded to, we give special attention to the more recent results – namely those which pertain to the discretized, pursuit, and estimator algorithms. Finally, we mention that the bibliography cited here is by no means comprehensive. It is brief and is intended to serve as a pointer to the representative papers in the theory and applications of LA.

12.2 A Learning Automaton

In the field of automata theory, an automaton can be defined as a quintuple consisting of a set of states, a set of outputs or actions, an input, a function that maps the current state and input to the next state, and a function that maps a current state (and input) into the current output [12.3, 8–11].

Definition 12.1

A LA is defined by a quintuple $\langle A, B, Q, F(\cdot,\cdot), G(\cdot)\rangle$, where:

(i) $A = \{\alpha_1, \alpha_2, \dots, \alpha_r\}$ is the set of outputs or actions, and $\alpha(t)$ is the action chosen by the automaton at any instant t.

(ii) $B = \{\beta_1, \beta_2, \dots, \beta_m\}$ is the set of inputs to the automaton. $\beta(t)$ is the input at any instant t. The set B can be finite or infinite. In this chapter, we consider the case when $m = 2$, i. e., when $B = \{0, 1\}$, where $\beta = 0$ represents the event that the LA has been rewarded, and $\beta = 1$ represents the event that the LA has been penalized.

(iii) $Q = \{q_1, q_2, \dots, q_s\}$ is the set of finite states, where $q(t)$ denotes the state of the automaton at any instant t.

(iv) $F(\cdot,\cdot) : Q \times B \to Q$ is a mapping in terms of the state and input at the instant t, such that, $q(t+1) = F(q(t), \beta(t))$. It is called a *transition function*, i. e., a function that determines the state of the automaton at any subsequent time instant $t+1$. This mapping can either be deterministic or stochastic.

(v) $G(\cdot)$ is a mapping $G : Q \to A$, and is called the *output function*. Depending on the state at a particular instant, this function determines the output of the automaton at the same instant as $\alpha(t) = G(q(t))$. This mapping can, again, be either deterministic or stochastic. Without loss of generality, G is deterministic.

If the sets Q, B, and A are all finite, the automaton is said be *finite*.

12.3 Environment

The environment E typically refers to the medium in which the automaton functions. The environment possesses all the external factors that affect the actions of the automaton. Mathematically, an environment can be abstracted by a triple $\langle A, C, B\rangle$. A, C, and B are defined as:

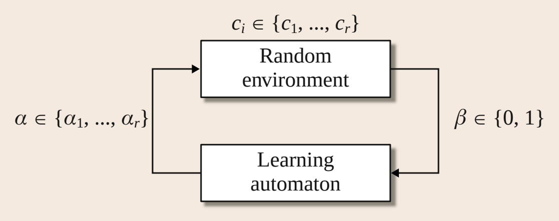
(i) $A = \{\alpha_1, \alpha_2, \dots, \alpha_r\}$ is the set of actions.

(ii) $B = \{\beta_1, \beta_2, \dots, \beta_m\}$ is the output set of the environment. Again, we consider the case when $m = 2$, i. e., with $\beta = 0$ representing a *reward*, and $\beta = 1$ representing a *penalty*.

(iii) $C = \{c_1, c_2, \dots, c_r\}$ is a set of penalty probabilities, where element $c_i \in C$ corresponds to an input action α_i.

The process of learning is based on a learning loop involving the two entities: the random environment (RE), and the LA, as illustrated in Fig. 12.1. In the process of learning, the LA continuously interacts with the environment to process responses to its various actions (i. e., its choices). Finally, through sufficient interactions, the LA attempts to learn the optimal action offered by the RE. The actual process of learning is represented as a set of interactions between the RE and the LA.

The RE offers the automaton with a set of possible actions $\{\alpha_1, \alpha_2, \dots, \alpha_r\}$ to choose from. The automaton chooses one of those actions, say α_i, which serves as an input to the RE. Since the RE is *aware* of the underlying penalty probability distribution of the system, depending on the *penalty probability* c_i corresponding to α_i, it *prompts* the LA with a reward (typically denoted by the value 0), or a *penalty* (typically denoted by the value 1). The reward/penalty information (corresponding to the action) provided to the LA helps it to choose the subsequent action. By repeating the above



$c_i \in \{c_1, ..., c_r\}$
Random environment
$\alpha \in \{\alpha_1, ..., \alpha_r\}$
$\beta \in \{0, 1\}$
Learning automaton

Fig. 12.1 The automaton–environment feedback loop

process, through a series of environment–automaton interactions, the LA finally attempts to learn the *optimal* action from the environment.

We now provide a few important definitions used in the field. $\boldsymbol{P}(t)$ is referred to as the action probability vector, where, $\boldsymbol{P}(t) = [p_1(t), p_2(t), \ldots, p_r(t)]^\top$, in which each element of the vector

$$p_i(t) = \Pr[\alpha(t) = \alpha_i] , \quad i = 1, \ldots, r , \tag{12.1}$$

such that

$$\sum_{i=1}^{r} p_i(t) = 1 \quad \forall t .$$

Given an action probability vector, $\boldsymbol{P}(t)$ at time t, the *average penalty* is

$$\begin{aligned} M(t) &= E[\beta(t)|\boldsymbol{P}(t)] = \Pr[\beta(t) = 1|\boldsymbol{P}(t)] \\ &= \sum_{i=1}^{r} \Pr[\beta(t) = 1|\alpha(t) = \alpha_i]\Pr[\alpha(t) = \alpha_i] \\ &= \sum_{i=1}^{r} c_i p_i(t) . \end{aligned} \tag{12.2}$$

The average penalty for the *pure-chance* automaton is given by

$$M_0 = \frac{1}{r} \sum_{i=1}^{r} c_i . \tag{12.3}$$

As $t \to \infty$, if the average penalty $M(t) < M_0$, at least asymptotically, the automaton is generally considered to be better than the pure-chance automaton. $E[M(t)]$ is given by

$$E[M(t)] = E\{E[\beta(t)|\boldsymbol{P}(t)]\} = E[\beta(t)] . \tag{12.4}$$

A LA that performs better than by pure chance is said to be *expedient*.

Definition 12.2
A LA is considered *expedient* if

$$\lim_{t\to\infty} E[M(t)] < M_0 .$$

Definition 12.3
A LA is said to be *absolutely expedient* if $E[M(t+1)|\boldsymbol{P}(t)] < M(t)$, implying that $E[M(t+1)] < E[M(t)]$.

Definition 12.4
A LA is considered *optimal* if $\lim_{t\to\infty} E[M(t)] = c_l$, where $c_l = \min_i\{c_i\}$.

Definition 12.5
A LA is considered ϵ-*optimal* if

$$\lim_{n\to\infty} E[M(t)] < c_l + \epsilon , \tag{12.5}$$

where $\epsilon > 0$, and can be arbitrarily small, by a suitable choice of some parameter of the LA.

It should be noted that no optimal LA exist. Marginally suboptimal performance, also termed above ϵ-optimal performance, is what LA researchers attempt to attain.

12.4 Classification of Learning Automata

12.4.1 Deterministic Learning Automata

An automaton is termed a *deterministic automaton*, if both the transition function $F(\cdot,\cdot)$ and the output function $G(\cdot)$ defined in Sect. 12.2 are deterministic. Thus, in a deterministic automaton, the subsequent state and action can be uniquely specified, provided that the present state and input are given.

12.4.2 Stochastic Learning Automata

If, however, either the transition function $F(\cdot,\cdot)$ or the output function $G(\cdot)$ are stochastic, the automaton is termed a *stochastic automaton*. In such an automaton, if the current state and input are specified, the subsequent states and actions cannot be specified uniquely. In such a case, $F(\cdot,\cdot)$ only provides the probabilities of reaching the various states from a given state. Let $\mathbf{F}^{\beta_1}, \mathbf{F}^{\beta_2}, \ldots, \mathbf{F}^{\beta_m}$ denote the conditional probability matrices, where each of these conditional matrices $\mathbf{F}^{\beta}$ (for $\beta \in B$) is a $s \times s$ matrix, whose arbitrary element f_{ij}^{β} is

$$\begin{aligned} &f_{ij}^{\beta} = \Pr[q(t+1) = q_j|q(t) = q_i, \beta(t) = \beta] , \\ &i, j = 1, 2, \ldots, s . \end{aligned} \tag{12.6}$$

In (12.6), each element f_{ij}^{β} of the matrix $\mathbf{F}^{\beta}$ represents the probability of the automaton moving from state q_i to the state q_j on receiving an input signal β from the RE. $\mathbf{F}^{\beta}$ is a Markov matrix, and hence

$$\sum_{j=1}^{s} f_{ij}^{\beta} = 1\,, \quad \text{where } \beta \in B;\, i = 1, 2, \ldots, s\,. \tag{12.7}$$

Similarly, in a stochastic automaton, if $G(\cdot)$ is stochastic, we have

$$g_{ij} = \Pr\{\alpha(t) = \alpha_j | q(t) = q_i\}\,, \quad i, j = 1, 2, \ldots, s\,, \tag{12.8}$$

where g_{ij} represents the elements of the conditional probability matrix of dimension $s \times r$. Intuitively, g_{ij} denotes the probability that, when the automaton is in state q_i, it chooses the action α_j. As in (12.7), we have

$$\sum_{j=1}^{r} g_{ij} = 1\,, \quad \text{for each row } i = 1, 2, \ldots, s\,. \tag{12.9}$$

Fixed Structure Learning Automata

In a stochastic LA, if the conditional probabilities f_{ij}^{β} and g_{ij} are constant, i. e., they do not vary with the time step t and the input sequence, the automaton is termed a *fixed structure stochastic automaton* (FSSA). The popular examples of these types of automata were proposed by *Tsetlin* [12.1, 2], *Krylov* [12.26], and *Krinsky* [12.27] – all of which are ϵ-optimal. Their details can be found in [12.3].

Variable Structure Learning Automata

Unlike the FSSA, *variable structure stochastic automata* (VSSA) are those in which the state transition probabilities are not fixed. In such automata, the state transitions or the action probabilities themselves are updated at every time instant using a suitable scheme. The transition probabilities f_{ij}^{β} and the output function g_{ij} vary with time, and the action probabilities are updated on the basis of the input. These automata are discussed here in the context of linear schemes, but the concepts discussed below can be extended to nonlinear updating schemes as well. The types of automata that update transition probabilities with time were introduced in 1963 by *Varshavskii* and *Vorontsova* [12.6]. A VSSA depends on a random-number generator for its implementation. The action chosen is dependent on the action probability distribution vector, which is, in turn, updated based on the reward/penalty input that the automaton receives from the RE.

Definition 12.6
A VSSA is a quintuple $\langle Q, A, B, T\rangle$, where Q represents the different states of the automaton, A is the set of actions, B is the set of responses from the environment to the LA, G is the output function, and T is the action probability updating scheme $T : [0,1]^r \times A \times B \mapsto [0,1]^r$, such that

$$\boldsymbol{P}(t+1) = T[\boldsymbol{P}(t), \alpha(t), \beta(t)]\,, \tag{12.10}$$

where $\boldsymbol{P}(t)$ is the action probability vector.

Normally, VSSA involve the updating of both the state and action probabilities. For the sake of simplicity, in practice, it is assumed that in such automata, each state corresponds to a distinct action, in which case the action transition mapping G becomes the identity mapping, and the number of states, s, is equal to the number of actions, r $(s = r < \infty)$.

VSSA can be analyzed using a discrete-time Markov process, defined on a suitable set of states. If a probability updating scheme T is time invariant, $\{\boldsymbol{P}(t)\}_{t\geq 0}$ is a discrete-homogenous Markov process, and the probability vector at the current time instant $\boldsymbol{P}(t)$ (along with $\alpha(t)$ and $\beta(t)$) completely determines $\boldsymbol{P}(t+1)$. Hence, each distinct updating scheme, T, identifies a different type of learning algorithm, as follows:

- *Absorbing algorithms* are those in which the updating scheme, T, is chosen in such a manner that the Markov process has absorbing states;
- *Nonabsorbing algorithms* are those in which the Markov process has no absorbing states;
- *Linear algorithms* are those in which $\boldsymbol{P}(t+1)$ is a linear function of $\boldsymbol{P}(t)$;
- *Nonlinear algorithms* are those in which $\boldsymbol{P}(t+1)$ is a nonlinear function of $\boldsymbol{P}(t)$.

In a VSSA, if a chosen action α_i is rewarded, the probability for the current action is increased, and the probabilities for all other actions are decreased. On the other hand, if the chosen action α_i is penalized, the probability of the current action is decreased, whereas the probabilities for the rest of the actions could, typically, be increased. This leads to the following different types of learning schemes for VSSA:

- **Reward–penalty (RP):** In both cases, i. e., when the automaton is rewarded as well as penalized, the action probabilities are updated;
- **Inaction–penalty (IP):** When the automaton is penalized the action probability vector is updated, whereas when the automaton is rewarded the action probabilities are neither increased nor decreased;
- **Reward–inaction (RI):** The action probability vector is updated whenever the automaton is rewarded, and is unchanged whenever the automaton is penalized.

A LA is considered to be a *continuous automaton* if the probability updating scheme T is continuous, i. e., the probability of choosing an action can be any real number in the closed interval [0, 1].

In a VSSA, if there are r actions operating in a stationary environment with $\beta = \{0, 1\}$, a general action probability updating scheme for a continuous automaton is described below. We assume that the action α_i is chosen, and thus, $\alpha(t) = \alpha_i$. The updated action probabilities can be specified as

$$\begin{aligned}&\text{for } \beta(t) = 0\,, \forall j \neq i\,, \quad p_j(t+1) = p_j(t) - g_j[\boldsymbol{P}(t)]\,,\\&\text{for } \beta(t) = 1\,, \forall j \neq i\,, \quad p_j(t+1) = p_j(t) + h_j[\boldsymbol{P}(t)]\,.\end{aligned} \tag{12.11}$$

Since $\boldsymbol{P}(t)$ is a probability vector, $\sum_{j=1}^{r} p_j(t) = 1$. Therefore,

$$\begin{aligned}&\text{when } \beta(t) = 0\,,\\&p_i(t+1) = p_i(t) + \sum_{j=1,\, j\neq i}^{r} g_j[\boldsymbol{P}(t)]\,,\\&\text{and when } \beta(t) = 1\,,\\&p_i(t+1) = p_i(t) - \sum_{j=1,\, j\neq i}^{r} h_j[\boldsymbol{P}(t)]\,.\end{aligned} \tag{12.12}$$

The functions h_j and g_j are *nonnegative* and *continuous* in [0, 1], and obey

$$\begin{aligned}&\forall i = 1, 2, \ldots, r\,, \forall P \in (0, 1)^R\,,\\&0 < g_j(P) < p_j\,, \quad \text{and}\\&0 < \sum_{j=1,\, j\neq i}^{r} [p_j + h_j(P)] < 1\,.\end{aligned} \tag{12.13}$$

For *continuous linear* VSSA, the following four learning schemes are extensively studied in the literature. They are explained for the two-action case; their extension to the r-action case, where $r > 2$, is straightforward and can be found in [12.3]. The four learning schemes are:

- The linear reward–inaction scheme (L_{RI})
- The linear inaction–penalty scheme (L_{IP})
- The symmetric linear reward–penalty scheme (L_{RP})
- The linear reward–ϵ-penalty scheme ($L_{\text{R}-\epsilon\text{P}}$).

For a two-action LA, let

$$\begin{aligned}&g_i[\boldsymbol{P}(t)] = a p_j(t) \quad \text{and}\\&h_j[\boldsymbol{P}(t)] = b(1 - p_j(t))\,.\end{aligned} \tag{12.14}$$

In (12.14), a and b are called the reward and penalty parameters, and they obey the following inequalities: $0 < a < 1$, $0 \leq b < 1$. Equation (12.14) will be used further to develop the action probability updating equations. The above-mentioned linear schemes are quite popular in LA because of their analytical tractability. They exhibit significantly different characteristics, as can be seen in Table 12.1.

The L_{RI} scheme was first introduced by *Norman* [12.28], and then studied by *Shapiro* and *Narendra* [12.29]. It is based on the principle that, whenever the automaton receives a favorable response (i. e., reward) from the environment, the action probabilities are

Table 12.1 Properties of the continuous learning schemes

Learning scheme	Learning parameters	Usefulness (good/bad)	Optimality	Ergodic/absorbing (when useful)
L_{RI}	$a > 0$, $b = 0$	Good	ϵ-optimal as $a \to 0$	Absorbing (stationary E)
L_{IP}	$a = 0$, $b > 0$	Very bad	Not even expedient	Ergodic (nonstationary E)
L_{RP} (symmetric)	$a = b$, $a, b > 0$	Bad	Never ϵ-optimal	Ergodic (nonstationary E)
$L_{\text{R}-\epsilon\text{P}}$	$a > 0$, $b \ll a$	Good	ϵ-optimal as $a \to 0$	Ergodic (nonstationary E)

updated in a *linear* manner, whereas if the automaton receives an unfavorable response (i. e., penalty) from the environment, they are unaltered.

The probability updating equations for this scheme can be simplified to

$$\begin{aligned}
&p_1(t+1) = p_1(t) + a[1-p_1(t)]\,,\\
&\quad \text{if } \alpha(t) = \alpha_1\,,\ \text{and } \beta(t) = 0\,,\\
&p_1(t+1) = (1-a)p_1(t)\,,\\
&\quad \text{if } \alpha(t) = \alpha_2\,,\ \text{and } \beta(t) = 0\,,\\
&p_1(t+1) = p_1(t)\,,\\
&\quad \text{if } \alpha(t) = \alpha_1 \text{ or } \alpha_2\,,\ \text{and } \beta(t) = 1\,.
\end{aligned} \tag{12.15}$$

We see that, if action α_i is chosen, and a reward is received, the probability $p_i(t)$ is increased, and the other probability $p_j(t)$ (i. e., $j \neq i$) is decreased. If either α_1 or α_2 is chosen, and a penalty is received, $\boldsymbol{P}(t)$ is unaltered.

Equation (12.15) shows that the L_{RI} scheme has the vectors $[1, 0]^\top$ and $[0, 1]^\top$ as two absorbing states. Indeed, with probability 1, it gets absorbed into one of these absorbing states. Therefore, the convergence of the L_{RI} scheme is dependent on the nature of the initial conditions and probabilities. The scheme is not suitable for nonstationary environments. On the other hand, for stationary random environments, the L_{RI} scheme is both absolutely expedient, and ϵ-optimal [12.3].

The L_{IP} and L_{RP} schemes are devised similarly, and are omitted from further discussions. They, and their respective analysis, can be found in [12.3].

The so-called symmetry conditions for the functions $g(\cdot)$ and $h(\cdot)$ to lead to absolutely expedient LA are also derived in [12.3, 8].

Discretized Learning Automata

The VSSA algorithms presented in Sect. 12.4.2 are *continuous*, i. e., the action probabilities can assume any real value in the interval [0, 1]. In LA, the choice of an action is determined by a random-number generator (RNG). In order to increase the speed of convergence of these automata, *Thathachar* and *Oommen* [12.30] introduced the *discretized* algorithms for VSSA, in which they suggested the discretization of the probability space. The different properties (absorbing and ergodic) of these learning automata, and the updating schemes of action probabilities for these discretized automata (like their continuous counterparts), were later studied in detail by *Oommen* et al. [12.31–34].

Discretized automata can be perceived to be somewhat like a hybrid combination of FSSA and VSSA. Discretization is conceptualized by restricting the probability of choosing the actions to only a fixed number of values in the closed interval [0, 1]. Thus, the updating of the action probabilities is achieved in steps rather than in a continuous manner as in the case of continuous VSSA. Evidently, like FSSA, they possess finite sets, but because they have action probability vectors which are random vectors, they behave like VSSA.

Discretized LA can also be of two types:

(i) *Linear* – in which case the action probability values are uniformly spaced in the closed interval [0, 1]
(ii) *Nonlinear* – in which case the probability values are unequally spaced in the interval [0, 1] [12.30, 32–34].

Perhaps the greatest motivation behind discretization is overcoming the persistent limitation of con-

Table 12.2 Properties of the discretized learning schemes

Learning scheme	Learning parameters	Usefulness (good/bad)	Optimality (as $N \to \infty$)	Ergodic/absorbing (when useful)
DL_{RI}	$N > 0$	Good	ϵ-optimal	Absorbing (stationary E)
DL_{IP}	$N > 0$	Very bad	Expedient	Ergodic (nonstationary E)
ADL_{IP}	$N > 0$	Good, sluggish	ϵ-optimal	Artificially absorbing (stationary environments)
DL_{RP}	$N > 0$	Reasonable	ϵ-optimal if $c_{\min} < 0.5$	Ergodic (nonstationary E)
ADL_{RP}	$N > 0$	Good	ϵ-optimal	Artificially absorbing (stationary E)
MDL_{RP}	$N > 0$	Good	ϵ-optimal	Ergodic (nonstationary E)

Part B | 12.4

tinuous learning automata, i. e., the slow rate of convergence. This is achieved by narrowing the underlying assumptions of the automata. Originally, the assumption was that the RNGs could generate real values with arbitrary precision. In the case of discretized LA, if an action probability is reasonably close to unity, the probability of choosing that action increases to unity (when the conditions are appropriate) directly, rather than asymptotically [12.30–34].

The second important advantage of discretization is that it is more practical in the sense that the RNGs used by continuous VSSA can only *theoretically* be assumed to adopt *any* value in the interval [0, 1], whereas almost all machine implementations of RNGs use pseudo-RNGs. In other words, the set of possible random values is not infinite in [0, 1], but finite.

Last, but not the least, discretization is also important in terms of implementation and representation. Discretized implementations of automata use integers for tracking the number of multiples of $1/N$ of the action probabilities, where N is the so-called *resolution* parameter. This not only increases the rate of convergence of the algorithm, but also reduces the time, in terms of the clock cycles it takes for the processor to do each iteration of the task, and the memory needed. Discretized algorithms have been proven to be both more time and space efficient than the continuous algorithms.

Similar to the continuous LA paradigm, the discretized versions, the DL_{RI}, DL_{IP}, and DL_{RP} automata, have also been reported. Their design, analysis, and properties are given in [12.30, 32–34], and are summarized in Table 12.2.

12.5 Estimator Algorithms

12.5.1 Rationale and Motivation

As we have seen so far, the rate of convergence of learning algorithms is one of the most important considerations, which was the primary reason for designing the family of *discretized* algorithms. With the same goal *Thathachar* and *Sastry* designed a new-class of algorithms, called the *estimator algorithms* [12.35–38], which have faster rate of convergence than all the previous families. These algorithms, like the previous ones, maintain and update an action probability vector. However, unlike the previous ones, these algorithms also keep running estimates for each action that is rewarded, using a *reward–estimate vector*, and then use those estimates in the probability updating equations. The reward estimates vector is, typically, denoted in the literature by $\hat{\boldsymbol{D}}(t) = [\hat{d}_1(t), \ldots, \hat{d}_r(t)]^\top$. The corresponding state vector is denoted by $Q(t) = \langle \boldsymbol{P}(t), \hat{\boldsymbol{D}}(t)\rangle$.

In a random environment, these algorithms help in choosing an action by increasing the confidence in the reward capabilities of the different actions; for example, these algorithms initially process each action a number of times, and then (in one version) could increase the probability of the action with the highest reward estimate [12.39]. This leads to a scheme with better accuracy in choosing the correct action. The previous nonestimator VSSA algorithms update the probability vector directly on the basis of the response of the environment to the automaton, where, depending on the type of vector updating scheme being used, the probability of choosing a rewarded action in the subsequent time instant is increased, and the probabilities of choosing the other actions could be decreased. However, estimator algorithms update the probability vector based on both the estimate vector and the current feedback provided by the environment to the automaton. The environment influences the probability vector both directly and indirectly, the latter being as a result of the estimation of the reward estimates of the different actions. This may, thus, lead to increases in action probabilities different from the currently rewarded action.

Even though there is an added computational cost involved in maintaining the reward estimates, these estimator algorithms have an order of magnitude superior performance than the nonestimator algorithms previously introduced. *Lanctôt* and *Oommen* [12.31] further introduced the discretized versions of these estimator algorithms, which were proven to have an even faster rate of convergence.

12.5.2 Continuous Estimator Algorithms

Thathachar and *Sastry* introduced the class of continuous estimator algorithms [12.35–38] in which the probability updating scheme T is continuous, i. e., the probability of choosing an action can be any real number in the closed interval [0, 1]. As mentioned subsequently, the discretized versions of these algorithms were introduced by *Oommen* and his co-authors, *Lanc-*

tôt and *Agache* [12.31, 40]. These algorithms are briefly explained in Sect. 12.5.3.

Pursuit Algorithm

The family of pursuit algorithms is a class of estimator algorithms that *pursue* an action that the automaton *currently* perceives to be the optimal one. The first pursuit algorithm, called the CP_{RP} algorithm, introduced by *Thathachar* and *Sastry* [12.36, 41], pursues the optimal action by changing the probability of the current optimal action whether it receives a reward or a penalty by the environment. In this case, the *currently perceived best action* is rewarded, and *its* action probability value is increased with a value directly proportional to its distance to unity, namely $1 - p_m(t)$, whereas the *less optimal actions* are penalized, and their probabilities decreased proportionally.

To start with, based on the probability distribution $\boldsymbol{P}(t)$, the algorithm chooses an action $\alpha(t)$. Whether the response was a reward or a penalty, it increases that component of $\boldsymbol{P}(t)$ which has the maximal current reward estimate, and it decreases the probability corresponding to the rest of the actions. Finally, the algorithm updates the running estimates of the reward probability of the action chosen, this being the principal idea behind keeping, and using, the running estimates. The estimate vector $\hat{\boldsymbol{D}}(t)$ can be computed using the following formula which yields the maximum-likelihood estimate

$$\hat{d}_i(t) = \frac{W_i(t)}{Z_i(t)}\ , \qquad \forall i = 1, 2, \dots, r\ , \tag{12.16}$$

where $W_i(t)$ is the number of times the action α_i has been rewarded until the current time t, and $Z_i(t)$ is the number of times α_i has been chosen until the current time t. Based on the above concepts, the CP_{RP} algorithm is formally given in [12.31, 39, 40].

The algorithm is similar in principle to the L_{RP} algorithm, because both the CP_{RP} and the L_{RP} algorithms increase/decrease the action probabilities of the vector, independent of whether the environment responds to the automaton with a reward or a penalty. The major difference lies in the way the reward estimates are maintained, used, and are updated on both reward/penalty. It should be emphasized that, whereas the nonpursuit algorithm moves the probability vector in the direction of the most recently rewarded action, the pursuit algorithm moves the probability vector in the direction of the action with the highest reward estimate. *Thathachar* and *Sastry* [12.41] have theoretically proven their ϵ-optimality, and experimentally proven that these pursuit algorithms are more accurate, and several orders of magnitude faster than the nonpursuit algorithms.

The reward–inaction version of this pursuit algorithm is also similar in design, and is described in [12.31, 40]. Other pursuit-like estimator schemes have also been devised and can be found in [12.40].

TSE Algorithm

A more advanced estimator algorithm, which we refer to as the TSE algorithm to maintain consistency with the existing literature [12.31, 39, 40], was designed by *Thathachar* and *Sastry* [12.37, 38].

Like the other estimator algorithms, the TSE algorithm maintains the running reward estimates vector $\hat{\boldsymbol{D}}(t)$ and uses it to calculate the action probability vector $\boldsymbol{P}(t)$. When an action $\alpha_i(t)$ is rewarded, according to the TSE algorithm, the probability components with a reward estimate greater than $\hat{d}_i(t)$ are treated differently from those components with a value lower than $\hat{d}_i(t)$. The algorithm does so by increasing the probabilities for all the actions that have a higher estimate than the estimate of the chosen action, and decreasing the probabilities of all the actions with a lower estimate. This is done with the help of an indicator function $S_{ij}(t)$ which assumes the value 1 if $\hat{d}_i(t) > \hat{d}_j(t)$ and the value 0 if $\hat{d}_i(t) \leq \hat{d}_j(t)$. Thus, the TSE algorithm uses both the probability vector $\boldsymbol{P}(t)$ and the reward estimates vector $\hat{\boldsymbol{D}}(t)$ to update the action probabilities. The algorithm is formally described in [12.39]. On careful inspection of the algorithm, it can be observed that $\boldsymbol{P}(t+1)$ depends indirectly on the response of the environment to the automaton. The feedback from the environment changes the values of the components of $\hat{\boldsymbol{D}}(t)$, which, in turn, affects the values of the functions $f(\cdot)$ and $S_{ij}(t)$ [12.31, 37–39].

Analyzing the algorithm carefully, we obtain three cases. If the i-th action is rewarded, the probability values of the actions with reward estimates higher than the reward estimate of the currently selected action are updated using [12.37]

$$\begin{aligned} &p_j(t+1) \\ &= p_j(t) - \lambda \left\{ f\left[\hat{d}_i(t) - \hat{d}_j(t)\right] \frac{[p_i(t) - p_j(t)p_i(t)]}{r-1} \right\}\ ; \end{aligned} \tag{12.17}$$

when $\hat{d}_i(t) < \hat{d}_j(t)$, since the function $f\left[\hat{d}_i(t) - \hat{d}_j(t)\right]$ is monotonic and increasing, $f\left[\hat{d}_i(t) - \hat{d}_j(t)\right]$ is seen to be negative. This leads to a higher value of $p_j(t+1)$ than that of $p_j(t)$, which indicates that the probability of choosing actions that have estimates greater than that of the estimates of the currently chosen action will increase.

For all the actions with reward estimates smaller than the estimate of the currently selected action, the probabilities are updated based on

$$p_j(t+1) = p_j(t) - \lambda f\left[\hat{d}_i(t) - \hat{d}_j(t)\right] p_j(t)\,. \tag{12.18}$$

The sign of the function $f\left[\hat{d}_i(t) - \hat{d}_j(t)\right]$ is negative, which indicates that the probability of choosing actions that have estimates less than that of the estimate of the currently chosen action will decrease.

Thathachar and *Sastry* have proven that the TSE algorithm is ϵ-optimal [12.37]. They have also experimentally shown that the TSE algorithm often converges several orders of magnitude faster than the L_{RI} scheme.

Generalized Pursuit Algorithm

Agache and *Oommen* [12.40] proposed a generalized version of the pursuit algorithm ($\mathrm{CP}_{\mathrm{RP}}$) proposed by *Thathachar* and *Sastry* [12.36, 41]. Their algorithm, called the *generalized pursuit algorithm* (GPA), generalizes Thathachar and Sastry's pursuit algorithm by pursuing all those actions that possess higher reward estimates than the chosen action. In this way the probability of choosing a wrong action is minimized. *Agache* and *Oommen* experimentally compared their pursuit algorithm with the existing algorithms, and found that their algorithm is the best in terms of the rate of convergence [12.40].

In the $\mathrm{CP}_{\mathrm{RP}}$ algorithm, the probability of the best estimated action is maximized by first decreasing the probability of all the actions in the following manner [12.40]

$$p_j(t+1) = (1-\lambda)p_j(t)\,, \qquad j = 1, 2, \ldots, r\,. \tag{12.19}$$

The sum of the action probabilities is made unity by the help of the probability mass Δ, which is given by [12.40]

$$\begin{aligned}\Delta &= 1 - \sum_{j=1}^{r} p_j(t+1) = 1 - \sum_{j=1}^{r}(1-\lambda)p_j(t)\\ &= 1 - \sum_{j=1}^{r} p_j(t) + \lambda \sum_{j=1}^{r} p_j(t) = \lambda\,.\end{aligned} \tag{12.20}$$

Thereafter, the probability mass Δ is added to the probability of the best estimated action. The GPA algorithm, thus, equidistributes the probability mass Δ to the action estimated to be superior to the chosen action. This gives us [12.40]

$$p_m(t+1) = (1-\lambda)p_m(t) + \Delta = (1-\lambda)p_m(t) + \lambda\,, \tag{12.21}$$

where $\hat{d}_m = \max_{j=1,2,\ldots,r}\left[\hat{d}_j(t)\right]$. Thus, the updating scheme is given by [12.40]

$$\begin{aligned}&p_j(t+1) = (1-\lambda)p_j(t) + \frac{\lambda}{K(t)}\,,\\ &\quad \text{if } \hat{d}_j(t) > \hat{d}_i(t)\,,\ j \neq i\,,\\ &p_j(t+1) = (1-\lambda)p_j(t)\,,\\ &\quad \text{if } \hat{d}_j(t) \leq \hat{d}_i(t)\,,\ j \neq i\,,\\ &p_i(t+1) = 1 - \sum_{j \neq i} p_j(t+1)\,,\end{aligned} \tag{12.22}$$

where $K(t)$ denotes the number of actions that have estimates greater than the estimate of the reward probability of the action currently chosen. The formal algorithm is omitted, but can be found in [12.40].

12.5.3 Discrete Estimator Algorithms

As we have seen so far, discretized LA are superior to their continuous counterparts, and the estimator algorithms are superior to the nonestimator algorithms in terms of the rate of convergence of the learning algorithms. Utilizing the previously proven capabilities of discretization in improving the speed of convergence of the learning algorithms, *Lanctôt* and *Oommen* [12.31] enhanced the pursuit and the TSE algorithms. This led to the designing of classes of learning algorithms, referred to in the literature as the *discrete estimator algorithms* (DEA) [12.31]. To this end, as done in the previous discrete algorithms, the components of the action probability vector are allowed to assume a finite set of discrete values in the closed interval [0, 1], which is, in turn, divided into a number of subintervals proportional to the resolution parameter N. Along with this, a reward estimate vector is maintained to keep an estimate of the reward probability of each action [12.31].

Lanctôt and *Oommen* showed that, for each member algorithm belonging to the class of DEAs to be ϵ-optimal, it must possess a pair of properties known as the *property of moderation* and the *monotone property*. Together these properties help prove the ϵ-optimality of any DEA algorithm [12.31].

Moderation Property

A DEA with r actions and a resolution parameter N is said to possess the *property of moderation* if the maximum magnitude by which an action probability can decrease per iteration is bounded by $1/(rN)$.

Monotone Property

Suppose there exists an index m and a time instant $t_0 < \infty$, such that $\hat{d}_m(t) > \hat{d}_j(t), \forall j$ s.t. $j \neq m$ and $\forall t$ s.t. $t \geq t_0$, where $\hat{d}_m(t)$ is the maximal component of $\hat{\boldsymbol{D}}(t)$. A DEA is said to possess the *monotone property* if there exists an integer N_0 such that, for all resolution parameters $N > N_0$, $p_m(t) \rightarrow 1$ with probability 1 as $t \rightarrow \infty$, where $p_m(t)$ is the maximal component of $\boldsymbol{P}(t)$.

The discretized versions of the pursuit algorithm, and the TSE algorithm possessing the moderation and monotone properties, are presented in the next section.

Discrete Pursuit Algorithm

The discrete pursuit algorithm (formally described in [12.31]), is referred to as the DPA in the literature, and is similar to a great extent to its continuous pursuit counterpart, i. e., the $\mathrm{CP}_{\mathrm{RI}}$ algorithm, except that the updates to the action probabilities for the DPA algorithm are made in discrete steps. Therefore, the equations in the $\mathrm{CP}_{\mathrm{RP}}$ algorithm that involve multiplication by the learning parameter λ are substituted by the addition or subtraction of quantities proportional to the smallest step size.

As in the $\mathrm{CP}_{\mathrm{RI}}$ algorithm, the DPA algorithm operates in three steps. If $\Delta = 1/(rN)$ (where N denotes the resolution, and r the number of actions) denotes the smallest step size, the integral multiples of Δ denote the step sizes in which the action probabilities are updated. Like the continuous reward–inaction algorithm, when the chosen action $\alpha(t) = \alpha_i$ is penalized, the action probabilities remain unchanged. However, when the chosen action $\alpha(t) = \alpha_i$ is rewarded, and the algorithm has not converged, the algorithm decreases, by the integral multiples of Δ, the action probabilities which do not correspond to the highest reward estimate.

Lanctôt and *Oommen* have shown that the DPA algorithm possesses the properties of moderation and monotonicity, and that it is thus ϵ-optimal [12.31]. They have also experimentally proved that, in different ranges of environments from simple to complex, the DPA algorithm is at least 60% faster than the $\mathrm{CP}_{\mathrm{RP}}$ algorithm [12.31].

Discrete TSE Algorithm

Lanctôt and *Oommen* also discretized the TSE algorithm, and have referred to it as the *discrete TSE algorithm* (DTSE) [12.31]. Since the algorithm is based on the continuous version of the TSE algorithm, it obviously has the same level of intricacy, if not more. Lanctôt and Oommen theoretically proved that, like the DPA estimator algorithm, this algorithm also possesses the *moderation* and the *monotone* properties, while maintaining many of the qualities of the continuous TSE algorithm. They also provided the proof of convergence of this algorithm.

There are two notable parameters in the DTSE algorithm:

1. $\Delta = 1/(rN\theta)$, where N is the resolution parameter as before
2. θ, an integer representing the largest value by which any of the action probabilities can change in a single iteration.

A formal description of the DTSE algorithm is omitted here, but can be found in [12.31].

Discretized Generalized Pursuit Algorithm

Agache and *Oommen* [12.40] provided a discretized version of their GPA algorithm presented earlier. Their algorithm, called the *discretized generalized pursuit algorithm* (DGPA), also essentially generalizes *Thathachar* and *Sastry*'s pursuit algorithm [12.36, 41]. However, unlike the TSE, it pursues all those actions that possess higher reward estimates than the chosen action.

In essence, in any single iteration, the algorithm computes the number of actions that have higher reward estimates than the current chosen action, denoted by $K(t)$, whence the probability of all the actions that have estimates higher than the chosen action is increased by an amount $\Delta/K(t)$, and the probabilities for all the other actions are decreased by an amount $\Delta/(r - K(t))$, where $\Delta = 1/(rN)$ denotes the resolution step, and N the resolution parameter. The DGPA algorithm has been proven to possess the *moderation* and *monotone* properties, and is thus ϵ-optimal [12.40]. The detailed steps of the DGPA algorithm are omitted here.

12.5.4 Stochastic Estimator Learning Algorithm (SELA)

The SELA algorithm belongs to the class of discretized LA, and was proposed by *Vasilakos* and *Papadimitriou* [12.42]. It has, since then, been used for solving problems in the domain of computer networks [12.18, 43]. It is an ergodic scheme, which has the ability to converge to the optimal action irrespective of the distribution of the initial state [12.18, 42].

As before, let $A = \{\alpha_1, \alpha_2, \ldots, \alpha_r\}$ denote the set of actions and $B = \{0, 1\}$ denote the set of responses that can be provided by the environment, where $\beta(t)$ represents the feedback provided by the environment corresponding to a chosen action $\alpha(t)$ at time t. Let the probability of choosing the k-th action at the t-th time instant be $p_k(t)$. SELA updates the estimated environmental characteristics as the vector $\boldsymbol{E}(t)$, which can be defined as $\boldsymbol{E}(t) = \langle D(t), M(t), U(t)\rangle$, explained below.

$\boldsymbol{D}(t) = \{d_1(t), d_2(t), \ldots, d_r(t)\}$ represents the vector of the reward estimates, where

$$d_k(t) = \sum_{i=1}^{W} \beta_k(t)\,. \tag{12.23}$$

In (12.23), the numerator on the right-hand side represents the total rewards received by the LA in the window size representing the last W times a particular action α_k was selected by the algorithm. W is called the *learning window*.

The second parameter in $\boldsymbol{E}(t)$ is called the *oldness vector*, and is represented as $\boldsymbol{M}(t) = \{m_1(t), m_2(t), \ldots, m_r(t)\}$, where $m_k(t)$ represents the time passed (counted as the number of iterations) since the last time the action $\alpha_k(t)$ was selected.

The last parameter $\boldsymbol{U}(t)$ is called the *stochastic estimator vector* and is represented as $\boldsymbol{U}(t) = \{u_1(t), u_2(t), \ldots, u_r(t)\}$, where the stochastic estimate $u_i(t)$ of action α_i is calculated using

$$u_i(t) = d_i(t) + N\left[0, {\sigma_i}^2(t)\right]\,, \tag{12.24}$$

where $N\left[0, {\sigma_i}^2(t)\right]$ represents a random number selected from a normal distribution that has a mean of 0 and a standard deviation of $\sigma_i(t) = \min\{\sigma_{\max}, a\, m_i(t)\}$, and a is a parameter signifying the rate at which the stochastic estimates become independent, and $\sigma_{\max}$ represents the maximum possible standard deviation that the stochastic estimates can have. In symmetrically distributed noisy stochastic environments, SELA is shown to be ϵ-optimal, and has found applications for routing in ATM networks [12.18, 43].

12.6 Experiments and Application Examples

All the continuous and the discretized versions of the estimator algorithms presented above were experimentally evaluated [12.31, 40]. *Lanctôt* and *Oommen* [12.31] compared the rates of convergence between the discretized and the continuous versions of the pursuit and the TSE estimator algorithms. In their experiments, they required that their algorithm achieve a level of accuracy of not making any errors in convergence in 100 experiments. To initialize the reward estimates vector, 20 iterations were performed for each action. The experimental results for the TSE algorithms are summarized in Table 12.3. The corresponding results of the pursuit algorithms are provided in Table 12.4 (the numbers indicate the number of iterations required to attain to convergence). The results show that the discretized TSE algorithm is faster (between 50–76%) than the continuous TSE algorithm. Similar observations were obtained for the pursuit algorithm. The discretized versions of the pursuit algorithms were found to be at least 60% faster than their continuous counterparts; for example, with $d_1 = 0.8$ and $d_2 = 0.6$, the continuous TSE algorithm required an average of 115 iterations to converge, whereas the discretized TSE took only 76. Another set of experimental

Table 12.3 The number of iterations until convergence in two-action environments for the TSE algorithms (after [12.31])

Probability of reward		Mean iterations	
Action 1	Action 2	Continuous	Discrete
0.800	0.200	28.8	24.0
0.800	0.400	37.0	29.0
0.800	0.600	115.0	76.0
0.800	0.700	400.0	380.0
0.800	0.750	2200.0	1200.0
0.800	0.775	8500.0	5600.0

Table 12.4 The number of iterations until convergence in two-action environments for the pursuit algorithms (after [12.31])

Probability of reward		Mean iterations	
Action 1	Action 2	Continuous	Discrete
0.800	0.200	22	22
0.800	0.400	22	39
0.800	0.600	148	125
0.800	0.700	636	357
0.800	0.750	2980	1290
0.800	0.775	6190	3300

Table 12.5 Comparison of the discrete and continuous estimator algorithms in a benchmark with ten-action environments (after [12.31])

Environment	Algorithm	Continuous	Discrete
E_{A}	Pursuit	1140	799
E_{A}	TSE	310	207
E_{B}	Pursuit	2570	1770
E_{B}	TSE	583	563

Table 12.6 Experimental comparison of the performance of the GPA and the DGPA algorithms in benchmark ten-action environments (after [12.40])

Environment	GPA		DGPA	
	λ	Number of iterations	N	Number of iterations
E_{A}	0.0127	948.03	24	633.64
E_{B}	0.0041	2759.02	52	1307.76

Note: The reward probabilities for the actions are:
E_{A} : 0.7 0.5 0.3 0.2 0.4 0.5 0.4 0.3 0.5 0.2
E_{B} : 0.1 0.45 0.84 0.76 0.2 0.4 0.6 0.7 0.5 0.3

comparisons was performed between all the estimator algorithms presented so far in several ten-action environments [12.31]. Their results [12.31] are summarized in Table 12.5, and show that the TSE algorithm is much faster than the pursuit algorithm. Whereas the continuous pursuit algorithm required 1140 iterations to converge, the TSE algorithm took only 310. The same observation applies to their discrete versions. Similarly, it was observed that the discrete estimator algorithms were much faster than the continuous estimator algorithms; for example, for environment E_{A}, while the continuous algorithm took 1140 iterations to converge, the discretized algorithm needed only 799 iterations. The GPA and the DGPA algorithms were compared for the benchmark ten-action environments. The results are summarized in Table 12.6. The DGPA algorithm was found to converge much faster than the GPA algorithm. This, once again, proves the superiority of the discretized algorithms over the continuous ones.

12.7 Emerging Trends and Open Challenges

Although the field of LA is relatively young, the *analytic* results that have been obtained are quite phenomenal. Simultaneously, however, it is also fair to assert that the tools available in the field have been far too underutilized in real-life problems.

We believe that the main areas of research that will emerge in the next few years will involve applying LA to a host of application domains. Here, as the saying goes, *the sky is the limit*, because LA can probably be used in *any* application where the parameters characterizing the underlying system are unknown and random. Some possible potential applications are listed below:

1. LA could be used in medicine to help with the diagnosis process.
2. LA have potential applications in intelligent tutorial (or tutorial-*like*) systems to assist in imparting imperfect knowledge to classrooms of students, where the teacher is also assumed to be imperfect. Some initial work is already available in this regard [12.44].
3. The use of LA in legal arguments and the associated decision-making processes is open.
4. Although LA have been used in some robotic applications, as far as we know, almost no work has been done for obstacle avoidance and intelligent path planning of real-life robots.
5. We are not aware of any results that use LA in the biomedical application domain. In particular, we believe that they can be fruitfully utilized for learning targets, and in the drug design phase.
6. One of the earliest applications of LA was in the routing of telephone calls over land lines, but the real-life application of LA in *wireless* and *multihop* networks is still relatively open.

We close this section by briefly mentioning that the main challenge in using LA for each of these application domains would be that of modeling what the *environment* and *automaton* are. Besides this, the practitioner would have to consider how the response of a particular solution can be interpreted as the reward/penalty for the automaton, or for the network of automata.

Part B | 12

12.8 Conclusions

In this chapter we have discussed most of the important learning mechanisms reported in the literature pertaining to learning automata (LA). After briefly stating the concepts of fixed structure stochastic LA, the families of continuous and discretized variable structure stochastic automata were discussed. The chapter, in particular, concentrated on the more recent results involving continuous and discretized pursuit and estimator algorithms. In each case we have briefly summarized the theoretical and experimental results of the different learning schemes.

13. Communication in Automation, Including Networking and Wireless

Nicholas Kottenstette, Panos J. Antsaklis

An introduction to the fundamental issues and limitations of communication and networking in automation is given. Digital communication fundamentals are reviewed and networked control systems together with teleoperation are discussed. Issues in both wired and wireless networks are presented.

13.1 Basic Considerations

13.1.1 Why Communication Is Necessary in Automated Systems

Automated systems use local control systems that utilize sensor information in feedback loops, process this information, and send it as control commands to actuators to be implemented. Such closed-loop feedback control is necessary because of the uncertainties in the knowledge of the process and in the environmental conditions. Feedback control systems rely heavily on the ability to receive sensor information and send commands using wired or wireless communications.

In automated systems there is control supervision, and also health and safety monitoring via supervisory control and data acquisition (SCADA) systems. Values of important quantities (which may be temperatures, pressures, voltages, etc.) are sensed and transmitted to monitoring stations in control rooms. After processing the information, decisions are made and supervisory commands are sent to change conditions such as set points or to engage emergency procedures. The data from sensors and set commands to actuators are sent via wired or wireless communication channels.

So, communication mechanisms are an integral part of any complex automated system.

13.1.2 Communication Modalities

In any system there are internal communication mechanisms that allow components to interact and exhibit a collective behavior, the system behavior; for example, in an electronic circuit, transistors, capacitors, resistances are connected so current can flow among them and the circuit can exhibit the behavior it was designed for. Such internal communication is an integral part of any system. At a higher level, subsystems that can each be quite complex interact via external communication links that may be wired or wireless. This is the case, for example, in antilock brake systems, vehicle stability systems, and engine and exhaust control systems in a car, or among unmanned aerial vehicles that communicate among themselves to coordinate their flight paths. Such external to subsystems communication is of prime interest in automated systems.

There are of course other types of communication, for example, machine to machine via mechanical links and human to machine, but here we will focus on electronic transmission of information and communication networks in automated systems.

Such systems are present in refineries, process plants, manufacturing, and automobiles, to mention but a few. Advances in computer and communication technologies coupled with lower costs are the main driving forces of communication methods in automated systems today. Digital communications, shared wired communication links, and wireless communications make up the communication networks in automated systems today.

In the following, after an introduction to digital communication fundamentals, the focus is on networked control systems that use shared communication links, which is common practice in automated systems.

13.2 Digital Communication Fundamentals

A digital communication system can generally be thought of as a system which allows either a continuous $x(t)$ or discrete random source of information to be transmitted through a channel to a given (set of) sink(s) (Fig. 13.1). The information that arrives at a given destination can be subject to delays, signal distortion, and noise. The digital communication channel typically is treated as a physical medium through which the information travels as an appropriately modulated analog signal, $s_{\mathrm{m}}(t)$, subject to linear distortion and additive (typically Gaussian) noise $n(t)$. As is done in [13.1] we choose to use the simplified single-channel network shown in Fig. 13.1 in which the source encoder/decoder and channel encoder/decoder are separate entities. The design of the source encoder/decoder can usually be performed independently of the design of the channel encoder/decoder. This is possible due to the *source-channel separation theorem* (*SCST*) stated by *Shannon* [13.2], which states that, as long as the *average* information rate of bit/s from the source encoder R_{s} is strictly below the channel capacity C, information can be reliably transmitted with an appropriately designed channel encoder. Conversely, if R_{s} is greater than or equal to C then it is impossible to send any information reliably. The interested reader should also see [13.3] for a more recent discussion as how the SCST relates to the single-channel case; [13.4] discusses the SCST as it applies to single-source broadcasting to many users, and [13.5] discusses how the SCST relates to many sources transmitting to one sink.

In Sect. 13.2.1 we will restate some of Shannon's key theorems as they relate to digital communication systems. With a clear understanding of the limitations and principles associated with digital communication systems we will address source encoder and decoder design in Sect. 13.2.2 and channel encoder and decoder design in the Appendix.

13.2.1 Entropy, Data Rates, and Channel Capacity

Entropy is a measure of uncertainty of a data source and is typically denoted by the symbol H. It can be seen as a measure of how many *bits* are required to describe

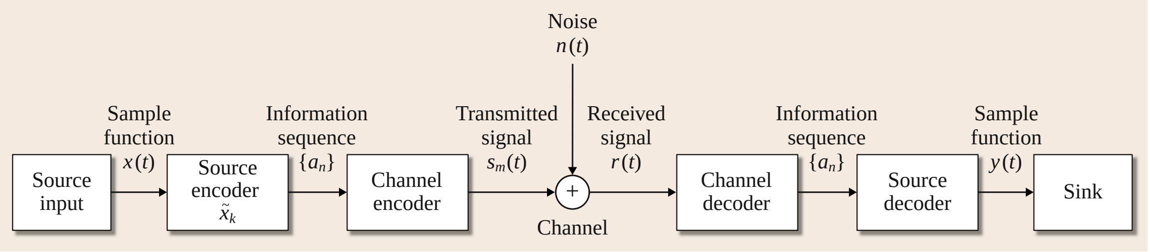

Fig. 13.1 Digital communication network with separate source and channel coding

a specific output *symbol* of the data source. Therefore, the natural unit of measure for entropy is bit/symbol and can also be used in terms of bit/s, depending on the context. Assuming that the source could have n outcomes in which each outcome has a probability p_i of occurrence the entropy has the form [13.2, Theorem 2]

$$H = -\sum_{i=1}^{n} p_i \log_2 p_i \,. \tag{13.1}$$

The entropy is greatest from a source where all symbols are equally likely; for example, given a 2 bit source in which each output symbol is {00, 01, 10, 11} with respective output probabilities $p_i = \left\{\frac{p_o}{3}, \frac{p_o}{3}, \frac{p_o}{3}, 1-p_o\right\}$, it will have the following entropy, which is maximized when all outcomes are equally likely

$$\begin{aligned} H &= -\frac{p_o}{3}\sum_{i=1}^{3}\log_2\frac{p_o}{3} - (1-p_o)\log_2(1-p_o) \\ &= -\frac{1}{4}\log_2\left(\frac{1}{4}\right) = \log_2(4) = 2 \,, \\ p_o &= \frac{3}{4} \,. \end{aligned} \tag{13.2}$$

Figure 13.2 shows a plot of entropy as a function of p_o; note that $H = 0$ bits when $p_o = 0$; since the source would only generate the symbol 11 there is no need to actually transmit it to the receiver. Note that our 2 bit representations of our symbols is an inefficient choice; for example if $p_o = 0.2$ we could represent this source with only 1 bit. This can be accomplished by encoding groups of symbols as opposed to considering individual symbols. By determining the redundancy of the source, efficient compression algorithms can be derived, as discussed further in Sect. 13.2.2.

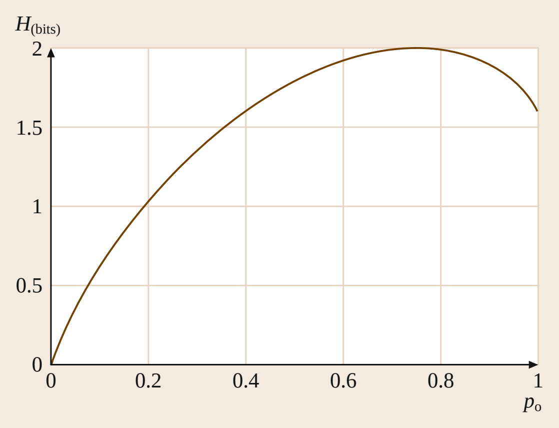

Fig. 13.2 Entropy of four-symbol source $p_i = \left\{\frac{p_o}{3}, \frac{p_o}{3}, \frac{p_o}{3}, 1-p_o\right\}$

In digital communication theory we are typically concerned with describing the entropy of joint events $H(x, y)$ in which events x and y have, respectively, m and n possible outcomes with a joint probability of occurrence $p(x, y)$. The joint probability can be computed using

$$H(x, y) = -\sum_{i,j} p(i, j)\log_2 p(i, j) \,,$$

in which it has been shown [13.2] that the following inequalities hold

$$H(x, y) \le H(x) + H(y) \tag{13.3}$$

$$= H(x) + H_x(y) \,, \tag{13.4}$$

$$H(y) \ge H_x(y) \,. \tag{13.5}$$

Equality for (13.3) holds if and only if both events are independent. The uncertainty of y ($H(y)$) is never increased by knowledge of x ($H_x(y)$), as indicated by the conditional entropy inequality in (13.4). These measures provide a natural way of describing channel capacity when digital information is transmitted as an analog waveform through a channel which is subject to random noise. The effective rate of transmission, R, is the difference of the source entropy $H(x)$ from the average rate of conditional entropy, $H_y(x)$. Therefore, the channel capacity C is the maximum rate R achievable

$$R = H(x) - H_y(x) \,, \tag{13.6}$$

$$C = \max(H(x) - H_y(x)) \,. \tag{13.7}$$

This naturally leads to the discrete channel capacity theorem given by *Shannon* [13.2, Theorem 11]. The theorem states that, if a discrete source has entropy H that is less than the channel capacity C, their exists an encoding scheme such that data can be transmitted with an arbitrarily small frequency of errors (small equivocation), otherwise the equivocation will approach $H - C + \epsilon$, where $\epsilon > 0$ is arbitrarily small.

13.2.2 Source Encoder/Decoder Design

Source Data Compression

Shannon's fundamental theorem for a noiseless channel is the basis for understanding data compression algorithms. In [13.2, Theorem 9] he states that, for a given source with entropy H (bit/symbol) and channel capacity C (bit/s), a compression scheme exists such that one can transmit data at an average rate $R = \frac{C}{H} - \epsilon$

(symbol/second), where $\epsilon > 0$ is arbitrarily small; for example, if one had a 10 bit temperature measurement of a chamber which 99% of the time is at 25 °C and all other measurements are uniformly distributed for the remaining 1% of the time then you would only send a single bit to represent 25 °C instead of all 10 bits. Assuming that the capacity of the channel is 100 bit/s, then instead of sending data at an *average* rate of $10 = \frac{100}{10}$ measurements per second you will actually send data at an *average* rate of $99.1 = \left(0.99\frac{100}{1} + 0.01\frac{100}{10}\right)$ measurements per second.

Note that, as this applies to source coding theory, we can also treat the channel capacity C as the ideal H for the source, and so H is the actual bit rate achieved R for a given source. Then $R = \sum_{i=1}^{n} p_i n_i$, where p_i is the probability of occurrence for each code word of length n_i bit. When evaluating a source coding algorithm we can look at the *efficiency* of the algorithm, which is $100H/R$%.

As seen in Fig. 13.2, if $p_o = 0.19$ then $H = 1.0$ bit/symbol. If we used our initial encoding for the symbols, we would transmit on average 2 bits/symbol with an *efficiency* of 50%. We will discover that by using a variable-length code and by making the following source encoder map $x_k = \{11, 00, 01, 10\} \rightarrow a_k = \{0, 01, 011, 111\}$ we can lower our average data rate to $R = 1.32$ bit/symbol, which improves the *efficiency* to 76%. Note that both mappings satisfy the *prefix condition* which requires that, for a given code word $\mathbf{C}_k$ of length k with bit elements $(b_1, b_2, \ldots, b_k)$, there is no other code word of length $l < k$ with elements $(b_1, b_2, \ldots, b_l)$ for $1 \leq l < k$ [13.6]. Therefore, both codes satisfy the Kraft inequality [13.6, p. 93].

In order to get closer to the ideal $H = 1.0$ bit/symbol we will use the Huffman coding algorithm [13.6, pp. 95–99] and encode pairs of letters before transmission (which will naturally increase H to 2.0 bit/symbol – pair).

Figure 13.3 shows the resulting code words for transmitting pairs of symbols. We see that the encoding results in an *efficiency* of 95% in which $H = 2.0$ and the average achievable transmission rate is $R = 2.1$. The table is generated by sorting in descending order each code word pair and its corresponding probability of occurrence. Next, a tree is made in which pairs are generated by matching the two least probable events and

are encoded with a corresponding 0 or 1. The probability of either event occurring is the sum of the two least probable events, as indicated. The tree continues to grow until all events have been accounted for. The code is simply determined by reading the corresponding 0 and 1 sequence from left to right.

Source Quantization

Due to the finite capacity (due to noise and limited bandwidth) of a digital communication channel, it is impossible to transmit an exact representation of a continuous signal from a source $x(t)$ since this would require an infinite number of bits. The question to be addressed is: how can the source be encoded in order to guarantee some minimal *distortion* of the signal when constrained by a given channel capacity C? For simplicity we will investigate the case when $x(t)$ is measured periodically at time T; the continuous sampled value is denoted as $x(k)$ and the quantized values is denoted as $\hat{x}(k)$. The *squared-error distortion* is a commonly used measure of distortion and is computed as

$$d\left(x_k, \hat{x}_k\right) = \left(x_k - \hat{x}_k\right)^2 \ . \tag{13.8}$$

Using $\boldsymbol{X}_n$ to denote n consecutive samples in a vector and $\hat{\boldsymbol{X}}_n$ to denote the corresponding quantized samples, the corresponding distortion for the n samples is

$$d\big(\boldsymbol{X}_n, \hat{\boldsymbol{X}}_n\big) = \frac{1}{n} \sum_{k=1}^{n} d\left(x_k - \hat{x}_k\right) \ . \tag{13.9}$$

Assuming that the source is stationary, the expected value of the distortion of n samples is

$$D = E\big[d\big(\boldsymbol{X}_n, \hat{\boldsymbol{X}}_n\big)\big] = E\left[d\left(x_k - \hat{x}_k\right)\right] .$$

Given a memoryless and continuous random source $\boldsymbol{X}$ with a probability distribution function (pdf) $p(x)$ and a corresponding quantized amplitude alphabet $\hat{\boldsymbol{X}}$ in which $x \in \boldsymbol{X}$ and $\hat{x} \in \hat{\boldsymbol{X}}$, we define the *rate distortion function* $R(D)$ as

$$R(D) \quad \min_{p(\hat{x}|x):E[d(\boldsymbol{X},\hat{\boldsymbol{X}})] \leq D} \quad I\big(\boldsymbol{X}; \hat{\boldsymbol{X}}\big) \ , \tag{13.10}$$

in which $I\big(\boldsymbol{X}; \hat{\boldsymbol{X}}\big)$ is denoted as the *mutual information* between $\boldsymbol{X}$ and $\hat{\boldsymbol{X}}$ [13.7].

It has been shown that the *rate distortion function* for any memoryless source with zero mean and finite variance σ_x^2 can be bounded as follows

$$H(\boldsymbol{X}) - \frac{1}{2}\log_2 2\pi\,\mathrm{e}D \leq R(D) \leq \frac{1}{2}\log_2\left(\frac{\sigma_x^2}{D}\right) ,$$
$$0 \leq D \leq \sigma_x^2 \ . \tag{13.11}$$

$H(\boldsymbol{X}) = \int_{-\infty}^{\infty} p(x)\log p(x)\,\mathrm{d}x$ is called the *differential entropy*. Note that the upper bound is the *rate distortion function* for a Gaussian source $H_{\mathrm{g}}(\boldsymbol{X})$. Similarly, the bounds on the corresponding distortion rate function are

$$\frac{1}{2\pi\,\mathrm{e}} 2^{-2(R-H(X))} \leq D(R) \leq 2^{-2R}\sigma_x^2 \ . \tag{13.12}$$

The *rate distortion function* for a band-limited Gaussian channel of width W normalized by σ_X^2 can be expressed in decibels as [13.6, pp. 104–108]

$$10\log\frac{D_{\mathrm{g}}(R)}{\sigma_x^2} = -\frac{3R}{W} \ . \tag{13.13}$$

Thus, decreasing the bandwidth of the source of information results in an exponential decrease in the *rate distortion function* for a given data rate R.

Similar to the grouped Huffman encoding algorithm, significant gains can be made by designing a quantizer $\hat{\boldsymbol{X}} = Q(\cdot)$ for a vector $\boldsymbol{X}$ of individual scalar components $\{x_k, 1 \leq k \leq n\}$ which are described by the joint pdf $p(x_1, x_2, \ldots, x_n)$. The optimum quantizer is the one which can achieve the minimum distortion $D_n(R)$

$$D_n(R) \min_{Q(\boldsymbol{X})} E\big[d\big(\boldsymbol{X}, \hat{\boldsymbol{X}}\big)\big] \ . \tag{13.14}$$

As the dimension $n \to \infty$ it can be shown that $D(R) = D_n(R)$ in the limit [13.6, p. 116–117]. One method to implement such a vector quantization is the K-means algorithm [13.6, p.117].

13.3 Networked Systems Communication Limitations

As we have seen in our review of communication theory, there is no mathematical framework that guarantees a bounded deterministic fixed delay in transmitting information through a wireless or a wired medium. All digital representations of an analog waveform are transmitted with an average delay and variance, which is typically captured by its distortion measure. Clearly wired media tend to have a relative low degree of distortion when delivering information from a certain source to destination; for example, receiving digitally encoded data from a wired analog-to-digital converter, sent to a single digital controller at a fixed rate of 8 kbit/s, occurs with little data loss and distortion (i. e., only the least-significant bits tend to have errors). When sending digital information over a shared network, the problem becomes much more complex, in which the communication channel, medium access control (MAC) mechanism, and the data rate of each source on the network come into play [13.8]. Even to determine the average delay of a relatively simple MAC mechanism such as time-division multiple access (TDMA) is a fairly complex task [13.9]. In practice there are wired networking protocols which attempt to achieve a relatively constant delay profile by using a token to control access to the network, such as ControlNet and PROFIBUS-DP. Note that the control area network (CAN) offers a fixed priority scheme in which the highest-priority device will always gain access to the network, therefore allowing it to transmit data with the lowest average delay, whereas the lower-priority devices will have a corresponding increase in average delay [13.10, Fig. 4]. Protocols such as ControlNet and PROFIBUS-DP, however, allow each member on the network an equal opportunity to transmit data within a given slot and can guarantee the same average delay for each node on a network for a given data rate. Usually the main source of variance in these delays is governed by the processing delays associated with the processors used on the network, and the additional higher-layer protocols which are built on top of these lower-layer protocols.

Wireless networks can perform as well as a wired network if the environmental conditions are ideal, for example, when devices have a clear line of sight for transmission, and are not subject to interference (high-gain microwave transmission stations). Unfortunately, devices which are used on a factory floor are more closely spaced and typically have isotropic antennas, which will lead to greater interference and variance of delays as compared with a wired network. Wireless token-passing protocols such as that described in [13.11] are a good choice to implement for control systems, since they limit interference in the network, which limits variance in delays, while providing a reasonable data throughput.

13.4 Networked Control Systems

One of the main advantages of using communication networks instead of point-to-point wired connections is the significantly reduced wiring together with the reduced failure rates of much lower connector numbers, which have significant cost implications in automated systems. Additional advantages include easier troubleshooting, maintenance, interoperability of devices, and integration of new devices added to the network [13.10]. Automated systems utilize digital shared communication networks. A number of communication protocols are used including Ethernet transmission control protocol/Internet protocol (TCP/IP), DeviceNet, ControlNet, WiFi, and Bluetooth. Each has different characteristics such as data speed and delays. Data are typically transmitted in packets of bits, for example an Ethernet IEEE 802.3 frame has a 112 or 176 bit header and a data field that must be at least 368 bits long.

Any automated system that uses shared digital wired or wireless communication networks must address certain concerns, including:

1. Bandwidth limitations, since any communication network can only carry a finite amount of information per unit of time
2. Delay jitter, since uncertainties in network access delay, or delay jitter, is commonly present
3. Packet dropouts, since transmission errors, buffer overflows due to congestion, or long transmission delays may cause packets to be dropped by the communication system.

All these issues are currently being addressed in ongoing research on networked control systems (NCS) [13.12].

13.4.1 Networked Control Systems

Figure 13.4 depicts a typical automation network in which two dedicated communication buses are used in order to control an overall process G_p with a dedicated controller G_c. The heavy solid line represents the control data network which provides timely sensor information y to G_c and distributes the appropriate control command u to the distributed controllers G_{c_i}. The heavy dashed solid line represents the monitor and configure data network, which allows the various controllers and sensors to be configured and monitored while G_p is being controlled. The control network usually has a lower data capacity but provides a fairly constant data delay with little variance in which field buses such as CAN, ControlNet, and PROFIBUS-DP are appropriate candidates. The monitoring and configuring network should have a higher data capacity but can tolerate more variance in its delays such that standard Ethernet or wireless networks using TCP/IP would be suitable. Sometimes the entire control network is monitored by a programmable logic controller (PLC) which acts as a gateway to the monitoring network as depicted in [13.10, Fig. 12]. However, there are advanced distributed controllers G_{c_i} which can both receive and deliver timely data over a control field bus such as CAN, yet still provide an Ethernet interface for configuration and monitoring. One such example is the πMFC, which is an advanced pressure-insensitive mass flow controller that provides both communication interfaces in which a low-cost low-power dual-processor architecture provides dedicated real-time control with advanced monitoring and diagnostic capabilities offloaded to the communications processor [13.13]. Although, not illustrated in this figure there is current research into establishing digital safety networks, as discussed in [13.10]. In particular the safety networks discussed are implemented over a serial–parallel line interface and implement the SafetyBUS p protocol.

Automated control systems with spatially distributed components have existed for several decades. Examples include chemical processes, refineries, power plants, and airplanes. In the past, in such systems the components were connected via hardwired connections and the systems were designed to bring all the information from the sensors to a central location, where the conditions were monitored and decisions were taken on how to act. The control policies were then implemented via the actuators, which could be valves, motors etc. Today's technology can put low-cost processing power at remote locations via microprocessors, and information can be transmitted reliably via shared digital networks or even wireless connections. These technology-driven changes are fueled by the high costs of wiring and the difficulty in introducing additional components into systems as needs change.

In 1983, Bosch GmbH began a feasibility study of using networked devices to control different functions in passenger cars. This appears to be one of the earliest efforts along the lines of modern networked control. The study bore fruit, and in February 1986 the innovative communications protocol of the control area network (CAN) was announced. By mid 1987, CAN hardware in the form of Intel's 82526 chip had been introduced, and today virtually all cars manufactured in Europe include embedded systems integrated through CAN. Networked control systems are found in abundance in many technologies, and all levels of industrial systems are now being integrated through various types of data networks. Although networked control system technologies are now fairly mature in a variety of industrial applications, the recent trend toward integrating devices through wireless rather than wired communication channels has highlighted important potential application advantages as well as several challenging problems for current research.

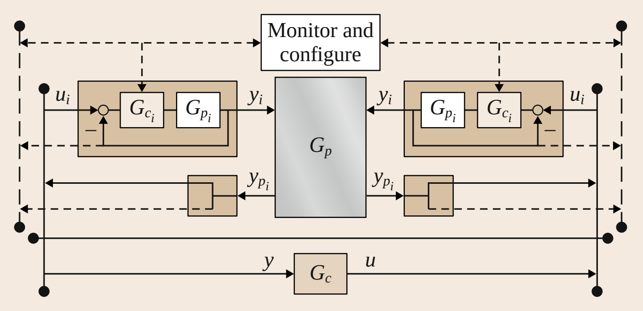

Fig. 13.4 Typical automation network

These challenges involve the optimization of performance in the face of constraints on communication bandwidth, congestion, and contention for communication resources, delay, jitter, noise, fading, and the management of signal transmission power. While the greatest commercial impact of networked control systems to date has undoubtedly been in industrial implementations, recent research suggests great potential together with significant technical challenges in new applications to distributed sensing, reconnaissance and other military operations, and a variety of coordinated activities of groups of mobile robot agents. Taking a broad view of networked control systems we find that, in addition to the challenges of meeting real-time demands in controlling data flow through various feedback paths in the network, there are complexities associated with mobility and the constantly changing relative positions of agents in the network.

Networked control systems research lies primarily at the intersection of three research areas: control systems, communication networks and information theory, and computer science. Networked control systems research can greatly benefit from theoretical developments in information theory and computer science. The main difficulties in merging results from these different fields of study have been the differences in emphasis in research so far. In information theory, delays in the transmitted information are not of central concern, as it is more important to transmit the message accurately even though this may sometimes involve significant delays in transmission. In contrast, in control systems, delays are of primary concern. Delays are much more important than the accuracy of the transmitted information due to the fact that feedback control systems are quite robust to such inaccuracies. Similarly, in traditional computer science research, time has not been a central issue since typical computer systems were interacting with other computer systems or a human operator and not directly with the physical world. Only recently have areas such as real-time systems started addressing the issues of hard time constraints where the computer system must react within specific time bounds, which is essential for embedded processing systems that deal directly with the physical world.

So far, researchers have focused primarily on a single loop and stability. Some fundamental results have been derived that involve the minimum average bit rate necessary to stabilize a linear time-invariant (LTI) system.

An important result relates the minimum bit rate R of feedback information needed for stability (for a single-input linear system) to the fastest unstable mode of the system via

$$R > \log_2 \exp\left(\sum \mathcal{R}(a_i)\right) . \tag{13.15}$$

Although progress has been made, much work remains to be done. In the case of a digital network over which information is typically sent in packets, the minimum average rate is not the only guide to control design. A transmitted packet typically contains a payload of tens of bytes, and so blocks of control data are typically grouped together. This enters into the broader set of research questions on the comparative value of sending 1 bit/s or 1000 bits every 1000 s – for the same average data rate. In view of typical actuator constraints, an unstable system may not be able to recover after 1000 s.

An alternative measure is to see how infrequently feedback information is needed to guarantee that the system remains stable; see, for example, [13.14] and [13.15], where this scheme has been combined with model-based ideas for significant increases in the periods during which the system is operating in an open-loop fashion. Intermittent feedback is another way to avoid taxing the networks that transmit sensor information. In this case, every so often the loop is closed for a certain fixed or varying period of time [13.16]. This may correspond to opportunistic, bursty situations in which the sensor sends bursts of information when the network is available. The original idea of intermittent feedback was motivated by human motor control considerations. There are strong connections with cooperative control, in which researchers have used spatial invariance ideas to describe results on stability and performance [13.17]. If spatial invariance is not present, then one may use the mathematical machinery of graph theory to describe the interaction of systems/units and to develop detailed models of groups of agents flying in formation, foraging, cooperation in search of targets or food, etc. An additional dimension in the wireless case is to consider channels that vary with time, fade, or disappear and reappear. The problem, of course, in this case becomes significantly more challenging. Consensus approaches have also been used, which typically assume rather simple dynamics for the agents and focus on the topology considering fixed or time-varying links in synchronous or asynchronous settings. Implementation issues in both hardware and software are at the center of successful deployment of networked control systems. Data integrity and security are also very important and may lead to special considerations in control system design even at early stages.

Overall, single loop and stability have been emphasized and studied under quantization of sensor measurements and actuator levels. Note that limits to performance in networked control systems appear to be caused primarily by delays and dropped packets. Other issues being addressed by current research are actuator constraints, reliability, fault detection and isolation, graceful degradation under failure, reconfigurable control, and ways to build increased degrees of autonomy into networked control systems.

13.4.2 Teleoperation

An important area of networked control is teleoperation. Teleoperation is the process of a human performing a remote task over a network with a *teleoperator* (TO). Ideally, the TO's velocity ($f_{\mathrm{top}}(t)$) should follow the human velocity commands ($f_{\mathrm{hsi}}(t) = f_{\mathrm{top}}(t-T)$) through a *human system interface* (HSI) [13.18]. Force feedback from the TO ($e_{\mathrm{top}}(t)$) is sent back to the HSI ($e_{\mathrm{hsi}}(t) = e_{\mathrm{top}}(t-T)$) in order for the operator to feel immersed in the remote environment. The controller (G_{top}) depicted in Fig. 13.5 is typically a proportional

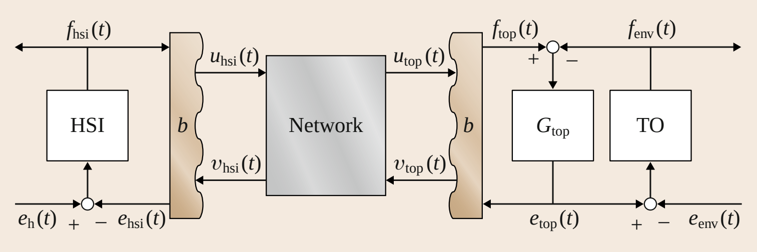

Fig. 13.5 Typical teleoperation network

derivative controller which maintains $f_{\text{top}}(t) = f_{\text{env}}(t)$ over a reasonably large bandwidth. The use of force feedback can lead to instabilities in the system due to small delays T in data transfer over the network. In order to recover stability the HSI velocity f_{hsi} and TO force e_{top} are encoded into *wave variables* [13.19], based on the wave port impedance b such that

$$u_{\text{hsi}}(t) = \frac{1}{\sqrt{2b}}(b\, f_{\text{hsi}}(t) + e_{\text{hsi}}(t)) \,, \tag{13.16}$$

$$v_{\text{top}}(t) = \frac{1}{\sqrt{2b}}(b\, f_{\text{top}}(t) - e_{\text{top}}(t)) \tag{13.17}$$

are transmitted over the network from the corresponding HSI and TO. As the delayed *wave variables* are received ($u_{\text{top}}(t) = u_{\text{hsi}}(t-T)$, $v_{\text{hsi}}(t) = v_{\text{top}}(t-T)$), they are transformed back into the corresponding velocity and force variables ($f_{\text{top}}(t)$, $e_{\text{hsi}}(t)$) as follows

$$f_{\text{top}}(t) = \sqrt{\frac{2}{b}}u_{\text{top}}(t) - \frac{1}{b}e_{\text{top}}(t) \,, \tag{13.18}$$

$$e_{\text{hsi}}(t) = b\, f_{\text{hsi}}(t) - \sqrt{2b}v_{\text{hsi}}(t) \,. \tag{13.19}$$

Such a transformation allows the communication channel to remain *passive* for fixed time delays T and allows the teleoperation network to remain stable. The study of teleoperation continues to evolve for both the continuous- and discrete-time cases, as surveyed in [13.20].

13.5 Discussion and Future Research Directions

In summary, we have presented an overview of fundamental digital communication principles. In particular, we have shown that communication systems are effectively designed using a separation principle in which the source encoder and channel encoder can be designed separately. In particular, a source encoder can be designed to match the *uncertainty* (*entropy*) of a data source (H). All of the encoded data can then be effectively transmitted over a communication channel in which an appropriately designed channel encoder achieves the channel capacity C, which is typically determined by the modulation and noise introduced into the communication channel. As long as the channel capacity obeys $C > H$, then an average H symbols will be successfully received at the receiver. In *source data compression* we noted how to achieve a much higher average data rate by only using 1 bit to represent the temperature measurement of 25 °C which occurs 99% of the time. In fact the average delay is roughly reduced from $10/100 = 0.1$ s to $(0.01 \cdot 10 + 0.99 \cdot 1)/100 = 0.0109$ s. The key to designing an efficient automation communication network effectively is to understand the effective entropy H of the system. Monitoring data, in which stability is not an issue, is a fairly straightforward task. When controlling a system the answer is not as clear; however, for deterministic channels (13.15) can serve as a guide for the classic control scheme. As the random behavior of the communication network becomes a dominating factor in the system an accurate analysis of how the delay and data dropouts occur is necessary. We have pointed the reader to texts which account for finite buffer size, and networking MAC to characterize communication delay and data dropouts [13.8, 9]. It remains to be shown how to incorporate such models effectively into the classic control framework in terms of showing stability, in particular when actuator limitations are present. It may be impossible to stabilize an unstable LTI system in any traditional stochastic framework when actuator saturation is considered. Teleoperation systems can cope with unknown fixed time delays in the case of *passive* networked control systems, by transmitting information using *wave variables*. We have extended the teleoperation framework to support lower-data-rate sampling and tolerate unknown time-varying delays and data dropouts without requiring any explicit knowledge of the communication channel model [13.21]. Confident that stability of these systems is preserved allows *much* greater flexibility in choosing an appropriate MAC for our networked control system in order to optimize system performance.

13.6 Conclusions

Networked control systems over wired and wireless channels are becoming increasingly important in a wide range of applications. The area combines concepts and ideas from control and automation theory, communications, and computing. Although progress has been made in understanding important fundamental issues much work remains to be done [13.12]. Understanding the effect of time-varying delays and designing systems to tolerate them is high priority. Research is needed to understand multiple interconnected systems over realistic channels that work together in a distributed fashion towards common goals with performance guarantee.

13.7 Appendix

13.7.1 Channel Encoder/Decoder Design

Denoting T (s) as the signal period, and W (Hz) as the bandwidth of a communication channel, we will use the ideal Nyquist rate assumption that $2TW$ symbols of $\{a_n\}$ can be transmitted with the analog wave forms $s_\mathrm{m}(t)$ over the channel depicted in Fig. 13.1. We further assume that *independent* noise $n(t)$ is added to create the received signal $r(t)$. Then we can state the following

1. The actual rate of transmission is [13.2, Theorem 16]

$$R = H(s) - H(n)\,, \tag{13.20}$$

in which the channel capacity is the best signaling scheme which satisfies

$$C \max_{P(s_\mathrm{m})} H(s) - H(n)\,. \tag{13.21}$$

2. If we further assume the noise is white with power N and the signals are transmitted at power P then the channel capacity C (bit/s) is [13.2, Theorem 17]

$$C = W \log_2 \frac{P+N}{N}\,. \tag{13.22}$$

Various channel coding techniques have been devised in order to transmit digital information to achieve rates R which approach this channel capacity C with a correspondingly low bit error rate. Among these *bit error correcting* codes are block and convolutional codes in which the *Hamming code* [13.6, pp. 423–425] and the *Viterbi algorithm* [13.6, pp. 482–492] are classic examples for the respective implementations.

13.7.2 Digital Modulation

A linear filter can be described by its frequency response $H(f)$ and *real* impulse response $h(t)$ ($H^*(-f) = H(f)$). It can be represented in an equivalent low-pass form $H_\mathrm{l}(f)$ in which

$$H_\mathrm{l}(f - f_\mathrm{c}) = \begin{cases} H(f), & f > 0 \\ 0, & f < 0\,, \end{cases} \tag{13.23}$$

$$H_\mathrm{l}^*(-f - f_\mathrm{c}) = \begin{cases} 0, & f > 0 \\ H^*(-f), & f < 0\,. \end{cases} \tag{13.24}$$

Therefore, with $H(f) = H_\mathrm{l}(f - f_\mathrm{c}) + H_\mathrm{l}^*(f - f_\mathrm{c})$ the impulse response $h(t)$ can be written in terms of the *complex*-valued inverse transform of $H_\mathrm{l}(f)$ ($h_\mathrm{l}(t)$) [13.6, p. 153]

$$h(t) = 2\mathrm{Re}\left[h_\mathrm{l}(t)\mathrm{e}^{\mathrm{i}2\pi f_\mathrm{c} t}\right]\,. \tag{13.25}$$

Similarly the signal response $r(t)$ of a filtered input signal $s(t)$ through a linear filter $H(f)$ can be represented in terms of their low-pass equivalents

$$R_\mathrm{l}(f) = S_\mathrm{l}(f) H_\mathrm{l}(f)\,. \tag{13.26}$$

Therefore it is mathematically convenient to discuss the transmission of equivalent low-pass signals through equivalent low-pass channels [13.6, p. 154].

Digital signals $s_\mathrm{m}(t)$ consist of a set of analog waveforms which can be described by an *orthonormal* set of waveforms $f_n(t)$. An *orthonormal* waveform satisfies

$$\langle f_i(t) f_j(t) \rangle_T = \begin{cases} 0, & i \neq j \\ 1, & i = j\,, \end{cases} \tag{13.27}$$

Table 13.1 Summary of PAM, PSK, and QAM

Modulation	$s_m(t)$	$f_1(t)$	$f_2(t)$
PAM	$s_m f_1(t)$	$\sqrt{\frac{2}{\mathcal{E}_g}}g(t)\cos 2\pi f_c t$	
PSK	$s_{m1} f_1(t)+s_{m2} f_2(t)$	$\sqrt{\frac{2}{\mathcal{E}_g}}g(t)\cos 2\pi f_c t$	$-\sqrt{\frac{2}{\mathcal{E}_g}}g(t)\sin 2\pi f_c t$
QAM	$s_{m1} f_1(t)+s_{m2} f_2(t)$	$\sqrt{\frac{2}{\mathcal{E}_g}}g(t)\cos 2\pi f_c t$	$-\sqrt{\frac{2}{\mathcal{E}_g}}g(t)\sin 2\pi f_c t$
Modulation	s_m		$d_{\min}^{(e)}$
PAM	$(2m-1-M)d\sqrt{\frac{\mathcal{E}_g}{2}}$		$d\sqrt{2\mathcal{E}_g}$
PSK	$\sqrt{\frac{\mathcal{E}_g}{2}}\left[\cos\frac{2\pi}{M}(m-1), \sin\frac{2\pi}{M}(m-1)\right]$		$\sqrt{\mathcal{E}_g\left(1-\cos\frac{2\pi}{M}\right)}$
QAM	$\sqrt{\frac{\mathcal{E}_g}{2}}\left[(2m_c-1-M)d, (2m_s-1-M)d\right]$		$d\sqrt{2\mathcal{E}_g}$

in which $\langle f(t)g(t)\rangle_T = \int_0^T f(t)g(t)\,\mathrm{d}t$. The *Gram–Schmidt procedure* is a straightforward method to generate a set of *orthonormal* wave forms from a basis set of signals [13.6, p. 163].

Table 13.1 provides the corresponding orthonormal wave forms and minimum signal distances ($d_{\min}^{(e)}$) for *pulse-amplitude modulation* (PAM), *phase-shift keying* (PSK), and *quadrature amplitude modulation* (QAM). Note that QAM is a combination of PAM and PSK in which $d_{\min}^{(e)}$ is a special case of amplitude selection where $2d$ is the distance between adjacent signal amplitudes. Signaling amplitudes are in terms of the low-pass signal pulse shape $g(t)$ energy $\mathcal{E}_g = \langle g(t)g(t)\rangle_T$. The pulse shape is determined by the transmitting filter which typically has a *raised cosine* spectrum in order to minimize intersymbol interference at the cost of increased bandwidth [13.6, p. 559]. Each modulation scheme allows for M symbols in which $k = \log_2 M$ and N_o is the average noise power per symbol transmission. Denoting P_M as the probability of a symbol error and assuming that we use a Gray code, we can approximate the average bit error by $P_b \approx \frac{P_M}{k}$. The corresponding symbol errors are:

1. For M-ary PAM [13.6, p. 265]
$$P_M = \frac{2(M-1)}{M} Q\left(\sqrt{\frac{d^2\mathcal{E}_g}{N_o}}\right) \tag{13.28}$$
2. For M-ary PSK [13.6, p. 270]
$$P_M \approx 2Q\left(\sqrt{\frac{\mathcal{E}_g}{N_o}}\sin\frac{\pi}{M}\right) \tag{13.29}$$
3. For QAM [13.6, p. 279]
$$P_M < (M-1)Q\left(\sqrt{\frac{\left[d_{\min}^{(e)}\right]^2}{2N_o}}\right) . \tag{13.30}$$

14. Artificial Intelligence and Automation

Dana S. Nau

Artificial intelligence (AI) focuses on getting machines to do things that we would call intelligent behavior. Intelligence – whether artificial or otherwise – does not have a precise definition, but there are many activities and behaviors that are considered intelligent when exhibited by humans and animals. Examples include seeing, learning, using tools, understanding human speech, reasoning, making good guesses, playing games, and formulating plans and objectives. AI focuses on how to get machines or computers to perform these same kinds of activities, though not necessarily in the same way that humans or animals might do them.

To most readers, *artificial intelligence* probably brings to mind science-fiction images of robots or computers that can perform a large number of human-like activities: seeing, learning, using tools, understanding human speech, reasoning, making good guesses, playing games, and formulating plans and objectives. And indeed, AI research focuses on how to get machines or computers to carry out activities such as these. On the other hand, it is important to note that the goal of AI is not to simulate biological intelligence. Instead, the objective is to get machines to behave or think intelligently, regardless of whether or not the internal computational processes are the same as in people or animals.

Most AI research has focused on ways to achieve intelligence by manipulating symbolic representations of problems. The notion that symbol manipulation is sufficient for artificial intelligence was summarized by *Newell* and *Simon* in their famous physical-symbol system hypothesis: *A physical-symbol system has the necessary and sufficient means for general intelligent action* and their heuristic search hypothesis [14.1]:

> *The solutions to problems are presented as symbol structures. A physical-symbol system exercises its intelligence in problem solving by search – that is – by generating and progressively modifying symbol structures until it produces a solution structure.*

On the other hand, there are several important topics of AI research – particularly machine-learning techniques such as neural networks and swarm intelligence – that are *subsymbolic* in nature, in the sense that they deal with vectors of real-valued numbers without attaching any explicit meaning to those numbers.

AI has achieved many notable successes [14.2]. Here are a few examples:

- Telephone-answering systems that understand human speech are now in routine use in many companies.

- Simple room-cleaning robots are now sold as consumer products.
- Automated vision systems that read handwritten zip codes are used by the US Postal Service to route mail.
- Machine-learning techniques are used by banks and stock markets to look for fraudulent transactions and alert staff to suspicious activity.
- Several web-search engines use machine-learning techniques to extract information and classify data scoured from the web.
- Automated planning and control systems are used in unmanned aerial vehicles, for missions that are too *dull, dirty or dangerous* for manned aircraft.
- Automated planning and scheduling techniques were used by the National Aeronautics and Space Administration (NASA) in their famous Mars rovers.

AI is divided into a number of subfields that correspond roughly to the various kinds of activities mentioned in the first paragraph. Three of the most important subfields are discussed in other chapters: machine learning in Chaps. 12 and 29, computer vision in Chap. 20, and robotics in Chaps. 1, 78, 82, and 84. This chapter discusses other topics in AI, including search procedures (Sect. 14.1.1), logical reasoning (Sect. 14.1.2), reasoning about uncertain information (Sect. 14.1.3), planning (Sect. 14.1.4), games (Sect. 14.1.5), natural-language processing (Sect. 14.1.6), expert systems (Sect. 14.1.7), and AI programming (Sect. 14.1.8).

14.1 Methods and Application Examples

14.1.1 Search Procedures

Many AI problems require a trial-and-error search through a search space that consists of *states of the world* (or *states*, for short), to find a path to a state s that satisfies some *goal condition* g. Usually the set of states is finite but very large: far too large to give a list of all the states (as a control theorist might do, for example, when writing a state-transition matrix). Instead, an initial state s_0 is given, along with a set O of *operators* for producing new states from existing ones.

As a simple example, consider Klondike, the most popular version of solitaire [14.3]. As illustrated in Fig. 14.1a, the initial state of the game is determined by dealing 28 cards from a 52-card deck into an arrangement called the tableau; the other 28 cards then go into a pile called the stock. New states are formed from old ones by moving cards around according to the rules of the game; for example, in Fig. 14.1a there are two possible moves: either move the ace of hearts to one of the foundations and turn up the card beneath the ace as shown in Fig. 14.1b, or move three cards from the stock to the waste. The goal is to produce a state in which all of the cards are in the foundation piles, with each suit in a different pile, in numerical order from the ace at the bottom to the king at the top. A *solution* is any path (a sequence of moves, or equivalently, the sequence of states that these moves take us to) from the initial state to a goal state.

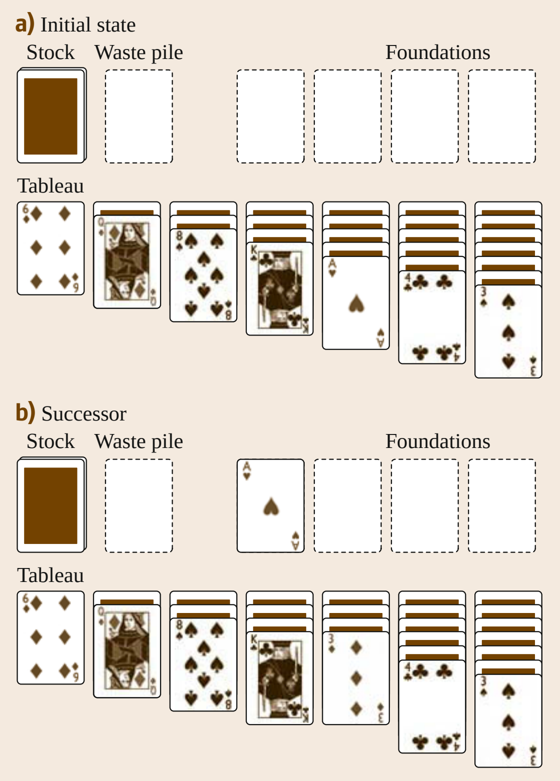

Fig. 14.1 **(a)** An initial state and **(b)** one of its two possible successors

Klondike has several characteristics that are typical of AI search problems:

- Each state is a combination of a finite set of features (in this case the cards and their locations), and the task is to find a path that leads from the initial state to a goal state.
- The rules for getting from one state to another can be represented using symbolic logic and discrete mathematics, but continuous mathematics is not as useful here, since there is no reasonable way to model the state space with continuous numeric functions.
- It is not clear a priori which paths, if any, will lead from the initial state to the goal states. The only obvious way to solve the problem is to do a trial-and-error search, trying various sequences of moves to see which ones might work.
- Combinatorial explosion is a big problem. The number of possible states in Klondike is well over 52!, which is many orders of magnitude larger than the number of atoms in the Earth. Hence a trial-and-error search will not terminate in a reasonable amount of time unless we can somehow restrict the search to a very small part of the search space – hopefully a part of the search space that actually contains a solution.
- In setting up the state space, we took for granted that the problem representation should correspond directly to the states of the physical system, but sometimes it is possible to make a problem much easier to solve by adapting a different representation; for example, [14.4] shows how to make Klondike much easier to solve by searching a different state space.

In many trial-and-error search problems, each solution path π will have a numeric measure $F(\pi)$ telling how desirable π is; for example, in Klondike, if we consider shorter solution paths to be more desirable than long ones, we can define $F(\pi)$ to be π's length. In such cases, we may be interested in finding either an *optimal* solution, i. e., a solution π such that $F(\pi)$ is as small as possible, or a *near-optimal* solution in which $F(\pi)$ is close to the optimal value.

Heuristic Search

The pseudocode in Fig. 14.2 provides an abstract model of state-space search. The input parameters include an initial state s_0 and a set of operators O. The procedure either fails, or returns a *solution path* π (i. e., a path from s_0 to a goal state).

```
1.  State-space-search($s_0$; $O$)
2.      $Active \leftarrow \{\langle s_0 \rangle\}$
3.      while $Active \neq \emptyset$ do
4.          choose a path $\pi = \langle s_0, \ldots, s_k \rangle \in Active$ and remove it from $Active$
5.          if $s_k$ is a goal state then return $\pi$
6.          $Successors \leftarrow \{\langle s_0, \ldots, s_k, o(s_k) \rangle : o \in O$ is applicable to $s_k\}$
7.          optional pruning step: remove unpromising paths from $Successors$
8.          $Active \leftarrow Active \cup Successors$
9.      repeat
10.     return failure
```

Fig. 14.2 An abstract model of state-space search. In line 6, $o(s_k)$ is the state produced by applying the operator o to the state s_k

As discussed earlier, we would like the search algorithm to focus on those parts of the state space that will lead to optimal (or at least near-optimal) solution paths. For this purpose, we will use a *heuristic function* $f(\pi)$ that returns a numeric value giving an approximate idea of how good a solution can be found by extending π, i. e.,

$$f(\pi) \approx \min\{F(\pi') : \\ \pi' \text{ is a solution path that is an extension of } \pi\} .$$

It is hard to give foolproof guidelines for writing heuristic functions. Often they can be very ad hoc: in the worst case, $f(\pi)$ may just be an arbitrary function that the user *hopes* will give reasonable estimates. However, often it works well to define an easy-to-solve *relaxation* of the original problem, i. e., a modified problem in which some of the constraints are weakened or removed. If π is a partial solution for the original problem, then we can compute $f(\pi)$ by extending π into a solution π' for the relaxed problem, and returning $F(\pi')$; for example, in the famous traveling-salesperson problem, $f(\pi)$ can be computed by solving a simpler problem called the assignment problem [14.5]. Here are several procedures that can make use of such a heuristic function:

- *Best-first search* means that at line 4 of the algorithm in Fig. 14.2, we always choose a path $\pi = \langle s_0, \ldots, s_k \rangle$ that has the smallest value $f(\pi)$ of any path we have seen so far. Suppose that at least one solution exists, that there are no infinite paths of finite cost, and that the heuristic function f has the following *lower-bound* property

$$f(\pi) \leq \min\{F(\pi') : \\ \pi' \text{ is a solution path that is an extension of } \pi\} . \tag{14.1}$$

  Then best-first search will always return a solution π^* that minimizes $F(\pi^*)$. The well-known A* search procedure [14.6] is a special case of best-first search, with some modifications to handle situations where there are multiple paths to the same state.

Best-first search has the advantage that, if it chooses an obviously bad state s to explore next, it will not spend much time exploring the subtree below s. As soon as it reaches successors of s whose f-values exceed those of other states on the $Active$ list, best-first search will go back to those other states. The biggest drawback is that best-first search must remember every state it has ever visited, hence its memory requirement can be huge. Thus, best-first search is more likely to be a good choice in cases where the state space is relatively small, and the difficulty of solving the problem arises for some other reason (e.g., a costly-to-compute heuristic function, as in [14.7]).

- In *depth-first branch and bound*, at line 4 the algorithm always chooses the longest path in $Active$; if there are several such paths then the algorithm chooses the one that has the smallest value for $f(\pi)$. The algorithm maintains a variable π^* that holds the best solution seen so far, and the pruning step in line 7 removes a path π iff $f(\pi) \geq F(\pi^*)$. If the state space is finite and acyclic, at least one solution exists, and (14.1) holds, then depth-first branch and bound is guaranteed to return a solution π^* that minimizes $F(\pi^*)$.

  The primary advantage of depth-first search is its low memory requirement: the number of nodes in $Active$ will never exceed bd, where d is the length of the current path. The primary drawback is that, if it chooses the wrong state to look at next, it will explore the entire subtree below that state before returning and looking at the state's siblings. Depth-first search does better in cases where the likelihood of choosing the wrong state is small or the time needed to search the incorrect subtrees is not too great.
- *Greedy search* is a state-space search without any backtracking. It is accomplished by replacing line 8 with $Active \leftarrow \{\pi_1\}$, where π_1 is the path in $Successors$ that minimizes $\{f(\pi') \mid \pi' \in Successors\}$. *Beam search* is similar except that, instead of putting just one successor π_1 of π into $Active$, we put k successors $\pi_1, \ldots, \pi_k$ into $Active$, for some fixed k.

  Both greedy search and beam search will return very quickly once they find a solution, since neither of them will spend any time looking for better solutions. Hence they are good choices if the state space is large, most paths lead to solutions, and we are more interested in finding a solution quickly than in finding an optimal solution. However, if most paths do not lead to solutions, both algorithms may fail to find a solution at all (although beam search is more robust in this regard, since it explores several paths rather than just one path). In this case, it may work well to do a modified greedy search that backtracks and tries a different path every time it reaches a dead end.

Hill-Climbing

A *hill-climbing* problem is a special kind of search problem in which *every* state is a goal state. A hill-climbing procedure is like a greedy search, except that $Active$ contains a single state rather than a single path; this is maintained in line 6 by inserting a single successor of the current state s_k into $Active$, rather than all of s_k's successors. In line 5, the algorithm terminates when none of s_k's successors looks better than s_k itself, i. e., when s_k has no successor s_{k+1} with $f(s_{k+1}) > f(s_k)$. There are several variants of the basic hill-climbing approach:

- *Stochastic hill-climbing and simulated annealing.* One difficulty with hill-climbing is that it will terminate in cases where s_k is a local minimum but not a global minimum. To prevent this from happening, a *stochastic hill-climbing* procedure does not always return when the test in line 5 succeeds. Probably the best known example is *simulated annealing*, a technique inspired by annealing in metallurgy, in which a material is heated and then slowly cooled. In simulated annealing, this is accomplished as follows. At line 5, if none of s_k's successors look better than s_k then the procedure will not necessarily terminate as in ordinary hill-climbing; instead it will terminate with some probability p_i, where i is the number of loop iterations and p_i grows monotonically with i.
- *Genetic algorithms.* A genetic algorithm is a modified version of hill-climbing in which successor states are generated not using the normal successor function, but instead using operators reminiscent of genetic recombination and mutation. In particular, $Active$ contains k states rather than just one, each state is a string of symbols, and the operators O are computational analogues of genetic recombination and mutation. The termination criterion in line 5 is generally ad hoc; for example, the algorithm may terminate after a specified number of iterations, and return the best one of the states currently in $Active$.

Hill-climbing algorithms are good to use in problems where we want to find a solution very quickly, then continue to look for a better solution if additional time is available. More specifically, genetic algorithms are useful in situations where each solution can be represented as a string whose substrings can be combined with substrings of other solutions.

Constraint Satisfaction and Constraint Optimization

A constraint-satisfaction problem is a special kind of search problem in which each state is a set of assignments of values to variables $\{X_i\}_{i=1}^n$ that have finite domains $\{D_i\}_{i=1}^n$, and the objective is to assign values to the variables in such a way that some set of constraints is satisfied.

In the search space for a constraint-satisfaction problem, each state at depth i corresponds to an assignment of values to i of the n variables, and each branch corresponds to assigning a specific value to an unassigned variable. The search space is finite: the maximum length of any path from the root node is n since there are only n variables to assign values to. Hence a depth-first search works quite well for constraint-satisfaction problems. In this context, some powerful techniques have been formulated for choosing which variable to assign next, detecting situations where previous variable assignments will make it impossible to satisfy the remaining constraints, and even restructuring the problem into one that is easier to solve [14.8, Chap. 5].

A *constraint-optimization* problem combines a constraint-satisfaction problem with an objective function that one wants to optimize. Such problems can be solved by combining constraint-satisfaction techniques with the optimization techniques mentioned in *Heuristic Search*.

Applications of Search Procedures

Software using AI search techniques has been developed for a large number of commercial applications. A few examples include the following:

- Several universities routinely use constraint-satisfaction software for course scheduling.
- *Airline ticketing.* Finding the best price for an airline ticket is a constraint-optimization problem in which the constraints are provided by the airlines' various rules on what tickets are available at what prices under what conditions [14.9]. An example of software that works in this fashion is the ITA software (itasoftware.com) system that is used by several airline-ticketing web sites, e.g., Orbitz (orbitz.com) and Kayak (kayak.com).
- *Scheduling and routing.* Companies such as ILOG (ilog.com) have developed software that uses search and optimization techniques for scheduling [14.10], routing [14.11], workflow composition [14.12], and a variety of other applications.
- *Information retrieval from the web.* AI search techniques are important in the web-searching software used at sites such as Google News [14.2].

Additional reading. For additional reading on search algorithms, see *Pearl* [14.13]. For additional details about constraint processing, see *Dechter* [14.14].

14.1.2 Logical Reasoning

A *logic* is a formal language for representing information in such a way that one can reason about what things are true and what things are false. The logic's *syntax* defines what the *sentences* are; and its *semantics* defines what those sentences mean in some *world*. The two best-known logical formalisms, propositional logic and first-order logic, are described briefly below.

Propositional Logic and Satisfiability

Propositional logic, also known as *Boolean algebra*, includes sentences such as $A \wedge B \Rightarrow C$, where A, B, and C are variables whose domain is $\{true, false\}$. Let w_1 be a world in which A and C are *true* and B is *false*, and let w_2 be a world in which all three of the Boolean variables are *true*. Then the sentence $A \wedge B \Rightarrow C$ is false in w_1 and true in w_2. Formally, we say that w_2 is a *model* of $A \wedge B \Rightarrow C$, or that it *entails* S_1. This is written symbolically as

$$w_2 \models A \wedge B \Rightarrow C \, .$$

The *satisfiability problem* is the following: given a sentence S of propositional logic, does there exist a world (i. e., an assignment of truth values to the variables in S) in which S is true? This problem is central to the theory of computation, because it was the very first computational problem shown to be NP-complete. Without going into a formal definition of NP-completeness, NP is, roughly, the set of all computational problems such that, if we are given a purported solution, we can check *quickly* (i. e., in a polynomial amount of computing time) whether the solution is correct. An *NP-complete* problem is a problem that is one of the hardest problems in NP, in the sense that solving any NP-complete problems would provide a solution to every problem in NP. It is conjectured that no NP-complete problem can be solved in a polynomial amount of computing time. There is a great deal of evidence for believing the conjecture, but nobody has ever been able to prove it. This is the most famous unsolved problem in computer science.

First-Order Logic

A much more powerful formalism is *first-order logic* [14.15], which uses the same logical connectives as in propositional logic but adds the following syntactic elements (and semantics, respectively): constant symbols (which denote the objects), variable symbols (which range over objects), function symbols (which represent functions), predicate symbols (which represent relations among objects), and the quantifiers $\forall x$ and $\exists x$, where x is any variable symbol (to specify whether a sentence is true for every value x or for at least one value of x).

First-order logic includes a standard set of *logical axioms*. These are statements that must be true in every possible world; one example is the transitive property of equality, which can be formalized as

$$\forall x\, \forall y\, \forall z\, (x = y \wedge y = z) \Rightarrow x = z\,.$$

In addition to the logical axioms, one can add a set of *nonlogical axioms* to describe what is true in a particular kind of world; for example, if we want to specify that there are exactly two objects in the world, we could do this by the following axioms, where a and b are constant symbols, and x, y, z are variable symbols

$$a \neq b\,, \tag{14.2a}$$

$$\forall x\, \forall y\, \forall z\; x = y \vee y = z \vee x = z\,. \tag{14.2b}$$

The first axiom asserts that there are at least two objects (namely a and b), and the second axiom asserts that there are no more than two objects.

First-order logic also includes a standard set of *inference rules*, which can be used to infer additional true statements. One example is *modus ponens*, which allows one to infer a statement Q from the pair of statements $P \Rightarrow Q$ and P.

The logical and nonlogical axioms and the rules of inference, taken together, constitute a *first-order theory*. If $\mathcal{T}$ is a first-order theory, then a *model* of $\mathcal{T}$ is any world in which $\mathcal{T}$'s axioms are true. (In science and engineering, a *mathematical model* generally means a formalism for some real-world phenomenon; but in mathematical logic, *model* means something very different: the formalism is called a theory, and the the real-world phenomenon *itself* is a model of the theory.) For example, if $\mathcal{T}$ includes the nonlogical axioms given above, then a model of $\mathcal{T}$ is any world in which there are exactly two objects.

A *theorem* of $\mathcal{T}$ is defined recursively as follows: every axiom is a theorem, and any statement that can be produced by applying inference rules to theorems is also a theorem; for example, if $\mathcal{T}$ is any theory that includes the nonlogical axioms (14.2a) and (14.2b), then the following statement is a theorem of $\mathcal{T}$

$$\forall x\; x = a \vee x = b\,.$$

A fundamental property of first-order logic is *completeness*: for every first-order theory $\mathcal{T}$ and every statement S in $\mathcal{T}$, S is a theorem of $\mathcal{T}$ if and only if S is true in all models of $\mathcal{T}$. This says, basically, that first-order logical reasoning does exactly what it is supposed to do.

Nondeductive Reasoning

Deductive reasoning – the kind of reasoning used to derive theorems in first-order logic – consists of deriving a statement y as a consequence of a statement x. Such an inference is *deductively valid* if there is no possible situation in which x is true and y is false. However, several other kinds of reasoning have been studied by AI researchers. Some of the best known include *abductive reasoning* and *nonmonotonic reasoning*, which are discussed briefly below, and *fuzzy logic*, which is discussed later.

Nonmonotonic Reasoning. In most formal logics, deductive inference is *monotone*; i. e., adding a formula to a logical theory never causes something *not* to be a theorem that was a theorem of the original theory. Nonmonotonic logics allow deductions to be made from *beliefs* that may not always be true, such as the *default assumption* that birds can fly. In nonmonotonic logic, if b is a bird and we know nothing about b then we may conclude that b can fly; but if we later learn that b is an ostrich or b has a broken wing, then we will retract this conclusion.

Abductive Reasoning. This is the process of inferring x from y when x entails y. Although this can produce results that are incorrect within a formal deductive system, it can be quite useful in practice, especially when something is known about the probability of different causes of y; for example, the Bayesian reasoning described later can be viewed as a combination of deductive reasoning, abductive reasoning, and probabilities.

Applications of Logical Reasoning

The satisfiability problem has important applications in hardware design and verification; for example, electronic design automation (EDA) tools include satisfiability checking algorithms to check whether a given digital system design satisfies various criteria. Some EDA tools use first-order logic rather than propositional logic, in order to check criteria that are hard to express in propositional logic.

First-order logic provides a basis for automated reasoning systems in a number of application areas. Here are a few examples:

- *Logic programming*, in which mathematical logic is used as a programming language, uses a particular kind of first-order logic sentence called a Horn clause. Horn clauses are implications of the form $P_1 \wedge P_2 \wedge \ldots \wedge P_n \Rightarrow P_{n+1}$, where each P_i is an *atomic formula* (a predicate symbol and its argument list). Such an implication can be interpreted logically, as a statement that P_{n+1} is true if $P_1, \ldots, P_n$ are true, or procedurally, as a statement that a way to show or solve P_{n+1} is to show or solve $P_1, \ldots, P_n$. The best known implementation of logic programming is the programming language Prolog, described further below.
- *Constraint programming*, which combines logic programming and constraint satisfaction, is the basis for ILOG's CP Optimizer (http://www.ilog.com/products/cpoptimizer).
- The web ontology language (OWL) and DAML + OIL languages for semantic web markup are based on description logics, which are a particular kind of first-order logic.
- Fuzzy logic has been used in a wide variety of commercial products including washing machines, refrigerators, automotive transmissions and braking systems, camera tracking systems, etc.

14.1.3 Reasoning About Uncertain Information

Earlier in this chapter it was pointed out that AI systems often need to reason about discrete sets of states, and the relationships among these states are often nonnumeric. There are several ways in which uncertainty can enter into this picture; for example, various events may occur spontaneously and there may be uncertainty about whether they will occur, or there may be uncertainty about what things are currently true, or the degree to which they are true. The two best-known techniques for reasoning about such uncertainty are Bayesian probabilities and fuzzy logic.

Bayesian Reasoning

In some cases we may be able to model such situations probabilistically, but this means reasoning about discrete random variables, which unfortunately incurs a combinatorial explosion. If there are n random variables and each of them has d possible values, then the joint probability distribution function (PDF) will have d^n entries. Some obvious problems are (1) the worst-case time complexity of reasoning about the variables is $\Theta(d^n)$, (2) the worst-case space complexity is also $\Theta(d^n)$, and (3) it seems impractical to suppose that we can acquire accurate values for all d^n entries.

The above difficulties can be alleviated if some of the variables are known to be independent of each other; for example, suppose that the n random variables mentioned above can be partitioned into $\lceil n/k \rceil$ subsets, each containing at most k variables. Then the joint PDF for the entire set is the product of the PDFs of the subsets. Each of those has d^k entries, so there are only $\lceil n/k \rceil n^k$ entries to acquire and reason about.

Absolute independence is rare; but another property is more common and can yield a similar decrease in time and space complexity: *conditional* independence [14.16]. Formally, a is *conditionally independent of b given c* if $P(ab|c) = P(a|c)P(b|c)$.

Bayesian networks are graphical representations of conditional independence in which the network topology reflects knowledge about which events *cause* other events. There is a large body of work on these networks, stemming from seminal work by Judea Pearl. Here is a simple example due to *Pearl* [14.17]. Figure 14.3 represents the following hypothetical situation:

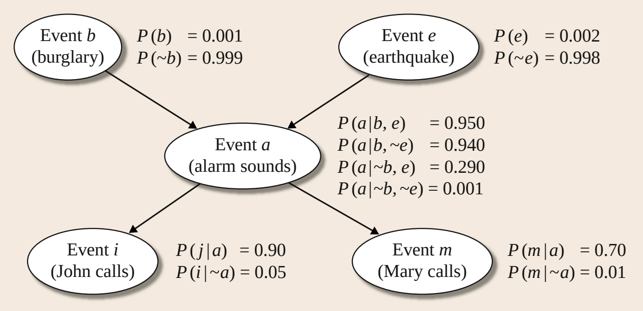

Fig. 14.3 A simple Bayesian network

> *My house has a burglar alarm that will usually go off (event a) if there's a burglary (event b), an earthquake (event e), or both, with the probabilities shown in Fig. 14.3. If the alarm goes off, my neighbor John will usually call me (event j) to tell me; and he may sometimes call me by mistake even if the alarm has not gone off, and similarly for my other neighbor Mary (event m); again the probabilities are shown in the figure.*

The joint probability for each combination of events is the product of the conditional probabilities given in Fig. 14.3

$$\begin{aligned} P(b,e,a,j,m) &= P(b)P(e)P(a|b,e) \\ &\quad \times P(j|a)P(m|a)\,, \\ P(b,e,a,j,\neg m) &= P(b)P(e)P(a|b,e)P(j|a) \\ &\quad \times P(\neg m|a)\,, \\ P(b,\neg e,\neg a,j,\neg m) &= P(b)P(\neg e)P(\neg a|b,\neg e) \\ &\quad \times P(j|\neg a)P(\neg m|\neg a)\,, \\ &\ldots \end{aligned}$$

Hence, instead of reasoning about a joint distribution with $2^5 = 32$ entries, we only need to reason about products of the five conditional distributions shown in the figure.

In general, probability computations can be done on Bayesian networks much more quickly than would be possible if all we knew was the joint PDF, by taking advantage of the fact that each random variable is conditionally independent of most of the other variables in the network. One important special case occurs when the network is acyclic (e.g., the example in Fig. 14.3), in which case the probability computations can be done in low-order polynomial time. This special case includes decision trees [14.8], in which the network is both acyclic and rooted. For additional details about Bayesian networks, see *Pearl* and *Russell* [14.16].

Applications of Bayesian Reasoning. Bayesian reasoning has been used successfully in a variety of applications, and dozens of commercial and freeware implementations exist. The best-known application is spam filtering [14.18, 19], which is available in several mail programs (e.g., Apple Mail, Thunderbird, and Windows Messenger), webmail services (e.g., gmail), and a plethora of third-party spam filters (probably the best-known is spamassassin [14.20]). A few other examples include medical imaging [14.21], document classification [14.22], and web search [14.23].

Fuzzy Logic

Fuzzy logic [14.24, 25] is based on the notion that, instead of saying that a statement P is true or false, we can give P a *degree of truth*. This is a number in the interval [0, 1], where 0 means false, 1 means true, and numbers between 0 and 1 denote partial degrees of truth.

As an example, consider the action of moving a car into a parking space, and the statement *the car is in the parking space*. At the start, the car is not in the parking space, hence the statement's degree of truth is 0. At the end, the car is completely in the parking space, hence the statement's degree of is 1. Between the start and end of the action, the statement's degree of truth gradually increases from 0 to 1.

Fuzzy logic is closely related to fuzzy set theory, which assigns degrees of truth to set membership. This concept is easiest to illustrate with sets that are intervals over the real line; for example, Fig. 14.4 shows a set S having the following set membership function

$$\text{truth}(x \in S) = \begin{cases} 1\,, & \text{if } 2 \le x \le 4\,, \\ 0\,, & \text{if } x \le 1 \text{ or } x \ge 5\,, \\ x-1\,, & \text{if } 1 < x < 2\,, \\ 5-x\,, & \text{if } 4 < x < 5\,. \end{cases}$$

The logical notions of conjunction, disjunction, and negation can be generalized to fuzzy logic as follows

$$\begin{aligned} \text{truth}(x \wedge y) &= \min[\text{truth}(x), \text{truth}(y)]\,; \\ \text{truth}(x \vee y) &= \max[\text{truth}(x), \text{truth}(y)]\,; \\ \text{truth}(\neg x) &= 1 - \text{truth}(x)\,. \end{aligned}$$

Fuzzy logic also allows other operators, more linguistic in nature, to be applied. Going back to the example of a full gas tank, if the degree of truth of *g is full* is d, then one might want to say that the degree of truth of *g is very full* is d^2. (Obviously, the choice of d^2 for *very* is subjective. For different users or different applications, one might want to use a different formula.) Degrees of truth are semantically distinct from probabilities, although the two concepts are often confused;

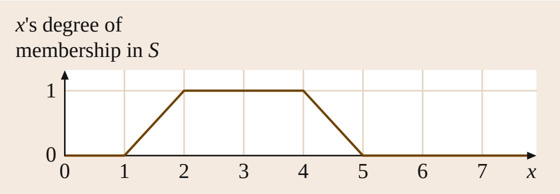

Fig. 14.4 A degree-of-membership function for a fuzzy set

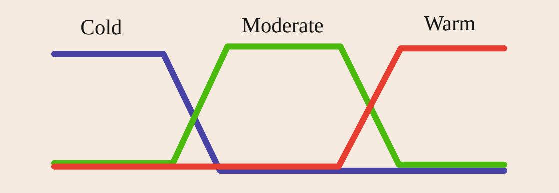

Fig. 14.5 Degree-of-membership functions for three overlapping temperature ranges

for example, we could talk about the probability that someone would say the car is in the parking space, but this probability is likely to be a different number than the degree of truth for the statement that the car is in the parking space.

Fuzzy logic is controversial in some circles; e.g., many statisticians would maintain that probability is the only rigorous mathematical description of uncertainty. On the other hand, it has been quite successful from a practical point of view, and is now used in a wide variety of commercial products.

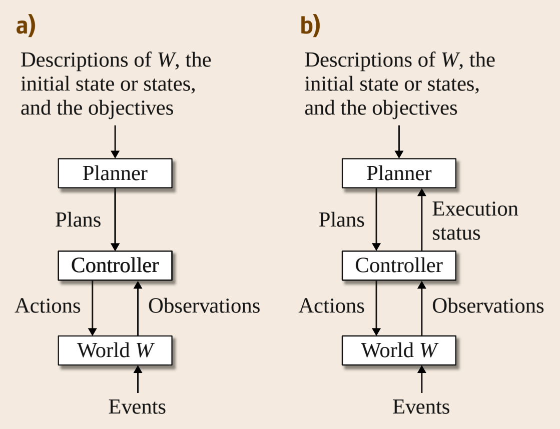
Applications of Fuzzy Logic. Fuzzy logic has been used in a wide variety of commercial products. Examples include washing machines, refrigerators, dishwashers, and other home appliances; vehicle subsystems such as automotive transmissions and braking systems; digital image-processing systems such as edge detectors; and some microcontrollers and microprocessors.

In such applications, a typical approach is to specify fuzzy sets that correspond to different subranges of a continuous variable; for instance, a temperature measurement for a refrigerator might have degrees of membership in several different temperature ranges, as shown in Fig. 14.5. Any particular temperature value will correspond to three degrees of membership, one for each of the three temperature ranges; and these degrees of membership could provide input to a control system to help it decide whether the refrigerator is too cold, too warm, or in the right temperature range.

14.1.4 Planning

In ordinary English, there are many different kinds of plans: project plans, floor plans, pension plans, urban plans, floor plans, etc. AI planning research focuses specifically on *plans of action*, i. e., [14.26]:

> *... representations of future behavior ... usually a set of actions, with temporal and other constraints on them, for execution by some agent or agents.*



a)
Descriptions of W, the initial state or states, and the objectives
Planner
Plans
Controller
Actions
Observations
World W
Events
b)
Descriptions of W, the initial state or states, and the objectives

Plans
Execution status
Controller
Actions
Observations
World W
Events

Fig. 14.6a,b Simple conceptual models for **(a)** offline and **(b)** online planning

Figure 14.6 gives an abstract view of the relationship between a planner and its environment. The planner's input includes a description of the world W in which the plan is to be executed, the initial state (or set of possible initial states) of the world, and the objectives that the plan is supposed to achieve. The planner produces a plan that is a set of instructions to a *controller*, which is the system that will execute the plan. In *offline planning*, the planner generates the entire plan, gives it to the controller, and exits. In *online planning*, plan generation and plan execution occur concurrently, and the planner gets feedback from the controller to aid it in generating the rest of the plan. Although not shown in the figure, in some cases the plan may go to a *scheduler* before going to the controller. The purpose of the scheduler is to make decisions about when to execute various parts of the plan and what resources to use during plan execution.

Examples. The following paragraphs include several examples of offline planners, including the sheet-metal bending planner in *Domain-Specific Planners*, and all of the planners in *Classical Planning* and *Domain-Configurable Planners*. One example of an online planner is the planning software for the Mars rovers in *Domain-Specific Planners*. The planner for the Mars rovers also incorporates a scheduler.

Domain-Specific Planners

A *domain-specific* planning system is one that is tailor-made for a given planning domain. Usually the design of the planning system is dictated primarily by the detailed requirements of the specific domain, and the

Fig. 14.7 One of the Mars rovers

Fig. 14.8 A sheet-metal bending machine

system is unlikely to work in any domain other other than the one for which it was designed.

Many successful planners for real-world applications are domain specific. Two examples are the autonomous planning system that controlled the Mars rovers [14.27] (Fig. 14.7), and the software for planning sheet-metal bending operations [14.28] that is bundled with Amada Corporation's sheet-metal bending machines (Fig. 14.8).

Classical Planning

Most AI planning research has been guided by a desire to develop principles that are *domain independent*, rather than techniques specific to a single planning domain. However, in order to make any significant headway in the development of such principles, it has proved necessary to make restrictions on what kinds of planning domains they apply to.

In particular, most AI planning research has focused on *classical* planning problems. In this class of planning problems, the world W is finite, fully observable, deterministic, and static (i.e., the world never changes except as a result of our actions); and the objective is to produce a finite sequence of actions that takes the world from some specific *initial* state to any of some set of *goal* states. There is a standard language, planning domain definition language (PDDL) [14.29], that can represent planning problems of this type, and there are dozens (possibly hundreds) of classical planning algorithms.

One of the best-known classical planning algorithms is GraphPlan [14.30], an iterative-deepening algorithm that performs the following steps in each iteration i:

1. Generate a *planning graph* of depth i. Without going into detail, the planning graph is basically the search space for a greatly simplified version of the planning problem that can be solved very quickly.
2. Search for a solution to the original unsimplified planning problem, but restrict this search to occur solely within the planning graph produced in step 1. In general, this takes much less time than an unrestricted search would take.

GraphPlan has been the basis for dozens of other classical planning algorithms.

Domain-Configurable Planners

Another important class of planning algorithms are the *domain-configurable planners*. These are planning systems in which the planning engine is domain independent but the input to the planner includes domain-specific information about how to do planning in the problem domain at hand. This information serves to constrain the planner's search so that the planner searches only a small part of the search space. There are two main types of domain-configurable planners:

- *Hierarchical task network* (HTN) planners such as O-Plan [14.31], SIPE-2 (system for interactive planning and execution) [14.32], and SHOP2 (simple hierarchical ordered planner 2) [14.33]. In these planners, the objective is described not as a set of goal states, but instead as a collection of *tasks* to perform. Planning proceeds by decomposing tasks into subtasks, subtasks into sub-subtasks, and so forth in a recursive manner until the planner reaches *primitive* tasks that can be performed using actions similar to those used in a classical planning system. To guide the decomposition process, the planner uses a collection of *methods* that give ways of decomposing tasks into subtasks.

- *Control-rule* planners such as temporal logic planner (TLPlan) [14.34] and temporal action logic planner (TALplanner) [14.35]. Here, the domain-specific knowledge is a set of rules that give conditions under which nodes can be pruned from the search space; for example, if the objective is to load a collection of boxes into a truck, one might write a rule telling the planner "do not pick up a box unless (1) it is not on the truck and (2) it is supposed to be on the truck." The planner does a forward search from the initial state, but follows only those paths that satisfy the control rules.

Planning with Uncertain Outcomes

One limitation of classical planners is that they cannot handle uncertainty in the outcomes of the actions. The best-known model of uncertainty in planning is the Markov decision process (MDP) model. MDPs are well known in engineering, but are generally defined over continuous sets of states and actions, and are solved using the tools of continuous mathematics. In contrast, the MDPs considered in AI research are usually discrete, with the relationships among the states and actions being symbolic rather than numeric (the latest version of PDDL [14.29] incorporates the ability to represent planning problems in this fashion):

- There is a set of states S and a set of actions A. Each state s has a reward $R(s)$, which is a numeric measure of the desirability of s. If an action a is applicable to s, then $C(a,s)$ is the cost of executing a in s.
- If we execute an action a in a state s, the outcome may be any state in S. There is a probability distribution over the outcomes: $P(s'|a,s)$ is the probability that the outcome will be s', with $\sum_{s'\in S} P(s'|a,s) = 1$.
- Starting from some *initial state* s_0, suppose we execute a sequence of actions that take the MDP from s_0 to some state s_1, then from s_1 to s_2, then from s_2 to s_3, and so forth. The sequence of states $h = \langle s_0, s_1, s_2, \ldots \rangle$ is called a *history*. In a *finite-horizon* problem, all of the MDP's possible histories are finite (i.e., the MDP ceases to operate after a finite number of state transitions). In an *infinite-horizon* problem, the histories are infinitely long (i.e., the MDP never stops operating).
- Each history h has a utility $U(h)$ that can be computed by summing the rewards of the states minus the costs of the actions

$$U(h) = \begin{cases} \sum_{i=0}^{n-1} R(s_i) - C(s_i, \pi(s_i)) + R(s_n)\,, \\ \quad \text{for finite-horizon problems}\,, \\ \sum_{i=0}^{\infty} \gamma^i R(s_i) - C(s_i, \pi(s_i)) \\ \quad \text{for infinite-horizon problems}\,. \end{cases}$$

  In the equation for infinite-horizon problems, γ is a number between 0 and 1 called the *discount factor*. Various rationales have been offered for using discount factors, but the primary purpose is to ensure that the infinite sum will converge to a finite value.
- A *policy* is any function $\pi : S \to A$ that returns an action to perform in each state. (More precisely, π is a *partial* function from S to A. We do not need to define π at a state $s \in S$ unless π can actually generate a history that includes s.) Since the outcomes of the actions are probabilistic, each policy π induces a probability distribution over MDP's possible histories

$$P(h|\pi) = P(s_0)P(s_1|\pi(s_0), s_0)P(s_1|\pi(s_1), s_1) \\ \times P(s_2|\pi(s_2), s_2)\ldots$$

  The *expected utility* of π is the sum, over all histories, of h's probability times its utility: $\mathrm{EU}(\pi) = \sum_h P(h|\pi)U(h)$. Our objective is to generate a policy π having the highest expected utility.

Traditional MDP algorithms such as value iteration or policy iteration are difficult to use in AI planning problems, since these algorithms iterate over the entire set of states, which can be huge. Instead, the focus has been on developing algorithms that examine only a small part of the search space. Several such algorithms are described in [14.36]. One of the best-known is real-time dynamic programming (RTDP) [14.37], which works by repeatedly doing a forward search from the initial state (or the set of possible initial states), extending the frontier of the search a little further each time until it has found an acceptable solution.

Applications of Planning

The paragraph on *Domain-Specific Planners* gave several examples of successful applications of domain-specific planners. Domain-configurable HTN planners such as O-Plan, SIPE-2, and SHOP2 have been deployed in hundreds of applications; for example a system for controlling unmanned aerial vehicles (UAVs) [14.38] uses SHOP2 to decompose high-level objectives into low-level commands to the UAV's controller.

Because of the strict set of restrictions required for classical planning, it is not directly usable in most application domains. (One notable exception is a cybersecurity application [14.39].) On the other hand, several domain-specific or domain-configurable planners are based on generalizations of classical planning techniques. One example is the domain-specific Mars rover planning software mentioned in *Domain-Specific Planners*, which involved a generalization of a classical planning technique called *plan-space planning* [14.40, Chap. 5]. Some of the generalizations included ways to handle action durations, temporal constraints, and other problem characteristics. For additional reading on planning, see *Ghallab* et al. [14.40] and *LaValle* [14.41].

14.1.5 Games

One of the oldest and best-known research areas for AI has been classical games of strategy, such as chess, checkers, and the like. These are examples of a class of games called *two-player perfect-information zero-sum turn-taking games*. Highly successful decision-making algorithms have been developed for such games: Computer chess programs are as good as the best grandmasters, and many games – including most recently checkers [14.42] – are now completely solved.

A *strategy* is the game-theoretic version of a policy: a function from states into actions that tells us what move to make in any situation that we might encounter. Mathematical game theory often assumes that a player chooses an entire strategy in advance. However, in a complicated game such as chess it is not feasible to construct an entire strategy in advance of the game. Instead, the usual approach is to choose each move at the time that one needs to make this move.

In order to choose each move intelligently, it is necessary to get a good idea of the possible future consequences of that move. This is done by searching a *game tree* such as the simple one shown in Fig. 14.9. In this figure, there are two players whom we will call Max and Min. The square nodes represent states where it is Max's move, the round nodes represent states where it is Min's move, and the edges represent moves. The terminal nodes represent states in which the game has ended, and the numbers below the terminal nodes are the payoffs. The figure shows the payoffs for both Max and Min; note that they always sum to 0 (hence the name *zero-sum* games).

From von Neuman and Morgenstern's famous Minimax theorem, it follows that Max's *dominant* (i. e., best) strategy is, on each turn, to move to whichever state s has the highest *minimax value* $m(s)$, which is defined as follows

$$m(s) = \begin{cases} \text{Max's payoff at } s\,, \\ \quad \text{if } s \text{ is a terminal node}\,, \\ \max\{m(t) : t \text{ is a child of } s\}\,, \\ \quad \text{if it is Max's move at } s\,, \\ \min\{m(t) : t \text{ is a child of } s\}\,, \\ \quad \text{if it is Min's move at } s\,, \end{cases} \tag{14.3}$$

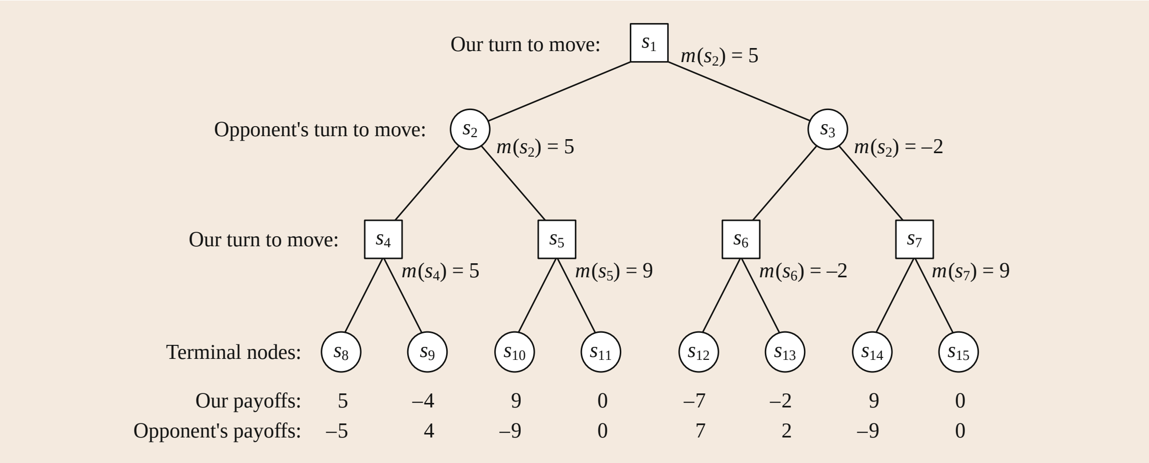

Fig. 14.9 A simple example of a game tree

where *child* means any immediate successor of s; for example, in Fig. 14.9,

$$m(s_2) = \min(\max(5, -4)\,, \max(9, 0)) = \min(5, 9) = 5\,; \quad (14.4)$$

$$m(s_3) = \min(\max(s_{12})\,, \max(s_{13})\,, \max(s_{14})\,, \max(s_{15})) = \min(7, 0) = 0\,. \quad (14.5)$$

Hence Max's best move at s_1 is to move to s_2.

A brute-force computation of (14.3) requires searching every state in the game tree, but most nontrivial games have so many states that it is infeasible to explore more than a small fraction of them. Hence a number of techniques have been developed to speed up the computation. The best known ones include:

- *Alpha–beta pruning*, which is a technique for deducing that the minimax values of certain states cannot have any effect on the minimax value of s, hence those states and their successors do not need to be searched in order to compute s's minimax value. Pseudocode for the algorithm can be found in [14.8, 43], and many other places.

  In brief, the algorithm does a modified depth-first search, maintaining a variable α that contains the minimax value of the best move it has found so far for Max, and a variable β that contains the minimax value of the best move it has found so far for Min. Whenever it finds a move for Min that leads to a subtree whose minimax value is less than α, it does not search this subtree because Max can achieve at least α by making the best move that the algorithm found for Max earlier. Similarly, whenever the algorithm finds a move for Max that leads to a subtree whose minimax value exceeds β, it does not search this subtree because Min can achieve at least β by making the best move that the algorithm found for Min earlier.

  The amount of speedup provided by alpha–beta pruning depends on the order in which the algorithm visits each node's successors. In the worst case, the algorithm will do no pruning at all and hence will run no faster than a brute-force minimax computation, but in the best case, it provide an exponential speedup [14.43].
- *Limited-depth search*, which searches to an arbitrary *cutoff depth*, uses a *static evaluation function* $e(s)$ to estimate the utility values of the states at that depth, and then uses these estimates in (14.3) as if those states were terminal states and their estimated utility values were the exact utility values for those states [14.8].

Games with Chance, Imperfect Information, and Nonzero-Sum Payoffs

The game-tree search techniques outlined above do extremely well in perfect-information zero-sum games, and can be adapted to perform well in perfect-information games that include chance elements, such as backgammon [14.44]. However, game-tree search does less well in imperfect-information zero-sum games such as bridge [14.45] and poker [14.46]. In these games, the lack of imperfect information increases the effective branching factor of the game tree because the tree will need to include branches for all of the moves that the opponent *might* be able to make. This increases the size of the tree exponentially.

Second, the minimax formula implicitly assumes that the opponent will always be able to determine which move is best for them – an assumption that is less accurate in games of imperfect information than in games of perfect information, because the opponent is less likely to have enough information to be able to determine which move is best [14.47].

Some imperfect-information games are *iterated* games, i. e., tournaments in which two players will play the same game with each other again and again. By observing the opponent's moves in the previous *iterations* (i. e., the previous times one has played the game with this opponent), it is often possible to detect patterns in the opponent's behavior and use these patterns to make probabilistic predictions of how the opponent will behave in the next iteration. One example is Roshambo (rock–paper–scissors). From a game-theoretic point of view, the game is trivial: the best strategy is to play purely at random, and the expected payoff is 0. However, in practice, it is possible to do much better than this by observing the opponent's moves in order to detect and exploit patterns in their behavior [14.48]. Another example is poker, in which programs have been developed that play nearly as well as human champions [14.46]. The techniques used to accomplish this are a combination of probabilistic computations, game-tree search, and detecting patterns in the opponent's behavior [14.49].

Applications of Games

Computer programs have been developed to take the place of human opponents in so many different games of strategy that it would be impractical to list all of them here. In addition, game-theoretic techniques have application in several of the behavioral and social sciences, primarily in economics [14.50].

Highly successful computer programs have been written for chess [14.51], checkers [14.42, 52], bridge [14.45], and many other games of strategy [14.53]. AI game-searching techniques are being applied successfully to tasks such as business sourcing [14.54] and to games that are models of social behavior, such as the iterated prisoner's dilemma [14.55].

14.1.6 Natural-Language Processing

Natural-language processing (NLP) focuses on the use of computers to analyze and understand human (as opposed to computer) languages. Typically this involves three steps: part-of-speech tagging, syntactic parsing, and semantic processing. Each of these is summarized below.

Part-of-Speech Tagging

Part-of-speech tagging is the task of identifying individual words as nouns, adjectives, verbs, etc. This is an important first step in parsing written sentences, and it also is useful for *speech recognition* (i. e., recognizing spoken words) [14.56].

A popular technique for part-of-speech tagging is to use hidden Markov models (HMMs) [14.57]. A hidden Markov model is a finite-state machine that has states and probabilistic state transitions (i. e., at each state there are several different possible *next* states, with a different probability of going to each of them). The states themselves are not directly observable, but in each state the HMM emits a symbol that we can observe.

To use HMMs for part-of-speech tagging, we need an HMM in which each state is a pair (w, t), where w is a word in some finite lexicon (e.g., the set of all English words), and t is a part-of-speech tag such as *noun*, *adjective*, or *verb*. Note that, for each word w, there may be more than one possible part-of-speech tag, hence more than one state that corresponds to w; for example, the word *flies* could either be a plural noun (the insect), or a verb (the act of flying).

In each state (w, t), the HMM emits the word w, then transitions to one of its possible next states. As an example (adapted from [14.58]), consider the sentence, *Flies like a flower.* First, if we consider each of the words separately, every one of them has more than one possible part-of-speech tag:

Flies	could be a plural noun or a verb;
like	could be a preposition, adverb, conjunction, noun or verb;
a	could be an article or a noun, or a preposition;
flower	could be a noun or a verb;

Here are two sequences of state transitions that could have produced the sentence:

- Start, (Flies, noun), (like, verb), (a, article), (flower, noun), End

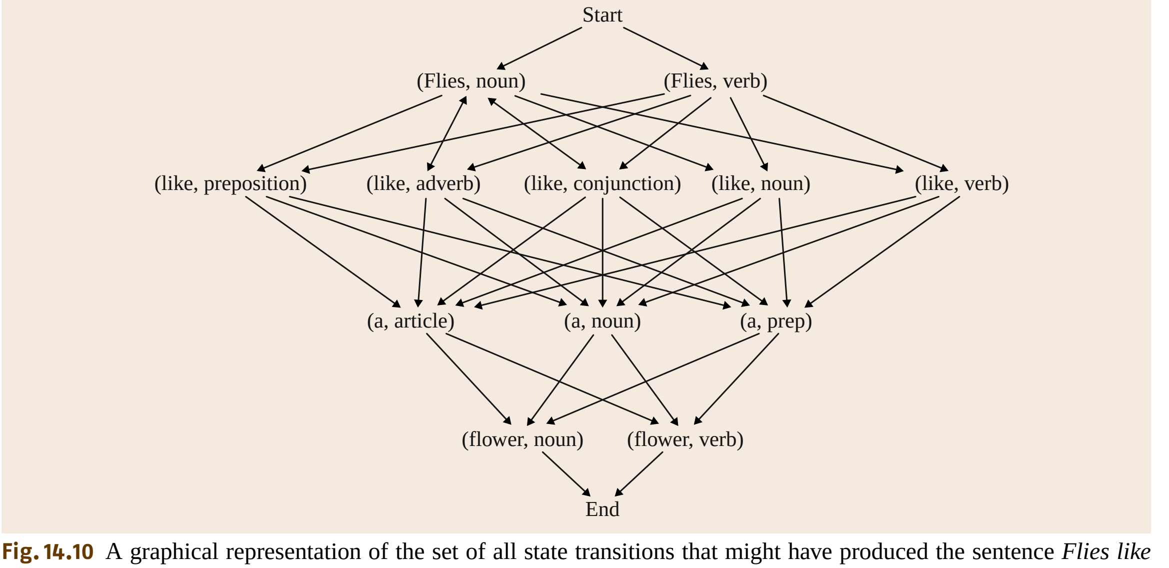

Fig. 14.10 A graphical representation of the set of all state transitions that might have produced the sentence *Flies like a flower.*

- Start, (Flies, verb), (like, preposition), (a, article), (flower, noun), End.

But there are many other state transitions that could also produce it; Fig. 14.10 shows all of them. If we know the probability of each state transition, then we can compute the probability of each possible sequence – which gives us the probability of each possible sequence of part-of-speech tags.

To establish the transition probabilities for the HMM, one needs a source of data. For NLP, these data sources are language *corpora* such as the Penn Treebank (http://www.cis.upenn.edu/˜treebank/).

Context-Free Grammars

While HMMs are useful for part-of-speech tagging, it is generally accepted that they are not adequate for parsing entire sentences. The primary limitation is that HMMs, being finite-state machines, can only recognize *regular* languages, a language class that is too restricted to model several important syntactical features of human languages. A somewhat more adequate model can be provided by using *context-free grammars* [14.59].

In general, a *grammar* is a set of rewrite rules such as the following:

$$
\begin{aligned}
\text{Sentence} &\rightarrow \text{NounPhrase}\ \ \text{VerbPhrase}\\
\text{NounPhrase} &\rightarrow \text{Article}\ \ \text{NounPhrase1}\\
\text{Article} &\rightarrow \text{the} \mid \text{a} \mid \text{an}\\
&\ldots
\end{aligned}
$$

The grammar includes both *nonterminal symbols* such as *NounPhrase*, which represents an entire noun phrase, and *terminal symbols* such as *the* and *an*, which represent actual words. A *context-free grammar* is a grammar in which the left-hand side of each rule is always a single nonterminal symbol (such as Sentence in the first rewrite rule shown above).

Context-free grammars can be used to *parse* sentences into parse trees such as the one shown in Fig. 14.11, and can also be used to generate sentences. A parsing algorithm (parser) is a procedure for searching through the possible ways of combining grammatical rules to find one or more parses (i. e., one or more trees similar to the one in Fig. 14.11) that match a given sentence.

Features. While context-free grammars are better at modeling the syntax of human languages than regular grammars, there are still important features of human languages that context-free grammars cannot handle well; for example, a pronoun should not be plural unless it refers to a plural noun. One way to handle these is to augment the grammar with a set of *features* that restrict the circumstances under which different rules can be used (e.g., to restrict a pronoun to be plural if its referent is also plural).

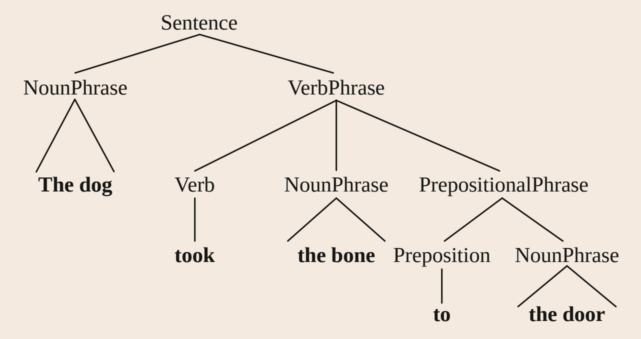

Fig. 14.11 A parse tree for the sentence *The dog took the bone to the door.*

PCFGs. If a sentence has more than one parse, one of the parses might be more likely than the others: for example, *time flies* is more likely to be a statement about time than about insects. A *probabilistic context-free grammar* (PCFG) is a context-free grammar that is augmented by attaching a probability to each grammar rule to indicate how likely different possible parses may be.

PCFGs can be learned from a parsed language corpora in a manner somewhat similar (although more complicated) than learning HMMs [14.60]. The first step is to acquire CFG rules by reading them directly from the parsed sentences in the corpus. The second step is to try to assign probabilities to the rules, test the rules on a new corpus, and remove rules if appropriate (e.g., if they are redundant or if they do not work correctly).

Applications

NLP has a large number of applications. Some examples include automated language-translation services such as Babelfish, Google Translate, Freetranslation, Teletranslator and Lycos Translation [14.61], automated speech-recogition systems used in telephone call centers, systems for categorizing, summarizing, and retrieving text (e.g., [14.62, 63]), and automated evaluation of student essays [14.64].

For additional reading on natural-language processing, see *Wu*, *Hsu*, and *Tan* [14.65] and *Thompson* [14.66].

14.1.7 Expert Systems

An *expert system* is a software system that performs, in some specialized field, at a level comparable to a human expert in the field. Most expert systems are *rule-based systems*, i. e., their *expert knowledge* consists of a set of logical inference rules similar to the Horn clauses discussed in Sect. 14.1.2.

Often these rules also have probabilities attached to them; for example, instead of writing

if A_1 and A_2 **then** conclude A_3

one might write

if A_1 and A_2 **then** conclude A_3 with probability p_0 .

Now, suppose A_1 and A_2 are known to have probabilities p_1 and p_2, respectively, and to be stochastically independent so that $P(A_1 \wedge A_2) = p_1 p_2$. Then the rule would conclude $P(C) = p_0 p_1 p_2$.

If A_1 and A_2 are not known to be stochastically independent, or if there are several rules that conclude A_3, then the computations can get much more complicated. If there are n variables $A_1, \ldots, A_n$, then the worst case could require a computation over the entire joint distribution $P(A_1, \ldots, A_n)$, which would take exponential time and would require much more information than is likely to be available to the expert system.

In some of the early expert systems, the above complication was circumvented by assuming that various events were stochastically independent even when they were not. This made the computations tractable, but could lead to inaccuracies in the results. In more modern systems, conditional independence (Sect. 14.1.3) is used to obtain more accurate results in a computationally tractable manner.

Expert systems were quite popular in the early and mid-1980s, and were used successfully in a wide variety of applications. Ironically, this very success (and the hype resulting from it) gave many potential industrial users unrealistically high expectations of what expert systems might be able to accomplish for them, leading to disappointment when not all of these expectations were met. This led to a backlash against AI, the so-called *AI winter* [14.67], that lasted for some years. but in the meantime, it became clear that simple expert systems were more elaborate versions of the decision logic already used in computer programming; hence some of the techniques of expert systems have become a standard part of modern programming practice.

Applications. Some of the better-known examples of expert-system applications include medical diagnosis [14.68], analysis of data gathered during oil exploration [14.69], analysis of DNA structure [14.70], configuration of computer systems [14.71], as well as a number of expert system *shell* (i. e., tools for building expert systems).

14.1.8 AI Programming Languages

AI programs have been written in nearly every programming language, but the most common languages for AI programming are Lisp, Prolog, C/C++, and Java.

Lisp

Lisp [14.72, 73] has many features that are useful for rapid prototyping and AI programming. These features include garbage collection, dynamic typing, functions as data, a uniform syntax, an interactive programming and debugging environment, ease of extensibility, and a plethora of high-level functions for both numeric and symbolic computations. As an example, Lisp has a built-in function, append, for concatenating two lists – but even if it did not, such a function could easily be written as follows:

```
(defun concatenate (x y)
  (if (null x)
    y
      (cons (first x)
        (concatenate (rest x) y))))
```

The above program is *tail-recursive*, i. e., the recursive call occurs at the very end of the program, and hence can easily be translated into a loop – a translation that most Lisp compilers perform automatically.

An argument often advanced in favor of conventional languages such as C++ and Java as opposed to Lisp is that they run faster, but this argument is largely erroneous. As of 2003, experimental comparisons showed compiled Lisp code to run nearly as fast as C++, and substantially faster than Java. (The speed comparison to Java might not be correct any longer, since a huge amount of work has been done since 2003 to improve Java compilers.) Probably the misconception about Lisp's speed arose from the fact that early Lisp systems ran Lisp code interpretively. Modern Lisp systems give users the option of running their code interpretively (which is useful for experimenting and debugging) or compiling their code (which provides much higher speed).

See [14.74] for a discussion of other advantages of Lisp. One notable disadvantage of Lisp is that, if one has a computer program written in a conventional language such as C, C++ or Java, it is difficult for such a program to call a Lisp program as a subroutine: one must run the Lisp program as a separate process in order to provide the Lisp execution environment. (On the other hand, Lisp programs can quite easily invoke subroutines written in conventional programming languages.)

Applications. Lisp was quite popular during the expert-systems boom of the mid-1980s, and several *Lisp machine* computer architectures were developed and marketed in which the entire operating system was written in Lisp. Ultimately these machines did not meet with long-term commercial success, as they were eventually surpassed by less-expensive, less-specialized hardware such as Sun workstations and Intel x86 machines.

On the other hand, development of software systems in Lisp has continued, and there are many current examples of Lisp applications. A few of them include the visual lisp extension language for the AutoCAD computer-aided design system (autodesk.com), the Elisp extension language for the Emacs editor (http://en.wikipedia.org/wiki/Emacs_Lisp)the Script-Fu plugins for the GNU Image Manipulation Program (GIMP), the Remote Agent software deployed on NASA's *Deep Space 1* spacecraft [14.75], the airline fare shopping engine used by Orbitz [14.9], the SHOP2 planning system [14.38], and the Yahoo Store e-commerce software. (As of 2003, about 20 000 Yahoo stores used this software. The author does not have access to more recent statistics.)

Prolog

Prolog [14.76] is based on the notion that a general theorem-prover can be used as a programming environment in which the program consists of a set of logical statements. As an example, here is a Prolog program for concatenating lists, analogous to the Lisp program given earlier

```
   concatenate([],Y,Y).
   concatenate([First|Rest],Y,[First|Z]) :-
concatenate(Rest,Y,Z).
```

To concatenate two lists [a,b] and [c], one asks the theorem prover if there exists a list *Z* that is their concatenation; and the theorem prover returns *Z* if it exists

```
?- concatenate([a,b],[c],Z)
Z=[a,b,c].
```

Alternatively, if one asks whether there are lists *X* and *Y* whose concatenation is a given list *Z*, then there are several possible values for *X* and *Y*, and the theorem prover will return *all* of them

```
?- concatenate(X,Y,[a,b])
X = []; Y = [a,b]
X = [a]; Y = [b]
X = [a,b]; Y = []
```

One of Prolog's biggest drawbacks is that several aspects of its programming style – for example, the lack of an assignment statement, and the automated backtracking – can require workarounds that feel unintuitive to most programmers. However, Prolog can be good for problems in which logic is intimately involved, or whose solutions have a succinct logical characterization.

Applications. Prolog became popular during the the expert-systems boom of the 1980s, and was used as the basis for the Japanese Fifth Generation project [14.77], but never achieved wide commercial acceptance. On the other hand, an extension of Prolog called constraint logic programming is important in several industrial applications (see *Constraint Satisfaction and Constraint Optimization*).

C, C++, and Java

C and C++ provide much less in the way of high-level programming constructs than Lisp, hence developing code in these languages can require much more effort. On the other hand, they are widely available and provide fast execution, hence they are useful for programs that are simple and need to be both portable and fast; for example, neural networks need very fast execution in order to achieve a reasonable learning rate, and a back-propagation procedure can be written in just a few pages of C or C++ code.

Java is a lower-level language than Lisp, but is higher-level than C or C++. It uses several ideas from Lisp, most notably garbage collection. As of 2003 it ran much more slowly than Lisp, but its speed has improved in the interim and it has the advantages of being highly portable and more widely known than Lisp.

14.2 Emerging Trends and Open Challenges

AI has gone through several periods of optimism and pessimism. The most recent period of pessimism was the *AI winter* mentioned in Sect. 14.1.7. AI has emerged from this period in recent years, primarily because of the following trends. First is the exponential growth improvement in computing power: computations that used to take days or weeks can now be done in minutes or seconds. Consequently, computers have become much better able to support the intensive computations that AI often requires. Second, the pervasive role of computers in everyday life is helping to erase the apprehension that has often been associated with AI in popular culture. Third, there have been huge advances in AI research itself. AI concepts such as search, planning, natural-language processing, and machine learning have developed mature theoretical underpinnings and extensive practical histories.

AI technology is widely expected to become increasingly pervasive in applications such as data mining, information retrieval (especially from the web), and prediction of human events (including anything from sports forecasting to economics to international conflicts).

During the next decade, it appears quite likely that AI will be able to make contributions to the behavioral and social sciences analogous to the contributions that computer science has made to the biological sciences during the past decade. To make this happen, one of the biggest challenges is the huge diversity among the various research fields that will be involved. These include behavioral and social sciences such as economics, political science, psychology, anthropology, and sociology, and technical disciplines such as AI, robotics, computational linguistics, game theory, and operations research. Researchers from these fields will need to forge a common understanding of principles, techniques, and objectives. Research laboratories are being set up to foster this goal (one example is the University of Maryland's Laboratory for Computational Cultural Dynamics (http://www.umiacs.umd.edu/research/LCCD/), which is co-directed by the author of this chapter), and several international conferences and workshops on the topic have been recently established [14.78, 79].

One of the biggest challenges that currently faces AI research is its fragmentation into a bewilderingly diverse collection of subdisciplines. Unfortunately, these subdisciplines are becoming rather insular, with their own research conferences and their own (sometimes idiosyncratic) notions of what constitutes a worthwhile research question or a significant result. The achievement of human-level AI will require integrating the best efforts among many different subfields of AI, and this in turn will require better communication amongst the researchers from these subfields. I believe that the field is capable of overcoming this challenge, and that human-level AI will be possible by the middle of this century.

15. Virtual Reality and Automation

P. Pat Banerjee

Virtual reality of human activities (e.g., in design, manufacturing, medical care, exploration or military operations) often concentrates on an automated interface between virtual reality (VR) technology and the theory and practice of these activities. In this chapter we focus mainly on the role of VR technology in developing this interface. Although the scope and range of applications is large, two illustrative areas (production/service applications and medical applications) are explained in some detail to offer some insight into the magnitude of the benefits and existing challenges.

15.1 Overview of Virtual Reality and Automation Technologies

Virtual manufacturing and automation first came into prominence in the early 1990s, in part as a result of the US Department of Defense Virtual Manufacturing Initiative. The topic broadly refers to the modeling of manufacturing systems and components with effective use of audio-visual and/or other sensory features to simulate or design alternatives for an actual manufacturing environment mainly through effective use of high-performance computers.

To understand the area, first we introduce a broader area of virtual reality (VR) and visual simulation systems. VR brings in a few exciting new developments. Firstly it provides a major redefinition of perspective projection, by introducing the concept of user-centered perspective. Traditional perspective projection is fixed, whereas in virtual reality one has the option to vary the perspective in real time, thus closely mimicking our natural experience of a three-dimensional (3-D) world. In the past few years, VR and visual simulation systems have made a huge impact in terms of industrial adoption; for example, Cyberedge Information Services conducted a survey [15.1] that provided the following details:

- Industry growth remains strong: 9.8% in 2003
- Industry value: US$ 42.6 billion worldwide
- Five-year forecast: industry value reaches US$ 78 billion in 2008
- Average system cost: US$ 356 310
- Number of systems sold in 2003: 338 000
- Companies involved in visual simulation worldwide: 17 334
- Most common visual display system: monoscopic desktop monitor
- Least common visual display system: autostereoscopic display
- Most common operating system: Microsoft Windows XP.

The survey [15.1] further comments on the top 17 applications of visual simulation systems from 1999–2003 as follows:

Table 15.1 Automation advantages of virtual reality (VR); * Unique to VR. General advantages of simulation, including less costs, less risks, less delay, and ability to study as yet unbuilt structures/objects are also valid

What is automated?	Application example	Advantage*
Application domain	• Testing a simulated mold of a new engine	• Better visualization of tested product
	• Developing battlefield tactics	• Greater ability to collaborate in planning and design of complex virtual situations
Human supervisory interface	• Training in dental procedures	• Detailed hands-on experience in a large simulated library of dental problems
	• Teleoperating robots	
Human feedback interface	• Improving the safety of a process	• Greater precision and quality of feedback through haptics
	• Learning the properties of surfaces	• Better understanding of simulated behaviors
Human application interaction	• Telerepair or teleassembly of remote objects	• Greater ability to obtain knowledge about and manipulate in remote global and space locations
		• Deeper sense of involvement and engagement by the interacting humans

In each of these application areas, VR is advantageous in automating and improving three critical areas, as shown in Table 15.1. A smaller subsection of VR and visual simulation is virtual manufacturing and automation, which often concentrates on an interface between VR technology and manufacturing and automation theory and practice. In this chapter we concentrate mainly on the role of VR technology in developing this interface. Some areas that can benefit from development of virtual manufacturing include product design [15.2, 3], hazardous operations modeling [15.4, 5], production process modeling [15.6, 7], training [15.8, 9], education [15.10, 11], information visualization [15.12, 13], telecommunications [15.14, 15], and teletravel. Lately a number of surgical simulation applications have emerged.

VR is closely associated with an environment commonly known as a virtual environment (VE). VE systems differ from other previously developed computer-centered systems in the extent to which real-time interaction is facilitated, the perceived visual space is three- rather than two-dimensional, the human–machine interface is multimodal, and the operator is immersed in the computer-generated environment. The interactive, virtual image displays are enhanced by special processing and by nonvisual display modalities, such as auditory and haptic, to convince users that they are immersed in a synthetic space.

The means of simulating a VE today is through immersion in computer graphics coupled with acoustic interface and domain-independent interacting devices, such as wands, and domain-specific devices such as the steering and brakes for cars, or earthmovers or instrument clusters for airplanes (Fig. 15.1a–c). Immersion gives the feeling of depth, which is essential for a three-dimensional effect. Head-mounted displays, stereoscopic projectors, and retinal display are some of the technologies used for such environments.

15.2 Production/Service Applications

15.2.1 Design

The immersive display technology can be used for creating virtual prototypes of products and processes. Integrated production system engineering environments can provide functions to specify, design, engineer, simulate, analyze, and evaluate a production system. Some examples of the functions which might be included in an integrated production system engineering environment are:

1. Identification of product specifications and production system requirements
2. Producibility analysis for individual products
3. Modeling and specification of manufacturing processes
4. Measurement and analysis of process capabilities
5. Modification of product designs to address manufacturability issues
6. Plant layout and facilities planning
7. Simulation and analysis of system performance
8. Consideration of various economic/cost tradeoffs of different manufacturing processes, systems, tools, and materials
9. Analysis supporting selection of systems/vendors
10. Procurement of manufacturing equipment and support systems
11. Specification of interfaces and the integration of information systems
12. Task and workplace design
13. Management, scheduling, and tracking of projects.

The interoperability of the commercial engineering tools that are available today is a challenge. Examples of production systems which may eventually be engineered using this type of integrated environment include: transfer lines, group technology cells, automated or manually operated workstations, customized multipurpose equipment, and entire plants.

15.2.2 Material Handling and Manufacturing Systems

An important outcome of virtual manufacturing is virtual factories of the future. When a single factory may cost over a billion US dollars (as is the case, for instance, in the semiconductor industry), it is evident that manufacturing decision-makers need tools that support good decision making about their design, deployment, and operation. However, in the case of manufacturing models, there is usually no testbed but the factory itself; development of models of manufacturing operations is very likely to disrupt factory operations while the models are being developed and tested.

Virtual factories are based on sophisticated computer simulations for a distributed, integrated, computer-based composite model of a total manufacturing environment, incorporating all the tasks and resources necessary to accomplish the operation of designing, producing, and delivering a product. With virtual factories capable of accurately simulating factory operations over time scales of months, managers would be able to explore many potential production configurations and schedules or different control and organizational schemes at significant savings of cost and time in order to determine how best to improve performance. A virtual factory model involves a comprehensive model or structure for integrating a set of heterogeneous and hierarchical submodels at various levels of abstraction. An ultimate goal would be the creation of a demonstration platform that would compare the results of real factory operations with the results of simulated factory operations. This demonstration platform would use a computer-based model of an existing factory and would compare its performance with that of a similarly equipped factory running the same product line, but using, for example, a new layout of equipment, a better scheduling system, a paperless product and process description, or fewer or more human operators. The entire factory would have to be represented in sufficient detail so that any model user, from factory manager to equipment operator, would be able to extract useful results. To accomplish this, two broad areas need to be addressed:

1. Hardware and software technology to handle sophisticated graphics and data-oriented models in a useful and timely manner
2. Representation of manufacturing expertise in models in such a way that the results of model operation satisfy manufacturing experts' needs for accurate responses.

Some of the research considerations related to virtual modeling technology are as follows:

- *User interfaces*. Since factory personnel in the 21st century will be interacting with many applications, it will not suffice for each application to have its own set of interfaces, no matter how good any individual one is. Much thought has to be given both to the nature of the specific interfaces and to the integration of interfaces in a system designed so as not to confuse the user. Interface tools that allow the user to filter and abstract large volumes of data will be particularly important.
- *Model consistency*. Models will be used to perform a variety of geographically dispersed functions over a short time scale during which the model information must be globally accurate. In addition, pieces of the model may themselves be widely distributed. As a result, a method must be devised to ensure model consistency and concurrency, perhaps for extended time periods. The accuracy of models used concurrently for different purposes is a key determinant of the benefits of using such models.
- *Testing and validation of model concepts*. Because a major use of models is to make predictions about matters that are not intuitively obvious to decision-makers, testing and validation of models and their use are very difficult. For factory operations and design alike, there are many potential *right answers* to important questions, and none of these is *provably correct* (e.g., what is the *right* schedule?). As a result, models have to be validated by being tested against understandable conditions, and in many cases, common sense must be used to judge if a model is *correct*. Because models must be tested under stochastic factory conditions, which are hard to duplicate or emulate, outside the factory environment, an important area for research involves developing tools for use in both testing and validating model operation and behavior. Tools for automating sensitivity analysis in the testing of simulation models would help to overcome model validation problems inherent in a stochastic environment. For more details, please refer to [15.16].

Figure 15.2 shows a schematic user interface for remote facility management using virtual manufacturing concepts. The foreground represents a factory floor layout that identifies important regions of the plant. The walls separating different regions have been removed to obtain a complete bird's eye view of the plant. Transmitted streaming motion from video capture of important regions can be provided as a background. For this purpose one needs to identify and specify the objects for motion streaming. A combination of video and VR is a powerful tool in this context. The advantage of streaming motion coordinates to animate the factory floor would be to give the floor manager an overview of the floor. A suitable set of symbols can be designed to designate the status modes of various regions, namely running state, breakdown state, shutdown state, waiting state (e.g., for parts, worker), scheduled maintenance state, etc. An avataric representation of the floor manager can

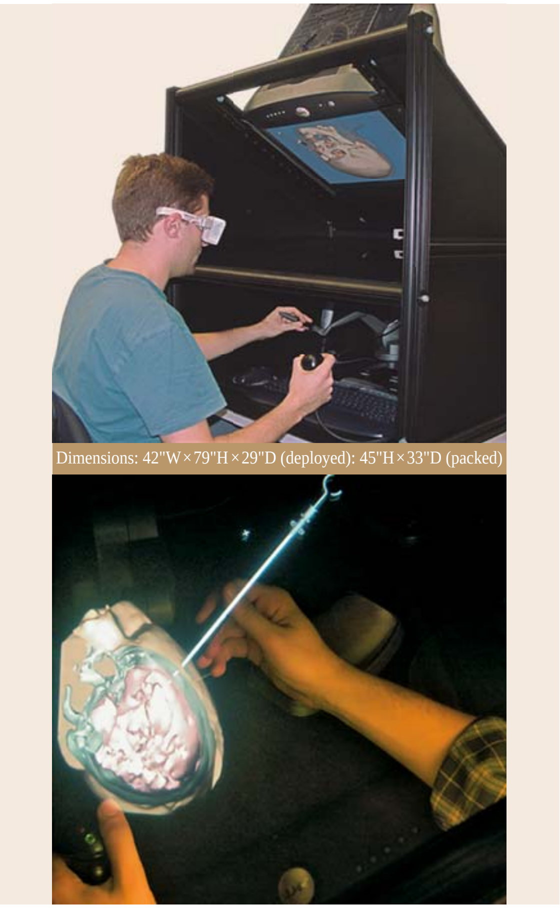
be used to guide operations. A window for the product testing area and communication with product designers can be used to efficiently streamline the product design process. A video camera device can be integrated to stream motion coordinates after the objects in the product design area and their layouts have been specified. Another window showing the assembly training of a new employee can illustrate the use of this concept for another important area of the plant. A similar feature can be designed for warehouse monitoring and supply chain management. A window for management of other plants can take one to different plants, located anywhere in the world. Finally a scrolling text window can pop up any important or emergency messages such as suddenly scheduled meetings, changes of deadline, sudden shifts in strategy, etc.

15.3 Medical Applications

Medical simulations using virtual automation have been a recent area of growth. Some of our activities in this area are highlighted in this Section. Using haptics and VR in high-fidelity open-surgical simulation, certain principles of design and operational prototyping can be highlighted. A philosophy of designing device prototypes by carefully analyzing contact based on open surgical simulation requirements and mapping them with open-source software and off-the-shelf hardware components is presented as an example. Applications in neurosurgery (ventriculostomy), ophthalmology (capsulorrhexis), and dentistry (periodontics) are illustrated. First, a prototype device known as ImmersiveTouch is described, followed by three applications.

ImmersiveTouch is a patent-pending [15.17] next-generation augmented VR technology invented by us, and is the first system that integrates a haptic device with a head and hand tracking system, and a high-resolution high-pixel-density stereoscopic display (Fig. 15.3). Its ergonomic design provides a comfortable working volume in the space of a standard desktop. The haptic device is collocated with the 3-D graphics, giving the user a more realistic and natural means to manipulate and modify 3-D data in real time. The high-performance, multisensorial computer interface allows relatively easy development of VR simulation and training applications that appeal to many stimuli: audio, visual, tactile, and kinesthetic.

ImmersiveTouch represents an integrated hardware and software solution. The hardware integrates 3-D stereo visualization, force feedback, head and hand tracking, and 3-D audio. The software provides a unified applications programming interface (API) to handle volume processing, graphics rendering, haptics rendering, 3-D audio feedback, and interactive menus and buttons. ImmersiveTouch is an evolutionary virtual-reality system resulting from the integration of a series of hardware solutions to 3-D display issues *and* the development of a unique VR software platform (API) drawing heavily on open-source software and databases.



Dimensions: 42"W × 79"H × 29"D (deployed): 45"H × 33"D (packed)

Fig. 15.3 Immersive touch and its neurosurgical application

15.3.1 Neurosurgical Virtual Automation

Neurosurgical procedures, particularly cranial applications, lend themselves to VR simulation. The working space around the cranium is limited. Anatomical relationships within the skull are generally fixed and respiratory or somatic movements do not significantly impair imaging or rendering. The same issues that make cranial procedures so suitable for intraoperative navigation also apply to virtual operative simulation. The complexity of so many cerebral structures also allows little room for error, making the need for skill-set acquisition prior to the procedure that much more significant. The emergence of realistic neurosurgical simulators has been predicted since the mid-1990s when the explosion in computer processing speed seemed to presage future developments [15.18]. VR techniques have been attempted to simulate several types of spinal procedures such as lumbar puncture, in addition to craniotomy-type procedures.

Ventriculostomy is a high-frequency surgical intervention commonly employed for treatment of head injury and stroke. This extensively studied procedure is a good example problem for augmented VR simulators. We investigated the ability of neurosurgery residents at different levels of training to cannulate the ventricle, using computer tomography data on an ImmersiveTouch workstation. After a small incision is made and a bur hole is drilled on a strategically chosen spot in the patient's skull, a ventriculostomy catheter is inserted, aiming for the ventricles. A distinct *popping* or puncturing sensation is felt as the catheter enters the frontal horn of the lateral ventricle [15.19].

The performance evaluation from the ImmersiveTouch simulator based on a large sample of neurosurgeons was comparable to clinical study findings, in which the average distance and standard deviation of the catheter tip to the foramen of Monroe in both cases were close [15.18].

15.3.2 Ophthalmic Virtual Automation

Cataract surgery is the most common surgical procedure performed by ophthalmic residents-in-training and general ophthalmologists in the USA. With over 1.5 million procedures performed every year, it represents the largest single surgical care provided under Medicare in the USA.

Cataract surgery involves the removal of the opacified crystalline lens by phacoemulsification and replacement of the lens with an intraocular lens implant. Over the years cataract surgery has become a highly technical procedure requiring a number of very fine skills, under an operating microscope. It involves the use and understanding of sophisticated technology, as well as fine hand–eye coordination movements. The training of this highly skilled procedure to residents has become a challenging task for teaching physicians because of its highly technical nature. Current ways of training residents include:

- Practising surgical procedures in a *wet lab* situation, where surgery is practised on animal eyes. Though this procedure has some similarity to human surgery, there are many problems associated with this technique, which include: (a) Porcine and bovine models that do not provide a realistic sense of tissue tension, nor do they mimic the accurate dimensions of the human eye; (b) Any assessment of skills acquired during such animal laboratory procedures with an observing physician is often subjective and repetition is difficult.
- Another technique that has been used extracts eyes from a postmortem human eye bank to perform phacoemulsification. These tissues are very difficult to obtain, and are fairly expensive to procure.
- A common technique, the *apprenticeship* technique, is a *see one, do one, teach one* approach. However, apprenticeship is not the best approach, especially for a highly skilled procedure such as phacoemulsification.

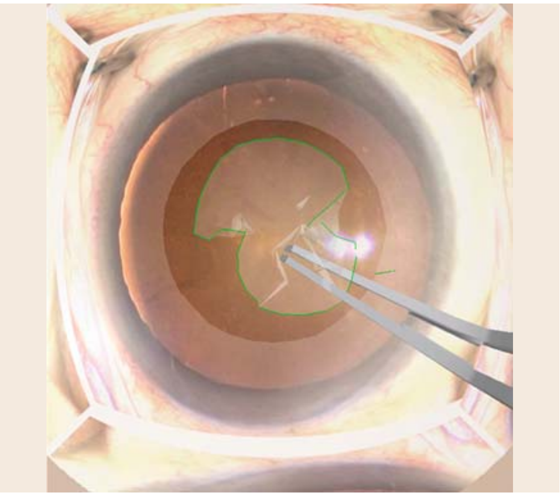


Fig. 15.4 Capsulorrhexis simulation in cataract surgery using virtual reality and haptics

In summary, all of the current paradigms available are suboptimal from the perspective of surgical education as well as patient care, and developments in virtual-reality simulation will allow the surgeon to gain realistic operative experience before their first cataract surgery.

The ophthalmic development of virtual-reality procedures has been minimal. The EYESI ophthalmic surgical simulator (VRmagic GmbH, Mannheim, Germany) simulates intraocular surgery but they have a heavy reliance on physical prototyping that is hard to reconfigure.

The various steps in cataract surgery can be broken down into many steps, including incision, performing capsulorrhexis, phacoemulsification of the cataract and removal, removal of cortex, and placement of the intraocular lens. Many of these steps are being simulated by us using virtual reality and haptics (Fig. 15.4).

15.3.3 Dental Virtual Automation

Dentistry provides a rich collection of clinical procedures which require dexterity in tactile feedback and thus provide a number of very interesting simulation problems. The rationale for using dental simulators is that, by using them, preclinical dental students learn procedure skills faster and more efficiently. The majority of current dental simulators use realistic manikins along with dentiform models (Kavo, Adec or Nevin) incorporated into a simulated dental operatory [15.19]. A number of dental schools also use the DentSim simulator (DenX Ltd., Jerusalem, Israel).

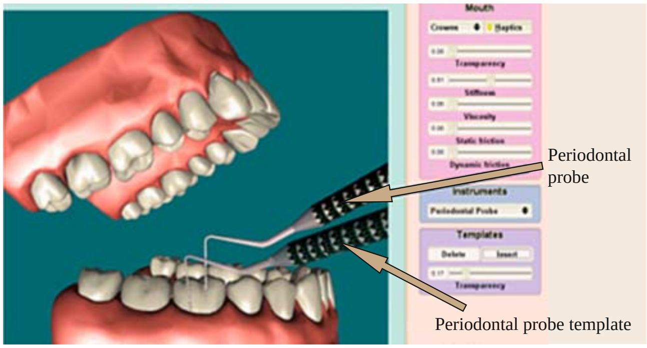

Fig. 15.5 Periodontal simulations

This is a more sophisticated manikin simulator incorporating computer-aided audiovisual simulations having a VR component. It uses a tracking system to trace the movements of a handpiece and scores the accuracy of a student's cavity preparation in a manikin's synthetic tooth.

The addition of haptics to dental simulators is extremely important because sensory motor skills must be developed by dental and hygiene trainees in order to be successful in their profession. This is especially true in the ability to perform a variety of periodontal procedures (i. e., scaling and root planning, periodontal probing, and the use of a periodontal explorer). These tactile skills are currently acquired by having trainees observe instructor demonstrations of a specific procedure and then having them practise on manikins or animal heads. After sufficient training and practice on models, the students proceed to patients. This time-consuming teaching process requires excessive one-on-one instructor–student interaction without students actually feeling what the instructor feels or being physically guided by the instructor while performing a procedure on a manikin or a patient. With the current critical shortage of dental faculty, the training problem has been compounded.

Dental simulators that have been developed include those from Novint Technologies (Novint, Albuquerque, NM) and Simulife Systems (Simulife Systems, Paris, France). Our work has led to PerioSim at the University of Illinois at Chicago, College of Dentistry [15.19, 20]. The PerioSim prototype system for periodontal probing is designed to provide a haptic force feedback and guidance system for interaction with an on-screen display. The display is a 3-D VR model of a periodontal probe and a human upper and lower dental arch, which includes teeth, their supportive structures, and other oral tissues. The fidelity of the haptic-based system is currently sufficiently sophisticated to differentiate between hard and soft, and normal and pathological tissues. While the development is taking place the other goals are to determine how realistic the PerioSim simulator is and the time required for learning how to use it.

The steps followed by a trainee are as follows: Using a control panel, one of three periodontal instruments can be selected for on-screen use: a periodontal probe, a periodontal explorer or a Gracy scaler. The monitor graphic display is used in conjunction with a haptic device (PHANToM from SensAble Corp., Woburn, MA) for force feedback and perceiving the textural feel of the gingival crevice/pocket area. The 3-D VR periodontal probe can be used to locate and measure crevice or pocket depths around the gingival margins of the teeth. These sites can be identified via the haptic feedback obtained from the PHANToM stylus with or without the actual instrument attached to the stylus. A trainee will be able to differentiate the textural feel of pocket areas and locate regions of subgingival calculus. Since the root surface is covered by gingiva, the trainee cannot see the area being probed or the underlying calculus and must depend totally on haptic feedback to identify these areas. This situation corresponds to conditions encountered clinically. The control panel, which can be made to appear or disappear as needed, has a variety of controls, including adjusting the haptic feel and the degree of transparency of the gingiva, roots, crowns, bone or calculus. The control panel also permits the instructor to insert a variety of templates to guide student instrument positioning in a 3-D display environment (Fig. 15.5).

15.4 Conclusions and Emerging Trends

Virtual-reality and automation technologies are aimed at reducing the time spent in providing service and desired training. At present almost all major companies operate globally. Management, control, and service of overseas facilities and products deployed overseas is a major challenge. Both processes and factories need to be simulated, although the current thrust seems to be on individual process simulation. One of the important emerging themes is constant evolution of enabling technologies.

A review of ongoing evolution of enabling technologies is available in *Burdea* and *Coiffet*'s book on VR technologies [15.21]. The two main areas in this regard are hardware and software technologies (e.g., [15.22]). The hardware can be broken down into input and output devices and computing hardware architectures. Input devices consist of various trackers; mechanical, electromagnetic, ultrasonic, optical, and hybrid inertial trackers are covered. Tracking is used to navigate and manipulate in a VR environment. There are many more three-dimensional navigation devices that are available, including hand and finger movement tracking. Output devices address graphics displays, sound, and haptic feedback. The graphics displays include head-mounted displays, binocular-type hand-supported displays, floor-supported displays, desktop displays, and large displays based on large monitors and projectors supporting multiple participants simultaneously. The haptics tactile feedback covers tactile mouse, touch-based glove, temperature-feedback glove, force-feedback joysticks, and haptic robotic arms. Hardware architectures include the two major rendering pipelines: graphics and haptics. Personal computer (PC) graphics accelerator cards such as those from nVidia are currently in vogue. Various distributed VR architectures addressing issues such as graphics and haptics pipelines synchronization, PC clusters for tiled visual displays, and multiuser shared virtual environments are equally important. Software challenges include those in modeling and VR programming. Modeling addresses geometric modeling, kinematics modeling, physical modeling, and behavior modeling. VR programming will continue to be aided by evolution of more powerful toolkits. The enabling technologies outlined above can provide answers to many of these challenges in virtual reality and automation.

16. Automation of Mobility and Navigation

Anibal Ollero, Ángel R. Castaño

This chapter deals with general concepts on the automation of mobility and autonomous navigation. The emphasis is on the control and navigation of autonomous vehicles. Thus, after an introduction with historical background and basic concepts, the chapter briefly reviews general concepts on vehicle motion control by using models of the vehicle, as well as other approaches based on the information provided by humans. Autonomous navigation is also studied, involving not only motion planning and trajectory generation but also interaction with the environment to provide reactivity and adaptation in the autonomous navigation. These interactions are represented by means of nested loops closed at different frequencies with different bandwidth requirements. The human interactions at different levels are also analyzed, taking into account transmission of control commands and feedback of sensory information. Finally, the chapter studies multiple mobile systems by analyzing coordinated navigation of multiple autonomous vehicles and cooperation paradigms for autonomous mission execution.

16.1 Historical Background

The ambition to emulate the motion of living things has been sustained throughout history, from old automata to humanoid robots today. The Ancient Greeks and also other cultures from around the world created many automata and managed to make animated statues of mechanical people, animals, and objects (e.g., the moving stone statues made by Daedalus in 520 BC, the flying magpie created by King-shu in 500 BC, the mechanical pigeon made by Archytas of Tarentum in 400 BC, the singing blackbird and other figures that drank and moved created by Ctesibius in 280 BC, etc.). In the 14th century, remarkable automata were produced in Europe (by Johannes Müller and Leonardo da Vinci). The descriptions of mechanical automata in the 16th, 17th, and 18th centuries are also well known (Gianello Della Tour, Salomon de Caus, Christiaan Huygens, Jacques de Vauçanson, etc.). They had complex mechanisms and produced sounds and music synchronized with the motions. Many interesting automata were made in the 19th century. This was the time when production techniques decreased in cost. The robots (*R.U.R.* (Rossum's Universal Robots), 1921) gave their name to many mechanical men built in the 1920 and 1930s to be shown in films or fairs or to demonstrate remote control techniques, such as the Westinghouse robots in the 1930s.

By the end of the 19th and beginning of the 20th century, mass industrial production required the development of automation. Mobility automation also played an important role. Then, for example, primitive conveyor belts were used in the 19th century and the technology was introduced into assembly lines by 1913 in Ford Motor Company's factory. Automation of mobility in general became a key issue in factory automation. The first programmable paint-spraying mechanism was designed in 1938. Industrial automation met robotics with the design in 1954 of the first programmable robot by Devol, who coined the term *universal automation*. General Motors applied the first industrial robot on a production line in 1962. From 1966 through 1972, the Artificial Intelligence Center at SRI International (then the Stanford Research Institute) conducted research on the mobile robot system *Shakey*.

Control and automation in the transportation of goods and people has also been the target for many centuries. Rudimentary elevators, operated by animal and human power or by water-driven mechanisms, were in use during the Middle Ages and can be traced back to the third century BC. The elevator as we know it today was first developed during the 19th century and relied on steam or hydraulic plungers for lifting capability under manual control. Thus, the valves governing the water flow were manipulated by passengers using ropes running through the cab, a system later enhanced with the incorporation of lever controls and pilot valves to regulate cab speed.

Control has also been a key concept in the development of vehicles. Watt's steam engines controlled by ball governor in 1787 played a central role in the railway developed by 1804 in Great Britain. Control also played a decisive role in the manned airplane flights of the Wright brothers in 1903. Automatic feedback control for flight guidance was possible by 1903 thanks to the gyroscope. Spinning gyroscopes were first mounted in torpedoes. The gyroscope resisted any change in direction by controlling the rudder, automatically correcting any deviation from a straight course. By 1910 gyroscopic stabilizing devices had been mounted in ships, and even in an airplane.

16.2 Basic Concepts

Automation of mobility can be examined by considering the degree of flexibility. Railways are mechanically constrained by the rails. Thus, railway automation has been accomplished since the 1980s in France, where automated subway lines have been in operation since the 1990s for mass transit. The same happens with elevators and industrial automated warehouse systems based on overhead trolleys, as shown in Fig. 16.1 [16.1]. This is an effective solution in many warehouse systems and industry transportation in general. In other cases the path of motion is also physically predetermined by different type of guides, such as inductive guide wires embedded in the floor, which are used in industrial automation to guide so-called *automated guided vehicles* (AGVs). Other AGVs use guideways painted in the floor that require maintenance to be detectable by AGV optical sensors. Installation of new AGVs or changing the pathways is time consuming and expensive in these systems. A more flexible solution consists of using beacons or marker arrangements installed in the factory. These systems are more flexible but require line-of-sight communication between devices to be mounted on the vehicles and a certain number of devices in the industrial environment. Increasing flexibility in industrial transportation has been an objective for many years. The application of industrial autonomous vehicles (Fig. 16.2) and mobile robots with onboard environment sensing for autonomous navigation provides higher flexibility but poses reliability problems. In general the trade-off between flexibility and reliability continues to be a critical aspect in many factory implementations.

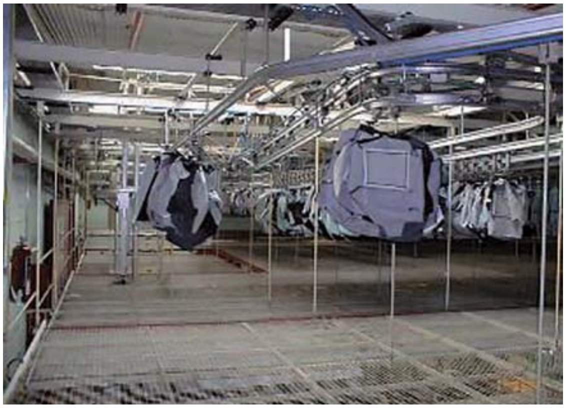

Fig. 16.1 Car seat covers industrial automated warehouse system based on overhead trolleys [16.1]

Flexible automation of transportation in outdoor environments poses significant challenges because of the difficulties in their conditioning and dynamic characteristics. Automation of cars for transportation has also been a research and development subject since the 1990s. The autonomous navigation of cars and vans has been a testbed for perception, planning, and control techniques for almost 20 years. Thus, for example, autonomous visual-based car navigation was demonstrated in Germany by the mid 1980s, and the NavLab project was running in Carnegie Mellon University by the end of the 1980s [16.2] (Fig. 16.3). Many demonstrations in different environments have also been presented. However, the daily operation of these systems is still constrained and only in operation at low speed and in short trips in restricted areas. In [16.3] the state of the technology and future directions of these so-called *cybercars* are analyzed. The use of dedicated infrastructures and the gradual transition from driver assistance to full automation are highlighted as realistic paths toward fully autonomous cars. Some applications require equipped infrastructures, such as guideways for automatic vans with magnetic tracks integrated in the road pavement. The majority of automated highways systems need an equipped road with an adapted architecture, i. e., the PATH (partners for advanced transit and highways) project [16.4].

So-called unmanned vehicles serve as means of carrying or transporting something, but explicitly do not carry a human being. Thus, unmanned ground vehicles in the broader sense includes any machine that moves across the surface of the ground, such as legged machines and machines with onboard tools and robot manipulators (Fig. 16.4). In this chapter, we will concentrate on the control and navigation aspects of these vehicles.

Unmanned aerial vehicles (UAVs) are self-propelled air vehicles that are either remotely controlled by a human operator (remotely piloted vehicles (RPV)) or are capable of conducting autonomous operations. During recent decades significant efforts have been devoted to increase the flight endurance, flight range, and payload of UAVs. Today, UAVs with several thousands of kilometers of flight range, more than 24 h of flight endurance, and more than 1000 kg of payload (Fig. 16.5) are in operation. Furthermore, autonomous airships, helicopters of different size (Fig. 16.6), and other vertical take-off and landing UAVs have also been developed. UAV technology has also evolved to increase the onboard computation and communication capabilities.

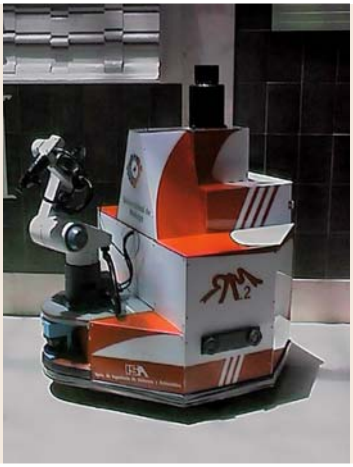

Fig. 16.4 RAM 2 Mobile robot with manipulator at the University of Málaga

Fig. 16.5 Global Hawk, Northrop Grumman Corporation

Fig. 16.6 Helicopter UAV at the University of Seville

The development of new navigation sensors, actuators, embedded control, and communication systems and the trend towards miniaturization point to mini- and micro-UAVs with increasing capabilities. In [16.5] many UAVs are presented and compared.

Autonomous underwater vehicles (AUV) and underwater robotics is also a very active field of research and development in which many new developments have been presented in recent years. These vehicles are natural extensions of the well-known remotely operated underwater vehicles (ROV) that are controlled and powered from the surface by an operator/pilot via an umbilical cable and have been used in many applications.

Finally, it should be noted that in many cases mobility is strongly constrained by the particular characteristics of the environment. Thus, for example, the internal inspection [16.6] and eventual repairing of pipes impose constraints on the design of the robots that should navigate inside the pipe, carrying cameras and other sensors and devices. However, these applications will be not considered in this chapter.

The autonomy of all of the above-mentioned vehicles is based on automatic motion control. The next section will summarize general concepts of vehicle

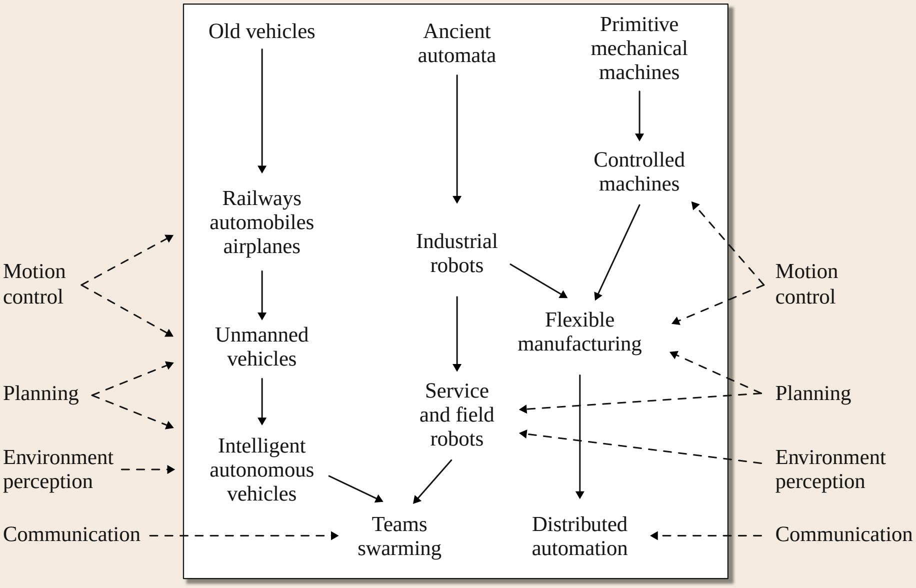

Fig. 16.7 Evolution of automation in mobility and navigation

motion control. Autonomous operation also requires environment perception. General concepts on environment perception and reactivity will be examined in the fourth section of this chapter. Another approach related to mobility enhancement is human augmentation, the objective of which is to augment human capabilities by means of motion-controlled devices interfacing with the human. Two different approaches can be followed. The first is to provide teleoperation capabilities to control the motion of remote vehicles or devices for transportation. The second approach is to augment the person's physical abilities by means of wearable devices or exoskeletons. The idea is not new, but recent progress in sensing human body signals and embedded control systems makes it possible to build exoskeletons to carry heavy loads and march faster and longer. The applications are numerous and include handicapped people, military, and others. Section 16.5 will be devoted to the human–machine interaction for mobility and particularly for vehicle guidance. Finally, in recent years, a general emerging trend is the development of fleets or teams of autonomous vehicles. This trend involves ground, aerial, and aquatic fleets of vehicles. Section 16.6 is devoted to the coordination of fleets of vehicles. In all the following sections the background and significance of each topic, as well as the existing methods and trends are described. Figure 16.7 shows the evolution of vehicles, robotics, and industrial automation related to the automation of mobility and navigation, illustrating the impact of motion control, motion planning, environment perception, and communication technology.

16.3 Vehicle Motion Control

The lowest-level vehicle control typically consists of the vehicle motion axis in which conventional linear proportional–integral-derivative (PID) motion controllers are usually applied. Other techniques such as fuzzy logic [16.7] are less commonly used. The reference signals of these servo controllers are provided by navigation control loops in which the objective is that the vehicle follows previously defined trajectories. In these control loops navigation sensors such as gyroscopes, accelerometers, compass, and global positioning systems (GPS) are used. The objectives are perturbation rejection and improving of dynamic response. The kinematics and dynamic behavior of the vehicle play an important role in these control loops. The usual formulation is given by the equation

$$\dot{x} = f(x, u) , \tag{16.1}$$

where $x \in \mathbb{R}^n$ is the vehicle state vector, usually consisting of the position, the Euler angles, the linear velocities, and the angular velocities, and $u \in \mathbb{R}^m$ are the control variables. In general the above equation involves the rigid-body kinematics and dynamics, the force and moment generation, and the actuator dynamics. Kinematics is usually considered by means of nonlinear transformations between the reference systems associated to the vehicle body and the global reference system. The nonholonomic constraints, $\phi(\dot{x}, x) = 0$, where ϕ is a nonintegral function, restrict the vehicle's admissible directions of motion and make the control problem more difficult. Thus, it has been shown [16.8] that it is not possible to stabilize a nonholonomic system to a given set-point by a continuous and time-invariant feedback control. Moreover, in many cases, there are underactuated control systems in which the number of control variables m is lower than the number of degrees of freedom. The dynamic model involves the relation between forces and torques, generated by the propulsion system and the environment, and the accelerations of the vehicle. These relations can be described by means of the Newton–Euler equations. Furthermore, in aerial vehicles, aerodynamics plays a significant role and should be considered.

In ground vehicles the tires–terrain interactions create significant complexity. Several models have been developed to consider these interactions [16.9, 10]. The complexity of the complete dynamic models means that there are a lot of vehicle, road, and tire parameters to estimate and tune. Besides, these models change with tire pressure, road surface and conditions, vehicle weight, etc. so they are more commonly used for controller analysis and simulation, braking controller research or tire failure detection [16.11, 12].

In many formulations only simplified dynamic models are considered and then only the position and angles are included in the state vector of the above equation. Furthermore, if the vehicles move in a plane and the interactions with the terrain are neglected, then only the position in the plane and the orientation angle are considered as state variables. Sometimes a simple actuator dynamic model [16.13] is added to these simplified models. Control theory has been extensively applied to vehicle control. Many linear and nonlinear control systems have been proposed to maintain stability and tracking paths or time trajectories [16.14]. The limitation in the stabilization of nonholonomic system has been avoided by means of time-varying state feedback and discontinuous feedback. The trajectory tracking can be formulated by defining the reference model

$$\dot{x}_{\mathrm{r}} = f(x_{\mathrm{r}}, u_{\mathrm{r}}) \,. \tag{16.2}$$

Then, if the model of the vehicle is (16.1), the problem is to find a control law $u = \varphi(x, x_{\mathrm{r}}, u, u_{\mathrm{r}})$ such that

$$\lim_{t\to\infty} |x(t) - x_{\mathrm{r}}(t)| = 0 \,. \tag{16.3}$$

The path tracking problem consists of the tracking of a defined path, taking into account the vehicle motion constraints defined by the equation above. Different trajectory and path tracking methods for ground vehicles have been formulated by implementing linear and nonlinear control laws, as shown and summarized in [16.14, 15]. Many practical implementations of path tracking are based on geometric methods [16.16–18]; for example, the simple *pure-pursuit method* is a linear proportional control law of the error of the vehicle position with respect to a goal point. The gain is given by the distance to this goal point defined in the path. The appropriate selection of this gain is a critical issue. Then, gain self-scheduling approaches can be applied. The stability of the path tracking control loop is analyzed in [16.19]. Even though these geometric methods are not optimal, they are usually easy to tune and have a good trade-off between performance and simplicity in real-time implementations as shown in the Defense Advanced Research Projects Agency (DARPA) Grand Challenge 2005 competition [16.20], where most of the teams used simple geometric approaches. Also traditional automatic control techniques such as generalized predictive control (GPC), robust control [16.21] or LQG/LQR (linear quadratic Gaussian/linear quadratic regulator) [16.22] have been successfully applied. These methods require a linear vehicle model so a simplified linearized version of more complex models, such as the previously commented ones, are typically employed.

The steering of ground articulated vehicles and tractor–trailer systems (see, for example, [16.23, 24]) also presents interesting control problems. Tractor–trailer systems (Fig. 16.8) have as an additional state variable the angle between the tractor and the trailer. They are usually underactuated and the saturation in the actuators can play a significant role, particularly when maneuvering backwards because the vehicle tends to reach a so-called *jack-knife* when the angle between the tractor and the trailer is greater than a certain value due to perturbations coming from the vehicle–terrain interaction.

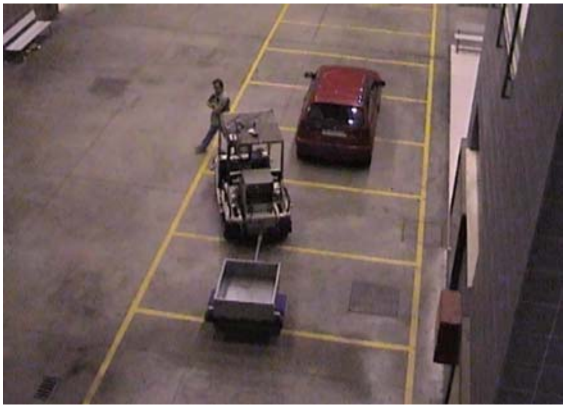

Fig. 16.8 Romeo 4R with trailer in a parking manoeuvre

In aerial and underwater vehicles the navigation problem is typically formulated in three-dimensional (3-D) space and different control levels involving the dynamic behavior of the vehicle can be identified. The objective of the lower levels is to keep the vehicle in a given attitude by maintaining the stability. The linear and angular velocities in the vehicle body axis, and orientation angles are usually considered as state variables. The higher-level motion control loop consists of the path or trajectory tracking (which includes precision timing). In this case, the course angle error and the cross-track distance can be considered as error signals in the guidance loop.

In [16.25] control techniques for autonomous aerial vehicles are reviewed. The navigation of these UAVs is based on GPS positioning but visual-based position estimation have also been applied [16.26], particularly in case of GPS signal loss (see the next section). In [16.27] model-based control techniques for autonomous helicopters are reviewed and different experiments involving dynamic nonlinear behaviors are presented. The position and orientation of an helicopter is usually controlled by means of five control inputs: the main rotor collective pitch, which has a direct effect on the helicopter height; the longitudinal cyclic, which modifies the helicopter pitch angle and the longitudinal translation; the lateral cyclic, which affects the helicopter roll angle and the lateral translation; the tail rotor, which controls the heading of the helicopter and compensates the antitorque generated by the main rotor; and the throttle control. It is a multivariable nonlinear system with strong coupling in some control loops. Autonomous helicopter control has been a classical control benchmark and many model-based control techniques have been applied, including multi-PID controllers, robust control, predictive control, and nonlinear control. The significance of each of these methods for practical implementations is still an open question. Safe landing on mobile platforms and transportation of loads by means of several UAVs overcoming the payload limitation of individual UAVs are open challenges. Very recently the joint transportation of a load by several helicopters has been demonstrated in the AWARE (acronym of the project *platform for autonomous self-deploying and operation of wireless sensor-actuator networks cooperating with aerial objects*) project [16.28].

There are also approaches in which learning from skilled human pilots or teleoperators plays the most significant role. In these approaches, fuzzy logic [16.29], neural networks [16.30], neurofuzzy techniques, and other artificial intelligence (AI) techniques are applied. Control theory and AI techniques have also been combined. Thus, for example, Takagi–Sugeno fuzzy systems have been applied to learn from human drivers by generating closed-loop control systems that can be analyzed and tuned by means of stability theory. These methods have been applied to drive autonomously trucks (Fig. 16.9) and heavy machines at high speed [16.31] by estimating the position of the vehicle by means of the fusion of GPS and dead-reckoning with simple vehicle models. The system has been applied to test the tires of vehicles navigating autonomously in testing tracks.

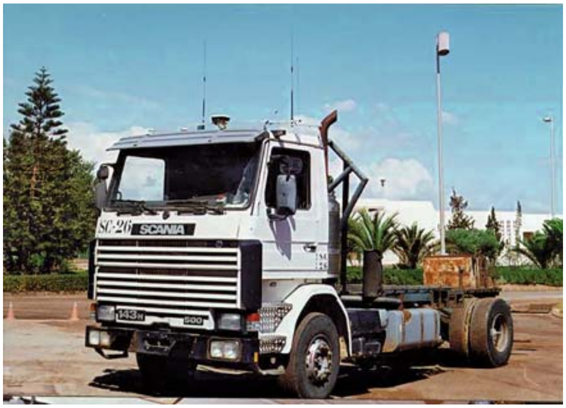

Fig. 16.9 Autonomous 16 t Scania truck

The general challenges are the analysis and design of reliable control techniques that could be implemented in real time at high frequency in the onboard processors, providing reactivity to perturbations while maintaining acceptable performance. This is particularly challenging when considering small or very small vehicles, such as micro-UAVs with important limitations in onboard processing. The application of micro-electromechanical systems (MEMS) to implement these control systems is an emerging technology trend. The practical application in real time of fault-detection techniques and fault-tolerant control systems to improve reliability is another emerging trend.

16.4 Navigation Control and Interaction with the Environment

The consideration of interactions with the environment is also an important problem in mobility and navigation automation. These interactions can also be represented by means of loops closed at different frequencies, as shown in Fig. 16.10. The vehicle control described in the above paragraphs is also embedded in this figure. Reactivity dominates the higher-frequency loops, which also require higher bandwidth in communication channels (inner loops, towards the right in the figure), while deliberation is the main component of the lower-frequency loops, which typically have lower bandwidth requirements in communication channels (outer loops, towards the left in the figure). The inner loops can be considered as the lower lever in the control hierarchy, while the outer loops are the higher levels in this hierarchy. This chapter will not provide details on mobile robot control architectures, but will merely describe the main interactions.

Environment perception is based on the use of sensors such as cameras, radars, lasers, ultrasonic, and other range sensors. Thus, cameras and radars have been applied extensively for the guidance of autonomous cars. The processing of the images leads to the computation of relevant environment features that can be used to guide the vehicle by means of visual servoing techniques (image-based visual servoing). Alternatively, the features can be used to compute the position/orientation of the vehicle and then apply position-based visual servoing. The stability of the visual control loop in the guidance of vehicles has been studied by several authors (see, for example, [16.32]). The main drawbacks of these methods are robustness to

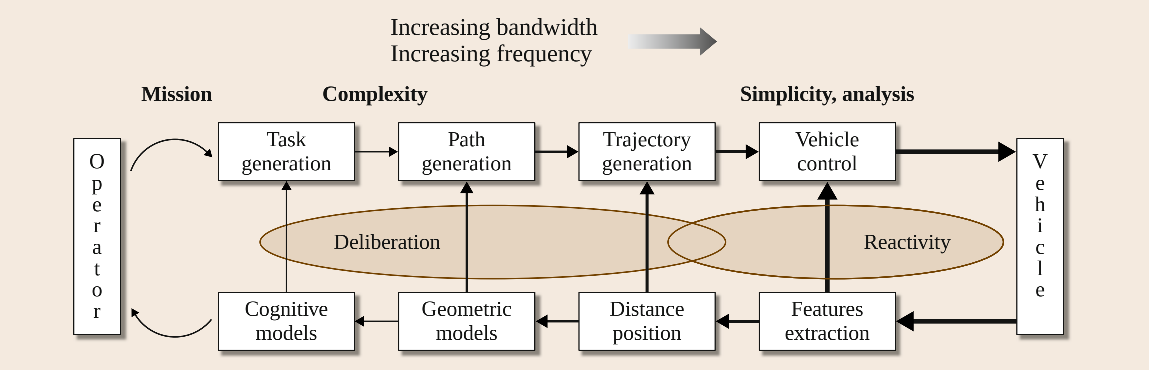

Fig. 16.10 Vehicle control and decision loops. The width of the arrows indicates the frequency of the loops and required bandwidth in communication. The inner loops (*right in the figure*) correspond to higher-frequency loops with higher bandwidth requirements, while the outer loops (*left in the figure*) correspond to lower-frequency loops with lower bandwidth requirements

illumination changes and real-time constraints. Laser-based environment perception techniques are also used in navigation [16.33], as shown by the 2005 DARPA Grand Challenge (DGC) [16.34]. However, even laser measurements have some drawbacks in outdoor environments; for example, dust clouds could be treated as transient obstacles or weeds and large rocks cannot be differentiated.

Compensation for such different environmental conditions plays an important role. The use of several sensors and the application of sensor data-fusion methods significantly improve robustness against changes in these conditions. Thus, for example, most autonomous vehicles in the DGC (see Fig. 16.11 for the 2007 Urban Grand Challenge) applied sensor data-fusion techniques for autonomous navigation. In some cases environment perception can substitute or complement GPS positioning, overcoming problems related to the visibility of satellites and degradation of the GPS signal.

Fig. 16.11 Winners of the Urban Grand Challenge, November 2007 [16.35]

The above-mentioned techniques to compute the position of the vehicle with respect to the environment can also be applied to generate trajectories in these environments. Trajectory generation methods can eventually consider the kinematics and dynamic constraints of the vehicles in order to obtain trajectories that can be realistically executed with the vehicle control system described in the previous section. The relevance of these techniques depends on the characteristics of the vehicles. Thus, for example, they are very relevant in the navigation of ground wheeled vehicles with conventional car-like locomotion systems or in fixed-wing airplanes, but could be ignored in omnidirectional ground vehicles navigating at low speeds.

The computation of distances and positions of the vehicle with respect to the environment can also be used to obtain geometric models of the environment. Particularly mapping techniques can be applied. Moreover, many probabilistic simultaneous localization and mapping techniques (SLAM) have been proposed and successfully applied in robotics in the last decade [16.36]. Most implementations have been carried out by using lasers in two-dimensional (2-D) environments. However, the methods for the application of SLAM in 3-D environments are also promising.

The results of vehicle position and environment mapping can be used for the planning of vehicle motion. The planning problem consists of the computation of a path for the vehicle from a starting configuration (position/orientation) to a goal position/orientation configuration, avoiding obstacles and minimizing a cost index usually related to the length of the path [16.37]. Today, many different techniques for automatic path planning can be applied. In the basic problem a geometric model of the vehicle is assumed and the model of the environment is assumed to be completely known (map known) and static, without other vehicles and moving obstacles. Many path planning methods are solved in the configuration space C, defined by the configuration variables $q \in \mathbb{R}^n$ that completely specify the position and orientation of the vehicle. Then, given $q_{\text{start}}, q_{\text{goal}} \in C$, the problem is to find a sequence of configurations in the obstacle-free configuration space $q_i \in C_{\text{free}}$ connecting q_{start} and q_{goal}.

The problem can be solved by searching in the discretized space. Well-known methods are visibility graphs and Voronoi diagrams. In these methods the connectivity of the free space is represented by means of a network of one-dimensional (1-D) curves. These methods have been extensively applied in 2-D environments. The consideration of 3-D models adds significant complexity for execution in real time. Another well-known strategy consists of searching in an adjacency graph of the free-space cells, obtained by discretization of the environment model into occupancy cells. These methods need the implementation of graph searching algorithms, such as A*, to find a solution and they are usually quite time consuming. The application of multiresolution techniques greatly improves the computational efficiency of these methods. On the other hand, in recent years, randomized methods and particularly so-called rapidly exploring random trees (RRT) [16.38], have been used to explore the free space, obtaining good results. This method makes it possible to explore high-dimensional configuration spaces, and even to include different constraints. Several of these techniques have been applied and extensively tested in the DGC 2005 competition.

There are also methods based on the optimization of potential functions attracting the vehicle to the goal (global minimum) by considering at the same time the effect of repulsive forces exerted by the obstacles. The obvious difficulty of these latter methods, initially proposed for real-time local collision avoidance [16.39], is the existence of local minima. The potential-based methods have also been applied for motion planning, eventually combined with other planning methods such as the space-cell decomposition mentioned above. Different potential functions have been proposed to avoid the local minima problem in these methods [16.40].

The extensions of the basic motion planning problem described above include the consideration of the nonholonomic and dynamic constraints of the vehicle [16.41]. Other extensions include the uncertainties in the models of the vehicle and the environment, as well as the motion of other vehicles and obstacles in the environment.

The stability of reactive navigation is studied in [16.42], where Lyapunov techniques, input/output stability (conicity criterion), and frequency response methods are applied to study the stability of the navigation of an autonomous ground vehicle by using ultrasonic sensors. The stability is related to the parameters of the reactive navigation such as the sensor range and the velocity. The influence of the time delay, due to communication and computation, on the stability of the reactive navigation is also considered. The analysis is based on the definition of the perception function $p = \psi(d, \theta)$, where d and θ are, respectively, the distance and angle at which an obstacle is detected. The values of p are provided to the closed-loop controller. Then, the feedback controller $u = \varphi(p)$ is applied to the vehicle with model given by (16.1).

Planning under uncertainty has been a research topic for many years. In the classical planning methods the world is assumed to be deterministic, and the state observable. The uncertainty can be taken into account by considering stochastic Markov decision processes (MDPs) with observable states, which leads to stochas-

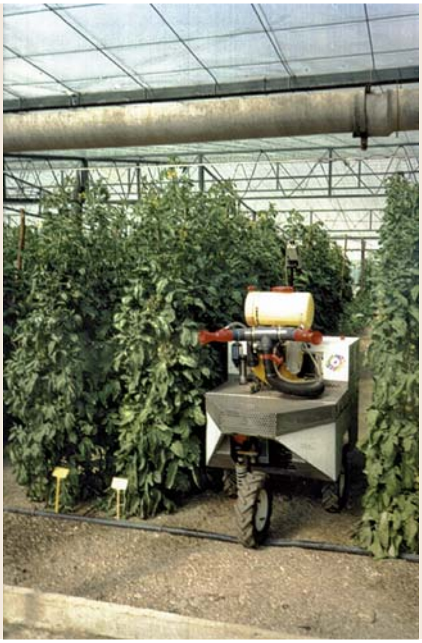

Fig. 16.12 The Aurora robot spraying a greenhouse

tic accurate models. If the state is assumed to be only partially observable, then partially observable Markov decision processes (POMDPs) can be used to consider stochastic inaccurate models.

The outer loop (the upper level in the control architecture) in Fig. 16.10 is based on the consideration of cognitive models of the environment obtained from the geometric representations, knowledge extracted from the sensorial information, i. e., identification of particular objects in the environment (i. e., traffic signals), and previous human knowledge on the existing relations between these objects and the vehicle navigation.

A key architectural issue is the appropriated combination of reactivity and planning. This is related to the interaction between the different levels or control loops in Fig. 16.10 and has a significant impact on the methods to be applied. Thus, some control architectures are based on the application of very simple motion strategies, without considering uncertainties or mobile objects in the environment, and providing reactivity based on real-time sensing of the environment. Reactive techniques can be implemented in behavior-based control architectures to navigate in natural environments without models or with a minimal model of the environment. Figure 16.12 shows the Aurora mobile robot [16.43] which uses a behavior-based architecture to navigate in greenhouses using ultrasonic sensors. Other architectures are based on dynamic planning by incorporating environment information in real time and producing a new plan that reacts appropriately to the new information. In the architecture presented in [16.42] planning techniques based on the kinematics model of the vehicle are used to generate parking maneuvers for articulated vehicles (Fig. 16.8).

One of the main general trends is the integration of control and perception components into embedded systems that can be networked using wired or wireless technologies, leading to *cooperating objects*, with sensing and/or actuation capabilities based on sensor fusion methods that allow full interaction with the environment. Open challenges are related to the development of tools for the analysis and design of these systems.

16.5 Human Interaction

In practice mobility automation requires the intervention of humans at a certain level. The key point is the level of interaction. Thus, with regards to Fig. 16.10, the human can be provided with information from the cognitive models, which encode expertise from other operators, and use this information to decompose a mission into tasks to be planned by the task generator module in the Fig. 16.10.

However, if the task planner does not exist, the human operator can interact with the second outer loop. In this case the human operator can use the map of the environment displayed on a suitable display to generate a sequence of waypoints for the vehicle using an appropriate interface to specify these waypoints by means of a joystick or a simple mouse. The human operator can also generate in the next inner loop a suitable trajectory assisted by computer tools to visualize in an appropriate way the distances to the surrounding obstacles and check the suitability of these trajectories to be executed by the particular vehicle being commanded. Going to the right in the control loops of Fig. 16.10, the operator could directly provide commands to the vehicle control loop by observing significant environment features in the images provided by the onboard camera or cameras.

The above-mentioned interactions involve hardware and software technologies to provide appropriate sensorial feedback (visual, audio . . .) to the human pilots and generate actions at different levels from direct guidance to waypoint and task specification.

At this point it is necessary to distinguish between human interventions onboard the vehicle and operation in a remote teleoperation station or from suitable remote devices such as personal digital assistants (PDAs) or even mobile phones involving the communication system, as shown in Fig. 16.13. The first approach can be considered as a compromise solution between vehicle full driving automation, which removes the driver from the control loop, to assisted driving to improve efficiency and reduce accidents, as mentioned in the Introduction. Integration of automatic functions in conventional cars has been a trend in the last years. Autonomous parking of conventional vehicles is an example of this trend. On the other hand, the development of mixed autonomous/manual driving cars seems a suitable approach for the gradual integration of autonomous vehicles on regular roads. Furthermore, the automation of functions in aircraft navigation is also well known.

In the following, the remote teleoperation of vehicles is considered. Figure 16.13 illustrates teleoperation schemes.

The low-level classical teleoperation approach consists of the presentation to the remote teleoperator of images from a camera or cameras mounted on the front of the vehicle. Then, the vehicle is guided manually using joysticks, pedals or similar interfaces to the ones existing in the driving position onboard the vehicles. This approach has many problems; for example, the images may be degraded due to bandwidth instability, leading to poor spatial resolution and variable update rates, degrading the perception of the motion. Furthermore, an important problem is the presence of delays in both the images and sensor data sent to the operator and the operator commands sent back to the vehicle. These delays may generate instability of the teleoperation control loop.

Various technologies have been proposed to overcome these problems. Thus, instead of showing in the display the data and images from the vehicles, it is possible to process these data to extract relevant features to be displayed. Note that this approach can be included in the inner (faster) control loop of Fig. 16.10. The computation of distances in the second loop could be relevant too. Moreover, the displaying of geometric representations of the environment around the vehicle (see also Fig. 16.13) combined with the images (augmented-reality technologies) could also be very useful.

A classical method to reduce the harmful effect of delays in the transmission of images is the use of predictive displays with a synthetic graphic of the vehicle obtained by means of a simulation model. The graphic is overlaid on the real delayed images from the vehicle. This representation leads the operator to perceive in advance the effect of his commands, which can be used to compensate for delays. This can be easily combined with the augmented reality mentioned above. Thus, real-world imagery is embedded within a display of computer-generated landmarks or objects representing the same scene. The computer-generated component of a display can be updated immediately in response to control inputs from the human operator, providing rapid feedback to the operator. If a model of the environment is known, it can be stored in databases and rendered based, for example, on the current GPS position of the vehicle.

Obviously the navigation conditions may have a significant effect on the operators. Thus, it has been pointed out that UAV operators may not modify their visual scanning methods to compensate for the nonrecreated multisensory cues. In order to improve the perception of the operators, haptic and multimodal interfaces (e.g., tactile and auditory) have been proposed. Multimodal interfaces may be used not just to compensate for the teleoperator's sensory environment, but more generally to reduce cognitive-perceptual workload levels. Thus, for example, [16.44] have found that audio and tactile messages can improve many aspects of flight control and overall awareness of the situation in UAV teleoperation.

The teleoperation methods presented above greatly depend on communication between the vehicle and the teleoperation station. The development of mobile communication in the last decade has changed the sit-

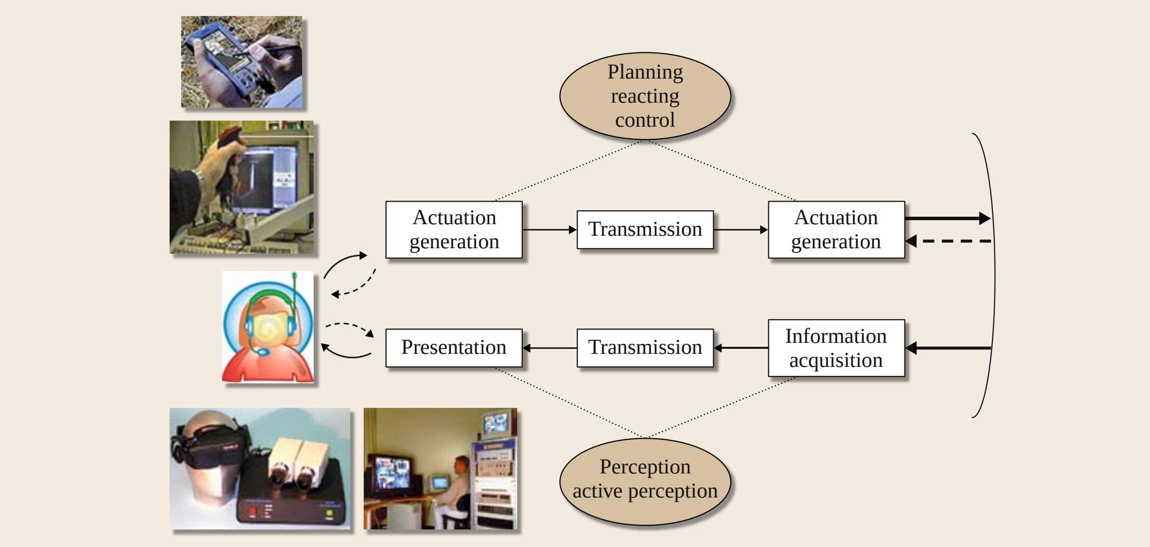

Fig. 16.13 Human interaction loops

uation when compared with the existing technologies when the first autonomous vehicles where developed in the 1980s. Obviously, the communication technologies to be applied greatly depend of the level of intervention of the human teleoperator in the architecture of Fig. 16.13. Thus, high-bandwidth communication is essential at the lower- and high-frequency loops, where vehicle onboard autonomy is low and generation of teleoperation commands depends on observation of the images and information from other sensors onboard the vehicle. However, if the vehicle has onboard autonomy, the communication with the user does not require high bandwidth. Thus, for example, GSM (global system for mobile communications) and GPRS (general packet radio service) have been used for communicating the vehicles with the users through their mobile phones and PDAs. Furthermore, Wi-Fi (IEEE 802.11) has been applied for communication with the vehicle at low velocity and short range. An emerging trend is the application of ad hoc mobile networks to take into account the particular mobility of vehicles.

The development of models of the loops in Fig. 16.13, as well as new analysis and design tools using these models, are important challenges to be addressed. These models should involve not only the vehicles, the control devices, and communication channels, but also suitable models of the human perception and action mechanisms, which typically require significant experimentation efforts to cope with the behavior of operators under different working conditions.

16.6 Multiple Mobile Systems

The automation of multiple vehicles offers many application possibilities. The interest in transportation is obvious. A basic configuration of multiple vehicles consists of a leader followed by vehicles in a single row. This is usually known as *platooning* [16.45]. The control of a platoon can be implemented by means of a local strategy, i. e., each vehicle is controlled from the unique data received from the vehicle at the front [16.46]. This approach relies mainly on the single-vehicle control problem considered above. The main drawback is that the regulation errors introduced by sensors noises grow from the first vehicle to the last one, leading to oscillations. Intervehicle communication can be used to overcome this problem [16.47]. Then, the distance, velocity, and acceleration with respect to the preceding vehicle are transmitted in order to predict the position and improve the controller by guaranteeing the stability of tight platoon applications [16.48]. Intervehicle communication can also be used to implement global control strategies.

The formation of multiple vehicles is also useful for applications such as searching and surveying, exploration and mapping, hazardous material handling systems, active reconfigurable sensing systems, and space-based interferometry. The advantages when comparing with single-vehicle solutions are increased efficiency, performance, reconfigurability, and robustness. An added advantage is that new formation members can be introduced to expand or upgrade the formation, or to replace a failed member. Thus several applications of aerial, marine, and ground vehicle formations have been proposed. In these formations, the members of the group of vehicles should keep user-defined distances from other group members. The control problem consists of maintaining these user-defined distances. Formation control involves the design of distributed control laws with limited and disrupted communication, uncertainty, and imperfect or partial measurements. The most common approach is the leader-follower [16.49]. This approach has limitations when considering the reliability of the leaders and the lack of explicit feedback from the follower to the leader. Then, if the follower is perturbed by some disturbances, the formation cannot be maintained. There are also alternative approaches based on virtual leaders [16.50], which is a reference point that moves according to the mission. The stability of the formation has been studied by many researchers that have proposed robust controllers to provide insensitivity to possibly large uncertainties in the motion of nearby agents, transmission delays in the feedback path, and the effect of quantized information. There are also behavior-based methods [16.51], which are often inspired by biology, where formation behaviors such as flocking and following are common. Different behaviors are defined as control laws for reaching and/or maintaining a particular goal. An emerging trend in formation control is the integration of obstacle avoidance into control schemes.

Other approaches are based on the consideration of teams of robots describing different trajectories to accomplish tasks. Furthermore, having a team with multiple heterogeneous vehicles offers additional advantages due to the possibility of exploiting the complementarities of vehicles with different mobility attributes and also different sensors with different perception functionalities. The vehicles need to be coordinated in time (synchronization) to accomplish missions such as monitoring. Spatial coordination is required to ensure that each vehicle will be able to perform its plan safely and coherently, regarding the plans of the others. Assuming that multiple robots share the same world, a path should be computed for each one that avoids collisions with obstacles and with other robots. Some formulations are based on the extension of single-robot path planning concepts such as the configuration space. If there are nr robots and each robot has a configuration space $C^i, i = 1, \ldots, nr$, the state space is defined as the Cartesian product $X = C^1 \times C^2 \times \cdots \times C^{nr}$ and the obstacle region in X is

$$X_{\text{obs}} = \left(\bigcup_{i=1}^{nr} X^i_{\text{obs}} \right) \cup \left(\bigcup_{ij, i \neq j}^{nr} X^{ij}_{\text{obs}} \right) , \tag{16.4}$$

where X^i_{obs} and X^{ij}_{obs} are the robot–obstacle and the robot–robot collision states. The problem is to find a continuous path in the free space from the initial state to the goal state, avoiding the obstacle region defined by (16.4). The classical planning algorithms for a single robot with multiple bodies [16.37] could be applied without adaptation in case of a centralized planning that takes into account all robots. The main concern, however, is that the dimension of the state space grows linearly in the number of robots. Complete algorithms require time that is at least exponential in dimension. Sampling-based algorithms are more likely to scale well in practice when there many robots, but the resulting dimension might still be too high. There are also decoupled path planning approaches such as the prioritized planning that considers one robot at a time according to a global priority.

On the other hand, cooperation is defined in the robotic literature as a *joint collaborative behavior that is directed toward some goal in which there is a common interest or reward*. According to [16.54], given some task specified by a designer, a multiple-robot system displays cooperative behavior if, due to some underlying mechanism, there is an increase in the total utility of the system. Cooperative perception can be defined as the task of creating and maintaining a consistent view of a world containing dynamic objects by a group of agents, each equipped with one or more sensors. Cooperative vision perception has become a relevant topic in the multirobot domain, mainly in structured environments [16.55, 56]. In [16.57] cooperative perception methods for multi-UAV system are proposed.

Fig. 16.14 Coordinated flights in the COMETS project [16.52]

These methods have been implemented in the architecture designed in the COMETS project (acronym of the project *real-time coordination and control of multiple heterogeneous unmanned aerial vehicles*) [16.58] (Fig. 16.14). Cooperative perception requires integration of the results of individual perception. Each robot extracts knowledge by applying individual perception techniques, and the overall cooperative perception is performed by merging the individual results. This approach requires knowing the relative position and orientation of the robots. If the GPS signal is not available, position estimation based on environment perception should be applied [16.59, 60]. The cooperation of mobile entities also involves the generation of appropriated motion of the involved entities. In [16.61] the coopera-

tion is categorized into: swarm type, dealing with a large number of homogeneous robots, usually involving numerous repetitions of the same activity over a relatively large area; and intentional cooperation, usually requiring a smaller number of possibly heterogeneous robots (Fig. 16.15) performing several distinct tasks. In these systems the multirobot task allocation problem [16.62] is applied to maximize the efficiency of the team and ensure proper coordination among team members to allow them to complete their mission successfully. Recently, a very popular approach to multirobot task allocation has been the application of market-based negotiation rules by means of the contract net protocol [16.63, 64].

Figure 16.16 shows the different types of multiple-vehicle systems and the methods that are applied in each type.

Communication and networking also play an important role in the implementation of control systems for multiple unmanned vehicles. The star-shaped network configuration with all the vehicles linked to the control station with an unshared link only works well with small teams. When the number of vehicles grows it could be necessary to apply wireless heterogeneous networks with radio nodes mounted at fixed ground stations, on ground vehicles, and in UAVs, and the routing techniques allow any two nodes to communicate either directly or through an arbitrary number of other nodes which act as relays. Furthermore, when there is little or no infrastructure, networks could be formed in an ad hoc fashion and information exchanges occur only via the wireless networking equipment carried by the individual UAVs.

Finally, it should be noted that the wireless networking of teams of robots with sensors and actuators embedded in the infrastructure is a new research and development trend with many potential applications. The AWARE project (http://www.aware-project.net) is developing a new platform for the cooperation of autonomous aerial vehicles with ground wireless sensor–actuator networks. This platform will have self-deployment and self-configuration features for operation in sites without sensing and communication infrastructure.

16.7 Conclusions

Mobility and navigation have been very relevant topics in automation. Thus, automation of mobility plays an important role in factory automation. The automation of the transportation of people and goods in noncontrolled environments is more difficult and its complexity depends on the flexibility. This chapter has analyzed automation of mobility and navigation by focusing on autonomous vehicles. Then, vehicle motion control has been examined, and the main problems in navigation control and interaction of the vehicle with the environment were also studied. Moreover, taking into account that practical applications usually require some degree of human intervention, human interaction and related technologies were reviewed. The last part of the chapter was devoted to systems of multiple autonomous vehicles, including formations and fleets of homogeneous vehicles and also teaming of heterogeneous vehicles. The control and cooperation of these autonomous vehicles to accomplish tasks is an emerging trend that poses different challenges.

17. The Human Role in Automation

Daniel W. Repperger, Chandler A. Phillips

A survey of the history of how humans have interacted with automation is presented. Starting with the early introduction of automation into the Industrial Revolution to the modern applications that occur in unmanned air vehicle systems, many issues are brought to light. Levels of automation are quantified and a preliminary list delineating what tasks humans can perform better than machines is presented. A number of application areas are surveyed that have or are currently dealing with positive and negative issues as humans interact with machines. The application areas where humans specifically interact with automation include agriculture, communications systems, inspection systems, manufacturing, medical and diagnostic applications, robotics, and teaching. The benefits and disadvantages of how humans interact with modern automation systems are presented in a trade-off space discussion. The modern problems relating to how humans have to deal with automation include trust, social acceptance, loss of authority, safety concerns, adaptivity of automation leading to unplanned unexpectancy, cost advantages, and possible performance gained.

The modern use of the term *automation* can be traced to a 1952 *Scientific American* article; today it is widely employed to define the interaction of humans with machines. Automation (machines) may be electrical, mechanical, require interaction with computers, involve informatics variables, or possible relate to parameters in the environment. As noted [17.1], the first actual automation was the mechanization of manual labor during the Industrial Revolution. As machines became increasingly useful in reducing the drudgery and danger of manual labor tasks, questions begin to arise concerning how best to proportion tasks between humans and machines. Present applications still address the delineation of tasks between humans and machines [17.2], where, e.g., in chemistry and laboratory tasks, the rule of thumb is to use automation to eliminate much of the *3-D tasks* (dull, dirty, and dangerous). In an effort to be more quantitative in the allocation of work and responsibility between humans and machines, *Fitts* [17.3] proposed a list to identify tasks

Table 17.1 Fitts' list [17.3]

Tasks humans are better at	Tasks machines are better at
Detecting small amounts of visual, auditory, or chemical energy	Responding quickly to control signals
Perceiving patterns of light or sound	Applying great force smoothly and precisely
Improvising and using flexible procedures	Storing information briefly, erasing it completely
Storing information for long periods of time and recalling appropriate parts	Reasoning deductively
Reasoning inductively	
Exercising judgment	

that are better performed by humans or machines (Table 17.1).

This list initially raised some concern that humans and machines were being considered equivalent in some sense and that human could easily be replaced by a mechanical counterpart. However, the important point that Fitts raised was that we should consider some proper allocation of tasks between humans and machines (functional allocation [17.4, 5]) which may be very specific to the skill sets of the human and those the machine may possess. This task-sharing concept has been discussed by numerous authors [17.6]. Ideas of this type have nowadays been generalized into how humans interact with computers, the Internet, and a host of other modern apparatus. It should be clarified, however, that present-day thinking has now moved away from this early list concept [17.7].

17.1 Some Basics of Human Interaction with Automation

In an attempt to be more objective in delineating the interaction of humans with machines, *Parasuraman* et al. [17.8] defined a simple four-stage model of human information processing interacting with computers with the various levels of automation possible delineated in Table 17.2. Note how the various degrees of automation affect decision and action selection. This list differs from other lists generated, e.g., using the concept of supervisory control [17.9, p. 26] or on a scale of *degrees of automation* [17.1, p. 62], but are closely related. As the human gradually allocates more work and responsibility to the machine, the human's role then

Table 17.2 Levels of automation of decision and action selection by the computer

Level	
High = 10	The computer decides everything, acts autonomously, ignoring the human
9	Informs the human only if the computer decides to
8	Informs the human only if asked
7	Executes automatically, then necessarily informs the human
6	Allows the human a restricted time to veto before automatic execution
5	Executes the suggestion if the human approves
4	Suggests one alternative
3	Narrows the selection down to a few alternatives
2	The computer offers a complete set of decision/action alternatives
Low = 1	The computer offers no help; the human must take all actions and make decisions

becomes as the supervisor of the mechanical process. Thus the level of automation selected in Table 17.2 also defines the roles and duties of the human acting in the position of supervisor. With these basics in mind, it is appropriate to examine a brief sample of modern application areas involving humans dealing with automation. After these applications are discussed, the current and most pertinent issues concerning how humans interact with automation will be brought to light.

17.2 Various Application Areas

Besides the early work by Fitts, automation with humans was also viewed as a topic of concern in the automatic control literature. In the early 1960s, *Grabbe* et al. [17.10] viewed the human operator as a component of an electrical servomechanism system. Many advantages were discovered at that time in terms of replacing some human function via automated means; for example, a machine does not have the same temperature requirements as humans, performance advantages may result (improved speed, strength, information processing, power, etc.), the economics of operation are significantly different, fatigue is not an issue, and the accuracy and repeatability of a response may have reduced variability [17.1, p. 163]. In more recent applications (for example, [17.11]) the issues of automation and humans extend into the realm of controlling multiple unmanned air vehicle systems. Such complex (unmanned) systems have the additional advantage that the aircraft does not need a life-support system (absence of oxygen supply, temperature, pressure control or even the requirement for a transparent windshield) if no humans are onboard. Hence the overall aircraft has lower weight, less expense, and improved reliability. Also there are political advantages in the situation of the aircraft being shot down. In this case, there would not be people involved in possible hostage situations. The mitigation of the political cost nowadays is so important that modern military systems see significant advantages in becoming increasingly autonomous (lacking a human onboard).

Concurrent with military applications is the desire to study automation in air-traffic control and issues in cockpit automation [17.12], which have been topics of wide interest [17.13–15]. In air-traffic control, software can help predict an aircraft's future position, including wind data, and help reduce near collisions. This form of predictive assistance has to be accepted by the air-traffic controller and should have low levels of uncertainty. *Billings* [17.13] lists seven principles of human-centered automation in the application domain of air-traffic control. The human-centered (user-centered) design is widely popularized as the proper approach to integrate humans with machines [17.14, 16, 17]. Automation also extends to the office and other workspace situations [17.18] and to every venue where people have to perform jobs.

Modern applications are also implicitly related to the revolution in information technology (IT) [17.19] noting that Fitts' list was preceded by Watson's (IBM's founder in the 1930s) concept that *Machines should work. People should think*. In the early stages of IT, *Licklider* envisioned (from the iron, mainframe computer) the potential for *man–computer symbiosis* [17.20], interacting directly with the brain. IT concepts also prevail in the military. *Rouse* and *Boff* [17.21] equate military success via the IT analogies whereas bits and bytes have become strategically equated with bombs and bullets and advances in networks and communications technologies which have dramatically changed the nature of conflict. A brief list of some current applications are now reviewed to give a flavor of some modern areas that are presently wrestling with future issues of human interaction with automation.

17.2.1 Agriculture Applications

Agriculture applications have been ubiquitous for hundreds of years as humans have interacted with various mechanical devices to improve the production of food [17.22, 23]. The advent of modern farm equipment has been fundamental to reducing some of the drudgery in this occupation. The term *shared control* occurs in situations where the display of the level of automation is rendered [17.9]. In related fields such as fish farming (aquaculture), there are mechanized devices that significantly improve production efficiency. Almost completely automated systems that segment fish, measure them, and process them for the food industry have been described [17.24]. In all cases examples prevail on humans dealing with various levels of automation to improve the quality and quantity of agriculture goods produced. Chapter 63 discusses in more detail automation in agriculture.

17.2.2 Communications Applications

The cellphone and other mobile remote devices have significantly changed how people deal with communications in today's world. The concept of *Bluetooth* [17.25] explores an important means of obviating some of the problems induced when humans have to deal with these communication devices. The Bluetooth idea is that the system will recognize the user when in reasonably close proximity and readjust its settings and parameters so as to yield seamless integration to the specific human operator in question. This helps mitigate the human–automation interaction problems by programming the device to be tailored to the user's specifications. Other mobile devices include remote controls that are associated with all types of new household and other communication devices [17.26]. Chapter 13 discusses in more detail communication in automation including networking and wireless.

17.2.3 Inspection Systems Applications

In [17.27], they discuss 100% automated inspection systems rather than having humans sample a process, e.g., in an assembly-line task. Prevailing thinking is that humans still outperform machines in most attribute-inspection tasks. In the cited evaluation, three types of inspection systems were considered, with various levels of automation and interaction with the human operator. For vision tasks [17.28] pattern irregularity is key to identification of a vector of features that may be untoward in the inspection process.

17.2.4 Manufacturing Applications

Applications in automation are well known to be complex [17.29], such as in factories where production and manufacturing provide a venue to study these issues. In [17.30] a human-centered approach is presented for several new technologies. Some of the negative issues of the use of automation discussed are increased need for worker training, concerns of reliability, maintenance, and upgrades of software issues, etc. In [17.31], manufacturing issues are discussed within the concept of the Internet and how distributed manufacturing can be controlled and managed via this paradigm. More and more modern systems are viewed within this framework of a machine with which the human has to deal by interfacing via a computer terminal connected to a network involving a number of distributed users. Chapters 49, 50, 51 presents different aspects of manufacturing automation.

17.2.5 Medical and Diagnostic Applications

Automation in medicine is pervasive. In the area of anesthesiology, it is analogous to piloting a commercial aircraft, ("hours of boredom interspersed by moments of terror" [17.32]). Medical applications (both treatment and diagnosis) now abound where the care-giver may have to be remote from the actual site [17.33]. An important example occurs in modern robotic heart surgery where it is now only required to make two small incisions in the patient's chest for the robotic end-effectors. This minimally invasive insult to the patient results in reduced recovery time of less than 1 week compared with typically 7 weeks for open heart surgery without using the robotic system. As noted by the surgeon, the greatest advantage gained is [17.34]:

> *Without the robot, we must make a large chest incision. The only practical reason for this action is because of the 'size of the surgeon's hands'. However, using the robot now obviates the need for the large chest incision.*

The accompanying reduction of medical expenses, decreased risk of infection, and faster recovery time are important advantages gained. The automation in this case is the robotic system. Again, as with Fitts' list, certain tasks of the surgery should be delegated to the robot, yet the other critically (medically) important tasks must be under the control and responsibility of the doctor. From a diagnostics perspective, the concept of remote diagnostic methods are explored [17.35]. As in the medical application, the operator (supervisor) must have an improved sense of presence about an environment remote from his immediate viewpoint and has to deal with a number of reduced control actions. Also, it is necessary to attempt to monitor and remotely diagnose situations when full information may not be typically available. Thus automation may have the disadvantage of limiting the quality of information received by the operator. Chapters 77, 78, 80, 82 provide more insights into automation in medical and healthcare systems.

17.2.6 Robotic Applications

Robotic devices, when they interact with humans, provide a rich venue involving problems of safety, task delegation, authority, and a host of other issues. In [17.36] an application is discussed which stresses the concept of *learning from humans*. This involves teaching the robotic device certain motion trajectories that emulate successful applications gleaned from humans performing similar tasks. In robotic training, it is common to use these *teach pendant* paradigms, in which the robotic path trajectory is stored in a computer after having a human move the end-effector through an appropriate motion field environment. In [17.37], the term *biomimicking motion* is commonly employed for service robots that directly interact with humans. Such assistive aids are commonly used, for example, in a hospital setting, where a robotic helper will facilitate transfer of patients, removing this task from nurses or other care-givers who are normally burdened with this responsibility. Chapter 21 provides an insightful discussion on industrial robots.

17.2.7 Teaching Applications

In recent years, there has been an explosive growth of teaching at universities involving long-distance learning classes. Many colleges and professional organizations now offer online courses with the advantage to the student of having the freedom to take classes at any time during the day, mitigating conflicts, travel, and other costs [17.38]. The subject areas abound, including pharmacy [17.39], software engineering [17.40], and for students from industry in various fields [17.41]. The problem of humans interacting with automation that occurs is when the student has to take a class and deal directly with a computer display and a possibly *not so user-friendly* web-based system. Having the ability to interrelate (student with professor) has now changed and there is a tradeoff space that occurs between the convenience of not having to attend class versus the loss of ability to fully interact, such as in a classroom setting. In [17.42], a variety of multimedia methods are examined to understand and help obviate the loss of full interactive ability that occurs in the classroom. The issue pertinent to this example is that taking the course online (a form of automation) has numerous advantages but incurs a cost of introducing certain constraints into the human–computer interaction.

These examples represent a small sample of present interactions of humans with automation. Derived from these and other applications, projections for some present and future issues that are currently of concern will be discussed in further detail in the next section.

17.3 Modern Key Issues to Consider as Humans Interact with Automation

17.3.1 Trust in Automation

Historically, as automation became more prevalent, concern was initially raised about the changing roles of human operators and automation. *Muir* [17.43] performed a literature review on trust in automated systems since there were alternative theories of trust at that time. More modern thinking clarifies these issues via a definition [17.44]:

> *Automation is often problematic because people fail to rely upon it appropriately. Because people respond to technology socially, trust influences reliance on automation. In particular, trust guides reliance when complexity and unanticipated situations make a complete understanding of the automation impractical. People tend to rely on automation they trust and tend to reject automation they do not.*

Taking levels of trust by pilots as an example, it was found [17.45] that, when trust in the automated system is too low and an alarm is presented, pilots spend extra time verifying the problem or will ignore the alarm entirely. These monitoring problems are found in systems with a high propensity for false alarms, which leads to a reduced level of trust in the automation [17.46]. From the other extreme, if too much trust is placed on the automation, a false sense of security results and other forms of data are discounted, much to the peril of the pilot. From a trust perspective, *Wickens* and colleagues tested heterogeneous and homogeneous crews based on flight experience [17.47] and found little difference in flying proficiency for various levels of automation. However, the homogeneous crews obtained increased benefit from automation, which may be due to, and interpreted in terms of, having a different authority gradient. In considering the level of trust (overtrust or undertrust), *Lee* and *Moray* [17.48] later noted that, as more and more false alarms occur, the operator will decrease their level of trust accordingly even if the automation is adapted. It is as if the decision-aiding system must first prove itself before trust is developed. In more recent work [17.49], a quantitative approach to the trust issue is discussed, showing that overall trust in a system has a significantly inverse relationship with the uncertainty of a system. Three levels of uncertainty were examined using National Institute of Standards (NIST) guidelines, and users rated their trust at each level through questionnaires. The bottom line was that performance of a hybrid system can be improved by decreasing uncertainty.

17.3.2 Cost of Automation

As mentioned previously, cost saving is one of the significant advantages of the use of automation, e.g., in an unmanned air vehicle, for which the removal of the requirement to have a life-support system makes such devices economically advantageous over alternatives. In [17.50] low-cost/cost-effective automation is discussed. By delegating some of the task responsibilities to the instrumentation, the overall system has an improved response. In a cost-effective sense, this is a better design. In [17.51] the application of a fuzzy-logic adaptive Kalman filter which has the ability to provide improved real-time control is discussed. This allows more intelligence at the sensor level and unloads the control requirements at the operator level. The costs of such devices thus drops significantly and they become easier to operate. See Chap. 41 for more details on cost-oriented automation.

17.3.3 Adaptive Versus Nonadaptive Automation

One could argue that, if automation could adapt, it could optimally couple the level of operator engagement to the level of mechanism [17.52]. To implement such an approach, one may engage biopyschometric measures for when to trigger the level of automation. This would seem to make the level of automation related to the workload on the human operator. One can view this concept as adaptive aiding [17.53]. For workload consideration, the well-known National Aeronautics and Space Administration (NASA) task load index (TLX) scale provides some of these objective measures of workload [17.54]. As a more recent example, in [17.55], adaptive function allocation as the dynamic control of tasks which involves responsibility and authority shifts between humans and machines is addressed. How this affects operator performance and workload is analyzed. In [17.56] the emphasis focuses on human-centered design for adaptive automation. The human is viewed as an active information processor in complex system control loops and supports situational awareness and effective performance. The issues of workload overload and situational awareness are researched.

17.3.4 Safety in Automation

Safety is a two-edged sword in the interaction of humans with automation. The human public demands safety in automation. As mentioned in regard to robotic surgery applications, the patient has a significantly reduced recovery time with the use of a robotic device, however, all such machines may fail at some time. When humans interact with robotic devices, they are always at risk and there are a number of documented cases in which humans have been killed by being close to a robotic device. In factories, safety when humans interact with machines has always been a key concern. In [17.57], a way to approach the safety assessment in a factory in terms of a safety matrix is introduced. This differs from the typical probability method. The elements of the matrix can be integrated to provide a quantitative safety scale. For traffic safety [17.58] human-centered automation is a key component to a successful system and is recommended to be multilayered. The prevailing philosophy is that it is acceptable for a human to give up some authority in return for a reduction in some mundane drudgery.

Remote control presents an excellent case for safety and the benefit of automation. Keeping the human out of harm's way through teleoperation and other means but providing a machine interface allows many more human interactions with external environments which may be radioactive, chemically adverse or have other dangers. See Chap. 39 for a detailed discussion on safety warnings for automation.

17.3.5 Authority in Automation

The problem of trading off authority between the human and computer is unsettling and risky, for example, in a transportation system, such as a car. Events that are unplanned or produce unexpectancy may degrade performance. Familiarity with antibrake systems can be a lifesaver for the novice driver first experiencing a skidding event on an icy or wet road. However, this could also work to the detriment of the driver in other situations. As mentioned earlier, automation has a tradeoff space with respect to authority. In Table 17.2 it is noted that, the higher the level of automation, the greater the loss of authority. With more automation, the effort from the operator is proportionally reduced; however, with loss of authority, the risk of a catastrophic disaster increases. This tradeoff space is always under debate. In [17.59] it is shown that some flexibility can be maintained. Applications where the tradeoff space exists between automation and authority include aircraft, nuclear power plants, etc., *Billings* [17.13] calls for the operator to maintain an active role in a system's operation regardless of whether the automation might be able to perform the particular function in question better than the operator. *Norman* [17.60] stresses the need for feedback to be provided to the operator, and this has been overlooked in many recent systems.

17.3.6 Performance of Automation Systems

There are many ways to evaluate human–machine system performance. Based on the signal detection theory framework, various methods have been introduced [17.61–63]. The concept of likelihood displays shows certain types of statistical optimality in reducing type 1 and type 2 errors and provides a powerful approach to measure the efficacy of any human–machine interaction. Other popular methods to quantify human–machine performance include the information-theoretic models [17.64] with measures such as baud rate, reaction time, accuracy, etc. Performance measurement is always complex since it is well known that three human attributes interact [17.65] to produce a desired result. The requisite attributes include skill, and rule- and knowledge-based behaviors of the human operator.

17.3.7 When Should the Human Override the Automation?

One way to deal with the adaptive nature of automation is to consider *when* the human should intervene [17.66]. It is well known that automation may not work to the advantage of the operator in certain situations [17.67]. Rules can be obtained, e.g., it is well known that it is easier to modify the automation rather than modify the human. A case in point is when high-workload situations may require the automation level to increase to alleviate some of the stress accumulated by the human in a critical task [17.68] in situations such as flight-deck management.

17.3.8 Social Issues and Automation

There are a number of issues of the use of automation and social acceptance. In [17.69] the discussion centers on robots that are socially acceptable. There must be a balance between a design which is human-centered versus the alternative of being more socially acceptable. Tradeoff spaces exist in which these designs have to be evaluated as to their potential efficacy versus agreement in the venue in which they were designed. Also humans are hedonistic in their actions, that is, they tend to favor decisions and actions that benefit themselves or their favored parochial classes. Machines, on the other hand, may not have to deal with these biases. Another major point deals with the disadvantages of automation in terms of replacing human workers. If a human is replaced, alienation may result [17.70], resulting in a disservice to society. Not only do people become unemployed, but they also suffer from loss of identity and reduced self-esteem. Also alienation allows people to abandon responsibility for their own actions, which can lead to reckless behavior. As evidence of this effect, the Luddites in 19th century England smashed the knitting machines that had destroyed their livelihood. Turning anger against an automation object offers, at best, only temporary relief of a long-term problem.

17.4 Future Directions of Defining Human–Machine Interactions

It is seen that the following parameters strongly affect how the level of automation should be modified with respect to humans:

- Trust
- Social acceptance
- Authority
- Safety
- Possible unplanned unexpectancy with adaptive automation
- Application-specific performance that may be gained

17.5 Conclusions

Modern application still wrestle with the benefit and degree of automation that may be appropriate for a task [17.71]. Emerging trends include how to define those jobs that are dangerous, mundane, and simple where there are benefits of automation. The challenges include defining a multidimensional tradeoff space that must take into consideration what would work best in a mission-effectiveness sense as humans have to deal with constantly changing machines that obviate some of the danger and drudgery of certain jobs. For further discussion of the human role in automation refer to the chapters on *Human Factors in Automation Design* Chap. 25 and *Integrated Human and Automation Systems, Including Automation Usability, Human Interaction and Work Design in (Semi)-Automated Systems* Chap. 34 later in this Handbook.

18. What Can Be Automated? What Cannot Be Automated?

Richard D. Patton, Peter C. Patton

The question of what can and what cannot be automated challenged engineers, scientists, and philosophers even before the term *automation* was defined. While this question may also raise ethical and educational issues, the focus here is scientific. In this chapter the limits of automation and mechanization are explored and explained in an effort to address this fundamental conundrum. The evolution of computer languages to provide domain-specific solutions to automation design problems is reviewed as an illustration and a model of the limitations of mechanization. The current state of the art and a general automation principle are also provided.

18.1 The Limits of Automation

The recent (1948) neologism *automation* comes from autom(atic oper)ation. The term *automatic* means self-moving or self-dictating (Greek *autómatos*) [18.1]. The *Oxford English Dictionary* (OED) defines it as

> *Automatic control of the manufacture of a product through a number of successive stages; the application of automatic control to any branch of industry or science; by extension, the use of electronic or other mechanical devices to replace human labor.*

Thus, the primary theoretical limit of automation is built into the denotative meaning of the word itself. Automation is all about self-moving or self-dictating as opposed to self-organizing. Another way of saying this is that the very notion of automation is based upon, and thus limited by, its own mechanical metaphor. In fact, most people would agree that, if an automated process began to self-organize into something else, then it would not be a very good piece of automation per se. It would perhaps be a brilliant act of creating a new form of *life* (i. e., a self-organizing system), but that is certainly not what automation is all about.

Automation is fundamentally about taking some process that itself was created by a life process and making it more mechanical or in the modern computing metaphor *hard-wired*, such that it can be executed without any volitional or further expenditure of *life-process* energy. This phenomenon can even be seen in living organisms themselves. The whole point of skill-building in humans is to drive brain and other neural processes to become more nearly *hard-wired*. It is well known that, as the brain executes some particular circuit more and more, it *hard-wires* itself by growing more and more synaptic connections. This, in effect, automates a volitional process by making it more mechanical and thus more highly automated. Such *nerve training* is driven by practice and repetition to achieve greater performance levels in athletes and musicians.

This is also what happens in our more conscious processes of automation. We create some new process and then seek to *automate* it by making it more mechanical. An objection to this notion might be to say that the brain itself is a mechanism, albeit a very complex one, and since the brain is capable of this self-organizing or volitional behavior how can we make this distinction? I think there are primarily two and possibly a third answer to this, depending on one's belief system.

1. For those who believe that there is life after death it seems to me conclusive to say that, if we live on then, there must be a distinction between our mind and our brain.
2. For almost everyone else there is good research evidence for a distinction between the mind and the brain. This can especially be seen in people with obsessive compulsive disorder and, in fact, *The Mind and the Brain* is very persuasive in showing that a person has a mind which is capable of programming their brain or overcoming some faulting programming of their brain – even when the brain has been hard-wired in some particularly un-useful way [18.2].
3. However, the utter materialist would further argue that the mind is merely an artifact of the electrochemical function of the brain as an ensemble of neurons and synapses and does not exist as a separate entity in spite of its phenomenological differences in functionality.

In any case, as long as we acknowledge that there is some operational degree of distinction between the mind as analogous to software and the brain as analogous to hardware, then we simply cannot determine to what extent the mind and the brain together are operating as a mechanism and to what extent they are operating as a self-organizing open system. The ethical and educational issues related to what can and cannot be automated, though important, are outside of the scope of this chapter. Readers are invited to read Chap. 47 on *Ethical Issues of Automation Management*, Chap. 17 on *The Human Role in Automation*, and Chap. 44 on *Education and Qualification*.

18.2 The Limits of Mechanization

So, another way of asking *what are the limits of automation* is to ask *what are the limits of mechanization?* or, *what are machines ultimately capable of doing autonomously?* But what does *mechanical* mean? Fundamentally it means linear or stepwise, i. e., able to carry out an algorithmically defined process having clear inputs and clear outputs. The well-known Carnot circle used by the military engineer and founder of thermodynamics L. N. S. Carnot (1796–1832) to describe the heat engine and other mechanical systems (Fig. 18.1) separates the engine or system under study from the rest of the universe by a circle with an arrow in for input and an arrow out for output. This is a simple but powerful philosophical (and graphical) tool for understanding the functions and limits of systems and familiar to every mechanical and systems engineer. More complex mechanical processes may have to go beyond strictly linear algorithmic control to include negative feedback, but still operate in such a way that they satisfy a clear objective function or goal. When the goal requires extremely precise positioning of the automation, a subprocess or correction function called *dither* is added to force the feedback loop to hunt for the precise solution or positioning in a heuristic manner but still subsidiary to and controlled by the algorithm itself. In any case, *mechanical* means non-context-sensitive and discrete, even if it involves dither. Machine theory is basically the opposite of general system theory. And by a *general system* we mean an open system, i. e., a system that is capable of locally overcoming entropy and is self-organizing. Today such systems are typically referred to as complex adaptive systems (CAS).

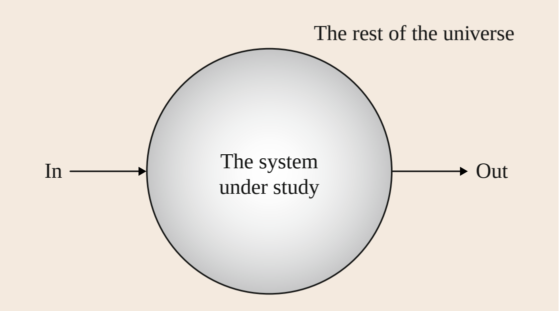

Fig. 18.1 The Carnot circle as a system definition tool

An open system is fundamentally different from a machine. The core difference is that an open system is nonlinear. That is, in general, everything within the system is sensitive to its entire context, i. e., to everything else in the system, not just the previous step in an algorithm. This is most easily seen in quantum theory with the two-slit experiment. Somehow the single electron is aware that there are two slits rather than one and thus behaves like a wave rather than a particle.

In essence, the single electron's behavior is sensitive to the entire experimental context. Now imagine a human brain with 100 billion neurons interconnected with some 100 trillion synapses, where even local synaptic structures make their own locally complex circuits. The human brain is also bathed in chemicals that influence the operation of this vast network of neurons whose resultant behavior then influences the mix of chemicals. And then there are the hypothesized quantum effects, giving rise to potential nonlocal effects, within any particular neuron itself. This is clearly a vastly different sort of thing than a machine: a difference in degree of context sensitivity that amounts to a difference in kind.

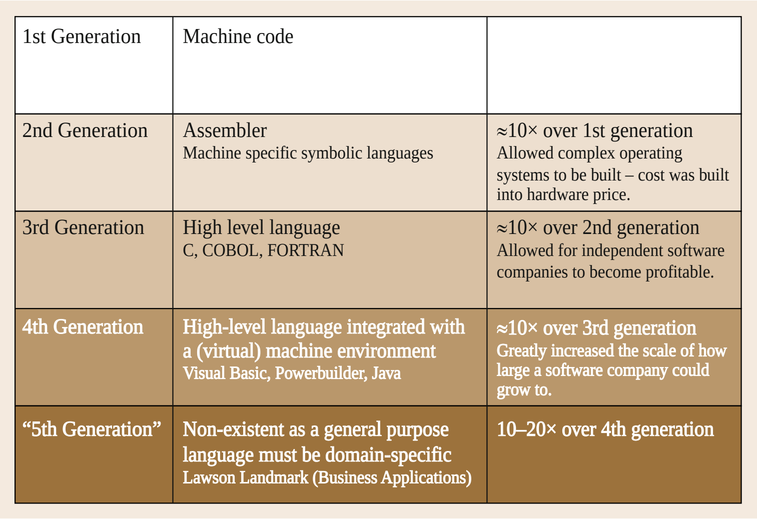
One way to illustrate this mathematically is to define a system of simultaneous differential equations. Denoting some measure of elements, $p_i (i = 1, 2, \ldots, n)$, by Q_i, these, for a finite number of elements and in the simplest case, will be of the form

$$\begin{aligned} \mathrm{d}Q_1/\mathrm{d}t &= f_1(Q_1, Q_2, \ldots, Q_n) \\ \mathrm{d}Q_2/\mathrm{d}t &= f_2(Q_1, Q_2, \ldots, Q_n) \\ &\ldots \\ \mathrm{d}Q_n/\mathrm{d}t &= f_n(Q_1, Q_2, \ldots, Q_n)\,. \end{aligned}$$

Change of any measure Q_i is therefore a function of all Q, from Q_1 to Q_n; conversely, change of any Q_i entails change of all other measures and of the system as a whole [18.3].

What has been missing from the Strong Artificial Intelligence (AI) debate and indeed from most of Western thought is the nature of open systems and their propensity to generate emergent behavior. We are still mostly caught up in the mechanical metaphor believing that it is possible to mechanize or *model* any system using machines or algorithms, but this is exactly the opposite of what is actually happening. It is systems themselves that use a mechanizing process to improve their performance and move onto higher levels of emergent behavior.

However, it is no wonder that we are so caught up in the mechanical metaphor, as it is the very basis of the industrial revolution and is thus responsible for much of our wealth today. In the field of business application software this peripheral blindness (or, rather, intense focus) has led to huge failures in building complex business application software systems. The presumption is that building a software system is like building a bridge; that it is like a construction project; that it is fundamentally an engineering problem where there is a design process and then a construction process where the design process can fully specify something that can be constructed using engineering principles; more specifically, that there is some design process done by designers and that the construction process is the process of programming done by programmers. However, it is not. It is really a design problem through and through and, moreover, a design problem that does not have general-purpose engineering-like principles and solutions that have already been *reduced to code* by years of practice. It is a design problem of pure logic where the logic can only be fully specified in a completed program where the *construction* process is then simply running a compiler against the program to generate machine instructions that carry out the logic.



1st Generation	Machine code	
2nd Generation	Assembler Machine specific symbolic languages	≈10× over 1st generation Allowed complex operating systems to be built – cost was built into hardware price.
3rd Generation	High level language C, COBOL, FORTRAN	≈10× over 2nd generation Allowed for independent software companies to become profitable.
4th Generation	High-level language integrated with a (virtual) machine environment Visual Basic, Powerbuilder, Java	≈10× over 3rd generation Greatly increased the scale of how large a software company could grow to.
"5th Generation"	Non-existent as a general purpose language must be domain-specific Lawson Landmark (Business Applications)	10–20× over 4th generation

Fig. 18.2 Software language generations

There are no general-purpose solutions to all logic design problems. There are only special-purpose domain-specific solutions. This can be seen in the evolution, or lately lack thereof, of computer languages. We went from first-generation languages (machine code) to second-generation languages (assembler) to third-generation languages (FORTRAN, COBOL, C) to fourth-generation languages (Java, Progress) where each generation represented some tenfold productivity improvement in our ability to produce systems (Fig. 18.2). This impressive progression however slowed down and essentially stopped dead in its tracks some 20 years ago in its ability to significantly improve productivity. Since then there have been many attempts to come up with the next (fifth) generation language or general-purpose framework for dramatically improving productivity. In the 1980s computer-aided software engineering (CASE) tools were the hoped-for solution. In the 1990s object-oriented frameworks looked promising as the ultimate solution and now the industry as a whole seems primarily focused on the notion of service-oriented architecture (SOA) as our best way forward. While these attempts have helped boost productivity to some extent they have all failed to produce an order of magnitude shift in the productivity of building software systems (Fig. 18.3). What they all have in common is the continuation of the mechanical metaphor. They are all attempts at general-purpose engineering-like solutions to this problem. General-purpose languages can only go so far in solving the productivity problem. However, special-purpose languages or domain-specific languages (DSL) take us much farther. There are multiple categories of DSLs. There are *horizontal* DSLs that address some functional layer, like SQL does for data access or UML does for conceptual design (as opposed to the detail design which is the actual complete program in this metaphor). And there are vertical DSLs which address some topical area such as mathematical analysis, molecular modeling or business process applications. There is also the distinction between a DSL and a domain-specific design language (DSDL). All DSDLs are DSLs but not all DSLs are DSDLs (a *prescission* distinction in Peirce's nomenclature [18.4]). A design language is distinct from a programming or implementation language in that in a design language everything is defined relative to everything else. This is like the distinction between a design within a CAD system and the actually built component. In the CAD system one can move a line and everything changes around it. In the actually built component that *line* is a physical entity in some hardened structural relationship. Then there is the further prescission distinction of a pattern language versus a DSDL. A pattern language is a DSDL that has built-in syntax that allows for specific design solutions to be applied to specific domain problems. This tends to be the most vertically domain-specific and also the most powerful sort of language for improving the productivity of building systems. Lawson Landmark is one example of a pattern language that delivers a 20 times improvement over fourth-generation languages in its particular domain.

Objects
CASE
General purpose & broad
3GL (C, COBOL)

Fig. 18.3 Productivity progression of languages

It is not possible to mechanize or model an entire complex system. We can only mechanize aspects of any particular system. To mechanize the entire system is to destroy the system as such; i. e., it is no longer a system. Analysis of a system into its constituent parts loses its essence as a system, if a system is truly *more than the sum of its parts*. That is, the mechanistic model lacks the system's inherent capability for self-organization and thus adaptability, and thus becomes more rigid and more limited in its capabilities, although, perhaps, much faster. And the limit to what aspects of a system can be mechanized is really the limit of our cognitive ability to model those aspects. In other words it is a design problem. In general the theoretical limit of mechanization is always the current limit of our capacity to design linear stepwise models in any particular solution domain. Thus the key to what can be automated is the depth of our knowledge and understanding within any specific problem domain, the depth required being that depth necessary to be able to design automatons that *fit*, where fit is determined both by the automaton actually producing what is expected as well as fitting appropriately within the system as a whole; i. e., if the automation disturbs the system that it is within beyond some threshold then the very system that gives rise to the useful automaton will change so dramatically that the automation is no longer useful. An example of this might be a software program for paying employees. If this program does pay employees correctly but requires dramatic changes to the manner in which time card information is gathered such that it becomes too great a burden on some part of the system then the program will likely soon be surrounded by organizational *T cells* and rejected.

Organisms *are* not machines, but they can to a certain extent *become* machines, or perhaps congeal into machines. Never completely, however, for a thoroughly mechanized organism would be incapable of reacting to the incessantly changing conditions of the outside world. The *principle of progressive mechanization* expresses the transition from undifferentiated wholeness to higher function, made possible by specialization and *division of labor*; this principle also implies loss of potentialities in the components and of regularity in the whole [18.5].

18.3 Expanding the Limit

Human business processes (buying, selling, manufacturing, invoicing, and so on), like actual organisms, operate fundamentally as open systems or rather complex adaptive system (CAS). Other examples of CAS are cities, insect colonies, and so on. The architecture of an African termite mound requires more bits to describe than the number of neurons in a termite brain. So, where do they store it? In fact, they do not, because each termite is programmed as an automaton to instinctively perform certain functions under certain stimuli and the combined activity of the colony produces and maintains the mound. Thus, the entire world is fundamentally made up of vastly complex interacting systems. When we automate we are ourselves engaging in the principle of progressive mechanization. We are mechanizing some portion or aspect of a system. We can only mechanize those aspects that are themselves already highly specialized within the system itself or that we can make highly specialized; for example, it is possible to make a mechanical heart but it is impossible to make a mechanical stem cell or a mechanical human brain. It is possible to make a mechanical payroll program but impossible to make a mechanical company that responds to dynamic market forces and makes a profit. The result of this is that any mechanization requires specific understanding of some particular specialization within some particular system. In other words, there are innumerable specific domains of specialization within all of the complex interacting systems in the world. And thus any mechanization is inherently domain- pecific and requires detailed domain knowledge. The process of mechanization is therefore fundamentally a domain-specific design problem. *Thus, the limit of mechanization is our ability to comprehend some particular aspect of a system well enough to be able to extract some portion or aspect of that system in which it is possible to define a boundary or Carnot circle with clear inputs and clear outputs along with a transfer function mapping those inputs to those outputs*. If we cannot enumerate the inputs and outputs and then describe what inputs result in what outputs then we simply cannot automate the process. This is the fundamental requirement of mechanization.

This does not, however, mean that we are limited to our current simple mechanical metaphor of a machine as a set of inputs into a box that transforms those inputs into their associated outputs. Indeed the next step of mechanization under way is to try to mimic aspects of how a system itself works. One aspect of this is the object-oriented revolution in software, which itself grew out of the work done in complex adaptive systems research. Unfortunately, the prevailing simple mechanical metaphor and lack of understanding of the nature of CAS has blunted the evolution of object-oriented technology and limited its impact.

Object-oriented concepts have taken us from a simplistic view of a machine as a *black box* process or function F as shown in Fig. 18.4, in which ($outputs = F(inputs)$), to conceptualizing a machine as an interacting set of agents or objects. These concepts have allowed us to manage higher levels of complexity in the machines we build but they have not taken us to a higher order of magnitude in our ability to mecha-

Input
The Black Box
Output

Fig. 18.4 The engineer's black box

nize complex systems. In the realm of business process software what has been missing is the following:

1. The full realization that what we are modeling with business process software is really a portion or aspect of a complex adaptive system
2. That this is fundamentally a logic design problem rather than an engineering problem
3. That, in this case, the problem domain is primarily about semiotics and pragmatics, i. e., the nature of sign processes and the impact on those who use them

Fortunately there is a depth of research in these areas that provides guidance toward more powerful techniques and tools for making further progress. John Holland, the designer of the Holland Machine, one of the first parallel computers, has done extensive research into CAS and has discovered many basic principles that all CAS seem to have in common. His work led to object-oriented concepts; however, the object-oriented community has not continued to seek to implement his further discoveries and principles regarding CAS into object-oriented computing languages. One very useful concept is how CAS systems use rule-block formations in driving their behavior and the nature of how adaptation continues to build rule-block hierarchies on top of existing rule-block structures [18.6].

Christopher Alexander [18.7] is a building architect who discovered the notion of a *pattern language* for designing and constructing buildings and cities [18.8]. In general, a pattern language is a set of patterns or design solutions to some particular design problem in some particular domain. The key insight here is that design is a domain-specific problem that takes deep understanding of the problem domain and that, once good design solutions are found to any specific problem, we can codify them into reusable patterns. A simple example of a pattern language and the nature of domain specificity is perhaps how farmers go about building barns. They do not hire architects but rather get together and, through a set of *rules of thumb* based on how much livestock they have and storage and processing considerations, build a barn with such and such dimensions. One simple pattern is that, when the barn gets to be too long for just doors on the ends, they put a door in the middle. Now, can someone use these *rules of thumb* or this pattern language to build a skyscraper in New York?

Charles Sanders Peirce was a 19th century American philosopher and semiotician. He is one of the founders of the quintessential American philosophy known as pragmatism, and came up with a triadic semiotics based on his metaphysical categories of firstness, secondness, and thirdness [18.9]. Firstness is the category of idea or possibility. Secondness is the category of brute fact or instance, and thirdness is the category of laws or behavior. Peirce argues that existence itself requires these categories; that they are in essence a unity and that there is no existence without these three categories. Using this understanding one could argue that this demystifies to some extent the Christian notion of God being a unity and yet also being triune by understanding the Father as firstness, the Son as secondness, and the Holy Spirit as thirdness. Thus the trinity of God is essentially a metaphysical statement about the nature of existence. Peirce goes on to build a system of signs or semiotics based on this triadic structure and in essence argues that reality is ultimately the stuff of signs; e.g., God *spoke* the universe into existence. At first one could seek to use this notion to support the Strong AI view that all intelligence is symbol representation and symbol processing and thus a computer can ultimately model this reality. However, a key concept of Peirce is that the meaning of a sign requires an *interpretant*, which itself is a sign and thus also requires a further interpretant to give it meaning in a never-ending process of meaning creation; that is, it becomes an eternally recursive process. Another way of viewing this is to say that this process of making meaning is ultimately an open system. And while machines can model and hence automate closed systems they cannot fully model open systems.

Peirce's semiotics and his notion of firstness, secondness, and thirdness provide the key insights required for building robust ontology models of any particular domain. The key to a robust ontology model is not that it is *right* once and for all but rather that it can be done using a design language and that it has perfect fidelity with the resulting execution model. An ontology model is never *right*; it is just more and more useful. This is because of the notion of the *relativity of categories*.

Perception is universally human, determined by man's psychophysical equipment. Conceptualization is culture-bound because it depends on the symbolic systems we apply. These symbolic systems are largely determined by linguistic factors, the structure of the language applied. Technical language, including the symbolism of mathematics, is, in the last resort, an efflorescence of everyday language, and so will not be independent of the structure of the latter. This, of course, does not mean that the content of mathematics is *true* only within a certain culture. It is a tautological system of a hypothetico-deductive nature, and hence any rational being accepting the premises must agree to all its deductions [18.10].

The most critical aspect of achieving the theoretical limit of automation is the ability to continue to make execution models that are more and more useful. And this is true for two reasons:

1. CAS are so complex that we cannot possibly understand large portions of them perfectly ab initio. We need to model them, explore them, and then improve them.
2. CAS are continually adapting. They are continually changing and thus, even if we perfectly modeled some aspect of a CAS, it will change and our model will become less and less useful.

In order to do this we need a DSDL capable of quickly building high-fidelity models. That is, models which are themselves the drivers of the actual execution of automation.

In order for the model of the CAS to ultimately actually drive the execution it is critical that the ontology model be in perfect fidelity with the execution model. Today there is a big disconnect between what one can build in an *analysis model* and the resultant executing code or execution model. This is analogous to having a design of a two-storey home on a blueprint and then having the result become a three-storey office building. What is required is a design language that can both model the ontology in its full richness as the analysis model but also be able to model the full execution in perfect fidelity with the ontology model. In essence this means a single model that fully incorporates firstness, secondness, and thirdness in all their richness that can then either be fully interpreted on a machine or fully generated to some other machine language or a combination of both.

Only with such a powerful design or pattern language can we overcome the inherent limitations we have in our ability to comprehend the workings of some particular CAS, model, and then automate those portions that can be mechanized and continue to keep pace with the continually evolving CAS that we are seeking to *progressively mechanize*.

18.4 The Current State of the Art

The computing industry in general is still very much caught up in the mechanical metaphor. While object-oriented design and programming technology is more than decades old, and there is a *patterns movement* in the industry that is just over a decade old, there are very few examples of this new DSDL technology in use today. However, where it has been used the results have been dramatic, i. e., on the order of a 20-fold reduction of complexity as measured in *lines of code*. Lawson Landmark$^{\text{TM}}$ is such a pattern language intended for the precise functional specification of business enterprise computer applications by domain specialists rather than programmers [18.11]. The result of the domain expert's work is then run through a metacompiler to produce Java code which can be loaded and tested against a transaction script also prepared by the same or another domain expert (i. e., accountant, supply-chain expert, etc.). The traditional application programmer does not appear in this modern business application development scenario because his or her function has been *automated*. It has taken nearly 50 years for specification-based programming to arrive at this level of development and utility and several other aggressive attempts at automation of intellectual functions have taken as long.

Automation of human intellectual functions is basically an aspect of AI, and the potential of AI is basically a philosophical rather than a technical question. The two major protagonists in this debate are the philosopher *Hubert Dreyfus* [18.12, 13] and *Ray Kurzweil* [18.14–16], an accomplished engineer. Dreyfus argues that computers will never ever achieve anything like human intelligence simply because they do not have consciousness. He gives the argument from what he calls associative or peripheral consciousness in the human brain. Kurzweil has written extensively as a futurist arguing that computers will soon exceed human intelligence and even develop spiritual capabilities.

Early in the computer era *Herbert Simon* hypothesized that a computer program that was able to play master-level chess would be exhibiting intelligence [18.17]. Dreyfus and other Strong AI opponents argue that it is not, because the chess program does not automatically play chess like a human does and therefore does not exhibit AI at all. They go on to show that is impossible for a program to play an even simpler game like Go well using this same technology. Playing chess was the straw man set up by Herbert Simon in the mid-1950s to be the benchmark of AI, i. e., if a computer could beat the best human chess player, then it would show true intelligence, but it actually does not. It took nearly 50 years to develop a special-purpose computer able to beat the leading human chess master, Gary Kasparov, but it does not automate or mechanize human intelligence to do so. In fact, it just came up with a different design for a computational algorithm that could play chess. This is analogous to the problem of flying. We did not copy how a bird flies but rather came up with a special-purpose design that suited our particular requirements. The Strong AI hypothesis appears to assume that all human thought, or at least intelligent thought, can be reduced to computation, and since computers can compute orders of magnitude faster than humans they will soon, says Ray Kurzweil, exhibit human-like intelligence, and eventually intelligence even superior to that of humans. Of course, the philosophers who gainsay the Strong AI hypothesis argue that not all intelligent human thought and its consequent behavior can be reduced to simple computation, or even logic.

An early goal of AI was to mechanize the function of an autonomous vehicle, that is, to give the vehicle a goal or set of objectives and the algorithms needed to accomplish them and let it function. The annual autonomous vehicle race in the Nevada desert shows that at least simple goals can be met autonomously or at least as well as a mildly intoxicated human driver. The semi-autonomous Mars rovers show off this technology even better but still fall far short of being *intelligent*.

Another of the early intrinsically human activities that AI researchers tried to automate was the typewriter. Prof. Marvin Minsky started his AI career as a graduate student at MIT in the mid-1950s working on a voice typewriter to type military correspondence for the Department of Defense (DoD). Now, more than 50 years later, the technology is modestly successful as a software program.

At the same time Prof. Anthony Oettenger did his dissertation at the Harvard Computation Laboratory on automatic language translation with the *Automatic Russian–English Dictionary*. It was modestly successful for a narrow genre of Russian technical literature and created the whole new field of computational linguistics. Today, more than 50 years later, a similar technology is available as a software program for Russian and a few other languages with a library of genre-specific and technical-area-specific vocabulary plug-ins sold separately. The best success story on automatic language translation today is the European Economic Community (EEC), which writes its memos in French in the Brussels headquarters and converts them into the 11 languages of the EEC and then sends them out to member nations. French bureaucratese is a very narrow language genre and probably the easiest case for autotranslation automation due not only to the genre but the source language. No one has ever suggested that *Eugene Onegin* will ever be translated automatically from Russian to English, since so far it has even resisted human efforts to do so. Amazing as it may seem, Shakespeare's poetry translates beautifully to Russian but Pushkin's does not translate easily to English.

Linguists are divided, like philosophers, on whether computational linguistics technology will ever really achieve true automation, but we think that it probably will, subject to human pre- and post-editing in actual volume production practice, and then only for very narrow subject areas in a few restricted genres. Technical prose in which the translator is only copying one fact at a time from one language to another will be possible, but poetry will always be too complex, since poetry always violates the rules of grammar of its own source language.

18.5 A General Principle

What we need is a general principle which will cleanly divide all the things that can be done into those which can be automated and those which cannot be automated. You cannot automate what you cannot do manually, but the converse it not true, since you cannot always automate everything you *can* do manually [18.4, 18, 19]. However, this principle is much too blunt. In his book *Darwin's Black Box* Professor *Michael Behe* argued from the principle of irreducible complexity that neo-Darwinism was inadequate to explain the development of the eye or of the endocrine system because too many mutations and their immediate useful adaptations had to happen at once, since each of 20 or more required mutations would have no competitive advantage in adaptation individually [18.20]. In his second book *The Edge of Evolution* he sharpens his principle significantly to divide biological adaptations into those which can be explained by neo-Darwinism (single mutations) and those which cannot (multiple mutations). The refined principle, while sharper, still leaves a ragged edge between the two classes of adaptive biological systems, according to *Behe* [18.21].

In our case we postulate the principle of design. Anything that can be copied can be copied automatically. However, any process involving design cannot be automated and any sufficiently (i. e., irreducibly) complex adaptive system cannot be automated (as Behe shows), however simple adaptive systems can be modeled to some extent mechanistically. Malaria can become resistant to a new antibiotic in weeks by Darwin's *black box* if it requires only a one-gene change, however in 10 000 years malaria has not been able to overcome the cell-cycle mutation in humans because it would require too many concurrent mutations.

We conclude that anything that can be reduced to an algorithm or computational process can be automated, but that some things, like most human thought and most functions of complex adaptive systems, are not reducible to a logical algorithm or a computational process and therefore cannot be automated.

Part C Automation Design: Theory, Elements, and Methods

Automation Design: Theory, Elements, and Methods Part C From theory to building automation machines, systems, and systems-of-systems this part explains the fundamental elements of mechatronics, sensors, robots, and other components useful for automation, and how they are combined with control and automation software, including models and techniques for automation software engineering, and the automation of the design process itself. Design theories and methods cover also soft automation, automation modeling and programming languages, real-time and autonomic techniques, and emerging networking and service grids for automation. Human factors engineering and science in the design of automation, including interaction and interface design, and issues of trust and collaboration focus on systems and infrastructures integrating people with decision-support and with teleoperated, remote automatic equipment. Also in this part are advanced design methods and tools of distributed agents, evolutionary techniques and computing algorithms for automation, and design of eight key automation functions to prevent or recover from errors and conflicts, to assure automation reliability and sustainability.

19. Mechatronic Systems – A Short Introduction

Rolf Isermann

Many technical processes and products in the area of mechanical and electrical engineering show increasing integration of mechanics with digital electronics and information processing. This integration is between the components (hardware) and the information-driven functions (software), resulting in integrated systems called mechatronic systems. Their development involves finding an optimal balance between the basic mechanical structure, sensor and actuator implementation, and automatic information processing and overall control. Frequently formerly mechanical functions are replaced by electronically controlled functions, resulting in simpler mechanical structures and increased functionality. The development of mechatronic systems opens the door to many innovative solutions and synergetic effects which are not possible with mechanics or electronics alone. This technical progress has a very strong influence on a multitude of products in the areas of mechanical, electrical, and electronic engineering and is increasingly changing the design, for example, of conventional electromechanical components, machines, vehicles, and precision mechanical devices.

19.1 From Mechanical to Mechatronic Systems

Mechanical systems generate certain motions or transfer forces or torques. For the oriented command of, e.g., displacements, velocities or forces, feedforward and feedback control systems have been applied for many years. The control systems operate either without auxiliary energy (e.g., a fly-ball governor), or with electrical, hydraulic or pneumatic auxiliary energy, to manipulate the commanded variables directly or with a power amplifier. A realization with added fixed wired (analog) devices turns out to enable only relatively simple and limited control functions. If these analog devices are replaced with digital computers in the form of, e.g., online coupled microcomputers, the information processing can be designed to be considerably more flexible and more comprehensive.

Figure 19.1 shows the example of a machine set, consisting of a power-generating machine (DC motor) and a power-consuming machine (circulation pump): (a) a scheme of the components, (b) the resulting sig-

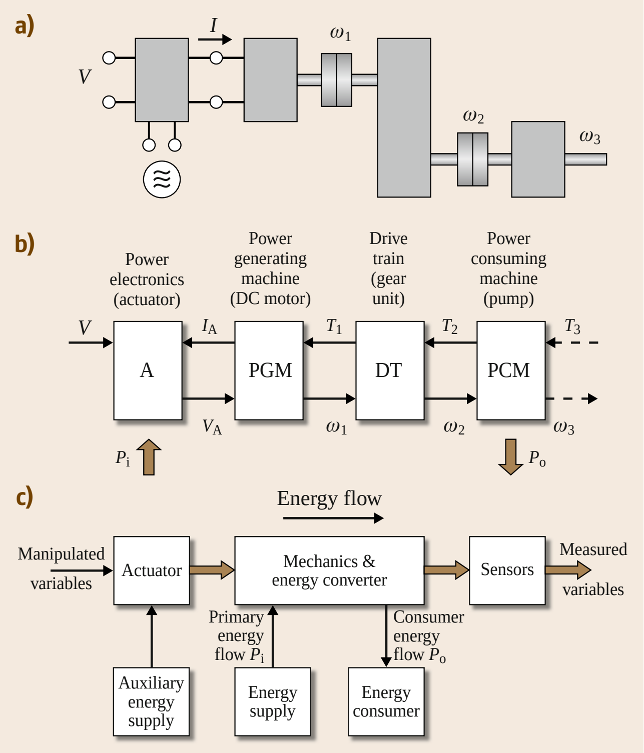

Fig. 19.1a–c Schematic representation of a machine set: **(a)** scheme of the components; **(b)** signal flow diagram (two-port representation); **(c)** open-loop process. nal flow diagram in two-port representation, and (c) the open-loop process with one or several manipulated variables as input variables and several measured variables as output variables. This process is characterized by different controllable energy flows (electrical, mechanical, and hydraulic). The first and last flow can be manipulated by a manipulated variable of low power (auxiliary power), e.g., through a power electronics device and a flow valve actuator. Several sensors yield measurable variables. For a mechanical–electronic system, a digital electronic system is added to the process. This electronic system acts on the process based on the measurements or external command variables in a feed-forward or feedback manner (Fig. 19.2). If then the electronic and the mechanical system are merged to an autonomous overall system, an integrated mechanical–electronic system results. The electronics processes information, and such a system is characterized at least by a mechanical energy flow and an information flow.

These integrated mechanical–electronic systems are increasingly called mechatronic systems. Thus, *mecha*nics and elec*tronics* are joined. The word *mechatronics* was probably first created by a Japanese engineer in 1969 [19.1] and had a trademark by a Japanese company until 1972 [19.2]. Several definitions can be found in [19.3–7]. All definitions agree that mechatronics is an interdisciplinary field, in which the following disciplines act together (Fig. 19.3):

- Mechanical systems (mechanical elements, machines, precision mechanics)
- Electronic systems (microelectronics, power electronics, sensor and actuator technology)
- Information technology (systems theory, control and automation, software engineering, artificial intelligence).

The *solution of tasks* to design mechatronic systems is performed on the mechanical as well as on the digital-electronic side. Thus, interrelations during design play an important role; because the mechan-

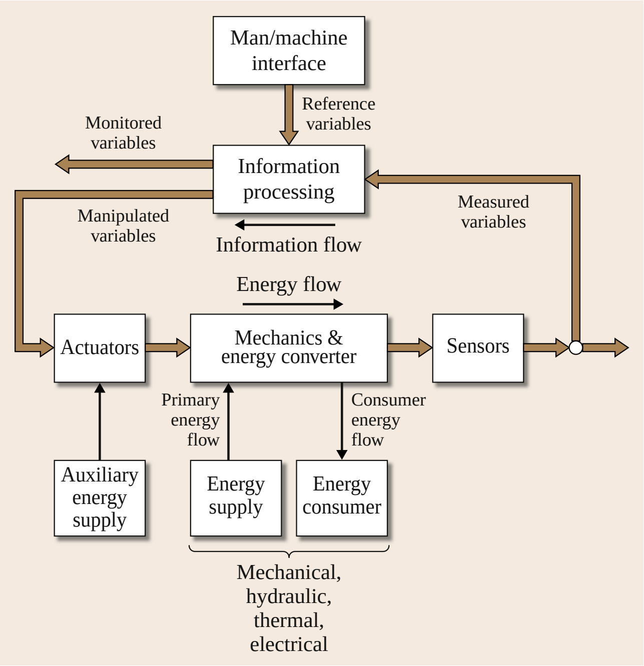

Fig. 19.2 Mechanical process and information processing develop towards a mechatronic system◀

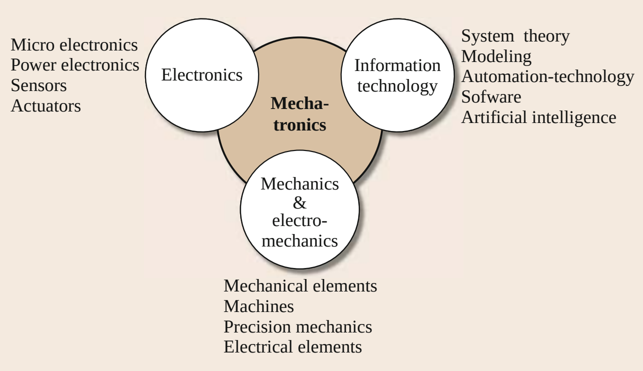

Fig. 19.3 Mechatronics: synergetic integration of different disciplines▸

ical system influences the electronic system, and vice versa, the electronic system influences the design of the mechanical system (Fig. 19.4). This means that simultaneous engineering has to take place, with the goal of designing an overall integrated system (an *organic system*) and also creating synergetic effects.

A further feature of mechatronic systems is integrated digital information processing. As well as basic control functions, more sophisticated control functions may be realized, e.g., calculation of nonmeasurable variables, adaptation of controller parameters, detection and diagnosis of faults and, in the case of failures, reconfiguration to redundant components. Hence, mechatronic systems are developing with adaptive or even learning behavior, which can also be called intelligent mechatronic systems.

The developments to date can be found in [19.2, 7–11]. An insight into general aspects are given editorially in journals [19.5, 6], conference proceedings such as [19.12–17], journal articles by [19.18–21], and books [19.22–27]. A summary of research projects at the Darmstadt University of Technology can be found in [19.28].

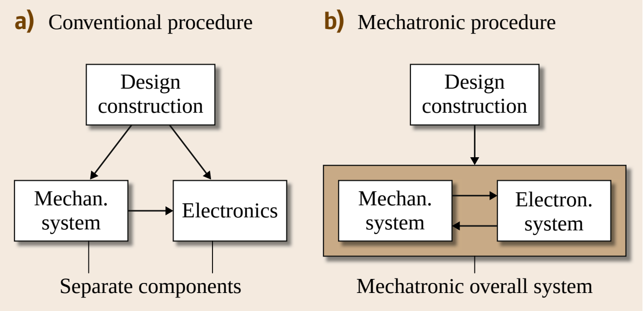

Fig. 19.4a,b Interrelations during the design and construction of mechatronic systems

19.2 Mechanical Systems and Mechatronic Developments

Mechanical systems can be applied to a large area of mechanical engineering. According to their construction, they can be subdivided into mechanical components, machines, vehicles, precision mechanical devices, and micromechanical components.

The design of mechanical products is influenced by the interplay of energy, matter, and information. With regard to the basic problem and its solution, frequently either the energy, matter or information flow is dominant. Therefore, one main flow and at least one side flow can be distinguished [19.29].

In the following some examples of mechatronic developments are given. The area of mechanical components, machines, and vehicles is covered by Fig. 19.5.

19.2.1 Machine Elements, Mechanical Components

Machine elements are usually purely mechanical. Figure 19.5 shows some examples. Properties that can be improved by electronics are, for example, self-adaptive stiffness and damping, self-adaptive free motion or pretension, automatic operating functions such as coupling or gear shifting, and supervisory functions. Some examples of mechatronic approaches are hydrobearings for combustion engines with electronic control of damping, magnetic bearings with position control [19.30], automatic electronic–hydraulic gears [19.31], and adaptive shock absorbers for wheel suspensions [19.32].

19.2.2 Electrical Drives and Servo Systems

Electrical drives with direct-current, universal, asynchronous, and synchronous motors have used integration with gears, speed sensors or position sensors and power electronics for many years. Especially the development of transistor-based voltage supplies and cheaper power electronics on the basis of transistors and thyristors with variable-frequency three-phase cur-

rent supported speed control drives also for smaller power. Herewith, a trend towards decentralized drives with integrated electronics can be observed. The way of integration or attachment depends, e.g., on space requirement, cooling, contamination, vibrations, and accessibility for maintenance. Electrical servo drives require special designs for positioning.

Hydraulic and pneumatic servo drives for linear and rotatory positioning show increasingly integrated sensors and control electronics. Motivations are requirements for easy-to-assemble drives, small space, fast change, and increased functions [19.33].

Multiaxis robots and mobile robots show mechatronic properties from the beginning of their design.

19.2.3 Power-Generating Machines

Machines show an especially broad variability. Power-producing machines are characterized by the conversion of hydraulic, thermodynamic or electrical energy and delivery of power. Power-consuming machines convert mechanical energy to another form, thereby absorbing energy. Vehicles transfer mechanical energy into movement, thereby consuming power.

Examples of mechatronic electrical power-generating machines are brushless DC motors with electronic commutation or speed-controlled asynchronous and synchronous motors with variable-frequency power converters.

Combustion engines increasingly contain mechatronic components, especially in the area of actuators. Gasoline engines showed, for example, the following steps of development: microelectronic-controlled injection and ignition (1979), electrical throttle (1991), direct injection with electromechanical (1999) and piezoelectric injection valves (2003), variable valve control (2004); see, for example, [19.34].

Diesel engines first had mechanical injection pumps (1927), then analog-electronic-controlled axial piston pumps (1986), and digital-electronic-controlled high-pressure pumps, since 1997 with common-rail systems [19.35]. Further developments are the exhaust turbochargers with wastegate or controllable vanes (variable turbine geometry, VTG), since about 1993.

19.2.4 Power-Consuming Machines

Examples of mechatronic power-consuming machines are multiaxis machine tools with trajectory control, force control, tools with integrated sensors, and robot transport of the products; see, e.g., [19.36]. In addition to these machine tools with open kinematic chains between basic frame and tools and linear or rotatory axes with one degree of freedom, machines with parallel kinematics will be developed. Machine tools show a tendency towards magnetic bearings if ball bearings cannot be applied for high speeds, e.g., for high-speed milling of aluminum, and also for ultracentrifuges [19.37]. Within the area of manufacturing, many machinery, sorting, and transportation devices are characterized by integration with electronics, but as yet they are mostly not fully hardware-integrated. For hydraulic piston pumps the control electronics is now attached to the casing [19.33]. Further examples are packing machines with decentralized drives and trajectory control or offset-printing machines with replacement of the mechanical synchronization axis through decentralized drives with digital electronic synchronization and high precision.

19.2.5 Vehicles

Many mechatronic components have been introduced, especially in the area of vehicles, or are in development: antilock braking control (ABS) [19.38], controllable shock absorbers [19.39], controlled adaptive suspensions [19.40], active suspensions [19.41, 42], drive dynamic control through individual braking (electronic stability program, ESP) [19.43, 44], electrohydraulic brakes (2001), and active front steering (AFS) (2003). Of the innovations for vehicles 80–90% are based on electronic/mechatronic developments. Here, the value of electronics/electrics of vehicles increases to about 30% or more.

19.2.6 Trains

Trains with steam, diesel or electrical locomotives have followed a very long development. For wagons the design with two boogies with two axes are standard. ABS braking control can be seen as the first mechatronic influence in this area [19.45, 46]. The high-speed trains (TGV, ICE) contain modern asynchronous motors with power electronic control. The trolleys are supplied with electronic force and position control. Tilting trains show a mechatronic design (1997) and actively damped and steerable boogies also [19.47]. Further, magnetically levitated trains are based on mechatronic construction; see, e.g., [19.47].

19.3 Functions of Mechatronic Systems

Mechatronic systems enable, after the integration of the components, many improved and also new functions. This will be discussed by using examples.

19.3.1 Basic Mechanical Design

The basic mechanical construction first has to satisfy the task of transferring the mechanical energy flow (force, torque) to generate motions or special movements, etc. Known traditional methods are applied, such as material selection, calculation of strengths, manufacturing, production costs, etc. By attaching sensors, actuators, and mechanical controllers, in earlier times, simple control functions were realized, e.g., the fly-ball governor. Then gradually pneumatic, hydraulic, and electrical analog controllers were introduced. After the advent of digital control systems, especially with the development of microprocessors around 1975, the information processing part could be designed to be much more sophisticated. These digitally controlled systems were first added to the basic mechanical construction and were limited by the properties of the sensors, actuators, and electronics, i. e., they frequently did not satisfy reliability and lifetime requirements under rough environmental conditions (temperature, vibrations, contamination) and had a relatively large space requirement and cable connections, and low computational speed. However, many of these initial drawbacks were removed with time, and since about 1980 electronic hardware has become greatly miniaturized, robust, and powerful, and has been connected by field bus systems. Based on this, the emphasis on the electronic side could be increased and the mechanical construction could be designed as a mechanical–electronic system from the very beginning. The aim was to result in more autonomy, for example, by decentralized control, field bus connections, plug-and-play approaches, and distributed energy supply, such that self-contained units emerge.

19.3.2 Distribution of Mechanical and Electronic Functions

In the design of mechatronic systems, interplay for the realization of functions in the mechanical and electronic parts is crucial. Compared with pure mechanical realizations, the use of amplifiers and actuators with electrical auxiliary energy has already led to considerable simplifications, as can be seen in watches, electronic typewriters, and cameras. A further considerable simplification in the mechanics resulted from the introduction of microcomputers in connection with decentralized electrical drives, e.g., for electronic typewriters, sewing machines, multiaxis handling systems, and automatic gears.

The design of lightweight constructions leads to elastic systems that are weakly damped through the material itself. Electronic damping through position, speed or vibration sensors and electronic feedback can be realized with the additional advantage of adjustable damping through algorithms. Examples are elastic drive trains of vehicles with damping algorithms in the engine electronics, elastic robots, hydraulic systems, far-reaching cranes, and space constructions (e.g., with flywheels).

The addition of closed-loop control, e.g., for position, speed or force, does not only result in precise tracking of reference variables, but also an approximate linear overall behavior, even though mechanical systems may show nonlinear behavior. By omitting the constraint of linearization on the mechanical side, the effort for construction and manufacturing may be reduced. Examples are simple mechanical pneumatic and electromechanical actuators and flow valves with electronic control.

With the aid of freely programmable reference variable generation, the adaptation of nonlinear mechanical systems to the operator can be improved. This is already used for driving-pedal characteristics within engine electronics for automobiles, telemanipulation of vehicles and aircraft, and in the development of hydraulically actuated excavators and electric power steering.

However, with increasing number of sensors, actuators, switches, and control units, the cables and electrical connections also increase, such that reliability, cost, weight, and required space are major concerns. Therefore, the development of suitable bus systems, plug systems, and fault-tolerant and reconfigurable electronic systems are challenges for the designer.

19.3.3 Operating Properties

By applying active feedback control, the precision of, e.g., a position is reached by comparison of a programmed reference variable with a measured control variable and not only through the high mechanical precision of a passively feedforward-controlled mechanical element. Therefore, the mechanical precision in design and manufacturing may be reduced somewhat and simpler constructions for bearings or slideways can be used. An important aspect in this regard is compensation of larger and time-variant friction by adaptive friction compensation. Larger friction at the cost of backlash may also be intended (e.g., gears with pretension), because it is usually easier to compensate for friction than for backlash. Model-based and adaptive control allow operation at more operating points (wide-range operation) compared with fixed control with unsatisfactory performance (danger of instability or sluggish behavior). A combination of robust and adaptive control enables wide-range operation, e.g., for flow, force, and speed control, and for processes involving engines, vehicles, and aircraft. Better control performance allows the reference variables to be moved closer to constraints with improved efficiencies and yields (e.g., higher temperatures, pressures for combustion engines and turbines, compressors at stalling limits, and higher tensions and higher speed for paper machines and steel mills).

19.3.4 New Functions

Mechatronic systems also enable functions that could not be performed without digital electronics. Firstly, nonmeasurable quantities can be calculated on the basis of measured signals and influenced by feedforward or feedback control. Examples are time-dependent variables such as the slip for tires, internal tensions, temperatures, the slip angle and ground speed for steering control of vehicles or parameters such as damping and stiffness coefficients, and resistances. The automatic adaptation of parameters, such as damping and stiffness for oscillating systems based on measurements of displacements or accelerations, is another example. Integrated supervision and fault diagnosis becomes increasingly important with more automatic functions, increasing complexity, and higher demands on reliability and safety. Then, fault tolerance by triggering of redundant components and system reconfiguration, maintenance on request, and any kind of teleservice makes the system more *intelligent*.

19.3.5 Other Developments

Mechatronic systems frequently allow flexible adaptation to boundary conditions. A part of the functions and also precision becomes programmable and rapidly changeable. Advanced simulations enable the reduction of experimental investigations with many parameter variations. Also, shorter time to market is possible if the basic elements are developed in parallel and the functional integration results from the software.

Table 19.1 Some properties of conventional and mechatronic designed systems

Conventional design	Mechatronic design
Added components	**Integration of components (hardware)**
Bulky	Compact
Complex	Simple mechanisms
Cable problems	Bus or wireless communication
Connected components	Autonomous units
Simple control	**Integration by information processing (software)**
Stiff construction	Elastic construction with damping by electronic feedback
Feedforward control, linear (analog) control	Programmable feedback (nonlinear) digital control
Precision through narrow tolerances	Precision through measurement and feedback control
Nonmeasurable quantities change arbitrarily	Control of nonmeasurable estimated quantities
Simple monitoring	Supervision with fault diagnosis
Fixed abilities	Adaptive and learning abilities

A far-reaching integration of the process and the electronics is much easier if the customer obtains the functioning system from one manufacturer. Usually, this is the manufacturer of the machine, the device or the apparatus. Although these manufacturers have to invest a lot of effort in coping with the electronics and the information processing, they gain the chance to add to the value of the product. For small devices and machines with large production numbers, this is obvious. In the case of larger machines and apparatus, the process and its automation frequently comes from different manufacturers. Then, special effort is needed to produce integrated solutions.

Table 19.1 summarizes some properties of mechatronic systems compared with conventional electromechanical systems.

19.4 Integration Forms of Processes with Electronics

Figure 19.6a shows a general scheme of a classical mechanical–electronic system. Such systems resulted from adding available sensors and actuators and analog or digital controllers to the mechanical components. The limits of this approach were the lack of suitable sensors and actuators, unsatisfactory lifetime under rough operating conditions (acceleration, temperature, and contamination), large space requirements, the required cables, and relatively slow data processing. With increasing improvements in the miniaturization, robustness, and computing power of microelectronic components, one can now try to place more emphasis on the electronic side and design the mechanical part from the beginning with a view to a mechatronic overall system. Then, more autonomous systems can be envisaged, e.g., in the form of encapsulated units with noncontacting signal transfer or bus connections and robust microelectronics.

Integration within a mechatronic system can be performed mainly in two ways: through the integration of components and through integration by information processing (see also Table 19.1).

The integration of components (hardware integration) results from designing the mechatronic system as an overall system and embedding the sensors, actuators, and microcomputers into the mechanical process (Fig. 19.6b). This spatial integration may be limited to the process and sensor or the process and actuator. The microcomputers can be integrated with the actuator, the process or sensor, or be arranged at several places. Integrated sensors and microcomputers lead to smart sensors, and integrated actuators and microcomputers develop into smart actuators. For larger systems, bus connections will replace the many cables. Hence, there are several possibilities for building an integrated overall system by proper integration of the hardware.

Integration by information processing (software integration) is mostly based on advanced control functions. Besides basic feedforward and feedback control, an additional influence may take place through process knowledge and corresponding online information processing (Fig. 19.6c). This means processing of available signals at higher levels, as will be discussed in the next Section. This includes the solution of tasks

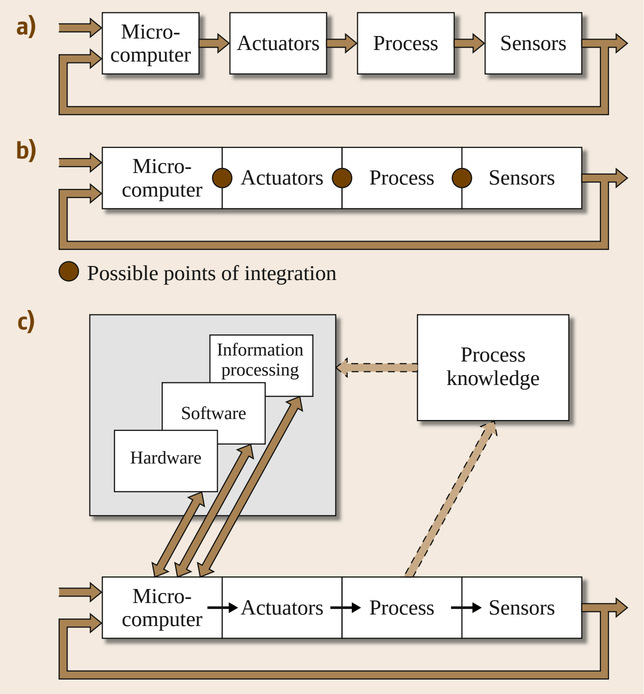

Fig. 19.6a–c Integration of mechatronic systems: **(a)** general scheme of a (classical) mechanical–electronic system; **(b)** integration through components (hardware integration); **(c)** integration through functions (software integration)

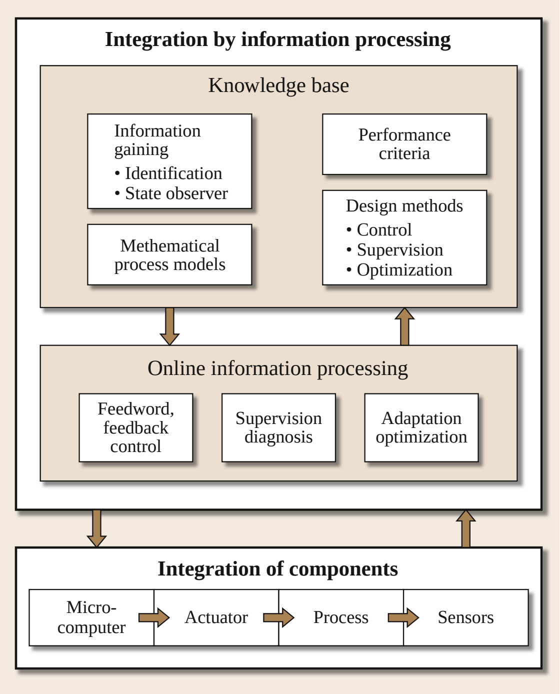

Fig. 19.7 Integration of mechatronic systems: integration of components (hardware integration); integration by information processing (software integration)

such as supervision with fault diagnosis, optimization, and general process management. The corresponding problem solutions result in online information processing, especially using real-time algorithms, which must be adapted to the properties of the mechanical process, e.g., expressed by mathematical models in the form of static characteristics, differential equations, etc. (Fig. 19.7). Therefore, a knowledge base is required, comprising methods for design and information gain, process models, and performance criteria. In this way, the mechanical parts are governed in various ways through higher-level information processing with intelligent properties, possibly including learning, thus resulting in integration with process-adapted software. Both types of integration are summarized in Fig. 19.7. In the following, mainly integration through information processing will be considered.

Recent approaches for mechatronic systems mostly use signal processing at lower levels, e.g., damping or control of motions or simple supervision. Digital information processing, however, allows the solutions of many more tasks, such as adaptive control, learning control, supervision with fault diagnosis, decisions for maintenance or even fault-tolerance actions, economic optimization, and coordination. These

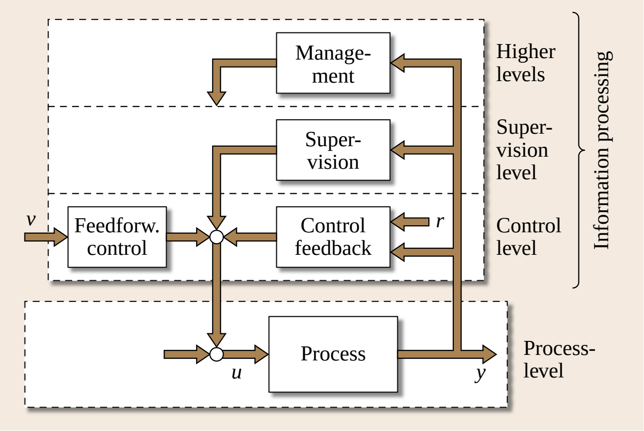

Fig. 19.8 Different levels of information processing for process automation. u: manipulated variables; y: measured variables; v: input variables; r: reference variables◀

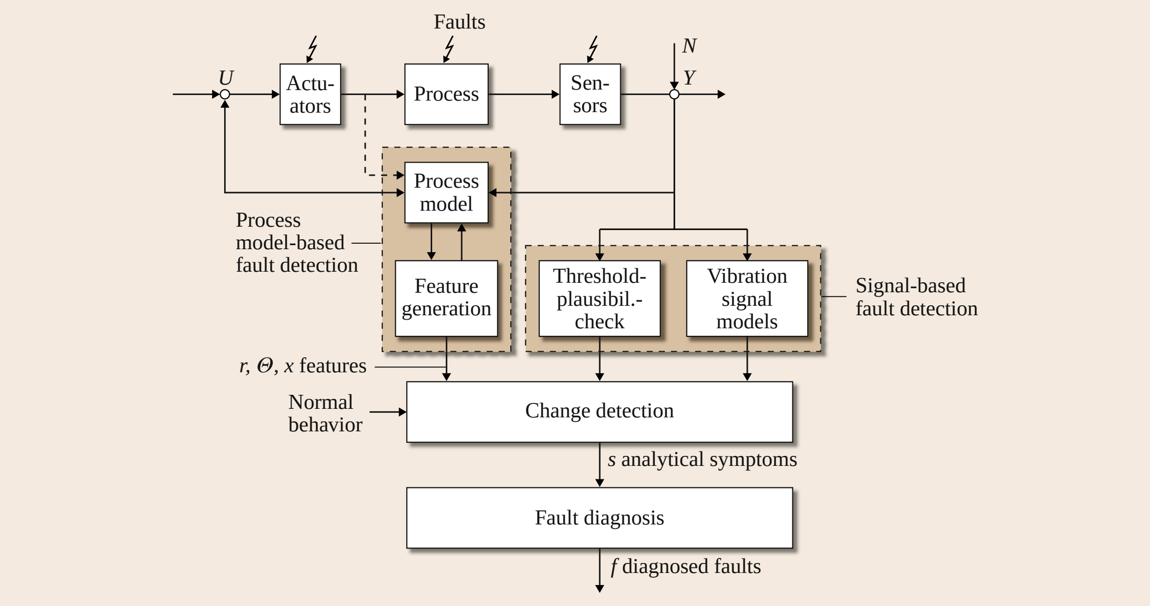

Fig. 19.9 Scheme for model-based fault detection

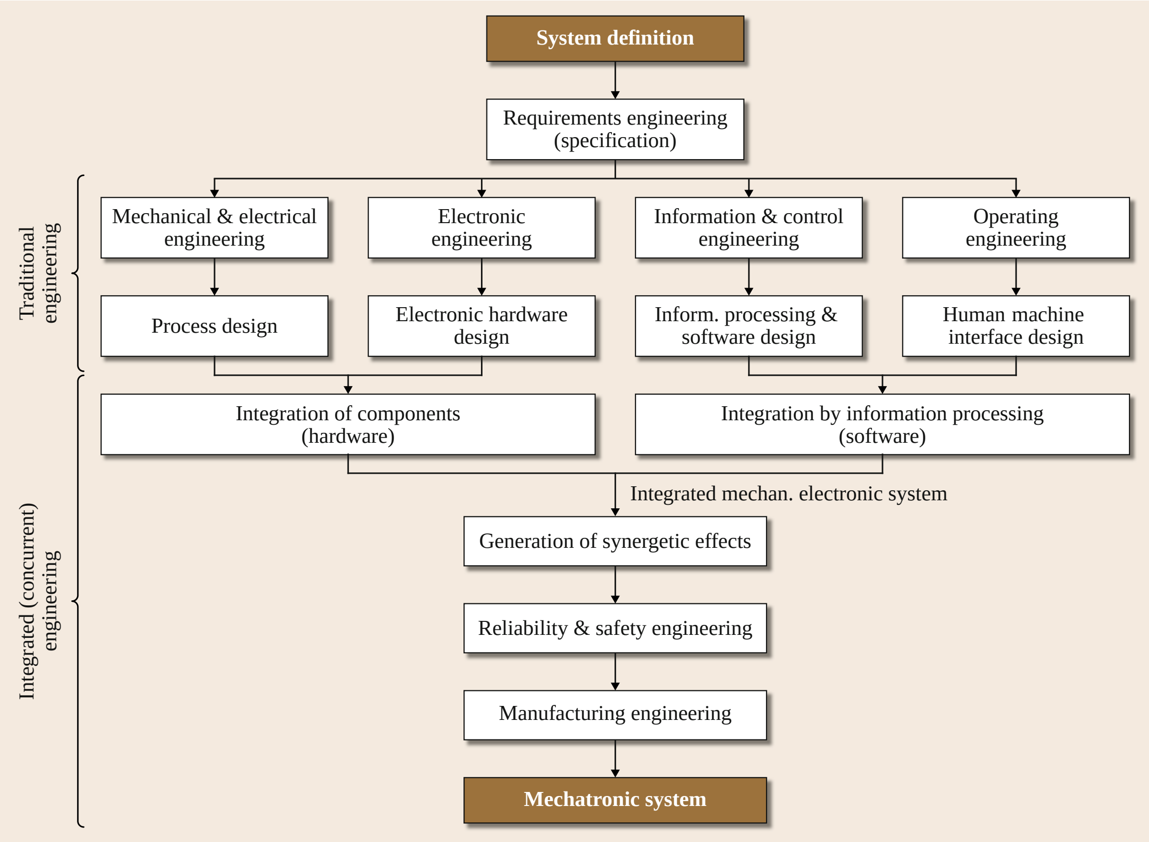
higher-level tasks are sometimes summarized as *process management*. Information processing at several levels under real-time condition is typical for extensive *process automation* (Fig. 19.8).

With the increasing number of automatic functions (autonomy) including electronic components, sensors, and actuators, increasing complexity, and increasing demands on reliability and safety, integrated supervision with fault diagnosis becomes increasingly important. This is, therefore, a significant natural feature of an intelligent mechatronic system. Figure 19.9 shows a process influenced by faults. These faults indicate unpermitted deviations from normal states and can be generated either externally or internally. External faults are, e.g., caused by the power supply, contamination or collision, internal faults by wear, missing lubrication, and actuator or sensor faults. The classic methods for fault detection are limit-value checking and plausibility checks of a few measurable variables. However, incipient and intermittent faults cannot usually be detected, and in-depth fault diagnosis is not possible with this simple approach. Therefore, model-based fault detection and diagnosis methods have been developed in recent years, allowing early detection of small faults with normally measured signals, also in closed loops [19.48–51]. Based on measured input signals $U(t)$, output signals $Y(t)$, and process models, features are generated by, e.g., parameter estimation, state and output observers, and parity equations (Fig. 19.9).

19.5 Design Procedures for Mechatronic Systems

The design of mechatronic systems requires systematic development and use of modern software design tools. As with any design, mechatronic design is also an iterative procedure. However, it is much more involved than for pure mechanical or electrical systems. Figure 19.10 shows that, in addition to traditional domain-specific engineering, integrated simultaneous (concurrent) engineering is required due to the integration of engineering across traditional boundaries that is typical of the development of mechatronic systems.

Hence, the mechatronic design requires a simultaneous procedure in broad engineering areas. Traditionally, the design of mechanics, electrics and electronics, control, and human–machine interface were performed in different departments with only occasionally contact,



System definition
Requirements engineering (specification)
Mechanical & electrical engineering
Electronic engineering
Information & control engineering
Operating engineering
Process design
Electronic hardware design
Inform. processing & software design
Human machine interface design
Integration of components (hardware)
Integration by information processing (software)
Integrated mechan. electronic system
Generation of synergetic effects
Reliability & safety engineering
Manufacturing engineering
Mechatronic system
Traditional engineering
Integrated (concurrent) engineering

Fig. 19.10 From domain-specific traditional engineering to integrated, simultaneous engineering (iteration steps are not indicated)

sometimes sequentially (bottom-up design). Because of the requirements for integration of hardware and software functions, these areas have to work together and the products have to be developed more or less simultaneously to an overall optimum (concurrent engineering, top-down design). Usually, this can only be realized with suitable teams.

The principle procedure for the design of mechatronic systems is, e.g., described in the VDI-Richtlinie (guideline) 2206 [19.11]. A flexible procedural model is described, consisting of the following elements:

1. Cycles of problem solutions at microscale:

- Search for solutions by analysis and synthesis of basis steps
- Comparison of requirements and reality
- Performance and decisions
- Planning

2. Macroscale cycles in the form of a V-model:

- Logical sequence of steps
- Requirements
- System design
- Domain-specific design
- System integration
- Verification and validation
- Modeling (supporting)
- Products: laboratory model, functional model, preseries product

3. Process elements for repeating working steps:

- Repeating process elements
- System design, modeling, element design, integration, . . .

The V-model, according to [19.11, 52], is distinguished with regard to system design and system

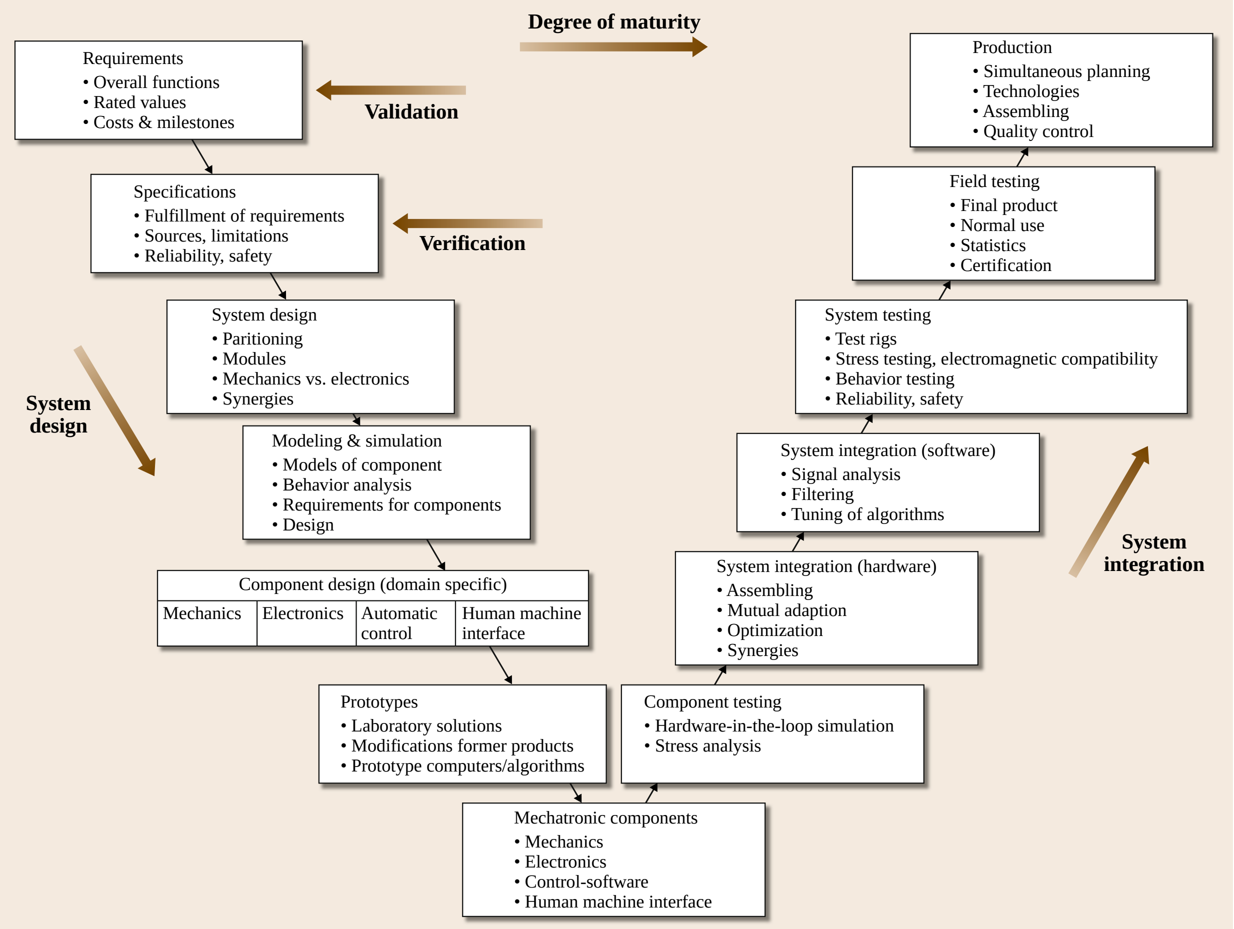


Fig. 19.11 A “V” development scheme for mechatronic systems

integration with domain-specific design in mechanical engineering, electrical engineering, and information processing. Usually, several design cycles are required, resulting, e.g., in the following intermediate products:

- Laboratory model: first functions and solutions, rough design, first function-specific investigations
- Functional model: further development, fine-tuning, integration of distributed components, power measurements, standard interfaces
- Pre-series product: consideration of manufacturing, standardization, further modular integration steps, encapsulation, field tests.

The V-model originates most likely from software development [19.53]. Some important design steps for mechatronic systems are shown in Fig. 19.11 in the form of an extended V-model, where the following are distinguished: system design up to laboratory model, system integration up to functional model, and system tests up to pre-series product.

The maturity of the product increases as the individual steps of the V-model are followed. However, several iterations have to be performed, which is not illustrated in the figure.

Depending on the type of product, the degree of mechatronic design is different. For precision mechanic devices the integration is already well developed. In the case of mechanical components one can use as a basis well-proven constructions. Sensors, actuators, and electronics can be integrated by corresponding changes, as can be seen, e.g., in adaptive shock absorbers, hydraulic brakes, and fluidic actuators. In machines and vehicles it can be observed that the basic mechanical construction remains constant but is complemented by mechatronic components, as is the case for machine tools, combustion engines, and automobiles.

19.6 Computer-Aided Design of Mechatronic Systems

The general goal in the design of mechatronic systems is the use of computer-aided design tools from different domains. A survey is given in [19.11]. The design model given in [19.52] distinguishes the following integration levels:

- Basic level: specific product development, computer-aided engineering (CAE) tools
- Process-oriented level: design packages, status, process management, data management
- Model-oriented level: common product model for data exchange (STEP)
- System-oriented level: coupling of information technology (IT) tools with, e.g., CORBA, DCOM, and JAVA

The domain-specific design is usually designed on general CASE tools, such as CAD/CAE for mechanics, two-dimensional (2-D) and three-dimensional (3-D) design with AutoCAD, computational fluid dynamics (CFD) tools for fluidics, electronics and board-layout (PADS), microelectronics (VHDL), and computer aided design of control systems CADCS tools for the control design (see, e.g., [19.52]).

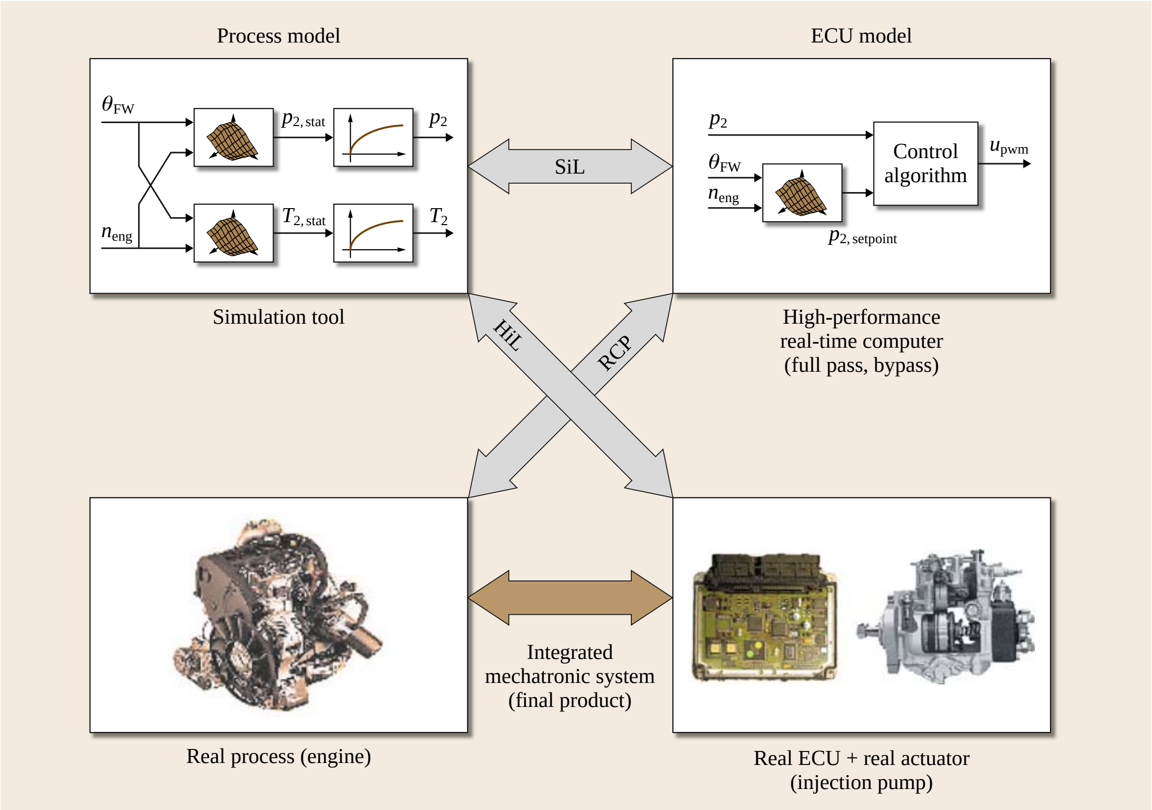

Fig. 19.12 Different couplings of process and electronics for a mechatronic design. SiL: software-in-the-loop; RCP: rapid control prototyping; HiL: hardware-in-the-loop

For overall modeling, object-oriented software is especially of interest based on the use of general model-building laws. The models are first formulated as noncausal objects installed in libraries. They are then coupled with graphical support (object diagrams) by using methods of herit and reusability.

Examples are MODELICA, MOBILE, VHDL-AMS, 20 SIM; see, e.g., [19.54–59]. A broadly used tool for simulation and dynamics design is MATLAB/SIMULINK.

To design mechatronic systems various simulation environment models have been developed, as shown in the V-model (Fig. 19.11). In the case of software-in-the-loop (SiL) simulation the process and its control is simulated in a higher language to carry out basic investigations (Fig. 19.12). This does not require real-time simulation and is directed towards consideration of general process behavior and control structure in an earlier stage to avoid too many prototypes.

If first mechatronic prototypes exist but the final hardware of the control is missing, the rapid-control-prototyping (RCP) procedure can be used. In this, a mechatronic prototype operates as a real system with a simulated control on a test rig in order to test, e.g., control algorithms under real conditions. The prototyping computer is a powerful real-time computer with higher-language programming.

Hardware-in-the-loop (HiL) simulation is used to perform various tests in a laboratory with final hardware (electronic control unit: ECU) and the final software together with the simulated process on a powerful computer. Through HiL simulation, extreme operational and environmental conditions can also be investigated, along with faults and failures that cannot be realized with a real process on a test rig or a real vehicle, because the situations would be either too dangerous or too expensive. HiL simulation requires special electronics for reconstruction of the sensor signals and usually includes real actuators (e.g., hydraulics, pneumatics or injection pumps). Through these simulation methods the development of mechatronic systems can be performed without synchronous development on the side of the process, the electronics, or the software.

When designing mechatronic systems the traditional borders of various disciplines have to be crossed. For the classical mechanical engineer this frequently means that knowledge of electronic components, information processing, and systems theory has to be deepened, and for the electrical/electronic engineer that knowledge on thermodynamics, fluid mechanics, and engineering mechanics has to be enlarged. For both, more knowledge on modern control principles, software engineering, and information technology may be necessary (see also [19.60]).

19.7 Conclusion and Emerging Trends

This Chapter could only give a brief overview of mechatronic systems. As outlined, mechatronic systems cover a very broad area of engineering disciplines. Advanced mechatronic components and systems are realized in many products such as automobiles, combustion engines, aircraft, electrical drives, actuators, robots, and precision mechanics and micromechanics. However, the integration aspects of mechanics and electronics include increasingly more components and systems in the wide areas of mechanical and electrical engineering.

As the development towards the integration of computer-based information processing into products and their manufacturing comprises large areas of engineering, suitable education in modern engineering and also training is fundamental for technological progress. This means, among others, to take multidisciplinary solutions and method-oriented procedures into account. The development of curricula for mechatronics as a proper combination of electrical and mechanical engineering and computer science during the last decade shows this tendency.

20. Sensors and Sensor Networks

Wootae Jeong

Sensors are essential devices in many industrial applications such as factory automation, digital appliances, aircraft/automotive applications, environmental monitoring, and system diagnostics. The main role of those sensors is to measure changes of physical quantities of surroundings. In general, sensors are embedded into sensory devices with a circuitry as a part of a system. In this chapter, various types of sensors and their working principles are briefly explained as well as their technical advancement to recent smart microsensors is introduced. Specifically, the individual sensor issue is also extended to emerging networked sensors and their applications from recent research activities. Through this chapter, readers can also understand how multisensors or networked sensors can be configured and how they can collaborate with each other to provide higher performance and reliability within networked sensor systems.

20.1 Sensors

A sensor is an instrument that responds to a specific physical stimulus and produces a measurable corresponding electrical signal. A sensor can be mechanical, electrical, electromechanical, magnetic or optical. Any devices that are directly altered in a predictable, measurable way by changes in a real-world parameter can be a sensor for that parameter. Sensors have an important role in daily life because of the need to gather information and process it conveniently for specific tasks. Recent advances in microdevice technology, microfabrication, chemical processes, and digital signal processing have enabled the development of micro/nanosized, low-cost, and low-power sensors called *microsensors*. Microsensors have been successfully applied to many practical areas, including medical and space devices, military equipment, telecommunication, and manufacturing applications [20.1, 2]. When compared with conventional sensors, microsensors have certain advantages, such as interfering less with the environment they measure, requiring less manufacturing cost, being used in narrow spaces and harsh environments, etc. The successful application of microsensors depends on sensor capability, cost, and reliability

20.1.1 Sensing Principles

Sensors can be technically classified into various types according to their working principle, as listed

Table 20.1 Technical classification of sensors according to their working principle

Sensing principle	Sensors
Resistance change	Strain gage, potentiometer, potentiometric throttle position sensor (TPS), resistance temperature detector (RTD), thermistor, piezoresistive sensor, magnetoresistive sensor, photoresistive sensor
Capacitance change	Capacitive-type torque meter, capacitance level sensor
Inductance change	Linear variable differential transformer (LVDT), inductive angular position sensor (magnetic pick-up), inductive torque meter
Electromagnetic induction	Electromagnetic flow meter
Thermoelectric effect	Thermocouple
Piezoelectric effect	Piezoelectric accelerometer, sound navigation and ranging (SONAR)
Photoelectric effect	Photodiode, phototransistor, photo-interrupter (optical encoder)
Hall effect	Hall sensor

in Table 20.1. That is, sensors can measure physical phenomena by capturing resistance change, capacitance change, inductance change, thermoelectric effect, piezoelectric effect, photoelectric effect, Hall effect, and so on [20.3, 4]. Among these effects, most sensors utilize the resistance change of a conductor, i. e., *resistivity*. As long as the current density is uniform in the insulator, the resistance R of a conductor of cross-sectional area A can be computed as

$$R = \frac{\rho l}{A}\,, \tag{20.1}$$

where l is the length of the conductor, A is the cross-sectional area, and ρ is the electrical resistivity of the material. Resistivity is a measure of the material's ability to oppose electric current. Therefore, change of resistance can be measured by detecting physical deformation (l or A) of conductive materials or by sensing resistivity (ρ) of conductor. As an example, a strain gage is a sensor that measures resistance by deformation of length or cross-sectional area, and a thermometer is a sensor that measures resistance by examining the resistivity change of a material. By expanding (20.1) in a Taylor series and then simplifying the equation, resistance change can be expressed as

$$\Delta R = \Delta\rho\frac{l}{A} + \Delta l\frac{\rho}{A} - \Delta A\frac{\rho l}{A^2}\,. \tag{20.2}$$

By dividing both side of (20.2) by the resistance R, the resistance change rate can be expressed as

$$\frac{\Delta R}{R} = \frac{\Delta\rho}{\rho} + \frac{\Delta l}{l} - \frac{\Delta A}{A} = \frac{\Delta\rho}{\rho} + \varepsilon + 2\nu\varepsilon\,, \tag{20.3}$$

where ε and ν are the strain and the Poisson's ratio of the material, respectively. When the resistivity (ρ) of a sensing material is close to constant, the resistance can be determined from the values of strain (ε) and Poisson's ratio (ν) of the material (e.g., strain gage). When the resistivity of a sensing material is sensitive to the measuring targets and values of ε, ν can be neglected; the resistance can be measured from the resistivity change ($\Delta\rho/\rho$) (e.g., resistance temperature detector (RTD)).

In capacitance-based sensors, the sensor measures the amount of electric charge stored between two plates of capacitors. The capacitance C can be calculated as

$$C = \frac{\varepsilon A}{d}\,, \tag{20.4}$$

where A is the area of each plate, d is the separation between the plates, and ε is the dielectric constant (or permittivity) of the material between the plates. The dielectric constant for a number of very useful dielectrics changes as a function of the applied electrical field. Thus, capacitance-based sensors utilize capacitance change by measuring the dielectric constant, the area (A) of, or the separation (d) between the plates. A capacitive-type torque meter is an example of a capacitance-based sensor.

Inductance-based sensors measure the ratio of the magnetic flux to the current. Linear variable differential transformers (LVDT; Fig. 20.1) and magnetic pick-up sensors are representative inductance-based sensors.

Electromagnetic induction-based sensors are based on Faraday's law of induction, which is involved in the operation of transformers, inductors, and many forms of electrical generators. The law states that *the induced*

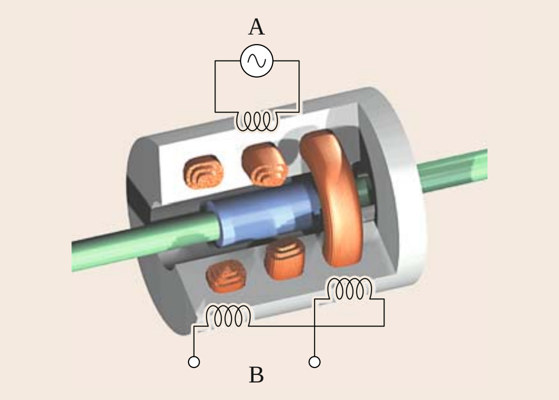

Fig. 20.1 Cutaway view of an LVDT. Current is driven through the primary coil at A, causing an induction current to be generated through the secondary coils at B

electromotive force (EMF) in any closed circuit is equal to the time rate of change of the magnetic flux through the circuit. Quantitatively, the law takes the following form

$$E = -\frac{\mathrm{d}\Phi_{\mathrm{B}}}{\mathrm{d}t} , \tag{20.5}$$

where E is the electromotive force (EMF) and Φ_{B} is the magnetic flux through the circuit.

Besides these types of sensors, thermocouples measure the temperature difference between two points rather than absolute temperature. In traditional applications, one of the junctions (the cold junction) is maintained at a reference temperature, while the other end is attached to a probe. Having available a cold junction at a known temperature is simply not convenient for most directly connected control instruments. They incorporate into their circuits an artificial cold junction using some other thermally sensitive device, such as a thermistor or diode, to measure the temperature of the input connections at the instrument, with special care being taken to minimize any temperature gradient between terminals. Hence, the voltage from a known cold junction can be simulated, and the appropriate correction applied. Photodiodes, phototransistors, and photo-interrupters are sensors that use the photoelectric effect. Other types of sensors are listed in Table 20.1.

20.1.2 Position, Velocity, and Acceleration Sensors

Sensors can also be classified by the physical phenomena measured, such as position, velocity, acceleration, heat, pressure, flow rate, sound, etc. This classification of sensors is briefly explained below.

Position Sensors

A position sensor is any device that enables position measurement. Position sensors include limit switches or proximity sensors that detect whether or not something is close to or has reached a limit of travel. Position sensors also include potentiometers that measures rotary or linear position. The linear variable differential transformer (LVDT) is an example of the potentiometers for measuring linear displacement, while resolvers and optical encoders measure the rotary position of a rotating shaft. The LVDT and resolver function much like a transformer. The optical encoder produces digital signals that convert motion into a sequence of digital pulses. In fact, there also exist optical encoders for measuring linear motion.

Some position sensors are classified by their measuring techniques. Sonars measure distance with sonic/ultrasonic waves and radar utilizes electronic/radio to detect or measure the distance between two objects. Many other sensors are used to measure position or distance.

Velocity Sensors

Speed measurement can be obtained by taking consecutive position measurements at known time intervals and computing the derivative of the position values. A tachometer is an example of a velocity sensor that does this for a rotating shaft. The typical dynamic time constant of a tachometer is in the range 10–100 μs. A tachometer is a passive analog sensor that provides an output voltage proportional to the velocity of a shaft. There is no need for an external reference or excitation voltage. Traditionally tachometers have been used for velocity measurement and control only, but all modern tachometers have quadratic outputs which are used for velocity, position, and direction measurements, making them effectively functional as position sensors.

Acceleration Sensors

An acceleration sensor or accelerometer is a sensor designed to measure continuous mechanical vibration such as aerodynamic flutter and transitory vibration such as shock waves, blasts or impacts. Accelerometers are normally mechanically attached or bonded to an object or structure for which acceleration is to be measured. The accelerometer detects acceleration along one axis and is insensitive to motion in orthogonal directions. Strain gages or piezoelectric elements constitute the sensing element of an accelerometer, converting vibration into a voltage signal. The design of an accelerometer is based on the inertial effects associated with a mass connected to a moving object.

Detailed information and technical working processes about position, velocity, and acceleration sensors can be found in many references [20.5, 6].

20.1.3 Miscellaneous Sensors

There are other groups of sensors to measure physical quantities such as force, strain, temperature, pressure, and flow. Force sensors are represented by a load cell that is used to measure a force. The load cell consists of several strain gages connected to a bridge circuit to yield a voltage proportional to the load. Temperature sensors are devices that indirectly measure quantities such as pressure, volume, electrical resistance, and strain and then convert the values using the physical relationship between the quantity and temperature; for example: (a) a bimetallic strip composed of two metal layers with different coefficients of thermal expansion utilizes the difference in the thermal expansion of the two metal layers, (b) a resistance temperature sensor constructed of metallic wire wound around a ceramic or glass core and hermetically sealed utilizes the resistance change of the metallic wire with temperature, and (c) a thermocouple constructed by connecting two dissimilar metals in contact produces a voltage proportional to the temperature of the junction [20.7, 8].

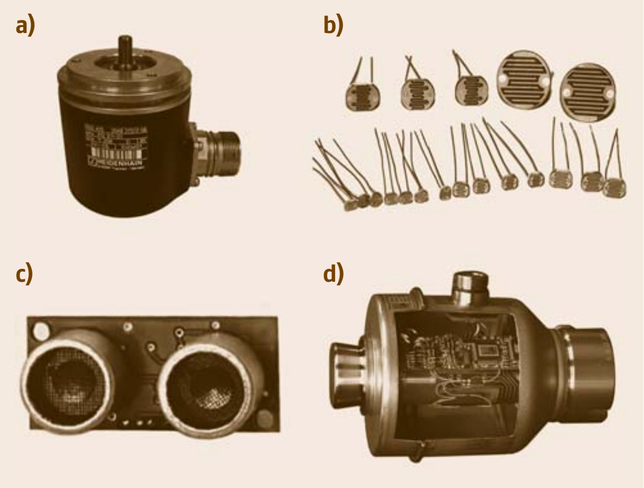

Fig. 20.2a–d Various sensors: **(a)** absolute encoder, **(b)** photoresistor, **(c)** sonar, **(d)** digital load cell cutaway (courtesy of Society of Robots)

Flow Sensors

A flow sensor is a device for sensing the rate of fluid flow. In general, a flow sensor is the sensing element used in a flow meter to record the flow of fluids. Some flow sensors have a vane that is pushed by the fluid (e.g., a potentiometer), while other flow sensors are based on heat transfer caused by the moving medium.

Ultrasonic Sensors

Ultrasonic sensors or transducer generates high-frequency sound waves and evaluate the echo received back by the sensor. An ultrasonic sensor computes the time interval between sending the signal and receiving the echo to determine the distance to an object. Radar or sonar works on a principal similar to that of the ultrasonic sensor. Some sensors are depicted in Fig. 20.2. However, there are many other groups of sensors not listed in this section. With the advent of semiconductor electronics and manufacturing technology, sensors have become miniaturized and accurate, and brought into existence micro/nanosensors.

Vision Sensors

Another widely used sensor is a vision sensor. A vision sensor is typically used embedded in a vision system. A vision system can be used to measure shape, orientation, area, defects, differences between parts, etc. Vision technology has improved significantly over the last decade in that they have become rather standard smart sensing components in most factory automation systems for part inspection and location detection. In general, a vision system consists of a vision camera, an image processing computer, and a lighting system. The basic principle of operation of a vision system is that it forms an image by measuring the light reflected from objects, and the sensor head analyzes the output voltage from the light intensity received. The sensor head consists of an array of photosensitive, photodiodes or charge-coupled devices (CCD). Currently, various signal-processing techniques for the reflected signals are applied for many industrial applications to provide accurate outputs, as illustrated in Fig. 20.3.

20.1.4 Micro- and Nanosensors

A microsensor is a miniature electronic device functioning similar to existing large-scale sensors. With recent micro-electromechanical system (MEMS) technology,

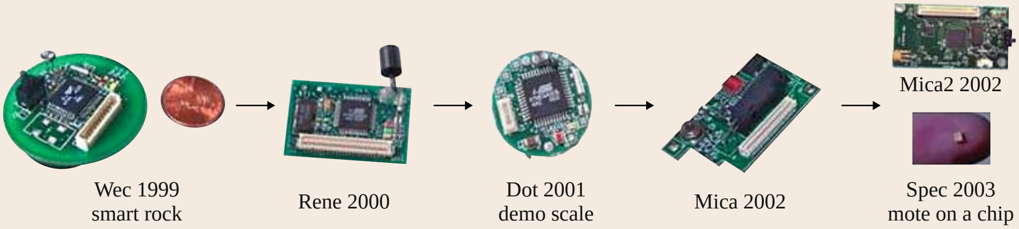

Fig. 20.4 Evolution of smart wireless microsensors (courtesy of Crossbow Technology Inc.)

microsensors are integrated with signal-processing circuits, analog-to-digital (A/D) converters, programmable memory, and a microprocessor, a so-called *smart microsensor* [20.9, 10]. Current smart microsensors contain an antenna for radio signal transmission. Wireless microsensors are now commercially available and are evolving with more powerful functionalities, as illustrated in Fig. 20.4.

In general, a wireless microsensor consists of a sensing unit, a processing unit, a power unit, and communication elements. The sensing unit is an electrical part detecting the physical variable from the environment. The processing unit (a tiny microprocessor) performs signal-processing functions, i. e., integrating

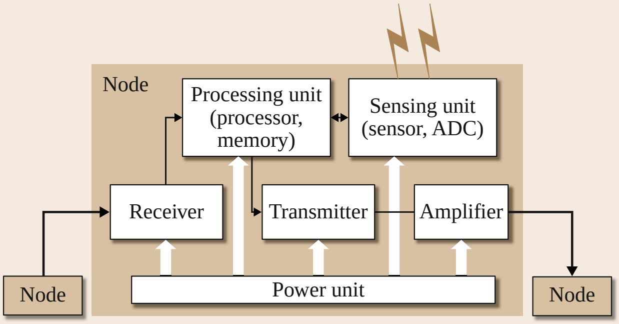

Fig. 20.5 Wireless micronode model. Each node has a sensing module (analog-to-digital converter (ADC)), processing unit, and communication elements

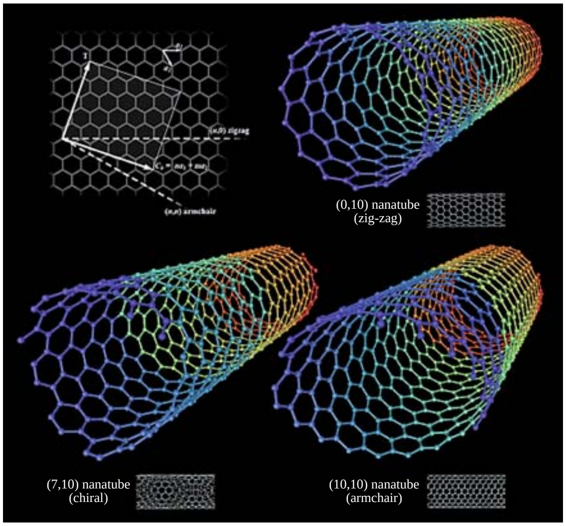

Fig. 20.6 Three-dimensional (3-D) model of three types of single-walled carbon nanotubes, like those used to make certain nanosensors (created by Michael Ströck on February 1, 2006)▶

data and computation required in the processing of information. The communication elements consist of a receiver, a transmitter, and an amplifier if needed. The power unit provides energy source with other units (Fig. 20.5). Basically, all individual sensor nodes are operated by a limited battery, but a base-station node as a final data collecting center can be modeled with an unlimited energy source.

Under the microscale, nanosensors are used in chemical and biological sensory applications to deliver information about nanoparticles. As an example, nanotubes are used to sense various properties of gaseous molecules, as depicted in Fig. 20.6. In developing and commercializing nanosensors, developers still need to overcome high costs of production and reliability challenges. In the near future, there is tremendous room to enhance the technology and implement various nanosensors in real-life applications.

20.2 Sensor Networks

20.2.1 Sensor Network Systems

Before the advent of microminiaturization technology, single-sensor systems had an important role in a variety of practical applications because they were relatively easy to construct and analyze. Single-sensor systems, however, were the only solution when there was critical limitation of implementation space. Moreover, single-sensor systems for recently emerging applications have various limitations and disadvantages:

- They have limited applications and uses; for instance, if a system should measure several variables, e.g., temperature, pressure, and flow rate, at the same time in the application, single-sensor systems are insufficient.
- They cannot tolerate a variety of failures which may take place unexpectedly.
- A single sensor cannot guarantee timely delivery of accurate information all of the time because it is inevitably affected by noise and other uncertain disruptions.

These limitations are critical when a system requires highly reliable and timely information. Therefore, single-sensor systems are not suitable when robust and accurate information is required in the application.

To overcome the critical disadvantages of single-sensor systems in most applications, multisensor network systems which require replicated sensory information have been studied, along with their communication network technologies. Replicated sensor systems are applicable not only because microfabrication technology enables production of various microsensors at low manufacturing cost, but also because microsensors can be embedded in a system with replicated deployment. These redundantly deployed sensors enable a system to improve accuracy and tolerate sensor failure, i. e., distributed microsensor arrays and networks (DMSA/DMSN) are built from collections of spatially scattered microsensor nodes. Each node has the ability to measure the local physical variable within its accuracy limit, process the raw sensory data, and cooperate with its neighboring nodes.

Sensors incorporated with dedicated signal-processing functions are called intelligent, or smart, sensors. The main roles of dedicated signal processing functions are to enhance design flexibility and realize new sensing functions. Additional roles are to reduce loads on central processing units and signal transmission lines by distributing information processing to the lower layers of the system [20.10].

A set of microsensors deployed close to each other to measure the same physical quantity of interest is called a cluster. Sensors in a cluster can be either of the same or different type to form a distributed sensor network (DSN). A DSN can be utilized in a widely distributed sensor system and implemented as a locally concentrated configuration with a high density.

20.2.2 Multisensor Data Fusion Methods

There are three major ways in which multiple sensors interact [20.11, 12]: (1) *complementary*, when sensors do not depend on each other directly, but are combined to give a more complete image of the phenomena being studied; (2) *competitive*, when sensors provide independent measurement of the same information regarding a physical phenomenon; and (3) *cooperative*, when sensors combine data from independent sensors to derive information that would be unavailable from the individual sensors.

In order to combine information collected from each sensor, various multisensory data fusion methods can be applied. Multisensor data fusion is the process of combining observations from a number of different sensors to provide a robust and complete description of an environment or process of interest. Most current data fusion methods employ probabilistic descriptions of observations and processes and use Bayes' rule to combine this information [20.13, 14].

Bayes' Rule

Bayes' rule lies at the heart of most data fusion methods. In general, Bayes' rule provides a means to make inferences about an object or environment of interest described by a state x, given an observation z. Based on the rule of conditional probabilities, Bayes' rule is obtained as

$$P(x|z)=\frac{P(z|x)P(x)}{P(z)}\,. \tag{20.6}$$

The conditional probability $P(z|x)$ serves the role of a sensor model. The probability is constructed by fixing the value of $\boldsymbol{x}=x$ and then asking what probability density $P(z|\boldsymbol{x}=x)$ on $\boldsymbol{x}$ is inferred. The multisensory form of Bayes' rule requires conditional independence

$$\begin{aligned}P(z_1,\ldots,z_n|x)&=P(z_1|x)\ldots P(z_n|x)\\&=\prod_{i=1}^{n}P(z_i|x_i)\,.\end{aligned} \tag{20.7}$$

The recursive form of Bayes' rule is

$$P(x|Z^k)=\frac{P(z_k|x)P(x|Z^{k-1})}{P\left(z_k|Z^{k-1}\right)}\,. \tag{20.8}$$

From this equation, one needs to compute and store only the posterior density $P(x|Z^{k-1})$, which contains a complete summary of all past information.

Probabilistic Grids

Probabilistic grids are the means to implement the Bayesian data fusion technique to problems in mapping [20.15] and tracking [20.16]. Practically, a grid of likelihoods on the states x_{ij} is produced in the form $P(\boldsymbol{z}=z|x_{ij})=\Lambda(x_{ij})$. It is then trivial to apply Bayes' rule to update the property value at each grid cell as

$$P^{+}(x_{ij})=C\Lambda(x_{ij})P(x_{ij})\quad\forall i,\,j\,, \tag{20.9}$$

where C is a normalizing constant obtained by summing posterior probabilities to 1 at node ij only. Computationally, this is a simple pointwise multiplication of two grids. Grid-based fusion is appropriate to situations where the domain size and dimension are modest. In such cases, grid-based methods provide straightforward and effective fusion algorithms. Monte Carlo and particle filtering methods can be considered as grid-based methods, where the grid cells themselves are samples of the underlying probability density for the state.

The Kalman Filter

The Kalman filter is a recursive linear estimator that successively calculates an estimate for a continuous-valued state on the basis of periodic observations of the state. The Kalman filter may be considered a specific instance of the recursive Bayesian filter [20.17] for the case where the probability densities on states are Gaussian.

The Kalman filter algorithm produces estimates that minimize mean-squared estimation error conditioned on a given observation sequence and so is the conditional mean

$$\hat{x}(i|j)\triangleq E[x(i)|z(1),\ldots,z(j)]\triangleq E[x(i)|Z^j]\,. \tag{20.10}$$

The estimate variance is defined as the mean-squared error in this estimate

$$P(i|j)\triangleq E\left\{[x(i)-\hat{x}(i|j)][x(i)-\hat{x}(i|j)]^{\top}|Z^j\right\}. \tag{20.11}$$

The estimate of the state at a time k, given all information up to time k, is written $\hat{x}(k|k)$. The estimate of the state at a time k given only information up to time $k-1$ is called a one-step-ahead prediction and is written $\hat{x}(k|k-1)$.

The Kalman filter is appropriate to data fusion problems where the entity of interest is well defined by a continuous parametric state. Thus, it would be useful to estimate position, attitude, and velocity of an object, or the tracking of a simple geometric feature. Kalman filters, however, are inappropriate for estimating properties such as spatial occupancy, discrete labels or processes whose error characteristics are not easily parameterized.

Sequential Monte Carlo Methods

The sequential Monte Carlo (SMC) filtering method is a simulation of the recursive Bayes update equations using sample support values and weights to describe the underlying probability distributions. SMC recursion begins with an a posterior probability density represented by a set of support values and weights $\{x^i_{k-1}, w^i_{k-1|k-1}\}^{N_{k-1}}_{i=1}$ in the form

$$P\left(x_{k-1}|Z^{k-1}\right) = \sum_{i=1}^{N_{k-1}} w^i_{k-1}\delta\left(x_{k-1} - x^i_{k-1}\right) . \tag{20.12}$$

Leaving the weights unchanged $w^i_k = w^i_{k-1}$ and allowing the new support value x^i_k to be drawn on the basis of old support value x^i_{k-1}, the prediction becomes

$$P\left(x_k|Z^{k-1}\right) = \sum_{i=1}^{N_{k-1}} w^i_{k-1}\delta\left(x_k - x^i_k\right) . \tag{20.13}$$

The SMC observation update step is relatively straightforward and described in [20.13, 18].

SMC methods are well suited to problems where state-transition models and observation models are highly nonlinear. However, they are inappropriate for problems where the state space is of high dimension. In addition, the number of samples required to model a given density faithfully increases exponentially with state-space dimension.

Interval Calculus

Interval representation of uncertainty has a number of potential advantages over probabilistic techniques. An interval to bound true parameter values provides a good measure of uncertainty in situations where there is a lack of probabilistic information, but in which sensor and parameter error is known to be bounded. In this technique, the uncertainty in a parameter x is simply described by a statement that the true value of the state x is known to be bounded between a and b, i. e., $x \in [a, b]$. There is no other additional probabilistic structure implied. With $a, b, c, d \in \mathbb{R}$, interval arithmetic is also possible as

$$\mathrm{d}([a, b], [c, d]) = \max(|a-c|, |b-d|) . \tag{20.14}$$

Interval calculus methods are sometimes used for detection, but are not generally used in data fusion problems because of the difficulties to get results converged to anything value, and to encode dependencies between variables.

Fuzzy Logic

Fuzzy logic has achieved widespread popularity for representing uncertainty in high-level data fusion tasks. Fuzzy logic provides an ideal tool for inexact reasoning, particularly in rule-based systems. In the conventional logic system, a membership function $\mu_{\mathrm{A}}(x)$ (also called the characteristic function) is defined. Then the fuzzy membership function assigns a value between 0 and 1, indicating the degree of membership of every x to the set A. Composition rules for fuzzy sets follow the composition processes for normal crisp sets as

$$A \cap B \rightleftharpoons \mu_{\mathrm{A}\cap\mathrm{B}}(x) = \min[\mu_{\mathrm{A}}(x), \mu_{\mathrm{B}}(x)] , \tag{20.15}$$

$$A \cup B \rightleftharpoons \mu_{\mathrm{A}\cup\mathrm{B}}(x) = \max[\mu_{\mathrm{A}}(x), \mu_{\mathrm{B}}(x)] . \tag{20.16}$$

The relationship between fuzzy set theory and probability is, however, still debated.

Evidential Reasoning

Evidential reasoning methods are qualitatively different from either probabilistic methods or fuzzy set theory. In evidential reasoning, belief mass cannot only be placed on elements and sets, but also sets of sets, while in probability theory a belief mass may be placed on any element $x_{\mathrm{r}} \in \chi$ and on any subset $A \subseteq \chi$. The domain of evidential reasoning is the power set 2^{χ}. Evidential reasoning methods play an important role in discrete data fusion, attribute fusion, and situation assessment, where information may be unknown or ambiguous.

Multisensory fusion methods and their models are summarized in Table 20.2, and details can be founded in [20.13, 14].

In addition, multisensor integration or fusion is not only the process of combining inputs from sensors with information from other sensors, but also the logical procedure of inducing optimal output from multiple inputs with one representative format [20.19]. In the fusion of

Table 20.2 Multisensor data fusion methods [20.13]

Approach	Method	Fusion model and rule
Probabilistic modeling	Bayes' rule	$P(x\|Z^k) = \frac{P(z_k\|x)P(x\|Z^{k-1})}{P\left(z_k\|Z^{k-1}\right)}$
	Probabilistic grids	$P^+(x_{ij}) = C\Lambda(x_{ij})P(x_{ij})$
	The Kalman filter	$P(i\|j)$ $\triangleq E\left\{[x(i)-\hat{x}(i\|j)][x(i)-\hat{x}(i\|j)]^\top \|Z^j\right\}$
	Sequential Monte Carlo methods	$P\left(x_k\|Z^k\right)$ $= C\sum_{i=1}^{N_k} w_{k-1}^i P\left(z_k = z_k\|x_k = x_k^i\right)\delta\left(x_k - x_k^i\right)$
Nonprobabilistic modeling	Interval calculus	$\mathrm{d}([a,b],[c,d]) = \max(\|a-c\|, \|b-d\|)$
	Fuzzy logic	$A\cap B \rightleftharpoons \mu_{\mathrm{A\cap B}}(x) = \min[\mu_\mathrm{A}(x), \mu_\mathrm{B}(x)]$ $A\cup B \rightleftharpoons \mu_{\mathrm{A\cup B}}(x) = \max[\mu_\mathrm{A}(x), \mu_\mathrm{B}(x)]$

large-size distributed sensor networks, an additional advantage of multisensor integration (MSI) is the ability to obtain more fault-tolerant information. This fault tolerance is based on redundant sensory information that compensates for faulty or erroneous readings of sensors. There are several types of multisensor fusion and integration methods, depending on the types of sensors and their deployment [20.20]. This topic has received increasing interest in recent years because of the sensibility of networks built with many low-cost micro- and nanosensors. As an example, a recent improvement of the fault-tolerance sensor integration algorithm (FTSIA) by *Liu* and *Nof* [20.21, 22] enables it not only to detect possibly faulty sensors and widely faulty sensors, but also to generate a final data interval estimate from the correct sensors after removing the readings of those faulty sensors.

20.2.3 Sensor Network Design Considerations

Sensor networks are somewhat different from traditional operating networks because sensor nodes, especially microsensors, are highly prone to failure over time. As sensor nodes weaken or even die, the topology of the active sensor networks changes frequently. Especially when mobility is introduced into the sensor nodes, maintaining the robustness and discovering topology consistently become challenging. Therefore, the algorithms developed for sensor network communication and task administration should be flexible and stable against changes of network topology and work properly under unexpected failure of sensors.

In addition, in order to be used in most applications, DSN systems should be designed with application-specific communication algorithms and task administration protocols because microsensors and their networking systems are extremely resource constrained. Therefore, most research efforts have focused on application-specific protocols with respect to energy consumption and network parameters such as node density, radio transmission range, network coverage, latency, and distribution. Current network protocols also use broadcasting for communication, while traditional and ad hoc networks use point-to-point communication. Hence, the routing protocols, in general, should be designed by considering crucial sensor network features as follows:

1. *Fault tolerance*: Over time, sensor nodes may fail or be blocked due to lack of power, physical damage or environmental interference. The failure of sensor nodes, however, should not affect the overall operation of the sensor network. Thus, fault tolerance or reliability is the ability to sustain sensor network functionality despite likely problems.
2. *Accuracy improvement*: Redundancy of information can reduce overall uncertainty and increase the accuracy with which events are perceived. Since nodes located close to each other are combining information about the same event, fused data improve the quality of the event information.
3. *Timeliness*: DSN can provide the processing parallelism that may be needed to achieve an effective integration process, either at the actual speed that a single sensor could provide, or at even faster operation speed.
4. *Network topology*: A large number of nodes deployed throughout the sensory field should be maintained by carefully designed topology because any changes in sensor nodes and their deployments

affect the overall performance of DSN. Therefore, a flexible and simple topology is usually preferred.

5. *Energy consumption*: Since each wireless sensor node is working with a limited power source, the design of power-saving protocols and algorithms is a significant issue for providing longer lifetime of sensor network systems.
6. *Lower cost*: Despite the use of redundancy, a distributed microsensor system obtains information at lower cost than the equivalent information expected from a single sensor because it does not require the additional cost of functions to obtain the same reliability and accuracy. The current cost of a microsensor node, e.g., dust mote [20.9], is still expensive (US$ 25–172), but it is expected to be less than US$ 1 in the near future, so that sensor networks can be justified.
7. *Scalability*: The coverage area of a sensor network system depends on the transmission range of each node and the density of the deployed sensors. The density of the deployed nodes should be carefully designed to provide a topology appropriate for the specific application.

To provide the optimal solution to meet these design criteria in the sensor network, researchers have considered various protocols and algorithms. However, none of these studies has been developed to improve all design factors because the design of a sensor network system has typically been application specific.

A distributed network of microsensor arrays (MSA) can yield more accurate and reliable results based on built-in redundancy. Recent developments of flexible and robust protocols with improved fault tolerance will not only meet essential requirements in distributed systems but will also provide advanced features needed in specific applications. While MEMS sensor technology has advanced significantly in recent years, scientists now realize the need for design of effective MEMS sensor communication networks and task administration.

20.2.4 Sensor Network Architectures

A well-designed distributed network of microsensor arrays can yield more accurate and reliable results based on built-in redundancy. Recent developments of flexible and robust protocols with improved fault tolerance will not only meet essential requirements in distributed systems but will also provide advanced features needed in specific applications. They can produce widely accessible, reliable, and accurate information about physical environments.

Various architectures have been proposed and developed to improve the performance of systems and fault-tolerance functionality of complex networks depending on their applications. General DSN structures for multisensor systems were first discussed by *Wesson* et al. [20.23]. *Iyengar* et al. [20.24] and *Nadig* et al. [20.25] improved and developed new architectures for distributed sensor integration.

A network is a general graph $G = (V, L)$, where V is a set of nodes (or vertices) and L is a set of communicating links (or edges) between nodes. For a DSN, a node means an intelligent sensing node consisting of a computational processor and associated sensors, and an edge is the connectivity of nodes. As shown in Fig. 20.7, a DSN consists of a set of sensor nodes, a set of cluster-head (CH) nodes, and a communication network interconnecting the nodes [20.20, 24]. In general, one sensor node communicates with more than one CH, and a set of nodes communicating with a CH is called a cluster. A clustering architecture can increase system capacity and enable better resource allocation [20.26, 27]. Data are integrated in CH by receiving required information from associated sensors of the cluster. In the cluster, CHs can interact not only with other CHs, but also with higher-level CHs or a base station. A number of network configurations have been developed to prolong network lifetime and reduce energy consumption in forwarding data. In order to minimize energy consumption, routing schemes can be broadly classified into two categories: (1) clustering-based data forwarding scheme (Fig. 20.7a,b) and (2) multihop data forwarding scheme without clustering (Fig. 20.7b,d).

In recent years, with the advancement of wireless mobile communication technologies, ad hoc wireless sensor networks (AWSNs) have become important. With this advancement, the above wired (microwired) architectures remain relevant only where wireless communication is physically prohibited; otherwise, wireless architectures are considered superior. The architecture of AWSN is fully flexible and dynamic, that is, a mobile ad hoc network represents a system of wireless nodes that can freely reorganize into temporary networks as needed, allowing nodes to communicate in areas with no existing infrastructure. Thus, interconnection between nodes can be dynamically changed, and the network is set up only for a short period of communication [20.28]. Now the AWSN with an optimal ad hoc routing scheme has become an important design concern.

In applications where there is no given pattern of sensor deployment, such as battlefield surveillance or environmental monitoring, the AWSN approach can provide efficient sensor networking. Especially in dynamic network environments such as AWSN, three main distributed services, i. e., lookup service, composition service, and dynamic adaptation service by self-organizing sensor networks, are also studied to control the system (see, for instance, [20.29]).

In order to route information in an energy-efficient way, directed diffusion routing protocols based on the localized computation model [20.30, 31] have been studied for robust communication. The data consumer will initiate requests for data with certain attributes. Nodes will then diffuse the requests towards producers via a sequence of local interactions. This process sets up gradients in the network which channel the delivery of data. Even though the network status is dynamic, the impact of dynamics can be localized.

A mobile-agent-based DSN (MADSN) [20.32] utilizes a formal concept of agent to reduce network bandwidth requirements. A mobile agent is a floating processor migrating from node to node in the DSN and performing data processing autonomously. Each mobile agent carries partially integrated data which will be fused at the final CH with other agents' information. To save time and energy consumption, as soon as certain requirements of a network are satisfied in the progress of its tour, the mobile agent returns to the base station without having to visit other nodes on its route. This logic reduces network load, overcoming network latency, and improves fault-tolerance performance.

20.2.5 Sensor Network Protocols

Communication protocols for distributed microsensor networks provide systems with better network capability and performance by creating efficient paths and accomplishing effective communication between the sensor nodes [20.29, 33, 34].

The point-to-point protocol (PTP) is the simplest communication protocol and transmits data to only one of its neighbors, as illustrated in Fig. 20.8a. However, PTP is not appropriate for a DSN because there is no communication path in case of failure of nodes or links.

In the flooding protocol (FP), the information sent out by the sender node is addressed to all of its neighbors, as shown in Fig. 20.8b. This disseminates data quickly in a network where bandwidth is not limited and links are not loss-prone. However, since a node always sends data to its neighbors, regardless of whether or not the neighbor has already received the data from another source, it leads to the implosion problem and wastes resources by sending duplicate copies of data to the same node.

The gossiping protocol (GP) [20.35, 36] is an alternative to the classic flooding protocol in which, instead of indiscriminately sending information to all its neighboring nodes, each sensor node only forwards the data to one randomly selected neighbor, as depicted in Fig. 20.8c. While the GP distributes information more slowly than FP, it dissipates resources, such as energy, at a relatively lower rate. In addition, it is not as robust relative to link failures as a broadcasting protocol (BP), because a node can only rely on one other node to resend the information for it in the case of link failure.

In order to solve the problem of implosion and overlap, *Heinzelman* et al. [20.37] proposed the sensor

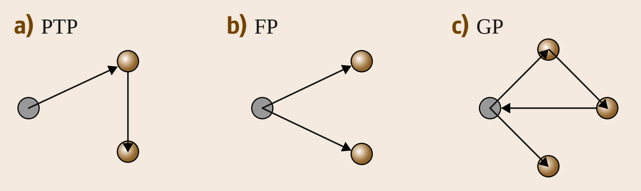

Fig. 20.8a–c Three basic communication protocols: **(a)** point-to-point protocol (PTP), **(b)** flooding protocol (FP), and **(c)** gossiping protocol (GP)

protocol for information via negotiation (SPIN). SPIN nodes negotiate with each other before transmitting data, which helps ensure that only useful transmission of information will be executed. Nodes in the SPIN protocol use three types of messages to communicate: ADV (new data advertisement), REQ (request for data), and DATA (data message). Thus, SPIN protocol works in three stages: ADV–REQ–DATA. The protocol begins when a node advertises the new data that is ready to be disseminated. It advertises by sending an ADV message to its neighbors, naming the new data (ADV stage). Upon receiving an ADV, the neighboring node checks to see whether it has already received or requested the advertised data to avoid implosion and the overlap problem. If not, it responds by sending a REQ message for the missing data back to the sender (REQ stage). The protocol completes when the initiator of the protocol responds to the REQ with a DATA message, containing the missing data (DATA stage).

In a relatively large sensor network, a clustering architecture with a local cluster-head (CH) is necessary. *Heinzelman* et al. [20.38] proposed the low-energy adaptive clustering hierarchy (LEACH), which is a clustering-based protocol that utilizes randomized rotation of local cluster base stations to evenly distribute the energy load of sensors in DSN. Energy-minimizing routing protocols have also been developed to extend the lifetime of the sensing nodes in a wireless network; for example, a minimum transmission energy (MTE) routing protocol [20.39] chooses intermediate nodes such that the sum of squared distances is minimized by assuming a square-of-distance power loss between two nodes. This protocol, however, results in unbalanced termination of nodes with respect to the entire network.

In recent years, a time-based network protocol has been developed. The objective of a time-based protocol is to ensure that, when any tasks keep the resource idle for too long, their exclusive service by the resource is disabled; that is, the time-based control protocol is intended to provide a rational collaboration rule among tasks and resources in the networked system [20.40]. Here, slow sensors will delay timely response and other sensors may need to consume extra energy. The patented fault tolerant time-out protocal (FTTP) uses the basic concept of a time-out scheme effectively in a microsensor communication control (FTTP is a patent-pending protocol of the PRISM Center at Purdue University, USA).

The design of industrial open protocols for mostly wired communication known as fieldbuses, such as DeviceNet and ControlNet, have also been evolved to provide open data exchange and a messaging framework [20.41]. Further development for wireless has been investigated in asset monitoring and maintenance using an open communication protocol such as ZigBee [20.42].

Wireless sensor network application designers also require a middleware to deliver a general runtime environment that inherits common requirements under application specifications. In order to provide robust functions to industrial applications under somewhat limited resource constraints and the dynamics of the environment, appropriate middleware is also required to contain embedded trade-offs between essential quality-of-service (QoS) requirements from applications. Typically, a sensor network middleware has a layered architecture that is distributed among the networked sensor systems. Based on traditional

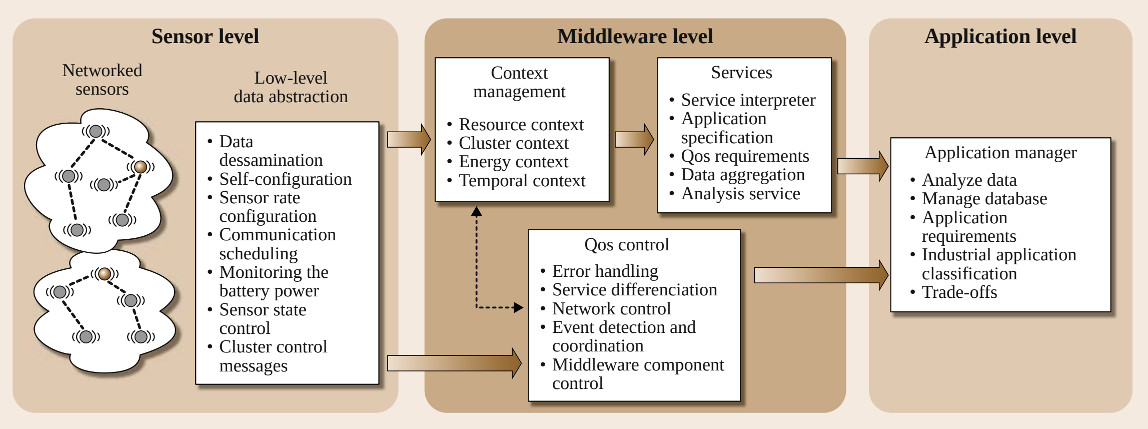

Fig. 20.9 Middleware architecture for facility sensor network applications (MidFSN) (after [20.36])

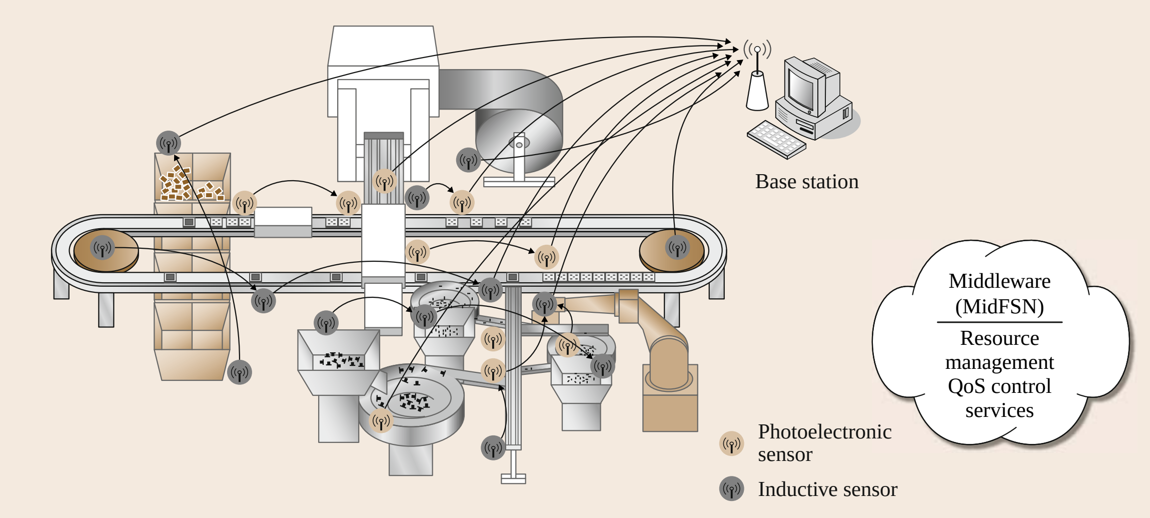

Fig. 20.10 Wireless microsensor network system with two different types of microsensor nodes in an industrial automation application (after [20.43])

architectures, researchers [20.43] have recently been developing a middleware for facility sensor network (MidFSN) whose layered structure is classified into three layers as depicted in Fig. 20.9.

20.2.6 Sensor Network Applications

Distributed microsensor networks have mostly been applied to military applications. However, a recent trend in sensor networks has been to apply the technology to various industrial applications. Figure 20.10 illustrates a networked sensor application used in factory automation. Environment applications such as examination of flowing water and detection of air contaminants require flexible and dynamic topology for the sensor network. Biomedical applications of collecting information from internal human body are based on bio/nanotechnology. For these applications, geometrical and dynamical characteristics of the system must be considered at the design step of network architecture [20.44]. It is also essential to use fault-tolerant network protocols to aggregate very weak signals without losing any critical signals. Specifically designed sensor network systems can also be applicable for intelligent transportation systems, monitoring material flow, and home/office network systems.

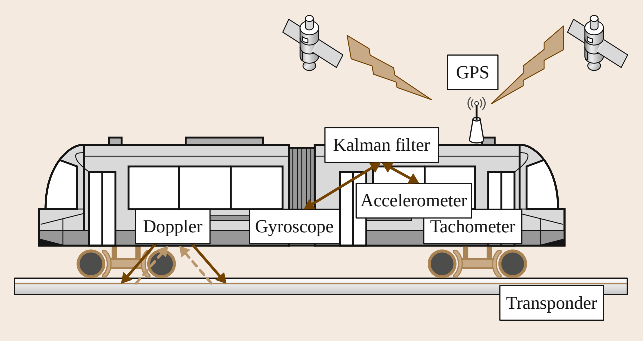

Fig. 20.11 Networked sensors for train tracking and tracing (global positioning system (GPS))

Public transportation systems are another example of sensor network applications. Sensor networks have been successfully implemented into highway systems for vehicle and traffic monitoring, providing key technology for intelligent transportation systems (ITS). Recently various networked sensors have been applied to railway system to monitor the location of rolling stocks and detect objects or obstacles on the rail in advance (Fig. 20.11). Networked sensors can cover a wide monitoring area and deliver more accurate information.

20.3 Emerging Trends

Energy-conserving microsensor network protocols have drawn great attention over the years. Other important metrics such as latency, scalability, and connectivity have also been deeply studied recently. However, it should be realized that there are still emerging research issues in sensor network systems. Although current wireless microsensor network research is moving forward to more practical application areas, emerging research on the following new topics should be further examined and will surface.

20.3.1 Heterogeneous Sensors and Applications

In many networked sensor applications and their performance evaluation, homogeneous or identical sensors were most commonly considered; therefore network performance was mainly determined by the geometrical distances between sensors and the remaining energy of each sensor. In practical applications other factors can also influence coverage, such as obstacles, environmental conditions, and noise. In addition to nonhomogeneous sensors, other sensor models can deal with nonisotropic sensor sensitivities, where sensors have different sensitivities in different directions.

The integration of multiple types of sensors such as seismic, acoustic, and optical sensors in a specific network platform and the study of the overall coverage of the system also present several interesting challenges. In addition, when sensor nodes should be shared by multiple applications with differing goals, protocols must efficiently serve multiple applications simultaneously. Therefore, for heterogeneous sensors and their network application development, several research questions should be considered:

1. How should resources be utilized optimally in heterogeneous sensor networks?
2. How should heterogeneous data be handled efficiently?
3. How much and what type of data should be processed to meet quality-of-service (QoS) goals while minimizing energy usage?

20.3.2 Security

Another emerging issue in wireless sensor networks is related to network security. Since the sensor network may operate in a hostile environment, security needs to be built into the network design and not as an afterthought. That is, network techniques to provide low-latency, survivable, and secure networks are required.

In general, low probability of communication detection is needed for networks because sensors are envisioned for use behind enemy lines. For the same reasons, the network should be protected again intrusion and spoofing. For the network security, some research questions should be examined:

1. How much and what type of security is really needed?
2. How can data be authenticated?
3. How can misbehaving nodes be prevented from providing false data?
4. Can energy and security be traded-off such that the level of network security can be easily adapted?

20.3.3 Appropriate Quality-of-Service (QoS) Model

Research in QoS has received considerable attention over the years. QoS has to be supported at media access control (MAC), routing, and transport layers. Most existing ad hoc routing protocols do not support QoS. The routing metric used in current work still refers to the shortest path or minimum hop. However, bandwidth, delay, jitter, and packet loss (reliability or data delivery ratio) are other important QoS parameters. Hence, mechanisms of current ad hoc routing protocols should allow for route selection based on both QoS requirements and QoS availability. In addition to establishing QoS routes, QoS assurance during route reconfiguration has to be supported too. QoS considerations need to be made to ensure that end-to-end QoS requirements continue to be supported. Hence, there is still significant room for research in this area.

20.3.4 Integration with Other Networks

In the near future, sensor networks may interface with other networks, such as a Wi-Fi network, a cellular network, or the Internet. Therefore, to find the best way to interface these networks will be a big issue. Sensor network protocols should support (or at least not compete with) the protocols of the other networks; otherwise sensors could have dual network interface capabilities.

21. Industrial Intelligent Robots

Yoshiharu Inaba, Shinsuke Sakakibara

It has been believed for a long time since the birth of the industrial robot that the only task it could perform was to play back simple motions that had been taught in advance. At the beginning of the 21st century, the industrial robot was born again as the industrial intelligent robot, which performs highly complicated tasks like skilled workers on a production site, mainly due to the rapid advancement in vision and force sensors. The industrial intelligent robot has recently been a key technology to solve issues that today's manufacturing industry is faced with, including the decreasing number of skilled workers and demands for reducing manufacturing costs and delivery time. In this chapter, the latest technology trends in its element technologies such as vision and force sensors are introduced with some of its applications such as the robot cell, which has succeeded in drastically reducing machining costs.

21.1 Current Status of the Industrial Robot Market

Industrial robots are now taking active part in various fields, including automotive and general industries. Today, industrial robots are used in many industries in many countries. The operational stock of industrial robots in major industrialized countries is shown in Table 21.1. Current industrial robots are typically used in such applications as spot welding, arc welding, spray painting, and material handling, as shown in Figs. 21.1–21.4, respectively.

Devol started the history of the industrial robot by filing the patent of its basic idea in 1954. A teaching-playback type industrial robot was delivered as a product for the first time in the USA in 1961. The robot featured two basic operations, teaching and playback, which are adopted in almost all robots on current factory floors.

21.2 Background of the Emergence of Intelligent Robots

The use of industrial robots on the production site started a rapid expansion in the 1980s because it came to be known that they had the possibility of improving productivity and making the quality of products stable. However, this led to a situation where, for example, dedicated equipment had to be prepared to supply work-

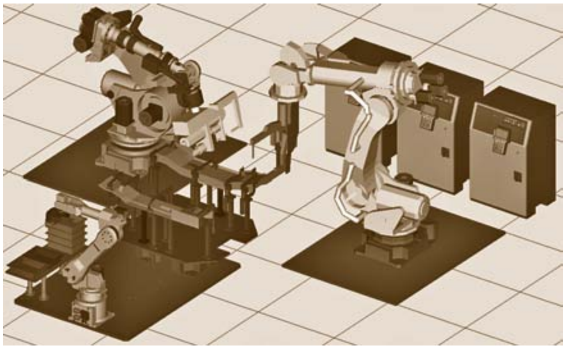

Fig. 21.1 Spot welding

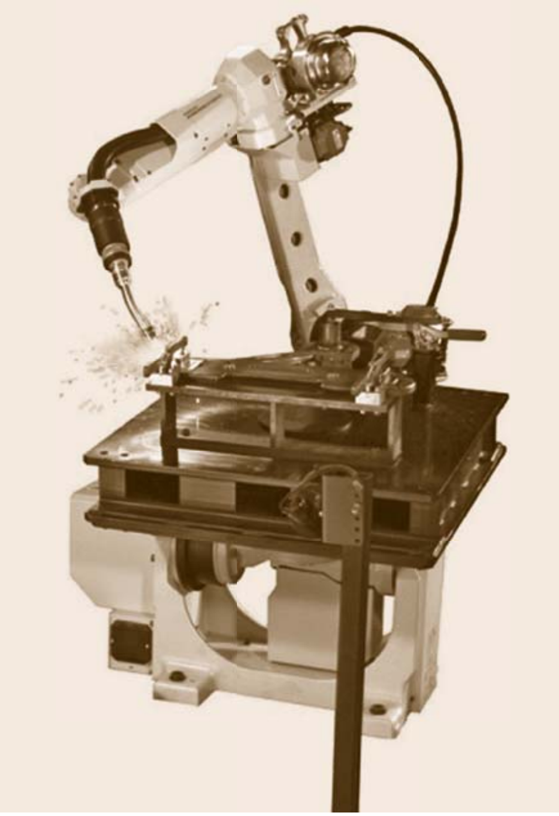

Fig. 21.2 Arc welding

pieces to a robot. Also, human operators had to prepare workpieces in alignment for the dedicated equipment before the robot loaded a workpiece to such a machine tool as a lathe. In 2001, the industrial intelligent robots (hereafter *intelligent robots*) appeared on the industrial scene mainly to automate loading workpieces to the fixtures of machine tools such as machining centers.

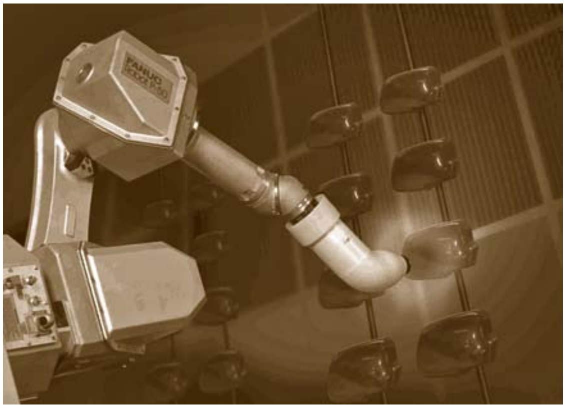

Fig. 21.3 Spray painting

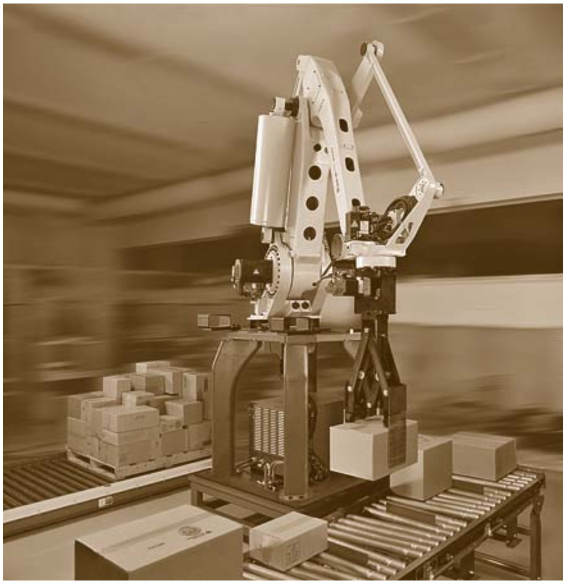

Fig. 21.4 Material handling

Before discussing specifics, it is necessary to look back at the history of machining process automation. The first private sector numerical control (NC) was developed in the 1950s, followed by the dramatic enhancement of the NC machine tool market. The machining itself was almost completely automated by the NC; however, loading and unloading of workpieces to and from machine tools were still done by human operators even in the 1990s. The intelligent robot appeared in 2001 for the first time. The term *intelligent robot* does not mean a humanoid robot that walks and talks like a human being, but rather one that performs highly complicated tasks like a skilled worker on the

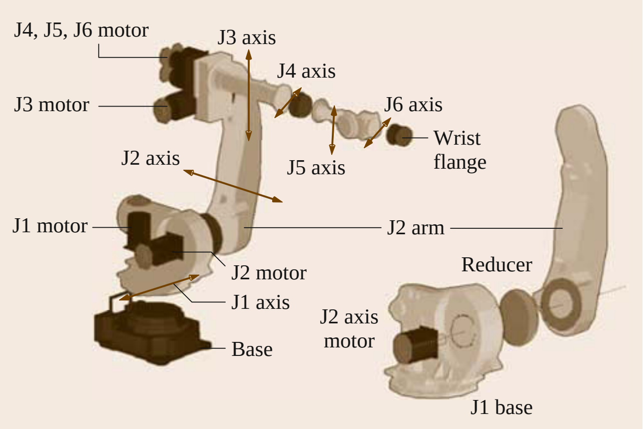

Fig. 21.5 Mechanical structure of an industrial robot

production site by utilizing vision sensors and force sensors. It has first enabled the automatic precision loading of workpieces to the fixture of the machining center and eliminated the need for dedicated parts supply equipment, as the robot picks up workpieces one by one using its vision sensor once the workpieces are delivered to a basket near the robot. This also eliminated a burdensome process imposed upon human operators; that of arraying workpieces for the dedicated equipment. In addition, the automation of several tasks, which follow the machining, such as deburring, most of which had been difficult for conventional robots, was also realized by the intelligent robot.

Thus, intelligent robots have recently been increasingly introduced in production, mainly due to their high potential for enhancing global competitiveness as a key technology to solve issues that today's manufacturing industry is faced with, including the decreasing number of skilled workers and demands for reducing manufacturing costs and delivery time. In this regard, the rapid advancement in vision and force sensors and offline programming, and the element technologies for intelligent robots support the trend of robotic automation.

21.3 Intelligent Robots

21.3.1 Mechanical Structure

Figure 21.5 shows a typical configuration of a vertical articulated type six-axis robot. There are no big differences between the mechanical structure of an intelligent robot and that of a conventional robot. It comprises several servomotors, reducers, bearings, arm castings, etc.

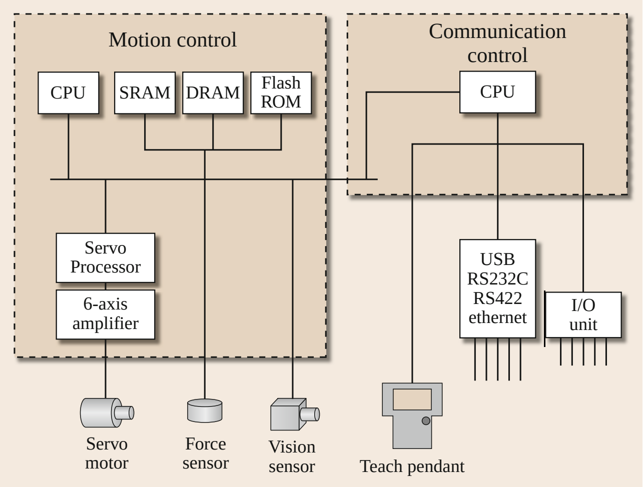

Fig. 21.6 Control system

21.3.2 Control System

As shown in Fig. 21.6, the sensor interface, which enables the connection of sensors such as vision sensors and/or force sensors to the controller, features the control system of an intelligent robot compared to that of a conventional robot. High-speed microprocessors and communication interface also features it. Operators of intelligent robots make robot motion programs by operating the teach pendant shown in Fig. 21.7 and moving the robot arm step by step.

The servo control of intelligent robots is similar to that of conventional robots as shown in Fig. 21.8. The performance of several servo control functions of intelligent robots, such as the interpolation period, are highly enhanced compared with that of conventional robots.

21.3.3 Vision Sensors

Two types of vision sensors are often used on the factory floor: two-dimensional (2-D) and three-dimensional (3-D) vision sensors. The 2-D vision sensors acquire two-dimensional images of an object by irradiating natural light or artificial light on the object and taking the image of the reflected light with a CCD or other type of camera. This enables obtaining a two-dimensional po-

Fig. 21.9 Images captured by 2-D vision sensor

sition and rotation angle of the object. Recently, 2-D vision sensors have been made useful under the severe production environment at the factory floor due to enhanced tolerance to change in brightness and image degradation based on improved processing algorithms and increased processing speed. Figure 21.9 shows several images captured and processed by 2-D vision sensors.

There are two major methods for 3-D vision sensors, the structured light method and the stereo method. Of these, the structured light method irradiates the structured light such as slit light or pattern light on an object, and takes images of the reflected light by a CCD or other type of camera to obtain images of the object. The 3-D position and posture of the object are calculated with high accuracy from these images. Additional information on sensors is also provided in Chap. 20.

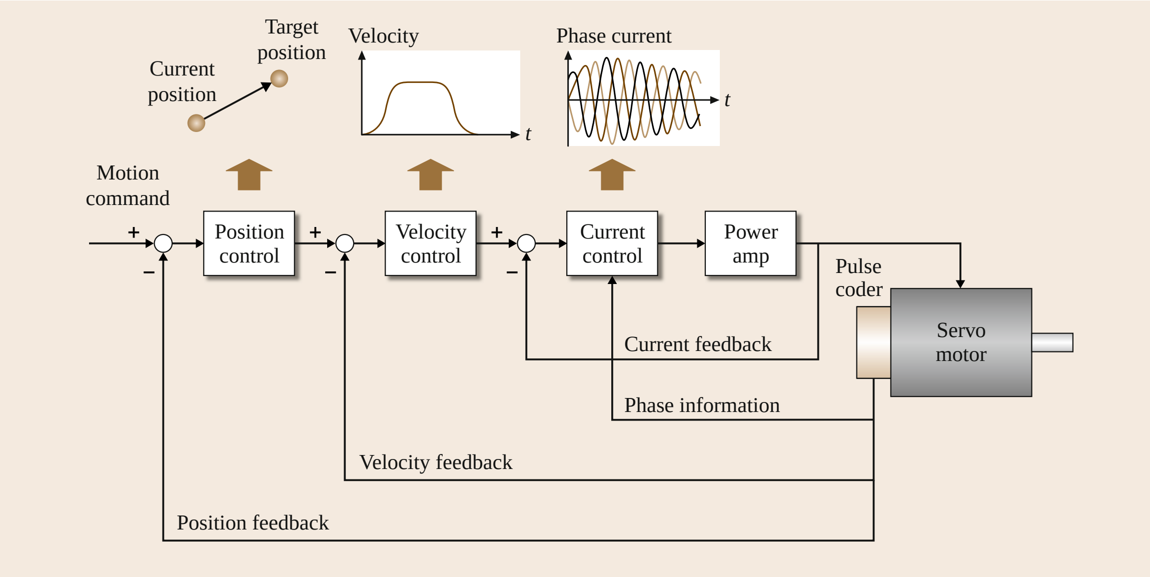

Fig. 21.8 Servo control

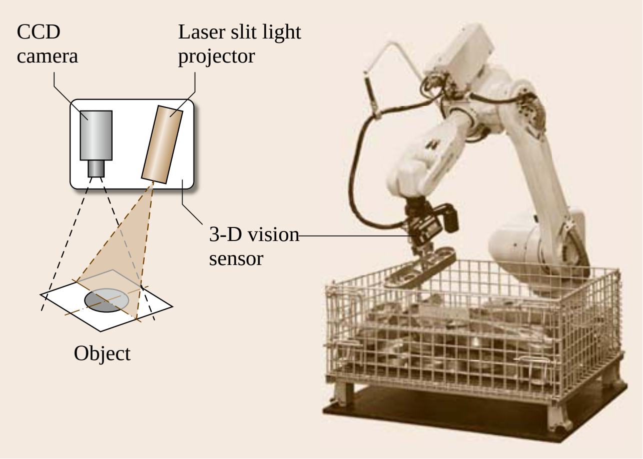

Fig. 21.10 Bin picking

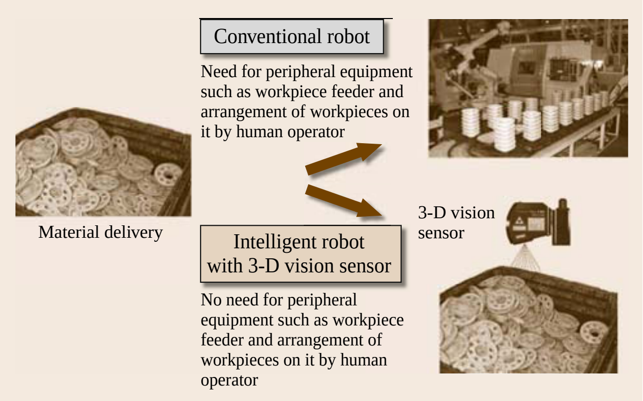
Figure 21.10 shows the bin-picking function realized by using the 3-D vision sensor with the structured light method. The robot can pick up workpieces one by one from those randomly piled in a basket using the 3-D vision sensor.

With respect to the economic effect of the 3-D vision sensor, this reduces the capital investment expense by simplifying the peripheral equipment such as the workpiece feeder, and relieves the operator from the daily burden of arraying workpieces as shown in Fig. 21.11.

Some of the vision sensors have control units built into the robot control system, which significantly enhances the reliability in use in severe production environments.

The following section explains the typical sequences needed to achieve the bin-picking function.



Conventional robot
Need for peripheral equipment such as workpiece feeder and arrangement of workpieces on it by human operator
Material delivery
3-D vision sensor
Intelligent robot with 3-D vision sensor
No need for peripheral equipment such as workpiece feeder and arrangement of workpieces on it by human operator

Fig. 21.11 Economic effect of the vision sensor

Overall Search for the Workpieces

The image of piled workpieces is taken from upper side by the far-sighted-eye, and the pretaught model is detected from within the image. This far-sighted-eye is calibrated in advance. Then the approximate position of each detected workpiece is acquired. The controller moves the hand-eye (a vision sensor mounted on the hand) near the work-piece based upon this 3-D position, and measurement instructions are issued to the sensor controller, then the trial measurement explained below is executed.

Trial Measurement

The purpose of the trial measurement is to acquire both the 3-D position and posture of the workpiece specified by the overall search. This trial measurement uses the hand-eye and its measurement position is calculated with the approximate position of the workpiece obtained from the overall search.

In the trial measurement the 3-D position and posture of the workpiece are obtained by projecting the structured light by the hand-eye sensor. Because the approximate position of the workpiece obtained from the overall search does not include the posture of the workpiece, the trial measurement position and posture are not always appropriate to the workpiece. This may cause unsuitable accuracy for workpiece handling. To compensate this condition, fine measurement is performed in the next step.

Fine Measurement

The hand-eye is able to come closer to the workpiece after the *overall search for the bin* and the *trial measurement*; thus it becomes very easy to measure the position and posture of the workpiece accurately.

Figure 21.12 shows accuracy improvement in measuring the position and posture of workpieces by

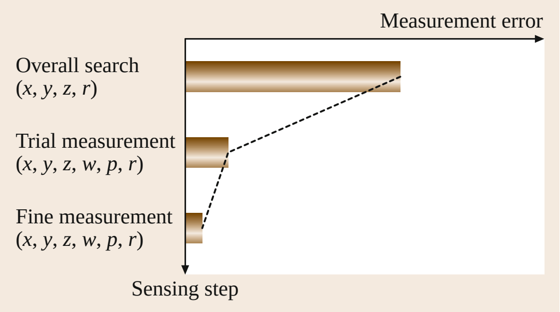


Fig. 21.12 Accuracy improvement by repetitive measurement

this repetitive measurement using the 3-D vision sensor.

Error Recovery

When building an automation system, it is desirable to prevent errors that might stop the system beforehand, but complete provisions to prevent errors are impossible, and the occurrence of unexpected errors is inevitable. For this reason, intelligent robots incorporate exception-handling functions that work in the event of an error occurring. Exception handling analyzes the cause of the error to recover the corresponding error state. This prevents the fall in the operation rate of the bin-picking system.

For instance, when a workpiece is taken out from among those in the basket, the interference of the robot and peripheral equipment might happen occasionally. Then the robot controller with its high sensitivity collision detection function, the details of which are shown in Fig. 21.13, detects the load suddenly added to the robot by the interference, and stops the movement of the robot instantaneously. The position and the posture of the robot are retrieved, and it becomes possible for the robot to continue to move afterwards. This function prevents robot and peripheral equipment from being damaged beforehand, and is useful for improving the operation rate of the system.

The other 3-D vision method, the stereovision method, uses images taken by two cameras, by matching corresponding points on the left and right images to calculate the objects' 3-D position and posture (Fig. 21.14). Although it takes some time to match corresponding points, this method may be advantageous in such a case where a mobile robot has to recognize its surroundings, as there is no need to irradiate auxiliary light as in the structured light method.

21.3.4 Force Sensors

A six-axis force sensor is used to give robots dexterity by mounting it on the wrist of the robot arm. A force sensor generally detects *x*-, *y*-, and *z*-direction forces and each axis' moment (a total of six degrees of freedom). The force sensor usually has a strain gauge on the distortion part, which becomes distorted when applied with force or moment and makes it possible to determine its value. Figure 21.15 shows an example of the force sensor. The use of force sensors has enabled the robot to do such tasks as shaft fitting and gear phase matching for precision machine parts assembly, as well as deburring and polishing, which require a certain pressure. Figure 21.16 shows the change of the force and the moment in a peg-in-hole operation.

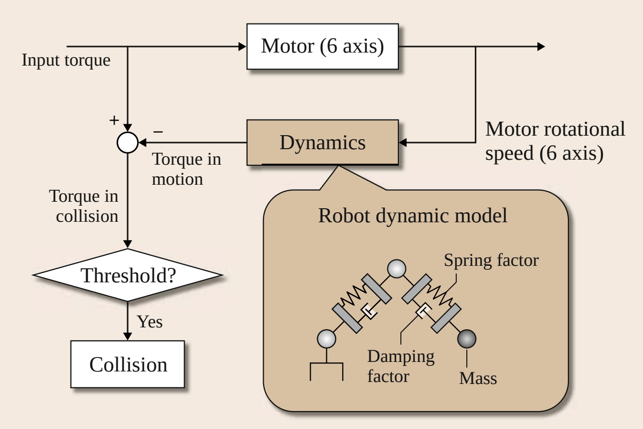

Fig. 21.13 Collision detection

Figure 21.17 shows an example of the assembly of the crank mechanical unit of injection molding machine with a force sensor. Figure 21.18 shows an example of the assembly of small electronic devices with force sensors.

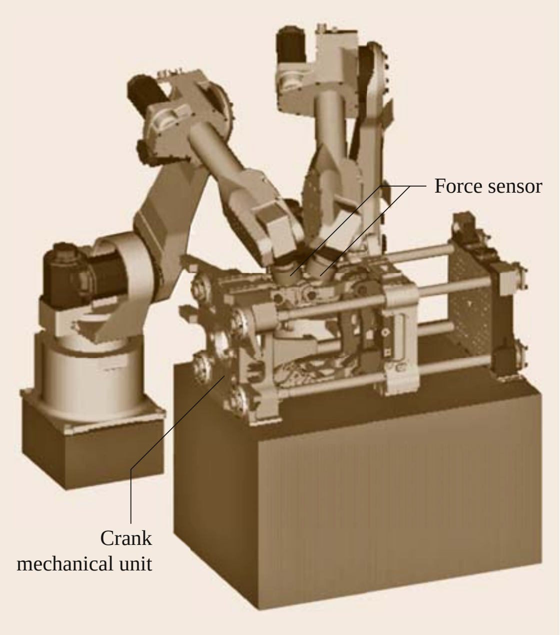

Fig. 21.17 Assembly of a crank mechanical unit with a force sensor

21.3.5 Control Functions

Flexible Control Function of a Robot Arm

Conventional robots have difficulties in loading a casting workpiece accurately onto the chuck of a lathe or the fixture of a machining center due to deviance in position or posture of the casting deriving from the casting's dimensional dispersion. In die-casting, there is also the risk that the conventional robot arm with a workpiece does not comply with the ejector motion when the workpiece is drawn out from the die-mold by the ejector. The robot arm's flexible control function enables the robot to softly control its arm in the

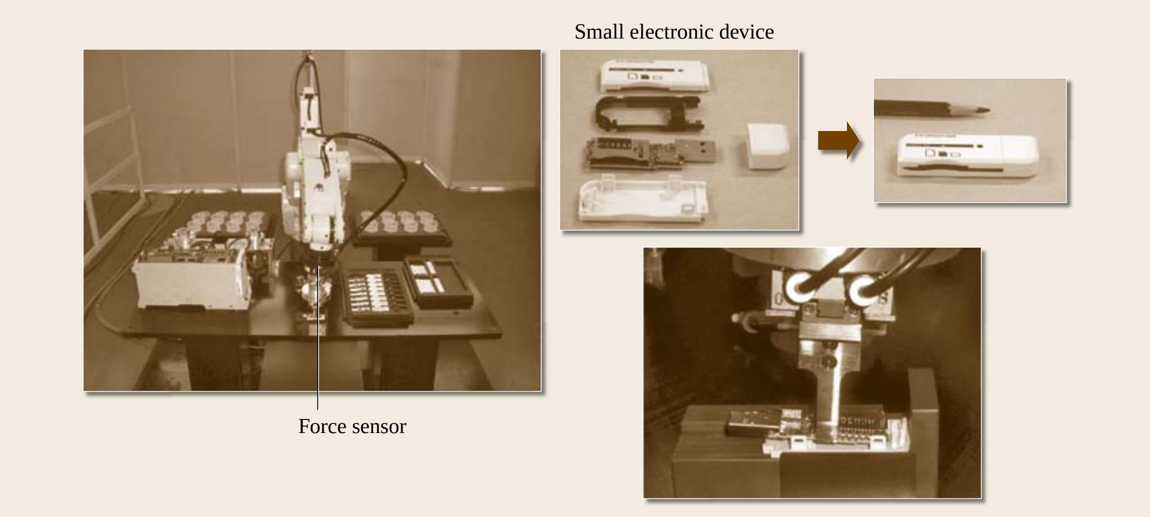

Fig. 21.18 Assembly of small electronic device with a force sensor

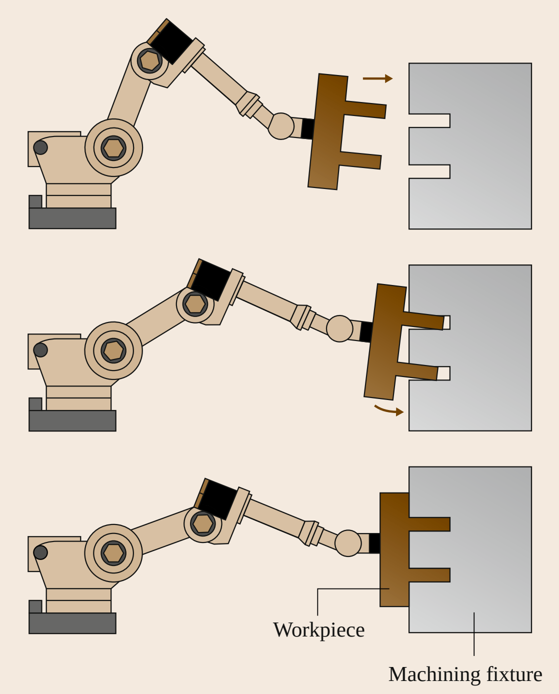

Fig. 21.19 Robot arm and workpiece comply with the machining fixture so as to fit the workpiece to the fixture

designated direction in orthogonal coordinate systems. It can thus accurately load a workpiece to the machine tool and draw out a workpiece from the die-mold without any disturbing force in the die-casting operation. Figure 21.19 shows the flexible control function of robot arm. It does not use any force sensors but rather the current of the servomotors that drive the robot arm.

Coordinated Control Function of Multiple Robots

Coordinated operation by multiple robots has been made possible by synchronizing robots connected to each other via the Ethernet. This function, for example, enables multiple robots to carry a heavy workpiece such as a car body in coordination, where the weight of the workpiece exceeds the payload capacity of one robot. Also, a flexible system can be configured as shown in Fig. 21.20, in which two robots rotate a workpiece while gripping it, where the two robots are used as rotating fixtures, and another robot arc-welds the workpiece in coordination with other robots' motion.

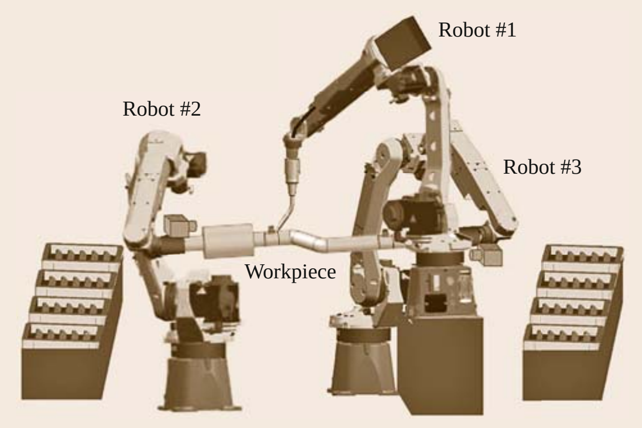

Fig. 21.20 Coordinated arc welding system with three robots

Collision Detection Function

Humans may have a sense of affinity with robots. However, robots are a highly rigid machine by nature, and may cause heavy damage to human beings or other machines at the time of collision. In the latest robot control technology, the drive power supply is immediately cut when a robot collides with an object because it detects the change in the servomotor current that drives the robot arm. This minimizes the damage if a robot collides with machines. Human beings must be separated from the robot in space and/or time by such safety means as fences.

21.3.6 Offline Programming System

Offline programming systems have greatly contributed to decreasing the robot's programming hours as PC performance has improved. There is usually a library of robot models in the offline programming system. The data of workpiece shapes, which has recently been compiled by using 3-D CAD systems, is read into the offline programming system. Peripheral equipment is often defined by using an easy shape generating function of the offline programming system, or by using 3-D CAD data. As shown in Fig. 21.21, after loading the workpiece's 3-D CAD data into the offline programming system, the robot motion program can easily be generated automatically, just by designating the deburring path and the posture of the deburring tool on the PC display.

However, the robot motion program automatically generated on the PC cannot immediately operate the robot on the production floor, as the positional relation of the robot and the workpiece on the PC display is

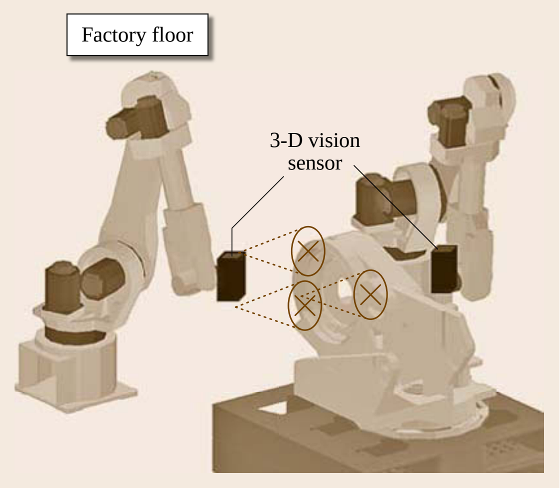

Fig. 21.22 Measurement of workpiece position and posture by the vision sensor

slightly different from that of the real robot and workpiece on the production site. The latest technology in robot vision sensors calculates the real workpiece's position and posture on the production floor, enabling an automatically generated program to be corrected automatically, as shown in Fig. 21.22, thus significantly decreasing the programming time for deburring.

21.3.7 Real-Time Supervisory and Control System

The real-time supervisory and control system is a software package to monitor and control the production system's real time, which is generally called SCADA (supervisory control and data acquisition). As shown in Fig. 21.23, the system enables an operator to generate screens interactively, by making use of modularized functions of data collection, graphical drawing and data analysis software, as well as standard communication network and common database. Various production data including machining data and cycle time can be controlled and analyzed from an office via the Ethernet, which links the office computers with the CNC machine tools and robots on the production floor. The plant manager can directly access the production outcome and operational status of machine tools and robots in the plant he/she is responsible for via internet or by using a mobile phone even during his/her travels abroad, to give precise and timely directions. For a related discussion see Chap. 23 on programming real-time systems for automation.

There is also a system available with a function to strongly support finding causes of temporal system stoppages during the system operation on the production floor.

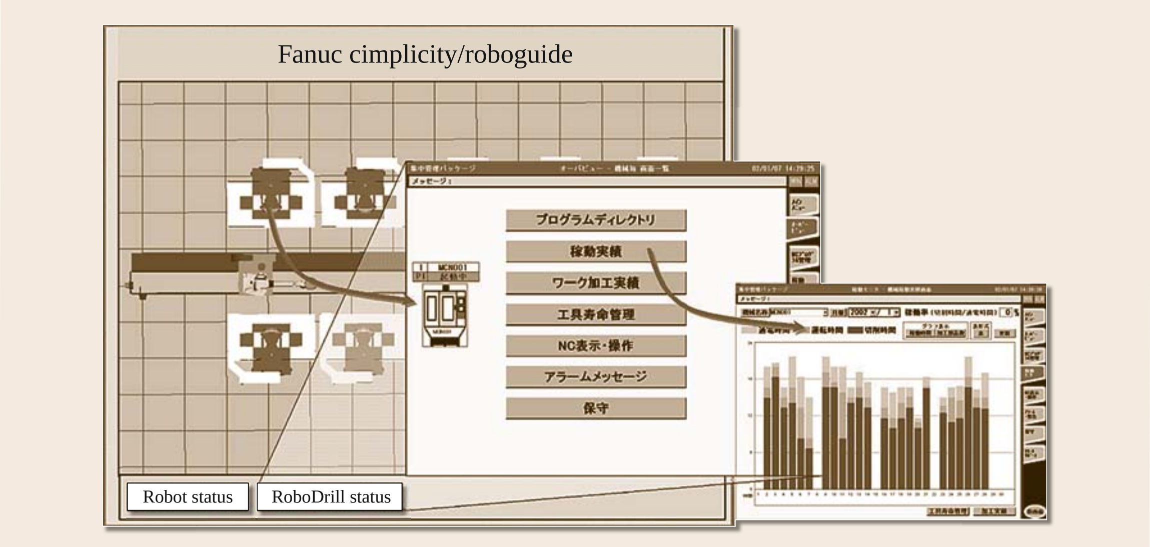

Fig. 21.23 Real-time supervisory and control system

21.4 Application of Intelligent Robots

21.4.1 High-Speed Handling Robot

In the food and pharmaceutical handling field, there has been a delay in robotic automation compared with heavy workpiece handling, as the goods handled in this field are relatively lighter, and as there is a stronger requirement for higher-speed and continuous handling operation. Figure 21.24 shows an example of the high-speed handling by an intelligent robot, which can operate continuously at high speeds, and is clean, washable, and chemical proof. This robot adopts the dual drive and torque tandem control method as shown in Fig. 21.25, the first case in robots, to achieve high-speed and continuous operation. Each basic axis has two motors, and by optimally controlling these motors, high acceleration/deceleration and continuous operation for high duty performance are achieved.

Using the visual tracking function, which combines a vision sensor and a tracking function, can increase handling efficiency. With the vision function built into the robot controller, the vision system has become highly reliable for use on the production floor. With its vision sensor the robot recognizes the position of a workpiece coming on the conveyer and compensates the robot motion trajectory by comparing the workpiece's position with the conveyor speed data received from the pulse coder. Also, the system allocates handling operations among multiple robots in order to increase handling efficiency. Figure 21.24 shows the visual tracking function by three high-speed handling robots, which can handle 300 parts/min.

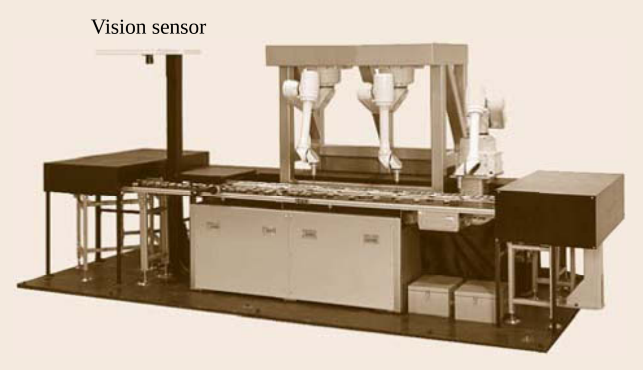

Fig. 21.24 Visual tracking system by high-speed handling robots

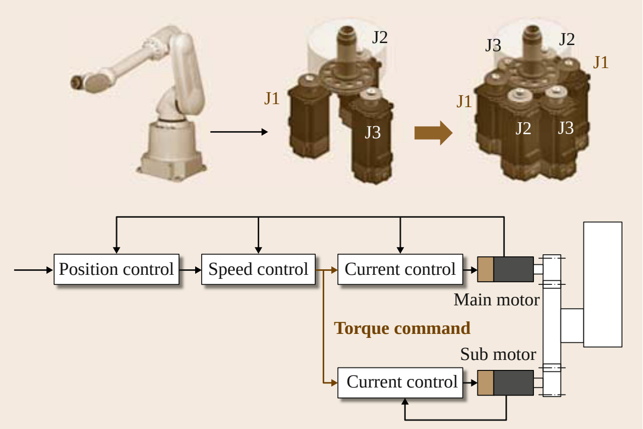

Fig. 21.25 Dual drive and torque tandem control

21.4.2 Machining Robot Cell – Integration of Intelligent Robots and Machine Tools

Generally, the machining system can reduce machining costs by operating long hours continuously. The history of machining system is summarized in Fig. 21.26.

1. In the 1980s, a 24 h continuous operation was achieved by introducing a CNC machine tool system equipped with pallet magazines (Fig. 21.26a).
2. In the 1990s, a 72 h continuous operation including weekends was achieved by introducing a machining system equipped with a large-scale multilayer pallet stocker (Fig. 21.26b).
3. In the 2000s, a robot cell system was developed in which an intelligent robot directly loads workpieces to the machining fixtures of the machining center, achieving 720 h per month, or 24 h for 30 days, continuous operation. The intelligent robot compensates the deviation in its gripping of the workpiece, resulting from the dimensional variation of the casting, with its 3-D vision sensor. Also, the workpiece is loaded to the machining fixture with precision, because the workpiece is pressed softly to the surface of the fixture by controlling the robot arm softly as shown in Fig. 21.19. The robot cell can substantially reduce labor and machining costs, as well as initial capital investment (Fig. 21.26c).

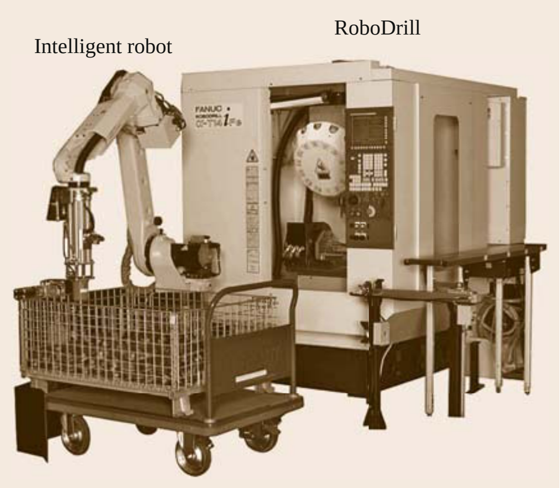

Fig. 21.27 Mini robot cell. Decreases machining cost of long hours of continuous machining drastically

Figure 21.27 shows a mini robot cell comprised of a CNC drill and an intelligent robot, in which the intelligent robot loads and unloads workpieces to and from the CNC drill, and measures the dimensions of the ma-

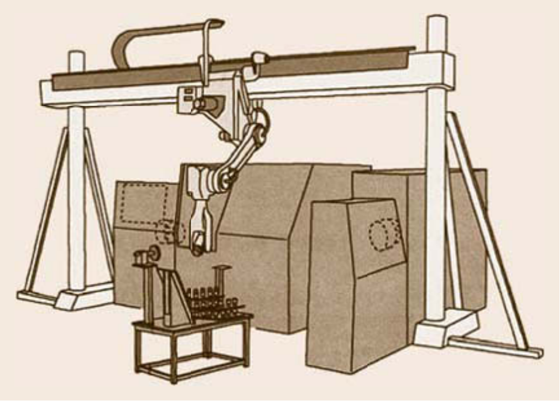

Fig. 21.28 Top mount loader robot

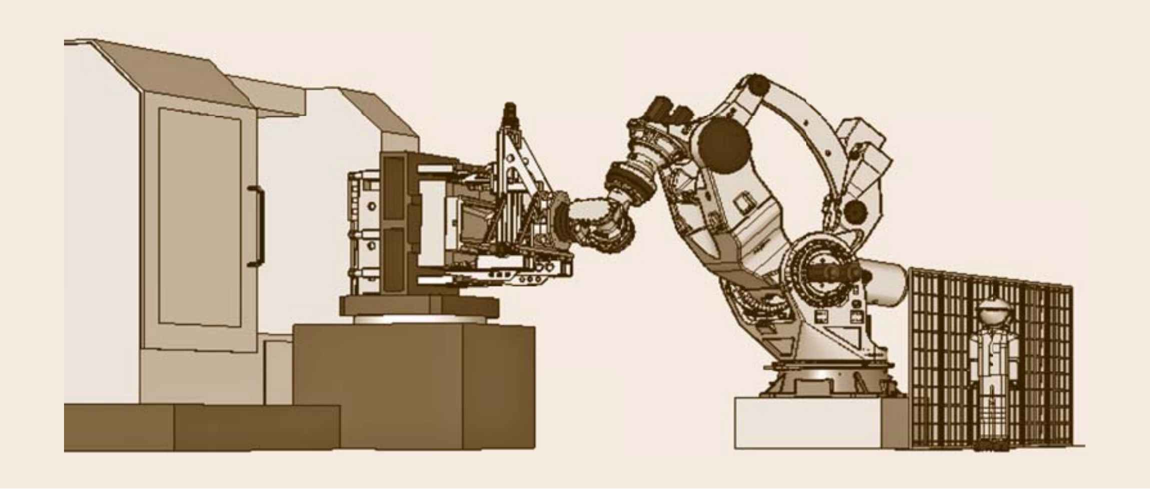

Fig. 21.29 Big robot

chined workpieces. An operator carries a basket filled with workpieces in front of the robot. The intelligent robot with a vision sensor picks up a workpiece from among those randomly placed in the basket and loads it to the drill. This robotic system eliminates dedicated workpiece supply equipment, as well as the manual work by human operators to array workpieces on it.

Mini robot cells are available from the minimum configuration of one machine tool and one intelligent robot to a system with multiple machine tools and robots, meeting the various requirements of users. In the case where multiple machine tools work on a workpiece for different machining processes, there is also a system in which a mobile intelligent robot runs between the machine tools to transfer the workpiece as shown in Fig. 21.28.

Until now, a heavy workpiece of about 1000 kg had to be handled by the coordination of more than two robots, and workers had to use the crane to handle the heavy workpiece. A big intelligent robot, whose payload is about 1000 kg appeared recently. This robot can simplify the robot cell as shown in Fig. 21.29.

21.4.3 Assembly Robot Cell

Intelligent robots are also expected to take an active role in the assembly job, which comprises as large a part of the machine industry as the machining job. The intelligent robot can perform highly accurate assembly jobs, picking up a workpiece from randomly piled workpieces on a tray, assembling it with the fitting precision of 10 μm or less clearance with its force sensor. Figure 21.30 shows an assembly robot cell in which intelligent robots are assembling mini robots.

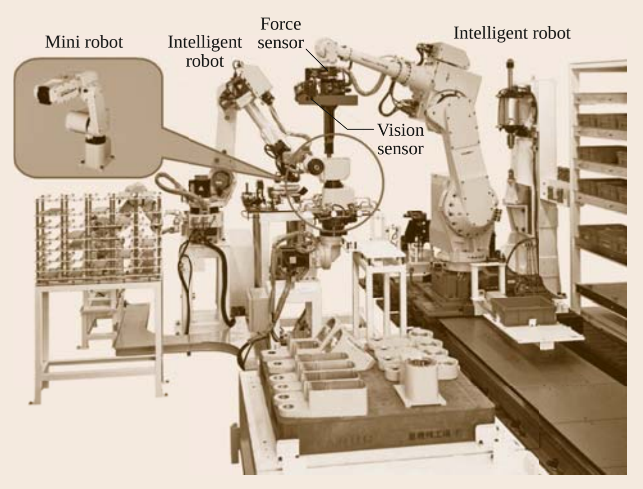

Fig. 21.30 Assembly robot cell

21.5 Guidelines for Installing Intelligent Robots

The following items are guidelines that should be examined before an intelligent robot is introduced.

21.5.1 Clarification of the Range of Automation by Intelligent Robots

Though the intelligent robot loads workpieces to the machine tool and assembles parts with high accuracy, it cannot do everything a skilled worker can do. For instance, the task such as the assembly of a flexible thing belongs to a field in which humans are more skillful than intelligent robots. It is necessary to clearly separate the range that can be automated from the range that relies on skilled workers before the introduction of intelligent robots.

21.5.2 Suppression of Initial Capital Investment Expense

The effect of the introduction of intelligent robots arises if the peripheral equipment can be simplified by making use of flexibility that is one of the major features of intelligent robots. This effect weakens if the initial capital investment expense is not suppressed due to an easy increase of the expense for peripheral equipment compared with that of the automation that does not use intelligent robots.

21.6 Mobile Robots

Figure 21.31 shows an autonomous mobile cleaning robot. The robot is mainly used for floor-cleaning in skyscrapers. It moves between stories by operating the elevator by itself, and cleans the floors at night. It autonomously returns to the start position after it has worked. More than 10 cleaning systems using the robots have already been introduced into several skyscrapers in Japan.

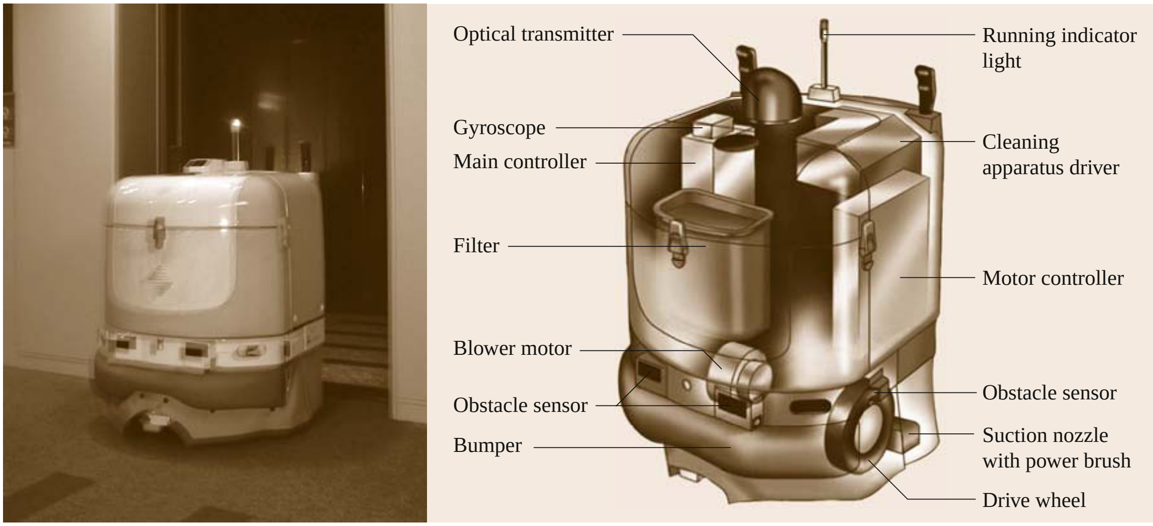

Fig. 21.31 Autonomous mobile cleaning robot (source: Fuji Heavy Industries Ltd.)

21.7 Conclusion

The intelligent robot appeared on the factory floor at the beginning of 2000 and has vision and force sensors. It can work unattended at night and during holidays because it reduces manual preparations such as arrangement of workpieces and/or the necessity of system monitoring compared with the conventional robot. Thus, the use efficiency of equipment rises, machining and assembly costs can be reduced, and the global competitiveness of a product can be improved.

The industrial intelligent robots still have tasks in which they cannot compete with skilled workers, though they have a high level of skills, as has been explained so far. The assembly task of flexible objects such as wire-harnesses is one such task. There are several on-going research and development activities in the world to solve these challenges. One idea is to automate such a task completely, and another is to do it partially. In the latter case, robots and skilled workers work together; robots assemble mechanical parts and skilled workers assemble flexible parts, for example. In any case, the degree of cooperation between humans and robots will increase in the near future.

22. Modeling and Software for Automation

Alessandro Pasetti, Walter Schaufelberger (△)

Automation is in most cases done through the use of hardware and software. Software-related costs account for a growing share of total development costs for automation systems. In the automation field, containment of software costs can be done either through the use of model-based tools (e.g., Matlab) or through a higher level of reuse. This chapter argues that both technologies have their place. The first strategy can be used for the design of software for a large number of identical installations or for the implementation of only part of the software (i. e., the control algorithms). The second strategy is advantageous in the case of industrial automation systems targeting niche markets where systems tend to be one-of-a-kind and where they can be organized in *families* of related applications. In many applications, a combination of the two approaches will produce the best results. Both approaches are treated in the paper. The main focus of the chapter is on developing software for automation. As such software will often be implemented for slightly different processes, it is highly appropriate that the production process is at least partly automated. As space is limited, this chapter can not cover all aspects of the design and implementation of software for automation, but we claim that the methods discussed here integrate very well with traditional methods of software and systems engineering.

Experience from contributions to various research projects recently performed at Swiss Federal Technical university (ETH) are also summarized.

Software plays an increasing role in the design and implementation of automation systems. The efficient construction of reliable software is therefore a general goal in many automation projects. Automation projects are demanding and multifunctional, and nonfunctional (timing, reliability, testability etc.) requirements have to be satisfied. From the early days of the development of computers, their use in automation was investigated, even if the cost of the computer was in many cases much higher than the cost of the plant in the early 1970s.

From these early days, two competing developments emerged. One line developed from the imperative programming languages used at the time (Fortran, later C and Pascal) and the other from the control engineer-

Fig. 22.1 Fortran program for a PI controller in 1970

ing approach of describing systems in a declarative way by block diagrams or similar means. Both of these ways were continued and led to solutions widely accepted today in industry.

A Fortran program for a proportional–integral (PI) controller on the hybrid computer available at the time to test ideas of digital control is shown in Fig. 22.1.

This is clearly an imperative style. In a text of the mid 1980s on real-time programming of automation systems [22.1], conventional programming was still the only way to program real-time systems, and the real-time industrial language PORTAL (similar to Pascal) was used for practical experiments, implementing PI and adaptive controllers.

A program we developed in the late 1980s for educational purposes with a graphics environment on a personal computer (PC) [22.2, 3] is shown next in Fig. 22.2 as controller for a small heating system. Simulink was not yet available at the time. At the time, Gem by Digital Research was found to be better suited than Windows for such tasks, the program was therefore written in Gem.

A block diagram is drawn interactively on screen as the declarative description of the control algorithm, which can be directly executed to produce experimental results. This is declarative in nature; the order of execution is not evident from the drawing. A major problem when realizing such programs at the time in Modula-2 was the fact that the language is strongly typed and that lists of function blocks had to be kept. Obviously, these function blocks are of differing types. Programming tricks had to be used to overcome this. A redesign in the object-oriented language Oberon [22.4] demonstrates how easily such programs can be designed with the appropriate mechanisms such as subclassing. In the object–process methodology (OPM) function, structure, and behavior are integrated into a single, unifying model, OPM significantly extends the system modeling capabilities of current object-oriented methods [22.5].

These early attempts to efficient program design and implementation clearly aimed at producing a program for a given task. Graphical and textual libraries were created, but essentially an individual program was the goal of the design. Though quite different in terms of the approach taken, these early attempts were all model based in the sense that a modeling or programming environment was available and that models were used in all stages of the development process.

This changed with the introduction of object-based and object-oriented techniques into software engineering. It became possible to design adaptive programs or programs for families of systems with better orientation on reuse. This is an issue we want to look at in more detail in the following sections.

First versions of Matlab became available in the late 1970s, and Matlab quickly became a de facto standard for control engineers, especially for system design.

22.1 Model-Driven Versus Reuse-Driven Software Development

The fundamental problem of software engineering is to translate a set of user requirements into executable code that implements them in a manner that is as cost effective as possible. There are several ways to solve this problem which, at least conceptually, can be arranged along a continuous spectrum that has at its two extremes the so-called *model-driven* and *reuse-driven approaches*. These two approaches are illustrated in Fig. 22.3.

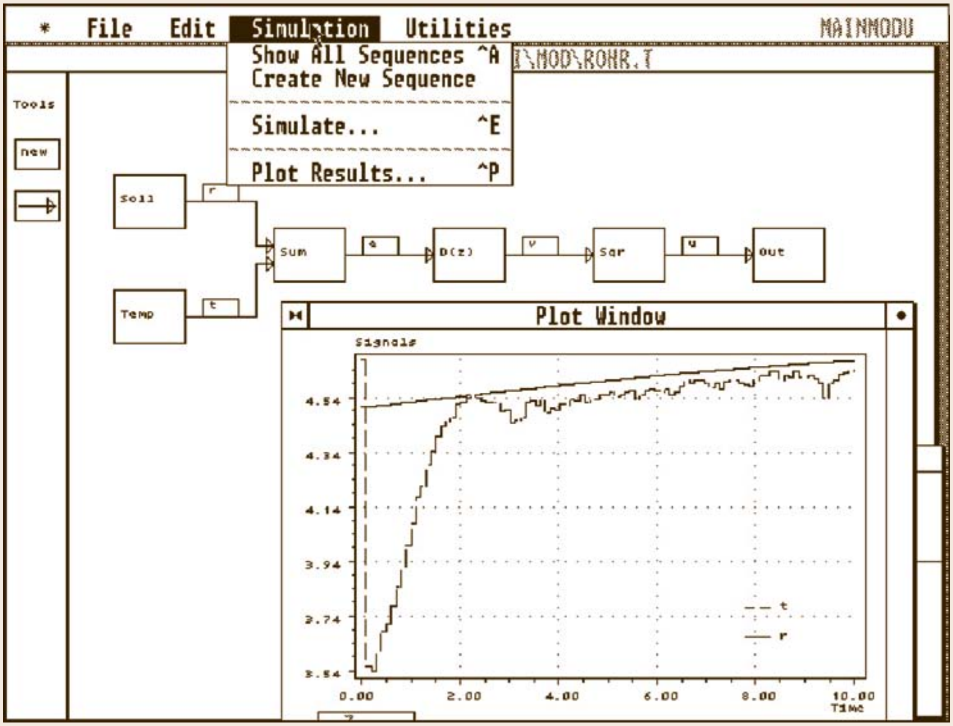

Fig. 22.2 An early programming and experiment environment

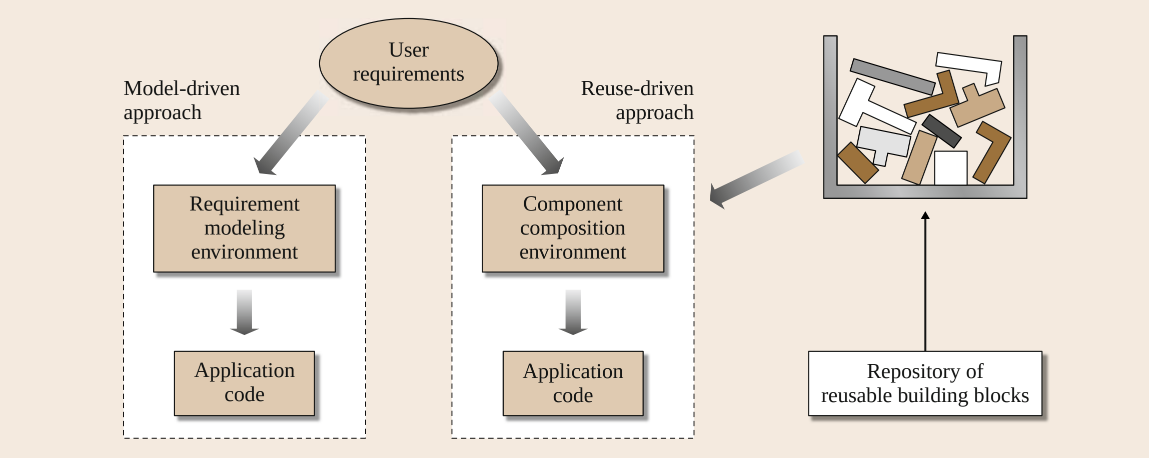
Although most projects will take an intermediate or mixed approach, it is useful to consider briefly the two extreme approaches in isolation from each other as a way to clarify their distinctive features.

In the model-driven approach (left-hand side of Fig. 22.3), the user requirements are expressed in a modeling environment that is capable of automatically generating the application code. The prototypical example of such an environment is the Matlab tool suite. The cost and schedule savings arise from the fact that the software design and implementation phases are fully automated.

In the reuse-driven approach (right-hand side of Fig. 22.3), the user requirements are implemented by configuring and composing a set of predefined software building blocks. The cost and schedule savings in this case originate from the possibility of reusing existing software artifacts (modules, components, code fragments, etc.). Traditionally, the reuse-driven approach was implemented by developing libraries of reusable modules. More recently, software frameworks have emerged as a more effective alternative to achieve the same aim of minimizing software development costs by leveraging reuse.

Each approach has its strengths and weaknesses. The model-driven approach holds the promise of completely automating the software development process, but is in reality limited by the expressive power of the selected modeling language. Thus, for instance, Matlab provides powerful modeling facilities for describing transfer functions and state machines but it does not support well modeling of other functionalities that are equally important in embedded applications (such as management of external units, generation of housekeeping data, processing of operator commands, management and implementation of failure detection and recovery mechanisms, etc.).

The reuse approach can be more flexible both because reusable building blocks can, in principle, be provided to cover as wide a range of functionalities as desired, and because it can be applied in an incremental way with repositories of reusable building blocks being built up over time. The main drawback of this approach is that the selection, configuration, and composition of



User requirements

Requirement modeling environment
Application code
Component composition environment
Application code
Repository of reusable building blocks

Fig. 22.3 Model-driven versus reuse-driven approach

the building blocks is difficult to automate and, if done by hand, remains a tedious and error-prone task.

In practice, no application is entirely reuse or model driven. Instead, the two approaches are complementary and are applied to different parts of the same application. Consider, for instance, the case of a typical satellite on-board application. A model-driven approach is ideally suited to cover the modeling and implementation of the control algorithms of the application. This is appropriate because there are very good modeling techniques for expressing control algorithms and there are very powerful tools for translating models into code-level implementations. The existence and high level of maturity of the modeling techniques and of the tools is in turn a consequence of the wide range of applications that need control algorithms.

A model-driven approach would, however, be unsuitable to cover functionalities such as the management of satellite sensors or the processing commands from the ground station. These functionalities are entirely specific to the satellite domain and this domain is too narrow to justify the effort required to develop dedicated modeling techniques and support tools. In these cases, a reuse-driven approach offers the most effective means to improve the efficiency of the software development process.

In general, the reuse-driven approach is appropriate wherever there is a need to model and implement functionalities that are specific to a particular domain. This is due to the high cost of developing industrial-quality model-driven environments. This type of tools only makes economic sense for functionalities that are widely used, namely for functionalities where there is a sufficiently large base of potential users to justify their development costs. In other cases, reuse-driven approaches remain the only viable option.

The model- and reuse-driven paradigms are considered in greater detail in the next two sections (Sects. 22.2 and 22.3). The model- and reuse-driven approaches represent the state of the practice. Section 22.4 extends the discussion to consider some current research trends.

22.2 Model-Driven Software Development

22.2.1 The Matlab Suite (Matlab/Simulink/Stateflow, Real-Time Workshop Embedded Coder)

The prototypical example of model-driven development in the control and automation field is the Matlab tool suite. This consists of Simulink and Stateflow as toolboxes for programming of continuous time, discrete-time systems, and state machines in graphical form and of the Real-Time Workshop to generate C code from Simulink and Stateflow models. This is a well-known solution, well covered on the World Wide Web (WWW) with many ex-

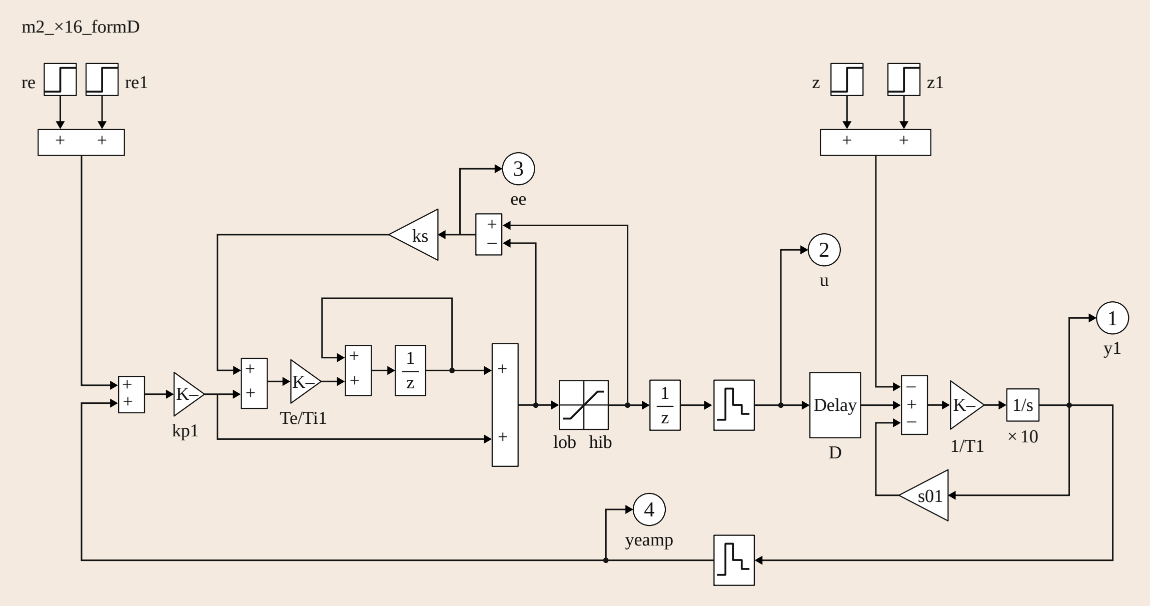

Fig. 22.4 Simulink diagram

amples and will for this reason not be treated in any detail here (see http://www.mathworks.com/ and http://www.mathworks.com/products/rtwembedded/).

A very useful fact worth mentioning here is that Simulink/Stateflow diagrams are stored in textual form and can be analyzed independently of the interpreter, which can also be replaced by other compilers or interpreters. One such case will be mentioned later.

Figure 22.4 shows a typical Simulink diagram of a nonlinear sampled data control system from [22.6].

22.2.2 Synchronous and Related Languages

Behind any model-driven environment there is a language that provides high-level abstractions allowing the designer to express his design. In the case of the Matlab tool suite, this language is hidden from the user, who only interacts with a graphical interface. In other cases, the designer is instead expected to make direct use of the modeling language.

Synchronous languages are one of the most successful families of modeling languages for control and automation systems. Their main strength is that the synchronous paradigm makes it easier to build verification engines that can automatically verify that a model satisfies certain functional properties. The development process then becomes as follows. The designer first builds a model that is intended to satisfy certain requirements. He then translates his initial requirements into functional properties expressed in a suitable formalism. The verification engine can then verify that the model does indeed implement the requirements. After successful verification, a code generator is used to translate the model into source code in a general-purpose language (typically C).

Several imperative and declarative synchronous languages have been developed following a data flow model of computation [22.7]. This is well adapted to the way in which control engineers model their systems by block diagrams. All the languages must have special constructs for time, concurrency, sequences of values (signals, flows), shift operators etc.

The language Lustre and its industrial version SCADE use data flow models well known to control engineers and all calculations are based on flows (signals). Esterel is an imperative language in the same domain, and Signal is another language more suitable for the design of systems.

Efforts are under way to generate Lustre programs automatically from subsets of Simulink and Stateflow descriptions [22.8]. This makes programs in Simulink/Stateflow accessible to formal analysis.

SCADE from Esterel Technologies [22.9] offers tools for the design and verification in the area of safety critical systems. A very simple example of a standard

Fig. 22.5 SCADE environment with a very simple example

control loop in a SCADE development environment is shown in Fig. 22.5.

A slightly different approach is taken by Giotto, a time-triggered language for embedded programming [22.10]. Here, the focus is to specify exactly the real-time interactions between the software components and the physical world.

22.2.3 Other Domain-Specific Languages

A more general version of the model-driven approach is the following: Given a problem area, design and implement a specific modeling language for this area, including an environment for editing, compilation etc. This procedure has special relevance at ETH, where Wirth designed and implemented many languages of general (Pascal, Modula, Oberon) and also of a more specific nature (Lola, a logic language). Worth mentioning here is Active Oberon by Jürg Gutknecht, an object-oriented language where every object can have an integrated thread of control. This high parallelism is of special interest for reactive systems. The next example will provide more information on this approach.

The IEC 61131 languages have been designed for use in automation. IEC 61131 is an International Electrotechnical Commission (IEC) standard for programmable logic controllers (PLCs). IEC 61131 specifies the syntax and semantics of a unified suite of programming languages for programmable controllers (PCs). These consist of two textual languages, IL (instruction list) and ST (structured text), and two graphical languages, LD (ladder diagram) and FBD (function block diagram). Sequential and parallel processing are possible. The standard is developed at http://www.plcopen.org/, where more information can be found.

22.2.4 Example: Software for Autonomous Helicopter Project

The autonomous helicopter project of ETHZ [22.11] is a typical example of a system where special languages were developed by Wirth and Sanvido for several tasks of the onboard processor. The operating system uses threads instead of tasks [22.12] for speed-up, the logic language Lola [22.13] is used for the design of field-programmable gate arrays (FPGAs), and the mission control language is used for missions. An excerpt from a program in the mission control language is easily readable, as shown in Fig. 22.6.

The controller for the helicopter has also been implemented in Giotto [22.14].

22.3 Reuse-Driven Software Development

22.3.1 The Product Family Approach

Within the reuse-driven paradigm, software product families have emerged as the most successful form of software reuse. A *software product family* [22.15] is a set of applications that can be constructed from a set of shared software assets. The shared assets can be seen as generic *building blocks* from which applications in the family can be built. Usually, a product family is aimed at facilitating the instantiation of applications within a narrow domain. Figure 22.7 illustrates the concept of product family. On the left-hand side, the building blocks offered by the product family are shown. These building blocks are used during the *family instantiation process* to construct a particular application within the family domain.

Product families are characterized by two distinct development processes (Fig. 22.8). In the *family creation process*, the family's reusable assets are designed and developed. In the *family instantiation process*, the reusable assets offered by the family are used to construct a specific application within the family domain.

The family creation process is in turn divided into three phases. In the *domain analysis phase*, the set of applications that must be covered by the family are identified and characterized. The output of this phase is a domain model. In the *domain design phase*, the reusable assets that are to support the instantiation of applications within the family are designed. The output of this phase is one or more models of the family assets. The models express various aspects of the domain design (e.g., there may be functional models, timing models, etc.) In the *domain implementation phase*, the family assets are implemented as concrete building blocks that can be used towards the construction of family applications.

Often, the implementation of the family assets is done automatically by processing the models defined in the domain design phase.

Three matching phases can be identified in the family instantiation process (bottom half of Fig. 22.8). In the *requirement definition phase*, the family domain model is used to verify whether the target application falls within the family domain. This decides whether the family assets can be used to help build the application. If this is the case, a sizable proportion of the application requirements can be expressed in terms of the domain model, for instance by identifying the features in the family domain that are needed by the target application. In the *tailoring phase*, the software assets required for the target application are selected from among those

```
PLAN Example;

END Example.
```

Fig. 22.6 Code for helicopter control

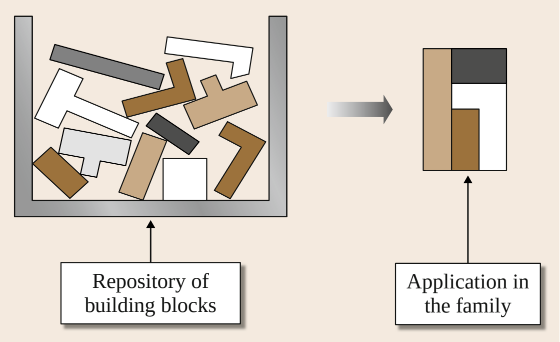

Fig. 22.7 Software product families

offered by the family. They are then adapted and configured to match the needs of the target application. Depending on how the family assets are organized and implemented, adaptation and configuration can be done either at the level of the asset models, or at the level of the implemented assets. Finally, in the *integration and testing phase*, the target application is constructed by assembling the configured and adapted building blocks offered by the framework. Usually, some integration with building blocks that are external to the family is also required in this phase.

22.3.2 The Software Framework Approach

The product family concept is very general and does not imply any assumptions about the nature of the building blocks (Are they components? Procedures? Code fragments? Design models?) or about their mutual relationships (Can they be used independently of each other or are they embedded within a higher-level structure?). The software framework concept particularizes the family concept. A *software framework* [22.16] is a kind of product family where the reusable building blocks consist of software components embedded within an architecture optimized for the target domain of the framework. Thus, a software framework is a particular way of organizing the shared assets of a software product family in the sense that it defines the type of building blocks that can be provided by the product family and it defines an architecture within which these building blocks are to be used.

Figure 22.9 recasts Fig. 22.7 to illustrate the concept of software framework. The figure highlights the fact that the family reusable assets (the building blocks in the repository) are now organized as a set of interacting entities embedded within an architecture that is itself reusable. The framework approach, in other words, allows the reuse not only of the individual items but also of their mutual interconnections (the latter being an important and often neglected added value).

Frameworks are component based in the sense that the reusable building blocks consist of software components. The term *component* is used to designate a software entity with the following characteristics:

- It can be deployed as a stand-alone unit (hence it owns a clear specification of its *required interface*).
- It provides an implementation for one or more interfaces (hence it owns a clear specification of its *provided interface*).
- It interacts with other components exclusively through these (required and provided) interfaces.

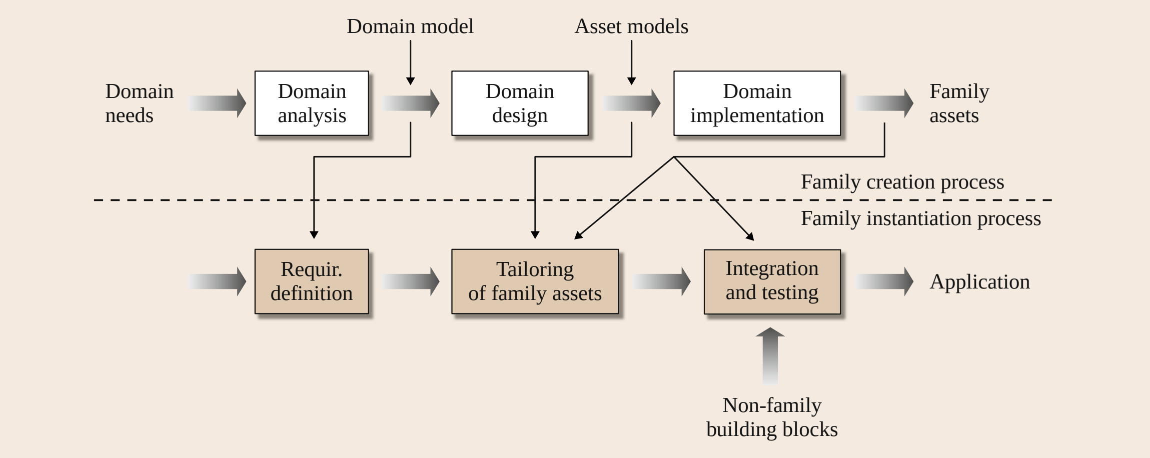

Fig. 22.8 Development process for software product families

The architecture predefined by the framework is defined by the set of interfaces that are implemented by the framework components. Thus, a software framework could also be defined as a product family whose reusable building blocks consist of components and interfaces. The interfaces define the architecture within which the components are to be used. The components encapsulate behavior that is factored out from all (or at least a sizable proportion of) applications in the framework domain.

Still another view is possible of what constitutes a building block of a software framework. This view sees a building block as a *unit of reuse*. At its most basic, the unit of reuse of a component-based framework is a component. This follows from the fact that one of the distinctive features of a component is that it is deployable as a stand-alone unit. The components provided by a software framework, however, are embedded within an architecture (which is also defined by the framework). Hence, users of the framework are likely to focus their attention not on individual components but on groups of cooperating components that, taken together, support the implementation of some function that is important within the framework domain. In fact, well-designed frameworks encourage this higher granularity of reuse by being organized as a bundle of functionalities that users (the application developers) can choose to include in their applications. Inclusion of such functionality implies that a whole set of cooperating components and interfaces are imported into the application. The true unit of reuse – and hence, according to this view, the true building block – is precisely such a set of components and interfaces.

An example may help clarify the above concept. Consider a software framework for satellite onboard applications. One typical functionality that is often found in such systems is the storage of key housekeeping data on a mass-memory device. Accordingly, the software framework would implement default mechanisms for managing such devices. This would probably be done through a set of cooperating components and interfaces. Application developers who need the mass-memory functionality for their target application and who decide to implement it with the help of the assets provided by the framework will import the entire set of components and interfaces. Use of individual components or interfaces is unlikely to make sense because the components and interfaces are specifically designed to work together within a certain architecture. The building block in this case is the set of components and interfaces that support the implementation of the mass-memory functionality.

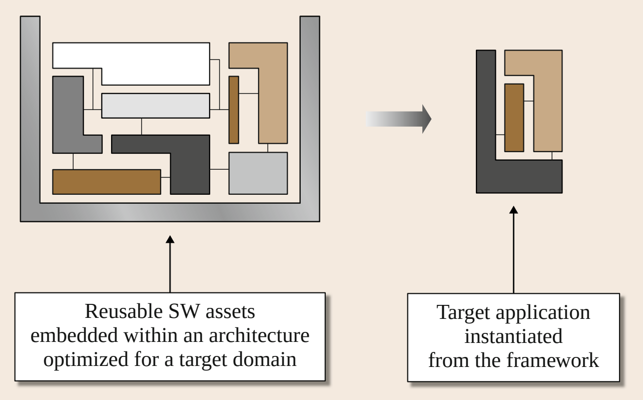

Fig. 22.9 The software framework concept

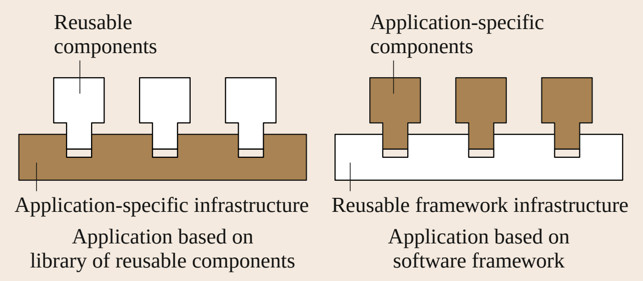

Fig. 22.10 Software frameworks and libraries of reusable components

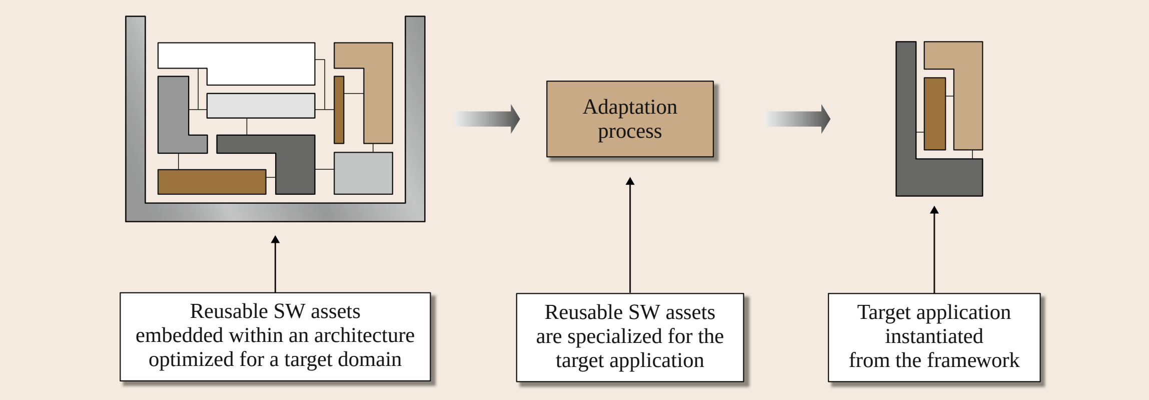
Figure 22.10 provides another view of the software framework concept that illustrates the difference from the more traditional forms of software reuse based on libraries of reusable software components. An application instantiated from a framework consists of a reusable architectural skeleton which has been customized with application-specific components (right-hand side in the figure). An application constructed with the help of items from libraries of reusable components (left-hand side in the figure) consists instead of an application-specific architectural skeleton that uses (calls) the services offered by the reusable components. The framework approach thus places emphasis on the reuse of entire architectures.

22.3.3 Software Frameworks and Adaptability

Software frameworks fall within the reuse-driven paradigm. To reuse a software asset (a component, a fragment of code, a design model, etc.) means to use it in different operational contexts. In practice, differ-



Adaptation process
Reusable SW assets embedded within an architecture optimized for a target domain
Reusable SW assets are specialized for the target application
Target application instantiated from the framework

Fig. 22.11 Software frameworks and adaptability

ent operational contexts will always impose differing requirements on the reusable assets. Hence, effective reuse requires that the reusable assets be *adaptable* to different requirements. In this sense, adaptability is the key to reusability and the availability of software adaptability techniques is the necessary precondition for software reusability [22.17].

The framework representation shown in the previous section should therefore be modified as in Fig. 22.11. The items that are selected from the repository are passed through an adaptation or tailoring stage before being integrated to build the target application. In the tailoring stage, the characteristics of the reusable assets are modified to make them match the requirements of the target application.

Software reuse is perhaps the oldest approach to the reduction of software costs and has often been tried in the past. Past attempts however had only mixed success primarily because they either ignored the adaptation phase shown in Fig. 22.11 or because the state-of-the-practice adaptation techniques available at the time were not sufficiently powerful to model the extent of variability in the target domain.

A software framework is defined as a repository of reusable building blocks embedded within an architecture optimized for applications within a certain domain. The quality of a software framework largely depends on the ease with which the artifacts it offers – components and interfaces – can be adapted to the requirements of its users. Software frameworks are therefore categorized on the basis of the adaptation technology they use. Virtually all frameworks built in recent years are object oriented in the sense that they use *inheritance* and *object composi-*

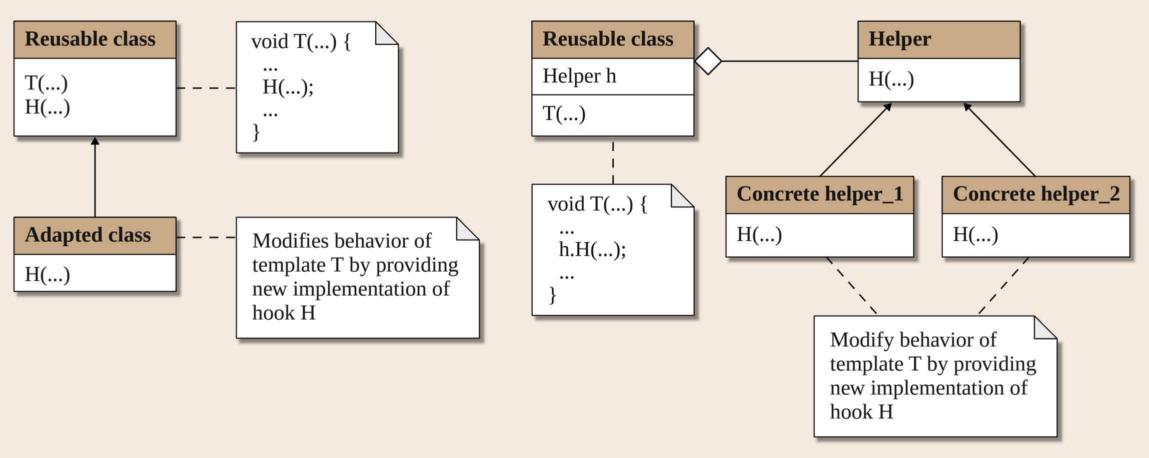


Fig. 22.12 Adaptability through inheritance (*left*) and object composition (*right*)

tion through abstract coupling as their chief adaptation techniques.

These two adaptation techniques are briefly illustrated in Fig. 22.12. The framework components are implemented as reusable classes. Inheritance (left-hand class diagram in the figure) allows a user to modify only a subset of the reusable class behavior. Object composition (right-hand class diagram in the figure) lets the reusable class delegate part of its behavior to an external class that is characterized through an abstract interface. It is notable that, in both cases, the behavior of the reusable class is adapted without touching its source code. This is important because it means that the reusable class can be qualified once at framework level and can then be adapted to different operational situations without having to undergo a full requalification process because its source code was not changed. Some delta qualification effort will always be required because of the different operational context but its extent will be more limited than would be the case if the adaptation had required manual modifications to the source code.

Object-oriented techniques provide adaptability with respect to functional requirements only. Control applications however are characterized by the presence of nonfunctional requirements covering issues such as timing, reliability, observability, testability, and so forth. The lack of techniques to model nonfunctional adaptability was one of the prime causes of the low level of reuse in the control domain. Recently, aspect-oriented programming (AOP) has emerged as a remedy for this problem.

Aspect-oriented programming [22.18] is a software paradigm that allows cross-cutting concerns to be expressed and implemented in a modular manner. At the most basic level, aspect-oriented techniques can be seen as a means to perform automatic transformations of some base source code. An aspect-oriented environment consists of two primary items: an *aspect language* and an *aspect weaver*. The aspect language allows the cross-cutting concerns to be specified and encapsulated in self-contained modules. The aspect weaver is a compiler-like tool that reads an aspect program and projects the changes it specifies onto some base code. This is illustrated in Fig. 22.13.

Current software engineering practice privileges the modeling of the functional aspects of an application. Most software modeling tools are accordingly designed to decompose a software system into functional units (which, depending on the implementation technology, can be modules, classes, objects, etc.). Nonfunctional issues tend to cross-cut such functional models and cannot therefore be easily dealt with. Aspect-oriented techniques can be used to encapsulate them and to facilitate their modeling and implementation. The use of aspect-oriented techniques, in other words, allows the application of the principle of separation of concerns to the nonfunctional aspects of a software system. As such, aspect-oriented techniques provide the means to achieve adaptability to nonfunctional requirements. Aspect-oriented techniques are very powerful but they are comparatively new and tool support is weak. One AOP tool that deserves mention because it is specifically targeted at critical systems is XWeaver [22.19]. XWeaver is a source-level weaver that allows source code to be modified in a controlled way that is designed to mimic the effect of manual modifications and to allow code inspections and other quality checks to be performed on the modified code.

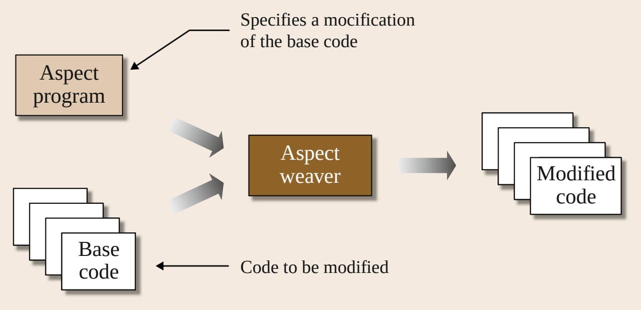

Fig. 22.13 Adaptability through aspect-oriented techniques

22.3.4 An Example: The OBS Framework

The on-board software (OBS) framework was partly developed at ETH and partly at P&P Software GmbH (a research spin-off of ETH) to investigate the application of advanced software engineering techniques to the development of embedded control systems. The framework currently exists only as a research prototype that has been instantiated in laboratory experiments.

The OBS framework was intended to demonstrate the industrial maturity of object-oriented techniques and generative technique [22.19, 20] for software frameworks for embedded control systems [22.20, 21].

The OBS framework was designed in 2002. The OBS framework is a software framework that aims to cover the onboard satellite application domain and in particular the attitude and orbit control system (AOCS)

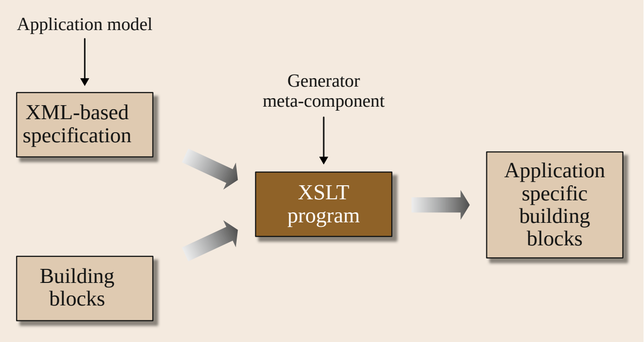

Fig. 22.14 Conceptual structure of a framework-based generative system

and data handling subsystems. The OBS framework is designed to offer reusable assets of four different types:

- *Design patterns* that describe high-level design solutions to recurring design problems in the framework domain
- *Abstract interfaces* that define abstract services that have to be provided by the framework
- *Concrete components* that provide default implementations for some of the services defined by the framework interfaces
- *Generator metacomponents* that encapsulate programs to generate application-specific implementations for some of the framework interfaces.

The design patterns are the vehicle through which the architecture predefined by the framework is captured. The architecture of a target application to be instantiated from the framework is derived by instantiating one or more framework design patterns. The abstract interfaces and the concrete components support the instantiation of the design patterns and will normally directly appear in the target application. The metacomponents do not directly enter the final application but are instead used to generate components that do, or to modify existing components so as to make them compatible with the requirements of a particular target application.

Generator metacomponents are perhaps the most innovative element of the OBS framework. They were introduced to partially automate the adaptation process whereby the assets provided by the framework are modified to match the needs of a target application. In the OBS framework, generator metacomponents are implemented as extensible stylesheet language transformation (XSLT) programs that process a specification written in extensible markup language (XML) and generate either code for the application-specific component or the configuration code for clusters of components. Their mode of operation is illustrated in Fig. 22.14.

The code generation process is driven by a set of specifications that are expressed in an XML document. This is the so-called application model which is a specification of the target application expressed in an XML-based language that is specifically tailored to the needs of the OBS framework.

One concrete example of generator metacomponents provided by the OBS framework is a set of XSLT programs that can automatically generate a wrapper for the code generated by the Matlab tool. The wrapper transforms the C routines generated by Matlab into components that are suitable for integration with other OBS framework components.

The architecture of the OBS framework is fully object oriented. The basic principles of this architecture are summarized in [22.21, 22]. Implementation is done using a restricted subset of C/C++. The OBS framework is packaged as a website which gives access to all the items provided by the OBS framework and to their documentation (www.pnp-software.com/ObsFramework).

22.4 Current Research Directions

As already indicated, the reuse- and model-driven approaches are complementary and are often used to realize different parts of the same application. Current research strengthens this complementarity because it tries to find ways to merge them. There are several ways in which such a merge can be done and the next two sections describe two ways that have been explored at ETH.

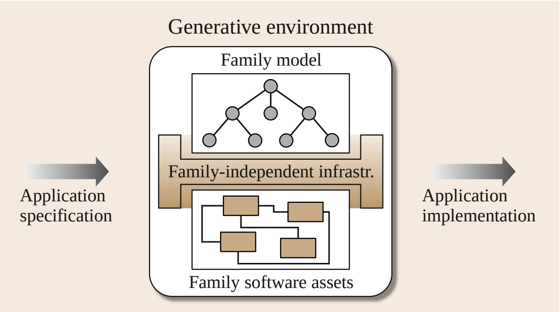
22.4.1 Automated Instantiation Environments

The effectiveness of the product family approach derives from the fact that the level of design abstraction is raised from that of individual applications to that of domains of related applications. This allows investment in the design and development of software assets to be reused across applications. Current research attempts to extend the effectiveness of product families further by automating their instantiation process. The objective is to arrive at a generative environment of the kind shown in Fig. 22.15. The environment automatically translates a specification of an application in the family domain into a configuration of the family assets that implements it.

An environment of the type shown in Fig. 22.15 would represent a synthesis of the model- and reuse-driven approach because it would allow the target application to be constructed automatically from its specification while at the same time taking advantage of the existence of predefined building blocks that implement part of the application functionality.

No practical generative environment is yet available, but some work has already been done in developing graphical user interface (GUI)-based tools where predefined components can be configured and linked together to form a complete application. A research prototype has been realized at ETH [22.23] and is described in [22.24, 25]. This tool is based on a modified version of a standard JavaBeans composition environment.

The JavaBeans standard [22.22] supports the definition of components to create GUI-based applications. Several commercial environments are available in which users can create GUI-based applications by composing JavaBean components. At their most basic, these environments offer a palette where the predefined components are shown, a canvas where the components can be linked together, and a property editor where the components can be configured. The user selects the components required for the application from the palette and pulls them down onto the canvas, where they can be linked through graphical or semigraphical operations. The attributes of the component are set in a wizard-like property editor.



Generative environment
Family model
Family-independent infrastr.
Family software assets
Application specification
Application implementation

Fig. 22.15 Automated instantiation environment for software product families

In our project, we modified a JavaBeans composition environment to handle the components provided by the AOCS framework (a predecessor of the OBS framework described in Sect. 22.3.4, see also [22.26]). The objective was to allow users to instantiate the framework without writing any code. The user selects the components required for the target application from a palette and composes and configures them in a GUI-based canvas and editor. When the task is completed, the framework instantiation code is automatically generated by the environment. The code is designed to be legible to allow manual modifications if required.

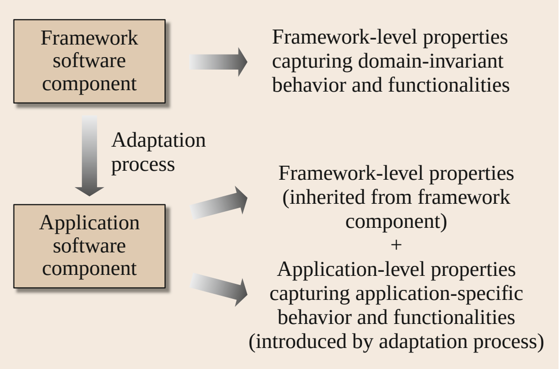
22.4.2 Model-Level Reuse

Automated instantiation environments represent one way in which the model- and reuse-driven paradigms can be merged. A second attempt to achieve the same goal of merging the two approaches and thus reaping the benefits of both is model-based reuse. In virtually all industrial applications of the framework approach, reuse takes place at code level: the reused entities are the framework components and the framework interfaces expressed as source code (or, sometimes, as binary entities). In reality, reuse could also take place at model level.

With reference to Fig. 22.8, in a framework development process, the output of the domain design phase is a set of design models that describe the framework interfaces and components. In practice, such design models are often expressed as generic universal modeling language (UML) design models [22.27, 28]. The semantics of UML is in many respects ambiguous. This means that the models can, at most, have a descriptive/informative role. Reusability can only take place at the code level because it is only the code that unambiguously describes the reusable assets provided by the framework.

The latest version of UML (UML2) includes profiling facilities that allow users to create their own version of the language with a precise semantics [22.29, 30]. This in turns means that the design models can be made as precise as code. In fact, it becomes possible to fully generate the implementation of the framework assets from their models. In this case, reuse can take place at the model level since the models contain the same information as the code.

Such a model-driven approach is being explored at ETH in the ASSERT project [22.31] and is described in [22.32]. It is being applied to industrial applications by P&P Software in the currently ongoing CORDET project (www.pnp-software.com/cordet). The approach



Framework software component

Adaptation process
Application software component
Framework-level properties (inherited from framework component)
+
Application-level properties capturing application-specific behavior and functionalities (introduced by adaptation process)

Fig. 22.16 Property-preserving framework adaptation

is based on a UML2 profile, the framework *(FW) profile*, that is specifically targeted at framework development [22.33]. This profile uses UML2 class diagrams to describe the interfaces of the framework components and UML2 state machines to describe their internal behavior. The profile also defines adaptation mechanisms that are based on both class and state machine extension.

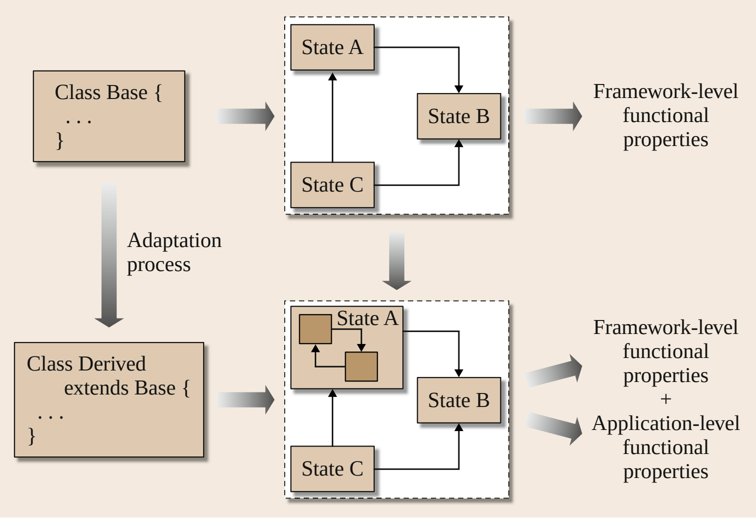
A framework is conceptualized as a repository of *models* (not code) of adaptable components. The framework-level models guarantee certain *properties* that represent functional invariants in the framework domain. Since the properties are associated to the design models, they can, if desired, be formally verified on the models.

The FW profile constrains the adaptation mechanisms of the models to ensure that the properties that are defined at framework level still hold at application level. This ensures that all applications that are instantiated from the framework will satisfy the properties defined at framework level. At application level, developers are of course free to add new properties that encapsulate application-specific behavior (Fig. 22.16).

Space does not permit to explain in detail how property invariance can be combined with extensibility and adaptation, but Fig. 22.17 gives a flavor of the approach. The top half of the figure represents the framework-level models which, as mentioned above, consist of class diagrams and state diagrams describing the internal behavior of the framework classes.

The framework-level properties express logical relationships among the variables that define the state of one or more framework components. Formally, functional properties may be expressed as formulas in linear temporal logic. Physically, they encapsulate functional invariants in the framework domain. In practice, the framework properties are defined as properties on the behavior of the state machines associated to the framework classes.

During the framework instantiation process, the framework-level models are extended to capture application-specific behavior. Both the framework classes and their state machines must be extended. However, since it is desired to ensure that applications that use the extended models still satisfy the properties defined at framework level, the extension mechanism must be such that the new classes and their state machines still satisfy the properties that were defined at framework level.



Class Base {
. . .
}

Class Derived extends Base {
. . .
}
State A
State B
State C
Framework-level functional properties
+
Application-level functional properties

Fig. 22.17 Class extension and state machine extension

The properties defined on the base state machine capture aspects of the state machine topology and of its state transition logic. Hence, the simplest way of preserving them during the extension process is to constrain the extension process to define the internal behavior of one or more of the states of the base state machine without altering its topology and transition logic. This is illustrated in Fig. 22.17, where the derived state machine differs from the base state machine only in having an embedded state machine added to one of the base states. The derived state machine, in other words, defines the internal behavior of a state that was initially defined as being a simple state.

The FW profile adopts the extension approach of Fig. 22.17 and forbids all other kinds of state machine extensions that are allowed by UML2 (redefinition of transitions, definition of new transitions between existing states, definition of new states or regions, etc.).

The extension mechanism sketched above, though very simple, corresponds to a realistic situation that often arises in framework design. This is the case that is described by the well-known template design pattern of [22.34]. This design pattern describes the case of a class that defines some skeleton behavior that offers hooks where application-specific behavior can be added by overriding virtual methods or by providing implementation for abstract methods. The behavior encapsulated in the skeleton is intended to be invariant.

In terms of the model underlying the FW profile, the invariant skeleton behavior is encapsulated by the base state machine, whereas the variable hook behavior is encapsulated by the nested state machines added by the derived class.

The modeling and adaptation concept sketched above is formally captured by the FW profile. The profile can also be seen as a domain-specific language that is targeted at the definition of the functional behavior of software frameworks. This approach thus has all the basic elements of both the model-based approach (design expressed through models with unambiguous semantics and use of domain-specific languages to express the models) and of the reuse-driven approach (definition of domain-specific, reusable, and adaptable software assets).

22.5 Conclusions and Emerging Trends

Software for automation has some inherent difficulties, such as real-time conditions, distributed and parallel operation, easy-to-use interfaces, data storage and reporting, etc.. The software often has to be implemented on one-of-a-kind processes or plants requiring a highly automated development. Two possible routes, which are often combined in practical solutions, have been presented in this chapter. One consists of automatically generating code from a textual or graphical description of the software (model driven) and the other consists of the use of frameworks (reuse driven). Both have their application domains; the framework approach seem to be better suited for the development of software for families of systems because of its inherent possibility of adaptation. Examples of both approaches from our work at ETH are given. Design of software is a challenging task; easy recipes and cookbooks are in our view not appropriate, and no attempt has been made in this direction.

While consulting tasks with industry are proprietary, a considerable shift has been noted over the last few years in the area of software development towards outsourcing and consulting services. Many small companies offer solutions, which often compete favorably with in-house solutions. In such circumstances, it may be advisable to order a framework instead of a program. To use existing frameworks provided under free or open software licences it may also be advisable to organize some training or consulting to speed up the development. The management of such software projects with several contributing teams is, however, still a challenging task.

23. Real-Time Autonomic Automation

Christian Dannegger

The world is becoming increasingly linked, integrated, and complex. Globalization, which arrives in waves of increasing and decreasing usage, results in a permanently dynamic environment. Global supply networks, logistics processes, and production facilities try to follow these trends and – if possible – anticipate the volatile demand of the market. This challenging world can no longer be mastered with static, monolithic, and inert information technology (IT) solutions; instead it needs autonomic, adaptive, and agile systems – living systems. To achieve that, new systems not only need faster processors, more communication bandwidth, and modern software tools – more than ever they have to be built following a new design paradigm. As determined by the industrial and business environment, systems have to mirror and implement the real-world distribution of data and responsibility, the market (money)-driven decision basis for all stakeholders in the (real or virtual) market, and the goal orientation of people, which leads to on-demand, loosely coupled, communication with relevant partners (other players, roles) based on reactive or proactive activities.

This chapter provides an insight into the core challenges of today's dynamics and complexity, briefly describes the ideas and goals of the new concept of software agents, and then presents and discusses industry-proven solutions in real-time environments based on this distributed solution design.

The following examples are discussed in detail in this chapter, covering the solution approach, challenges, and customer demand as well as relevant pros and cons:

- An autonomic machine control system applied to the adaptive control of a modular soldering machine. The particular case is concerned with the creation of a novel modular production machine with an integrated distributed agent control system, which has been sold worldwide since the middle of 2008. The agent model is described in terms of the specific customer requirements and the advantages of the approach.

- A solution to real-time road freight transportation optimization using a commercial multiagent-based system, LS/ATN (living systems adaptive transportation networks), which has been proven through real-world deployment to reduce transportation costs for both small and large fleets. After describing the challenges in this business domain and the real-time optimization approach, we discuss how the platform is currently evolving to accept live data from vehicles in the fleet in order to improve optimization accuracy. A selection of the predominant pervasive technologies available today for enhancing intelligent route optimization is described.

Both examples reflect their specific history and background, which motivated the customer and the developers to apply an autonomous automation approach.

Although software agents are a core principle of the autonomous automation examples in this chapter we only touch this field slightly, as other chapters in this book focus and elaborate on agent-based automation.

23.1 Theory

23.1.1 Dig into the Subject

First let us briefly delve deeper into the title of this chapter *Real-Time Autonomic Automation*, from right to left.

Automation always has been – and still is – the basic starting point to relieve workers of routine tasks and increase the utilization of resources, because of production machinery, transportation capacity, and limited material stock. Automation means using any kind of mechanical device or program to carry out a repetitive job faster, more reliably, and with higher quality than human beings can normally achieve. According to Wikipedia [23.1]:

> *Automation (ancient Greek: self dictated) ... is the use of control systems such as computers to control industrial machinery and processes, reducing the need for human intervention.*

Autonomic is already a term very close or even similar to the term *agent-based*. In many aspects both describe the same characteristics. Autonomic systems firstly have sensing capabilities to keep in touch constantly with their environment and *know what's going on* (belief). Then they know what they want – their purpose – their goals (desire). And finally autonomic systems are able to derive and decide what to do (intention) based on the current situation and predefined goals. Putting together these terms results in belief–desire–intention (BDI), which is a software model developed for programming intelligent agents. To again cite Wikipedia:

> *An autonomic system is a system that operates and serves its purpose by managing its own self without external intervention even in case of environmental changes.*

The last part of this definition gives the important hint that autonomic systems in particular are able to adapt to changes in the environment (making use of their sensors) in order to decide constantly on the best action according to the current situation.

Real time is a critical term, as it is used ambiguously and greatly depends on the environment in which it is applied. The main differentiation made is between hard and soft real-time systems. *Hard* real-time systems guarantee a configured time from an event to system response, since otherwise the whole system will fail, e.g., in brake control for cars or tail plane fin control for a jet fighter. However, hard real-time control could also apply to comparably *slow* systems as long as the response is guaranteed, such as a heating control where the reaction may take several minutes. *Soft* real-time control means that a system is typically fast enough to react in due time. Deadlines are normally met, but if not kept the system will not fail, but at most lose some quality; for example, in dispatching systems real-time reaction is important, but if a decision (to reshuffle order allocations) is delayed there might be a loss of efficiency and increased costs, but the system does not fail as a whole.

Since distributed systems such as those discussed specifically in this chapter require solutions supporting heterogeneous environments, developers of such systems are attracted by the platform independency of Java. Since its invention, Java has become increasingly fast, but does not have built-in real-time capabilities. Thus the real-time specification for Java (RTSJ, JSR-001 (Java specification request)) has been developed and implemented by Sun and others as an add-on to standard Java, and offered to the market as *real-time Java* or the Java real-time system (Java RTS). On their website Sun gives another short and concise definition of *real time*, which again emphasizes the difference between speed and predictability: "Real-time in the RTSJ context means the ability to reliably and predictably respond to a real-world event. So real-time is more about timing than speed." Additionally to a real-time programming environment a real-time operating system is needed, like Solaris 10, SUSE Linux Enterprise Real-Time 10 (SP2) or Red Hat Enterprise MRG 1.0.1 Errata releases.

Both examples described in this chapter do not fulfill and do not need to fulfill the hard real-time specification. Why? The second example is a decision support system for transport optimization where the dispatchers can still decide and become active independent of the systems, as with a navigation system. The first example has to fulfill hard real-time requirements, but the system design succeeded in keeping the critical real-time parts within the local controller of each module of the machine and thus outside the Java-based control logic. With this approach the control system where the system is normally fast enough to trigger the actuators and the reaction guarantee is given by the lowest-level controllers, the machine manufacturer could save significant costs by being able to use standard hardware, a standard operating system, and a standard runtime environment (Java SE).

Real Time through Autonomy

If hard real-time support will be needed in the future, this does not conflict with the system layout – quite the contrary: autonomous agent-based systems are initially designed to build real-time control systems. The major design principle to enhance real-time capabilities is the natural and elementary separation of responsibilities, and thereby the distribution of tasks. This design for scalability allows making use of all (local) processing power available in a solution and system environment. Keeping local tasks and local decisions entirely local results in high reactivity, independent of the overall system load.

23.1.2 Optimization: Linear Programming Versus Software Agents

To make things even more complex the real world has given us not only the challenge of real-time reactivity but also the parallel goal of optimal decisions (or at least decision support). This means that a software system not only has to cope with very complex, normally NP-hard (nondeterministic polynomial-time hard), optimization problems, but also should solve them again and again, building on the second by second changes in the environment. Unfortunately new design paradigms, such as software agents, are always compared with traditional approaches in terms of solution quality, despite the fact that traditional mathematical operation research (OR) methods are not designed to handle real-time events. For this reason the following descriptions summarize the major differences and objectives of both approaches; a more detailed discussion can be found in [23.2].

Linear Programming

Pro. Current optimizers, which means traditional OR methods such as linear programming, are designed to find *the* optimum for a problem, independent of the processing duration.

Con. However, it is very hard and time consuming to cover the full real-world complexity and map all different aspects into a linear equation system, not to mention changes of requirements, processes or business goals. Despite many traditional optimizers try to achieve real-time response, their basic intention to find the absolute optimum works against it. The optimization interval, even combined with tricks and workarounds, is normally too long to be considered real-time.

Result. The optimum can be found, but too late. The world might already have changed dramatically. The optimum was only valid for the past, when the optimization started. The difference between the calculated and the current optimum is large, and the accumulated error between the optimal curve and the found (to be optimal) curve increases significantly over time.

Software Agents

Con. The distributed negotiation approach with its bottom-up search space expansion is not designed to find the optimum.

Pro. Rather, it permanently strives for the optimum, as the optimization interval is very short and the approach maps the real-world complexity in all its details and can be customized to nearly any specific need without touching the core optimization principle.

Result. A close-to-optimal result is found every second or faster. The difference from the theoretical optimum is relatively small and the total error over time is kept to a minimum.

Conclusion

The optimum should not be seen and understood as a single point in time, but instead as the difference between the continuously calculated optimization curve and the real-world volatile optimum. This short excursion to real-time optimization and its application in automated systems is properly summarized in the following two statements: *How does it help knowing what would have been the optimum one hour ago?* Or: *Better be roughly right instead of precisely wrong*.

23.1.3 Classification of Agent-Based Solutions

To understand and correctly apply agent-based solutions it is important to follow a clear classification of software systems. Based on the short agent definition as a *sense–decide–act loop* it is straightforward to classify agent-based solutions (Fig. 23.1) depending on the existence of real-world or artificial interfaces for the sensors and actuators.

Simulation System

If you input only simulated, recorded historical data or forecasted data into an agent solution and only use the system output for analysis but not for direct decisions, then it is a simulation system. This applies, e.g., if real-time captured order data for a dispatching systems are fed into the dispatching system again, mostly for the purpose of verifying the system configuration (i. e., the cost model, see below). The result of the simulation is stored within databases, data warehouses or presented in business graphs, but not used directly to control or

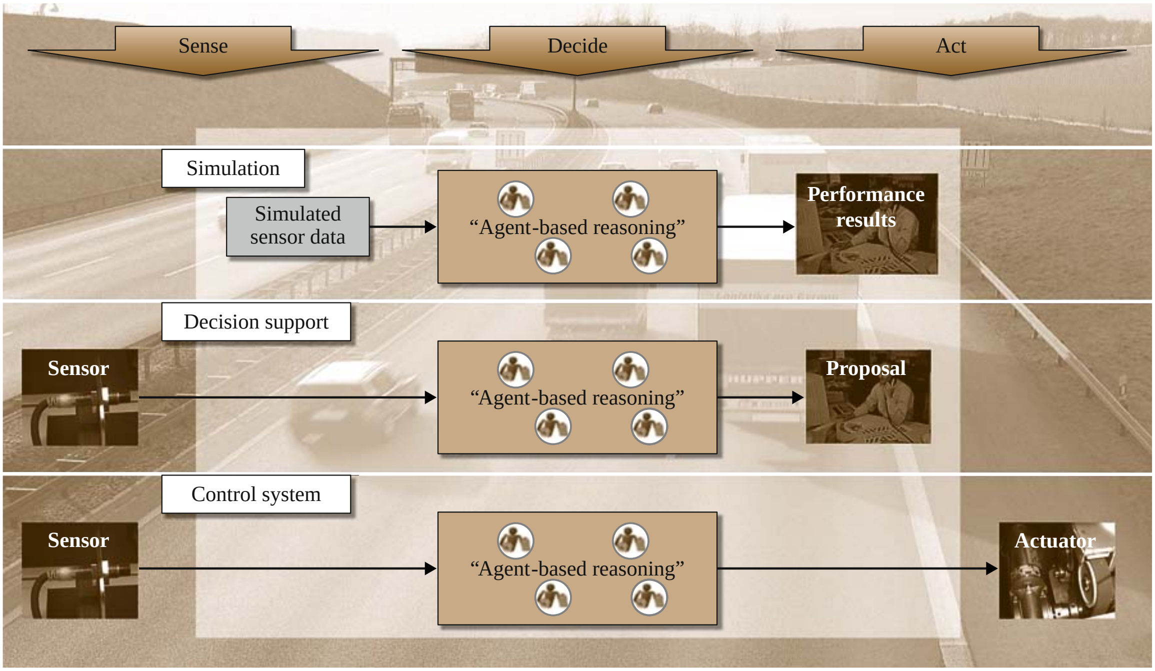

Fig. 23.1 Solution classification: depending on the existence of real-world or simulated sensors and actuators you can distinguish between three system types: simulation, decision support or control system

trigger any actions. It is important to understand that the core of the system – the optimization and decision algorithm – is not simulated, but instead the sensor input and actuator behavior, and hence the real world. Very often it needs even more effort to create a realistic simulation of the world model than *only* implementing the sensor and actuator interfaces.

Decision Support System

If the input is directly linked to real-world sensors (e.g., a telematics system) and the output is only used to support and inform the dispatcher, then we talk about a decision support system. A navigation system is a good example of a decision support system, as its sensors, the GPS (global positioning system) antenna, is directly linked to the real world, the GPS satellites. On the output side, the actions resulting from the best route are not directly executed; the navigation system does not turn the steering wheel. Instead it only suggests to the driver what he/she should do. However, the driver has the final decision.

Control System

If the sensors are real and the output directly executes decisions without human interaction, then it is a closed control loop and thus a control system. One typical representative is the antilock brake system of a car. It automatically – fully autonomic – releases the brake if needed without having the driver in the decision loop. This autonomic behavior is based on at least two different conflicting goals: first to reduce the speed of the car and second to keep the wheels turning.

In each mode of operation the core agent solution is the same; only the real-world interfaces differ. The transportation optimization system described in this chapter is mainly used as a decision support system, but is also used to analyze history and forecasts as a simulation. The discussed machine control system is, as the name implies, a control system, where the results of the decision algorithm directly influence, e.g., the drive speed of transportation belts, heating power, and pump strength.

23.1.4 Self-Management

The ever-accelerating complexity and dynamics of IT systems makes their administration and optimization with only human resources no longer feasible or at times even impossible. Hence, it is reasonable and necessary to equip IT systems with capabilities that increasingly allow them to administrate, monitor, and maintain themselves. These self-management properties of so-called autonomic solutions according to [23.3] are:

Self-configuration: The system automatically changes its operating parameters to adapt to mutable external conditions, some of which may even be unpredictable at the time of a system's development.

Self-optimization: The system continuously assesses its own performance, explores possible courses of actions that would result in performance improvements, and adopts the ones that are most promising.

Self-healing: The system has abilities to recover from certain unfavorable conditions that may result in malfunctions. It autonomously attempts to determine compensation actions and performs them.

Self-protection: The system detects threats against its functioning and takes preventive and corrective measures to ensure correct operation.

This group of properties are often also referred to as *self-properties* or self-* properties.

23.2 Application Example: Modular Production Machine Control

23.2.1 Motivation

Efforts to increase the flexibility of production lines are a pivotal trend in manufacturing. Whole assembly lines as well as individual machines are increasingly subdivided into modules in order to adapt precisely and just in time to constantly changing specifications (quasi make-to-order). An instance of this trend can be also found in microproduction.

However, the centralized, *hardwired* design of traditional control software imposes limits on dealing successfully with unpredictability. It is thus necessary to choose a novel approach to the development of control software, such that it is capable of managing modular machines dynamically and with minimal manual intervention while automatically maximizing the throughput and thereby optimize investment into production resources.

This allows a production line to adapt continuously to changing boundary conditions and order specifications. Such a control system stands out due to its superior flexibility and adaptivity, and drives the automation and optimization of modern production lines further, while at the same time embracing the increasing complexity and dynamics of its environment.

An innovative offering in this area is a key differentiator for all vendors and users of modular production lines. Whitestein's product living systems autonomic machine control (LS/AMC) makes use of these principles and applies them in the modular machine control market.

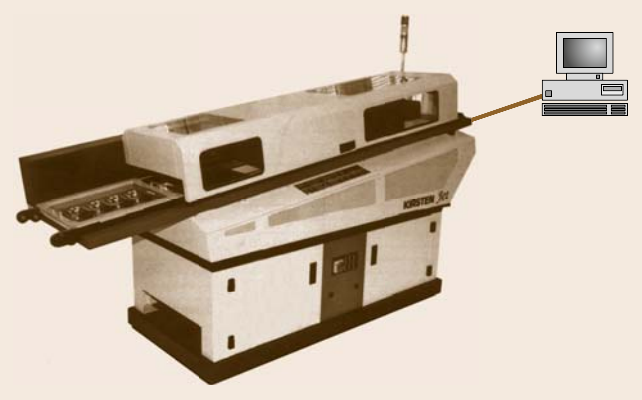

Fig. 23.2 Old machine design: the processing units (modules) are contained within one static monolithic block and centrally controlled

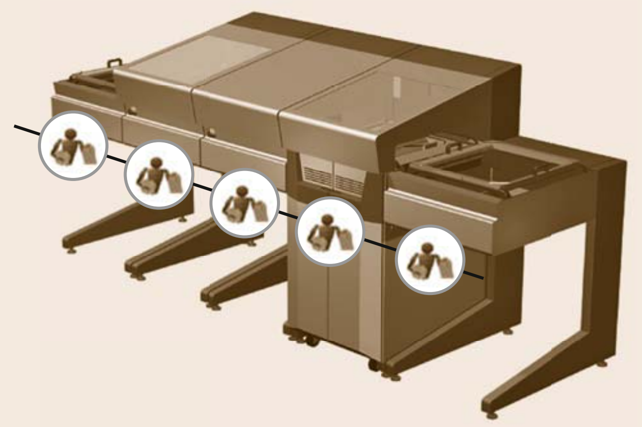

Fig. 23.3 New machine design: each module of the machine is controlled by its own agent

The particular case discussed is a concrete industrial application that entered live production in mid-2008 and is being offered as a solution to the general market.

23.2.2 Case Environment

The particular application case of the LS/AMC control system is a modular soldering machine wherein each module is governed by an independent local agent controller. Coordination of the individual module operational parameters and the transition of boards from one module to another are the key control aspects.

Machine Setup

After many years of successful soldering using a conventional monolithic machine, the project team decided to prepare for the future by initiating a redesign of the centrally controlled machine (Fig. 23.2) as a novel modular approach employing distributed control (Fig. 23.3).

The modular setup of the new design not only allows configuration of the machine according to the customer's needs, but also has a separate local control within each module. The single drive for the one and only conveyor belt also has been replaced by one conveyor and one drive per module. This gives broad processing flexibility, as the target market for this machine typically requires changing production programs in real time.

A typical machine setup is composed of a feeder, a fluxer, one to three heaters, a soldering wave module, and a cooler module.

Sensors and Actuators

Each machine module has several sensors and actuators connected to the local controller board. There are digital switch sensors such as *end-of-belt*, *zero-position*, *emergency-stop*, and *liquid level* as well as linear sensors including *temperature* and *encoder* of step motors. Actuators comprise motors, pumps, and heaters as well as fans and signal lights. Overall a small standard configuration with five modules already contains around 40 sensors and 50 actuators, which have to be managed and coordinated.

Customer Requirements

The goal of using agent technology in this project was to minimize the complexity of development, operation, and maintenance of machines, without reducing the degrees of freedom for future application scenarios. Specifically, this implies:

Autonomic Equipment Adaptation. The control software of a modern production line must autonomically adapt to the ideal equipment configuration for each order. This effectively eliminates the need for manual reconfiguration. It also ensures that future enhancements of the system remain possible with only minor outlay.

Dynamically Varying Solder Programs. Typically this machine is used for batch-size-one tasks, which means that each and every board is processed with different soldering parameters and the boards are processed in parallel, i. e., pipelined.

Dynamic Performance Optimization. The capability to optimize capacities dynamically with changing configurations and target values is a top priority. This ensures maximum throughput and minimizes idle capacities and quality failures.

Seamless Integration Capability. At the macrolevel it is required that the control software for modular production lines such as this offer standard interfaces to integrate into a total production control system.

Intuitive User Interface. Not least, such an advanced solution also needs to provide an intuitive user interface, which automatically adapts to the actual machine setup (Fig. 23.4). It offers simple controls for the machine operator, extended functionalities for specialists and technicians, and comprehensive remote maintenance capabilities via the Web.

23.2.3 Solution Design

Existing Solutions for Agent-Based Control

Whitestein Technologies has applied agent-based distributed control in many related domains throughout recent years. Before describing the path from monolithic to modular agent-based control we give three examples from other areas where distributed optimization is applied. The following examples all make use of multilateral negotiation algorithms to continuously seek optimal solutions.

Production Scheduling. The resources in a production environment including personnel, machines, and materials are represented by software agents that use negotiation algorithms (e.g., auctions) to offer and *sell* their capacity to bidding orders, which are also represented by agents. One of the prominent industry examples is described in [23.4].

Administrator

Fig. 23.4 The modularity of the machine is reflected on the graphical user interface

Road Logistics. To automate the creation of dispatching plans for transportation logistics systems each resource (vehicle) is represented by an agent, which coordinates and exchanges loads with others by making use of bilateral negotiations [23.5]. (See also the next application example.)

Supply Networks. All the players in a supply network continuously need to coordinate their demand forecasts and capacity availability. Agents can assist in this time-consuming and time-sensitive task perfectly. Monitoring agents along the supply chain fire an alarm and trigger activities if reality deviates too much from the plan [23.6].

From Monolithic to Modular Control

As in all previous examples, the LS/AMC-based soldering machine solution uses modular control principles because each module not only needs coordination with neighboring modules but also needs local, autonomic control to optimize the overall process; for example, the heater module must maintain the temperature within tolerance limits irrespective of environmental changes caused by a board running through the module or a user opening a lid. Each module must thus combine its local control tasks with overall process coordination.

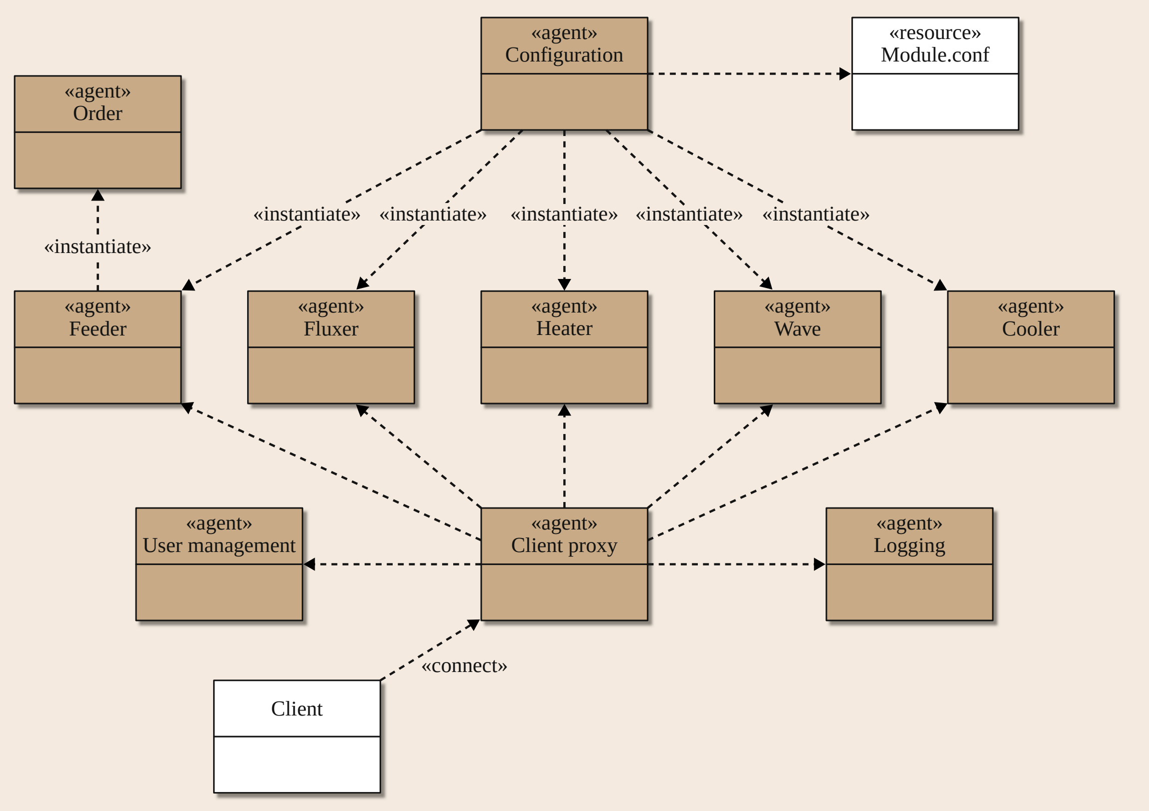

Fig. 23.5 The agent model in AML (agent modeling language)

Modular control also means that each module holds its own production schedule and is able to give a production forecast in a backward-chain manner to enable the feeder module to estimate when best to start a new board. The module agents combine this production planning part with the real-time control when a board physically appears and when target temperatures are reached in reality.

Agent Model

Besides an agent type per physically available module type, the agent model (Fig. 23.5) comprises one agent per order (printed circuit board (PCB) to be soldered) and some administrative agents for user management, configuration management, and client communication. To be precise, an agent in the agent model is an agent type, analogous to a class in object orientation. In a running application an agent is an instance of an agent type and thus correspondent to an object, as an instance of a class. The agent types used within this solution are:

- The *configuration agent* is responsible for detecting the attached modules of a concrete customer machine configuration via the CANopen (CAN: controller area network) bus. It then instantiates the corresponding module agents, where, depending on the detection, several agents of one type might be started, e.g., if two or more heater modules are used.
- One *module agent* type per physical module type, as there are:
  - the *feeder* module
  - the *fluxer* module
  - the *heater* module
  - the *wave* modules, one for the oil and one for the nitrogen version
  - the *cooler* module.

Each of these module agents control their module, e.g., heat up the tin, ensure the needed tin level or keep the temperature stable, and they communicate with neighboring modules for the preliminary and real-time scheduling of the soldering process. New module types will be developed and added to the configuration as needed, e.g., a lift module to bring a board back to the first module of the machine.

The feeder agent has the additional task of instantiating the *order agent* when it detects a new board and the user presses the start button. The order agent then prepares its processing schedule by *talking* to each module agent, and then supervises and logs its soldering process in detail.

The *client-proxy agent* collects and holds all information needed to keep the connected client(s) up to date.

Besides the *logging agent* and the *user-management agent* there are more administrative agents, which are not shown in the agent model diagram for reasons of clarity.

The following are the core features of the implemented agent model.

Autonomic Module Control. Every machine module is represented by a specifically adapted software agent that optimizes the module's operations and capacity utilization.

Superordinate Coordination. Through permanent bilateral negotiation and coordination between neighboring modules (i. e., of their software agents) the system constantly reaches a state of superordinate coordination. This eliminates the need for a central control instance.

Self-Managing Orders. As for every module (resource), software agents are also responsible for the control of each production unit (order). They self-manage the order's progress through the machine(s) autonomously and ensure that all requirements relating to (cost-)efficiency, speed, and quality are optimally satisfied.

Distributed Communication. The decentralized approach based on bilateral communication allows for virtually unlimited scaling possibilities, while at the same time increasing robustness against malfunctions and various external influences.

Standards Compliance. At the controller level the software provides full support for the CANopen industry-standard machine control and communication interface.

Interaction Model

One of the core principles of this solution is to dynamically create one agent per module detected on the CANbus and establish a communication link to the two neighbor agents. Consequently there is no global communication among the agents but only the one on the *left* and the *right* side. This bilateral communication model is very lean but still powerful enough to drive the backward scheduling and real-time synchronization between the modules.

Here is one example of this synchronization task. As each board (production job) and each module has different processing parameters the conveyor belts typically run at different speeds. To ensure clean handover from one to the next module, LS/AMC has implemented a communication protocol (Fig. 23.6) following a notify-and-pull principle, where the *sender* stops and notifies the *receiver* and, as soon as it is ready, the *receiver* sets the receiving speed and then grants the *sender* permission to send at this speed.

23.2.4 Advantages and Benefits

The following advantages are only qualitative. Detailed metrics are not yet available and proven comparisons with other (monolithic) approaches have not been conducted, as this is an ongoing project in its final deployment phase. However, during the course of the development we experienced many of the advantages in real life, and even unexpected ones.

Especially we found the modular design to be extremely helpful in a project like this with moving targets over more than 2 years. The moving target was caused by the learning curve while designing the machine – the hardware itself. Even though sensors, actuators, and their behavior changed every week, the core of the solution has been stable and unchanged since its initial design.

We received more feedback from real life just before the publishing of this Handbook. The machine has been extended for a new customer by two lift modules, two more transportation modules, and a barcode reader. The agent-based design of the solution has shown that it can schedule and optimize the throughput and performance of the machine without any change of the algorithm. The additionally instantiated module agents naturally latched into the processing chain. They coordinated with the *older* module agents to control the soldering process as expected.

At least some of the following – theoretical obvious – advantages have thus been materialized.

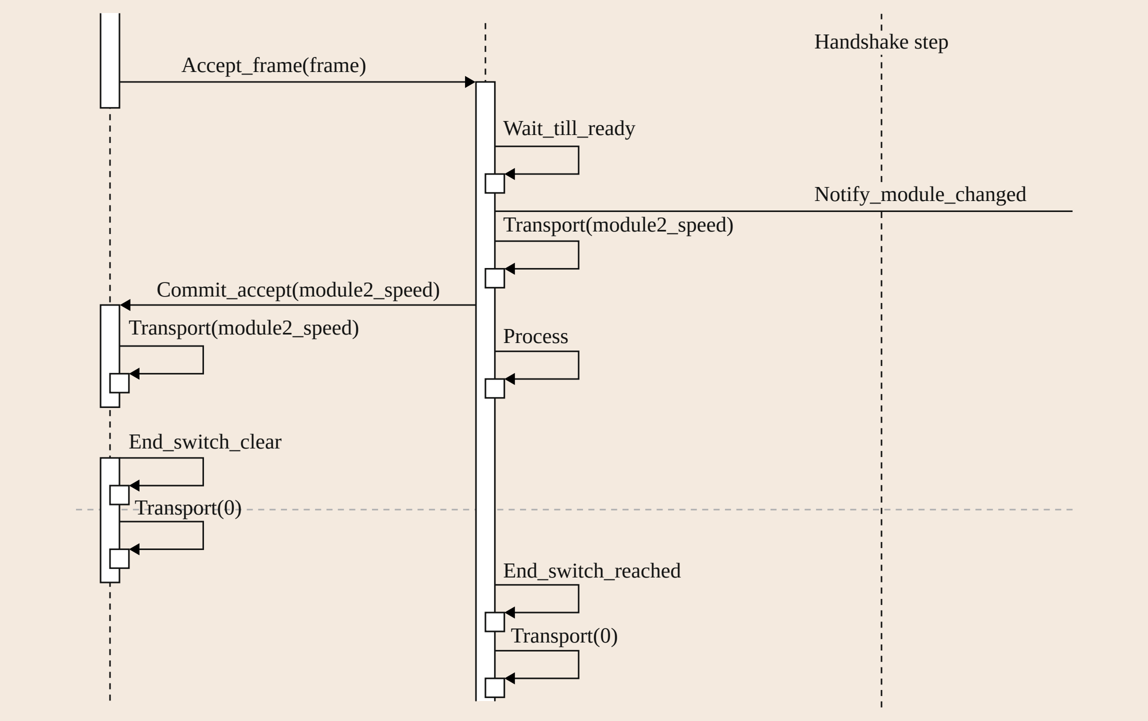

Fig. 23.6 Extract of the agent communication protocol: handshake step

Flexibility

The modular and distributed architecture of the LS/AMCs agent system allows for easy addition of new modules, without causing fundamental changes to the existing system architecture. The introduction of new kinds of machine modules only requires the development of a new module agent, which can be integrated into the current system with minimal effort.

Autonomic Adaptivity

New modules or modules that are failing or in need of maintenance can be exchanged while the system is running. Moreover thanks, to the LS/AMC distributed system architecture and intrinsic feedback-based adaptivity, machine control is updated autonomically at runtime without requiring restart of the control software.

Maintainability

Compared with traditional procedural or purely object-oriented approaches, the agent-oriented design of LS/AMC offers the advantage of intuitively mapping the real-world production line and order structure one-to-one. This makes the system better to understand and use, increases its durability, and improves its maintainability. An agent system also supports the easy and targeted customization of logging routines at the process level. This ensures the availability of more helpful and efficient methods of error monitoring and analysis.

Simulation

Complex simulation scenarios are easy to develop with LS/AMC, since a realistic mirror of a production line is more straightforward to simulate than an abstract model. Many different machine states and process flows can be recreated quickly and realistically. This significantly reduces the cost of quality control and improves personnel training and product demonstrations.

Goal Orientation

The software agents employed in this solution explicitly represent their behavior using partially conflicting logical goals. Order agents, for example, pursue the minimization of throughput time, and module agents have the goal of optimizing the modules' resource consumption. With LS/AMC these goals do not block one another but rather dynamically coordinate toward achieving optimal overall performance.

Dynamic Optimization

A production optimization program is coupled to each work item (board) and transitions together with it through the machine modules. Each module adapts to the particular program and dynamically anticipates parameter and control adjustments when appropriate. The program is linked to the individual order or batch and not tied to a central, fixed setting for the entire machine.

23.2.5 Future Developments and Open Issues

- Integration into preceding and successive processing machines, e.g., automated optical inspection (AOI), cleaning or packaging
- Machine-controlled board loaded through new combined lift/feeder modules. This allows throughput improvement by allowing agents to influence the sequence of production, which is not the case when boards are loaded manually
- Making use of optional surface temperature sensors to improve the control of the temperature curve directly on the processed board.

23.2.6 Reusability

The foundation for the customer- and machine-specific solution is a reusable and generic product kernel providing the following features and functionality:

- The standard agent platform, Living Systems Technology Suite (LS/TS) [23.7], is used as the runtime environment for the agent-based solution.
- The agent principle implies distributed autonomic control for each resource or entity in the system.
- The agent-type framework allows a jump-start for the solution building as it provides all general agents and templates for the application-specific agents.
- User, roles, and rights management is needed in every multiuser environment. New functions can easily be put under the generic access control.
- The built-in standard CANopen interface allows fast integration of every CANopen-compliant controller devices. LS/AMC has implemented a generic interface to CANopen to give each agent transparent access to its sensors and actuators.

23.3 Application Example: Dynamic Transportation Optimization

23.3.1 Motivation

Across Europe and worldwide, road freight transportation is a demanding high-pressure environment. Competition is fierce, margins are slender, and coordination is both distributed and often intensely complex. As a result many companies are seeking methods to control costs by enhancing their traditional dispatching methods with technology capable of intelligent, real-time freight capacity and route optimization. The former ensures that transport capacity is maximally used, while the latter ensures that trucks take the most efficient calculated route between order pickups and deliveries. These are tractable, yet complex, optimization problems because plans can effectively become obsolete the moment a truck leaves the loading dock due to unforeseen real-world events. It thus becomes mission-critical to assist human dispatchers with the computational tools to quickly replan capacity and routing.

A considerable volume of research exists concerning the domain of automatic planning and scheduling, but many real-world scheduling problems, and especially that of transportation logistics, remain difficult to solve. In particular, this domain demands schedule optimization for every vehicle in a transportation fleet where pickup and delivery of customer orders is distributed across multiple geographic locations, while satisfying time-window constraints on pickup and delivery per location.

Living systems adaptive transportation networks (LS/ATN) is a novel software agent-based resource management and decision support system designed to address this highly dynamic and complex domain in commercial settings. It makes use of agent cooperation algorithms to derive truck schedules that optimize the use of available resources, leading to significant cost savings. The solution is designed to support, rather than replace, the day-to-day activities of human dispatchers. The agent design chosen for optimization directly reflects the manner in which logistics companies actively manage the complexity of this domain. The global business is divided into regional business entities, which are usually dispatched via distributed dispatching centers. Interacting software agents represent this distribution.

While one of the largest customers of LS/ATN has demonstrated a reduction of 11.7% in costs compared with the manual dispatching solution, we typically guarantee a reduction of at least 4–6%. This improvement is significant for transportation companies with large numbers of orders to manage, significant costs, and small profit margins.

The achievements made thus far have been attained using only traditional manual communication (mobile phone) between the driver and dispatcher. Using this data LS/ATN generates global dispatching suggestions and improves the communication among the distributed dispatching centers. Incorporating sensor data on, for example, traffic conditions and vehicle status allows more accurate continuous estimation of vehicle estimated time of arrival (ETA), thus presenting yet further opportunities for cost savings and reduced fuel consumption. One key to this is the integration of real-time track-and-trace data feeds from en route vehicles, which act as feedback measures to an optimizer engine. This allows continuous adaptation and regeneration of dynamic route plans based on the real-world environment.

Close integration with key pervasive technologies such as GPS and reliable multinetwork communication offers the capability of enhancing core system intelligence with fast, timely, and accurate measures of the live environment [23.8]. Continuous transmission of vehicle state and location information provides live feedback metrics for the optimization platform, allowing human dispatchers to improve the efficiency of entire fleets. This flexibility enables logistics providers to react quickly to new customer requirements, altering transport routes at very short notice in order to accommodate unexpected events and new orders.

There can be little doubt that the future of freight transportation in Europe and beyond lies with the widespread adoption of pervasive technologies and intelligent transportation systems. One of the few questions remaining is simply how rapidly firms will adapt.

The remainder of this chapter examines the business domain characterizing the identified problems and then presents an industry-proven solution to these problems, LS/ATN (Fig. 23.7). It has been developed in close collaboration with worldwide logistics providers such as DHL, and has been proven through real-world deployment to reduce transportation costs through the optimized route solving for both small and large truck fleets. The primary aspects of our agent-based solution approach are discussed, followed by the presentation of benefits and savings, which are then continued with emerging options for incorporating state-of-the-art mobile technologies and pervasive computing into the solution.

23.3.2 Business Domain

Today most logistics companies use computational tools, collectively known as transport management sys-

tems (TMS), such as Transportation Planner from i2 Logistics, AxsFreight from Transaxiom, Cargobase, Elit, and Transflow, to plan their transportation network from a strategic level all the way through to subdaily route schedules. However, many TMS are unable to handle unexpected events adequately and generate plan alterations in real time. When dealing with large numbers of distributed customers, limited fleet size, last-minute changes to orders, or unexpected unavailability of vehicles due to traffic jams, breakdowns or accidents, static planning systems suffer from limited effectiveness. Significant human effort is required to manually adapt plans and control their execution.

In addition, vehicles can be of different types and capacities, are usually available at different locations, and drivers must observe regulated drive-time restrictions. To cope with all this, new intelligent approaches to route planning are emerging that are capable of continuously determining optimal routes in response to transportation requests arriving simultaneously from many customers. The key challenge lies in allocating a finite number of vehicles of varying capacity and available at different locations such that transportation time and costs are minimized, while the number of on-time pickups and deliveries, and therefore customer satisfaction, is maximized.

Road Freight Transportation

Road freight transportation is a very heterogeneous business environment serving a wide variety of customers with many different types of transportation, each configurable in many ways. In addition, large companies add the challenge of different business structures regarding processes, culture, and information technology.

One of the most significant challenges is the permanent handling of unexpected events such as traffic jams or other reasons for delays and new, changed or canceled customer orders. While new orders are an expected component of everyday business, their precise characteristics and appearance time are highly variable. A good solution must address the decentralized responsibilities of dispatchers working across the world with potentially overlapping geographical responsibilities, and supporting individual strategies and local approaches to dispatching.

To survive in an environment of significant cost pressure with margins of only 1–3%, logistics providers must address how to structure strong interaction between regional or organizational logistics networks and effectively manage the increasing complexity.

Core Challenge

The ongoing challenge for a logistics dispatcher is to find the best balance between:

- His reaction speed (time, effectiveness)
- The quality of a solution (schedule)
- The cost (efficiency) of a solution.

A comprehensive solution not only requires a core real-time optimization algorithm, but also a cooperative process bringing together all involved people.

Load Constraints

In a linear programming approach first of all you have to cover and configure the following load constraints:

- Precedence (pickup before delivery)
- Pairing (pickup and delivery by the same truck)
- Capacity limitation (dependent on truck type)
- Weight limitation (dependent on truck type)
- Order–truck compatibility (type, equipment)
- Order–order compatibility (dangerous goods)
- Last-in first-out (LIFO) loading of orders (optional).

Additionally it is important at least to take into account the following time constraints:

- Order-dependent load and unload durations
- Earliest and latest pickup
- Earliest and latest delivery
- Opening hours for pickup and delivery
- Legal drive-time restrictions
- Maximum allowed tour duration
- Lead time for ordering spot market trucks.

Problem Classification

One approach to tackle this optimization problem is by considering it as a multiple pick up and delivery problem with time windows (mPDPTW) [23.9], which concerns the computation of the optimal set of routes for a fleet of vehicles in order to satisfy a collection of transportation orders while complying with available time windows at customer locations. To solve the real-world challenge to an acceptable degree it is necessary to add another two aspects: first the capability to react in real time, and second to deal with time constraints in a flexible manner, using penalty costs to decide between a new vehicle or being late. This results in the even more complex multiple pick up and delivery problem with soft time windows in real time (R/T mPDPSTW) [23.10–12].

Thus, in addition to a pickup and delivery location, each order includes the time windows within which the order must be picked up and delivered. Vehicles are dispatched from selected starting locations and routes are computed such that each request can be successfully transferred from origin to destination. The goal of R/T mPDPSTW is to provide feasible schedules that satisfy the time window constraints for each vehicle to deliver to a set of customers with known demands on minimum-cost vehicle routes. Another aspect is the capability to suggest charter trucks (dynamically add resources) when appropriate, i.e., when charter trucks are cheaper than the company's own existing or fixed-contract trucks.

Further Challenges

A further significant challenge is managing opening hours, meaning to support multiple time windows during a day (e.g., lunch breaks). One of the major topics outside the optimization core problem is the ability to combine global dispatching suggestions automatically created by the system with local individual dispatcher decisions. Not forgetting the difficulty of combining continuous planning (perpetual with rolling horizon) with discrete decisions, track and trace, and billing processes. Then there is also the recurrent decision to transport direct or indirect (via a hub or depot) and to consider the limited docking or handling capacity at a hub.

Finally customer requests to parallelize the optimization of the three main resources, truck/tractor, trailer/swap body, and driver(s), must also be handled. Each may take a different route due to the pulling unit (truck/tractor), with drivers also potentially changing during a tour.

23.3.3 Solution Concept

The centralized, batch-oriented nature of traditional IT systems imposes intrinsic limits on dealing successfully with unpredictability and dynamic change. Multiagent systems are not restricted in this way because collaborating agents quickly adapt to changing circumstances and operational constraints. For real-time route optimization, it is simply not feasible to rerun a batch optimizer to adjust a transport plan every time a new event is received. Reality has shown that events such as order changes occur, on average, 1.3 times per order. Distributed, collaborating software processes, i. e., agents, can however work together by partitioning the optimization problem and following the bottom-up approach, thereby solving the optimization in near-real time.

Software Agents

To solve the domain challenges described above it is necessary and advantageous to apply a new software design concept: software agents. This technology offers an ideal approach to allow real-time system response and assessment in a distributed heterogeneous environment. Software agents are grounded by the notion of communication between independent active objects, each of which may have its own goal objectives and role assignments. These capabilities inherently mirror typical business structures and processes. Technically, software agents operate using sense–decide–act loops, which can be either purely reactive or proactively goal oriented.

In the transportation business domain an agent could be a packet, a pallet, a truck, a driver, an order or a dispatcher. They follow a reverse, bottom-up optimization principle with decentralized solution discovery and escalation strategies: first a dispatcher mentally optimizes within his domain of responsibility (e.g., 20 trucks), then in steps expands the search space to his office, his subsidiary, the region, the country, and finally tries to improve a solution globally.

Bilateral Order Trade

As mentioned, the agent design principle is based on communication and interaction among autonomous objects mirroring the real world. This optimization model closely follows cooperation in reality, where all trucks are driven and managed by self-employed drivers (and truck owners). They first accept each new order they get from any customer and then start to search, and negotiate with, other truck drivers in order to exchange or transfer orders looking for a win–win situation for both sides. This is triggered by each order event, where an order exchange also counts as an event. Each truck negotiates with other trucks in sequence with a tight restriction to bilateral order trades. However multiple trades can take place in parallel, always between a pair of trucks. This solution design allows fully distributed and parallel solution discovery, which scales very well and allows individual goals and strategies per truck (agent).

Agent Model and Strategy

To solve the R/T mPDPSTW problem dynamically, the LS/ATN transportation optimizer [23.13], used by DHL throughout Europe, segments and distributes the problem across a population of goal-directed software agents. Each agent represents a dispatcher, who manages one or more vehicles (resources). This is slightly different to exactly one agent per one truck, but the principle is the same, even closer to reality where a dispatcher manages more than one truck. The reason was technical performance optimization while keeping the core principle of bilateral negotiations.

The system is completely event driven: a new order, a changed order, a delay or a successful order exchange triggers a local activity. The dispatcher of the affected vehicle becomes active and tries to optimize by negotiating with *neighbor* trucks, trying to exchange or move loads and by checking and calculating all reasonable combinations and selecting the cheapest. The global optimum is striven for through a kind of *snowball effect*, which stops when there is no more optimization found. A threshold savings value, which avoids an order exchange for too little saving, reduces plan perturbation.

To find the optimal allocation the agents work on a strict cost basis. Each possible route is checked against a configurable, individual, and fully detailed cost model. This market-based approach, the money to be spent, is the common denominator to make the multiple conflicting goals comparable, which are:

- Reduction of empty driven distance
- Reduction of waiting times
- Increase of capacity utilization.

For R/T mPDPSTW optimization, an agent represents each geographical region, or business unit, with freight movement modeled as information flow between the agents (Fig. 23.8). Incoming transportation requests are distributed by an AgentRegionBroker (not shown) to the AgentRegionManager governing the region containing the pickup location. The number of such agents depends on the customer's setup of (regional) business units and varies between 6 and 60 for current deployments. In the larger case, 10 000 vehicles and up to 40 000 order requests are processed daily. This implies that no more than a few seconds are available to reoptimize a transportation plan when, for example, a new order must be integrated. Each AgentRegionManager generates a transportation plan specifying which orders to combine into which routes and which vehicles should be assigned to those routes. Agents exchange information using a negotiation protocol to insert transportation requests sequentially, while continually verifying vehicle availability, capacity, and costs.

While the optimization function is 100% cost based, other objectives must be satisfied in parallel when calculating routes. Some of these constraints are compulsory (hard), such as capacity and weight limitations of the vehicle, customer opening hours, that pickup date is before delivery date, and that pickup and delivery are performed by the same vehicle. Other soft constraints can be violated with a cost penalty, such as missing the latest possible pickup time or delivery time.

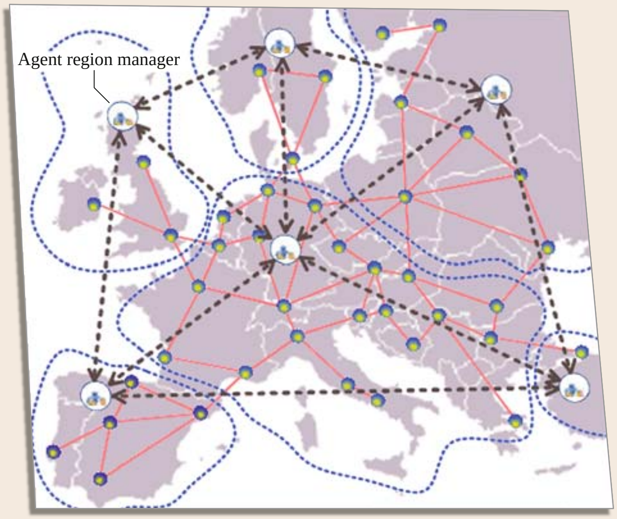

Fig. 23.8 Illustration of freight transportation in Europe partitioned into six regions, each with its own agent region manager. *Blue circles* represent major transport hubs and *red lines* indicate example routes connecting hubs

Experiments and First Findings

In the course of the software development we evaluated the effect of certain key parameters. One of these is the number of orders being negotiated and transferred between trucks (k). Our experiments showed that the runtime increases linearly with increasing k, but the

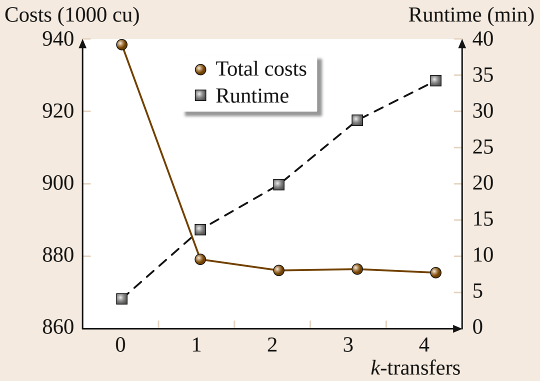

Fig. 23.9 Optimization results with increasing k (number of orders exchanged)

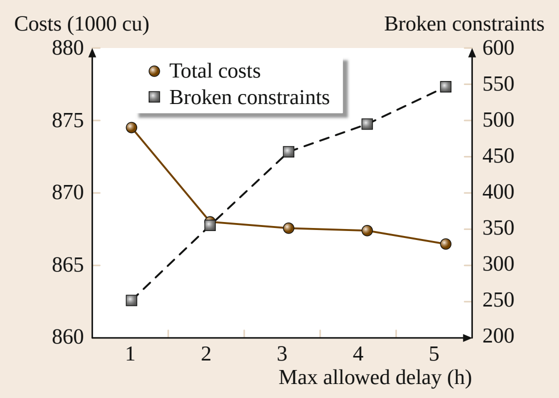

Fig. 23.10 Optimization results with increased soft time windows

costs decrease only marginally (Fig. 23.9). $k = 0$ means that there is no order exchange taking place, but only the first-time allocation.

Another experiment is the effect of the maximum allowed delay for soft time windows. The graph (Fig. 23.10) shows that a maximum delay above 2 h decreases the quality (number of broken constraints increase) while not reducing costs significantly.

The Decision Support Process of LS/ATN

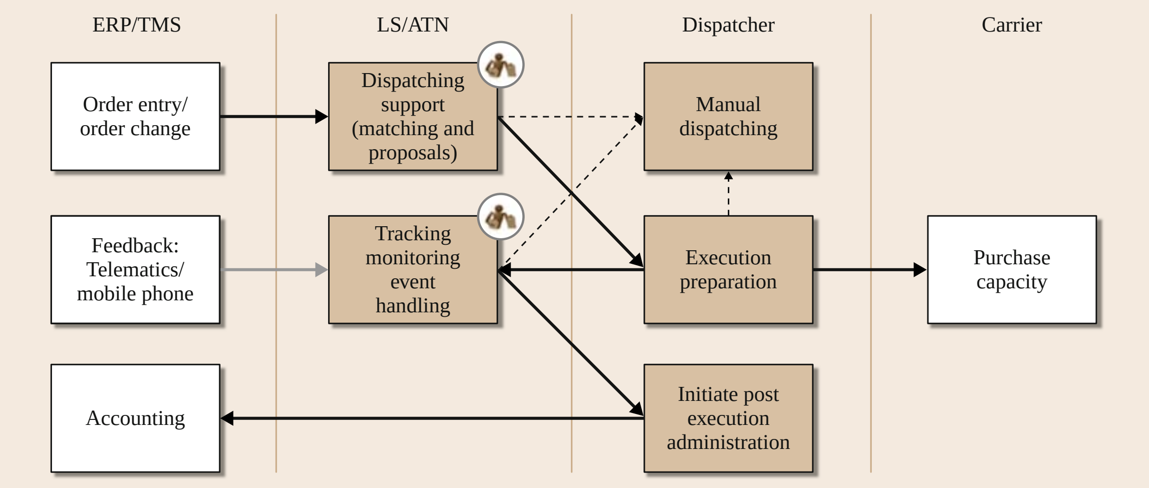
To integrate the globally generated optimization recommendations with the distributed dispatchers performing manual optimization we identify the following decision support process (Fig. 23.11): Orders arriving from an external system (ERP (enterprise ressource planning), TMS (tranportation management system) or other) flow into the core agent system, which generates dispatching recommendations in the form of a globally optimal matching proposal of orders to trucks. There is no time limit into the future; LS/ATN has an endless planning horizon. A certain lead time before the orders are to be checked and released, the system transfers them to the *to-do* board of the responsible dispatchers. They approve and adjust the suggested plan if needed prior to fixing the tour and purchasing the required transportation capacity. This automatically sends a confirmation to the subcontracted carrier and can issue a message to the truck driver, if equipped accordingly. The released routes then switch to tracking mode where the agents take over responsibility for monitoring incoming tracking messages, verifying whether they indicate an existing or upcoming time violation. The dispatcher is informed only if needed. As a final step the dispatcher releases a finished tour for billing.

This *ideal flow* covers the standard case, but reality often intercedes to force alterations in real time. In any situation a dispatcher can put a tour or an order into his manual dispatcher board and adjust the plan. This might be needed if, for example, an actual order differs from the booking only when loading it at the customer site.

23.3.4 Benefits and Savings

Higher Service Level at Reduced Cost

LS/ATN agent-based optimization guarantees a higher service level in terms of results quality. The high solution quality corresponds to a reduced number of



ERP/TMS

Initiate post execution administration

Fig. 23.11 Decision support process of LS/ATN

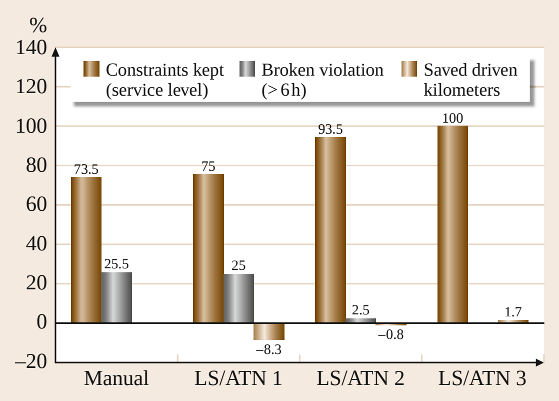

Fig. 23.12 Improvements obtained with LS/ATN over manual dispatching. Higher service level at reduced cost. Saved driven kilometers are compared with the manual figure

violated constraints. The system allows the desired level of service quality to be fine-tuned. Figure 23.12 presents results obtained from LS/ATN relative to the manual dispatching solution of very experienced dispatchers (manual).

The first proposed solution (LS/ATN 1), using relaxed soft constraints as the manual dispatchers do, provides a reduction of 8.3% in driven kilometers at the same service level with no more than 25% violated constraints.

The second solution (LS/ATN 2), configured with higher penalty costs for late delivery, shows a reduction in driven kilometers of 0.8% relative to the manual dispatching solutions, while providing a significant higher service level: only 2.5% violated constraints with more than 6 h delay.

The third solution (LS/ATN 3), not allowing any time window violation, shows an increase of only 1.7% in terms of driven kilometers, while meeting all the constraints to 100%.

In this analysis we compared the system results with real-world (manual) results, as the customers regard these metrics as optimal. Furthermore, there is the cost and resource problem if one would like to compare the results with the real optimum. This would require setup and development of a parallel solution based on linear programming, which is – according to our experience – not capable of covering all detailed requirements and constraints. Customers do not pay for such a comparison, as it is far too expensive and, even if one could develop a parallel solution fulfilling all requirements in the same way, there is no guarantee that the (one-time) optimal solution will end in due time.

Significantly Increased Process Efficiency

Through the use of automatic optimization a lower process cost is achieved. This is due to automatic handling of plan deviations and evaluation of solution options in real time. Moreover, through automation, the communication costs in terms of dispatcher's time and material is reduced. Better customer support can be guaranteed through fast, comprehensive, and up-to-date information about order execution. Automation also allows processing of a higher number of orders than with manual dispatching only. This is an important issue as the volume of data to be managed is constantly increasing.

Fig. 23.13 Significant cost savings through optimized capacity utilization

Significant Savings through Optimized Capacity Utilization

Cost savings cannot only be achieved by avoiding empty trips and reducing driven kilometers; an important aspect of cost reduction is the optimal use and allocation of the company's own and chartered trucks to a mixture of one-way, back-, and round-trips. Without the ability to reduce the driven kilometers significantly there is still a saving potential of up to 7%, as shown in Fig. 23.13.

Savings Potential in Numbers

A partial dataset from our major customer, DHL Freight, contains around 3500 real business transportation requests. In terms of the optimization results, obtained by comparing the solution of manual dispatching of these requests against processing the same orders with LS/ATN, a total 11.7% cost saving was achieved, where 4.2% of the cost savings stem from an equal reduction in driven kilometers. An additional achievement is that the number of vehicles used is 25.5% lower compared with the manual solution. The cost savings would be even higher if fixed costs for the vehicles were included, which is not the case in the charter business, but possibly in other transportation settings.

Combined with other real-world comparisons we can estimate an overall transportation cost saving of 5–10%, which are variable costs (subcontractor payment) and thus have an immediate effect. Fixed cost savings of 50–100% resulting from process and communication improvements are long-term effects, which only pay back when the resources are reallocated.

23.3.5 Emerging Trends: Pervasive Technologies

Although capacity and route optimization tools are proven to produce significant reductions in operating costs, many in the transportation industry are acutely aware that one key and often missing component of the optimization strategy is the provision of real-time feedback from en route vehicles. The objective is an intelligent transportation management system with every vehicle providing up-to-date information of progress through a pickup/delivery schedule and with onboard sensors detecting, for example, when freight is loaded and unloaded, and whether its condition (e.g., temperature) is within tolerance limits.

The *intelligent transportation management systems* model [23.14] developed within the transportation industry is grounded in the principle of vehicle tracking and incorporation of real-time information into the transportation management process using available pervasive technologies. The emerging approaches to realizing this model involve various combinations of pervasive technologies, some of which are all highlighted in the following section. This section highlights some of the most relevant technologies in use today, or in the early phases of adoption. LS/ATN is able to make use of data sourced from, manipulated by, or transmitted by any of these technologies to enhance the route optimization process.

Global Positioning System (GPS)

Automatic vehicle location (positional awareness) uses GPS signals for real-time persistent location monitoring of vehicles. Both human dispatchers and route planners such as LS/ATN can then track vehicles continuously as they move between pickup and delivery locations. Active GPS systems allow automatic location identification of a mobile vehicle; at selected time intervals the mobile unit sends out its latitude and longitude, as well its speed and other technical information. Passive GPS uses the onboard units (OBU) to log location and other GPS information for later upload. Accuracy can vary, typically between 2 and 20 m, according to the availability of enhancement technologies such as the wide-area augmentation system (WAAS), available in the USA. The European Galileo system will augment GPS to provide open-use accuracies in the region of 4–8 m within the European region.

The adoption of GPS is growing quickly as the technology becomes commoditized, but some transportation companies remain reliant on legacy equipment for measuring vehicle location. Some of the alternatives to GPS in use today include dead-reckoning, which uses a magnetic compass and wheel odometers to track distance and direction from a known starting point, and the long-range navigational (LORANC) system, which determines a vehicle's location using in-vehicle receivers and processors that measure the angles of synchronized radio pulses transmitted from at least two towers with predetermined position. Another system in use by some transportation companies is cellphone signal triangulation, which estimates vehicle location by movement between coverage cells. This only offers accuracy typically in the region of 50–350 m, but is a cheap and readily available means of determining location.

Onboard Units (OBU)

An OBU, otherwise known as a *black box*, is a vehicle-mounted module with a processor and local memory that is capable of integrating other onboard technologies such as load-status sensors, digital tachographs, toll collection units, onboard and fleet management systems, and remote communications facilities. The majority of OBUs in use today, such as the VDO FM Onboard series from Siemens, the CarrierWeb logistics platform, and EFAS from Delphi Grundig, are typically used to record vehicle location, calculate toll charges, and store vehicle-specific information such as identity, class, weight, and configuration. Some emerging OBUs will have increased processing capabilities allowing them to correlate and preprocess collected data locally prior to transmission. This offers the possibility of more computational intelligence installed within the vehicle, enabling in situ diagnostics and dynamic coordination with the remote planning optimizer such that the vehicle becomes an active participant in the planning process, rather than simply a passive provider and recipient of data.

Vehicle data, in its most common form, relates to the state of the vehicle itself, including, for example, tire pressure, engine condition, and emissions data. Automatic acquisition of this data by onboard sensors and its transmission to a remote system has been available within the automotive industry from some years and is now gaining substantial interest in the freight transportation business. The OBU gathers information from sensors with embedded processors capable of detecting unusual or deviant conditions, and informs a central control center if a problem is detected. Sensors also measure the status of a shipment while en route, such as detecting whether the internal temperature of refrigerated containers is within acceptable tolerance limits or whether a door is open or closed.

RFID

Many assets, including freight containers, swap-bodies, and transport vehicles, are now being fitted with transponders not only to identify themselves, but also to detect shipment contents and maintain real-time inventories. In the latter case, units are equipped with radiofrequency identification (RFID) readers tuned to detect RFID tags within the confined range of the container. Some tags, such as the Intermec Intellitag with an operating range of 4 m, are specifically designed for pallet and container tracking, where tags are attached to every item and automatically scanned whenever cargo is loaded or unloaded. The live inventory serves as both local information for the driver and as real-time feedback to the TMS, which uses it for record keeping and as input to the real-time route planner.

In addition, e-Seals, whether electronic or mechanical, are now often placed on shipments or structures to detect unauthorized entry and send remote alerts via the OBU. E-Seals on a container door can also store information about the container, the declaration of its contents, and its intended route through the system. They document when the seal was opened and, in combination with digital certificates and signatures, identify whether the people accessing the container are authorized to do so.

Mobile Communications

Electronic communication is the key enabler of pervasive technologies. In transportation the most basic form in use is the short message service (SMS), which is commonly used to communicate job status such as when a driver has delivered an order. Technology is already in place to automatically process SMSs and input the data into the route planner.

Also now in relatively widespread use is dedicated short-range communications (DSRC) operating in the short-range 5.8–5.9 GHz microwave band for use between vehicles and roadside transponders. Its primary use in Europe and Japan is for electronic toll collection. DSRC is also used for applications such as verifying whether a passing vehicle has a correctly operating OBU.

Currently, the technology with the greatest utility is machine-to-machine (M2M) [23.15] communication, which is the collective term for enabling direct connectivity between machines (e.g., a vehicle's OBU and the remote planning engine) using widespread wireless technologies. Legacy second-generation (2G) infrastructure is most commonly used as third-generation (3G) technologies enter the mainstream for day-to-day human telecommunications. M2M is quickly emerging as a principle enabler of networked embedded intelligence, the cornerstone of pervasive computing. It can eliminate the barriers of distance, time, and location, and as prices for the use of 2G continue to drop due to continued rollout of 3G technologies, many transportation companies are taking advantage and adopting M2M as their primary means of electronic communication.

Emerging solutions take M2M to another level by enabling always-on and highly reliable communication through automatic selection of connection technology, e.g., general packet radio service (GPRS), enhanced data rates for GSM evolution (EDGE), universal mobile telecommunications system (UMTS), satellite services, and WiFi according to availability. The LS/ATN route optimizer, for example, can be augmented with a remote connection agent module [23.16] installed in vehicles that offers seamless M2M over cellular technologies, wireless local-area network (LAN), and even short-range ad hoc connections if available. The selection of a particular communication technology can be made either manually or automatically, depending on several metrics including location, connection availability, transmission cost, and service type or task; for example, a fleet operator may prefer the use of satellite to communicate directly with a driver, but then a combination of cellular technologies for remote monitoring, trailer tracking, and diagnostics. Low-cost GPRS might be selected to download position coordinates from an onboard GPS; whereas, a higher-bandwidth (and cost) option such as UMTS/WCDMA (wideband code division multiple access) might be preferred for an over-the-air update to the OBU or onboard sensors.

The position information of a single vehicle is used to adjust dispatching plans immediately in the case of deviations (described below in more detail). If the number and density of vehicles in a region is high enough, this *floating vehicle data* may be integrated into a map containing real-time traffic flow information [23.17].

Opportunities of Using Pervasive Technologies

Transportation route optimizers can take advantage of real-time data sourced from vehicles equipped with pervasive technologies by incorporating information relating to vehicle location, state, and activity into their planning processes.

Figure 23.14 shows the major difference and step from the current deployment of the agent-based real-time dispatching system, only making use of traditional communication and track-and-trace capabilities with many manual human activities involved, toward a full real-time control loop leaving the dispatcher in a purely supervisor role. In the future, the sensor and actuator interfaces will be increasingly automated while the decision core system is already in place.

Pervasive communication provides a permanent bilateral link between the vehicles and the dispatching system. Onboard preprocessing is available to calculate continuously the estimated time of arrival (ETA) at the next node, which is periodically sent to the server in order to check immediately the impact on the dispatching plan. Taking speed and other local knowledge into account the local preprocessor is able to deduce traffic conditions and forward this (only temporarily valuable)

knowledge to other vehicles via the dispatching system. The combination of sensed speed with the current location can trigger an automatic status message if the truck is waiting for loading/unloading at a customer site or is idle in a traffic jam. A similar functionality is so-called *geo-fencing*, which issues a status messages when entering or leaving a destination. A further automation is the local communication between truck and a *smart container* for docking and undocking messages.

All of the above simplify and speed up execution tracking and dramatically increase status frequency, quality, and accuracy. Real-time plan adjustments ensure that a co-loading opportunity is never missed, or that time is never lost when informing the customer about short-term changes.

In particular, during the decision phase, route optimization and the derivation of schedules can directly use both information relating to vehicles movements as they proceed through delivery schedules and feedback from RFID transponders notifying when orders have been added to or removed. This real-time component implies that time windows can be more finely tuned according to current events, resulting in alternative schedules that can either compensate for delays or take advantage of time saved. Preliminary results with a prototype demonstrate that employing real-time data in the optimization process can further reduce transportation operating costs by up to 3% beyond the 5–10% achieved from the standard optimization process described earlier, depending on the particular case and system configuration.

23.3.6 Future Developments and Open Issues

There remain many scientific and practical challenges related to the design and use of real-time dispatching system. A selection of these that we consider relevant to LS/ATN and for consideration by the community at large are described below.

A major challenge is the effective handling of intercompany, interregion, and intermodal transportation. Transportation intrinsically involves multiple carriers operating both within and across sectors (i. e., road, air, and shipping) and across geographical boundaries. Each carrier has its own, often proprietary, systems that do not necessarily integrate easily with one another. Addressing this integration problem is a significant engineering issue to be faced as the technologies addressed in this chapter come into more widespread use.

The integration of transportation planners into supply chain and production systems is also important. As previously mentioned, freight is now often delivered directly to manufacturing plants without passing through transitional storage. Integration of these systems thus becomes a priority when shaping dynamic supply chains, and supply networks.

OBUs in use today typically consist of a simple processor, memory, and communication interfaces. Installed software is often designed solely for reading data from sensors and transmitting it to the TMS. One method of improving on this design is the integration of an autonomous software controller into the OBU to assist with the manipulation and coordination of collected onboard data. Example uses include assisting in the selection of M2M connection type in a multiprovider environment according to the type and volume of data to be transmitted and caching data locally if connections are temporarily unavailable. The controller can be further extended with a software agent that extends the distributed intelligence offered by the route optimizer. This agent essentially acts as a remote extension of the optimization platform, allowing the agent to act as a proxy representative of the vehicle itself within the context of route scheduling. Vehicles can thus become active participants in the planning process, forming a network overlay of communicating data processors.

Further research is required on so-called *smart* freight containers capable of announcing their presence and even negotiating with external devices; for example, a simple OBU fixed to a container will allow it to communicate with vehicles, customs checks, and equipment at freight consolidation centers. Many major transportation companies use such centers, distributed at strategic locations, with the primary goal of consolidating freight onto as few vehicles as possible to maximize use of available capacity. With the installation of RFID readers, incoming freight with RFID tags can be traced as it moves through a facility, providing TMS optimizers with complete coverage of freight location throughout its entire lifecycle within the business chain.

In addition, external factors also favor early adoption of pervasive technologies, such as the ongoing escalation of fuel prices, new regulations for pollution reduction, and constant increases in demand for fast, high-volume freight shipping. This is recognized in the European Union white paper *European Transport Policy for 2010* [23.18] which discusses the use of intelligent information services integrated with route planning systems and mobile communications to provide real-time, intelligent end-to-end freight and vehicle tracking and tracing.

There can be little doubt that the adoption of intelligent transportation planners capable of using real-time data sourced from pervasive technologies such as those discussed in this chapter is a major objective of many freight transportation operators both in Europe and other areas of the world. With these techniques now widely recognized as an important means of reducing operating costs, many companies are already well advanced on the path to adoption.

23.4 How to Design Agent-Oriented Solutions for Autonomic Automation

In the past decade a lot of work has been done on agent-oriented analysis and design. The works presented in [23.19] and [23.20] are only two examples, but very good starting points to dig into the agent world. More details about agent organization, agent platforms, tools and development can be found in [23.7, 21–23].

Other chapters in this Handbook also cover agent-based solutions, the following gives just a brief outline on how to start thinking in an agent-oriented way in the form of a questionnaire. A detailed discussion would be far beyond the scope of this Handbook.

Questions to structure the overall solution:

- What are the processes?
- Who/what drives the processes?
- Which roles do the process drivers play?

Questions to ask for each agent/role:

- What is the responsibility of the agent?
- Which goals does the agent aim at?
- What is the strategy to reach the goals?
- What knowledge does the agent need to follow this strategy?
- With which agents does he need to communicate?
- Which sensors and actuators are needed or available?

These questions have been discussed and answered to design and implement the two application examples contained in this chapter.

Two main aspects of an agent-based solution should be considered in order to analyze and prove the quality of the design. These aspects cannot be given as a concrete metric, but should be understood as general indicators relative to the size and type of the intended system:

- *Local knowledge*: A good agent solution has been achieved (or is possible) if the local knowledge needed by an agent to achieve its goals can be kept to a minimum. If a solution requires an agent to hold a large amount of data, or – in an extreme case – each agent needs to know *everything*, either the design should be rethought or an agent-based solution is not appropriate. Consider, for example, a sales representative (agent) for a car manufacturer, whose goal is to sell as many cars at the highest price possible. For that he does not need to know all the details about car production or supply chain organization. He only needs some extract of the whole business knowledge.
- *Communication*: Although message exchange and service-oriented architectures can accompany agent-based ideas, a good solution keeps communication to a minimum and makes careful use of resource *bandwidth*. If a design requires too much messaging among the participants then the role, and therefore the goal assignment, is not distinct enough. Agent-oriented design means to define a good level of responsibility and assign it to a software entity, which allows it to pursue its goals and to decide actions based on local knowledge. Cooperation with the environment is needed to sense *what's going on* but should not be needed to draw conclusions.

23.5 Emerging Trends and Challenges

23.5.1 Virtual Production and the Digital Factory

The automation industry, which includes at least all machine manufacturers, has the vision that all components of a production facility will be accompanied by a full digital description in a standardized format. Besides easy and straightforward integration into factory simulation tools, the goal is also to let modules carry their own electronic description to enable them to plug in and integrate automatically into a production system in the sense of self-configuration. Testing and putting into operation would become as easy as attaching a new mouse to a computer. Even though it is obvious that this will not work for all machines and that it is very hard to achieve, it is a very worthwhile goal to work towards. If the modules additionally come along with their own agents, they can also dynamically negotiate with the environment in which they are placed and (self-)optimize their activities.

23.5.2 Modularization

There is a clear trend and motivation in the industry to modularize machines and production facilities, yielding many advantages.

The customer (user) of a machine gets much greater flexibility, as he can order, configure, and dynamically adapt his production lines according to market needs. A common keyword in this regard is the selling argument *grow as you need*. On the maintenance side more cost reductions are possible as fewer spare parts are needed for modules built on the same framework, and if a defective module needs to be replaced this is normally easier than replacing a whole machine. Some production machines even offer a *shopping-cart*-like system, where a component can be exchanged without a screwdriver.

The manufacturer has smaller components to produce, which needs less space, at least for each production cell. In the same way quality tests become easier and faster because only a single module has to be tested. Last but not least, smaller modules are easier and cheaper to transport and deliver. The increased number of common parts leads to cheaper production because fewer tools are needed, and less space for many different parts and higher purchasing discounts can be achieved.

Overall, modularization is a win–win concept for all parties.

23.5.3 More RFID, More Sensors, Data Flooding

As RFID technology increasingly finds its way into industrial usage and other sensors based on video cameras, induction loops or microwaves we increase the amount of generated data day by day. Many companies are hungry for data, but have not clearly defined what to do with this new data flood. Admittedly the data and its accuracy have a high value, but one has to be aware that all this new data keeps its high value for only a very limited time. In other words: you have to process and gain the value from fresh data immediately. Because of the huge volumes involved, this can only be done by automated processes, which handle sensor input where it appears and drive activities without too much data transfer through the network. One can therefore conclude that RFID and other sensors increase the need for software agent concepts.

23.5.4 Pervasive Technologies

Limitations: Onboard Agents

As discussed in Sect. 23.5.1, one vision is to equip machine components and modules directly with their self-* logic (Sect. 23.1.4) and software representative. However, since the processing power of most controller boards is still not sufficient, and more importantly since such a huge variety of controller boards exist, it is not the first goal to support all of these directly. Instead it is much more convenient, faster, and not to forget cheaper to let the agent logic run on dedicated computers and *just* implement interfaces to the different controllers. This approach is not at odds with the general distributed solution design. It is just a special deployment decision. The very specific controller boards are not loaded with additional computing tasks, but only used as interfaces to the attached sensors and actuators. The software agents are deployed to one or more standard computers installed in the field as needed. A solution architect could theoretically use one dedicated personal computer (PC) per agent (per controller), which would directly reflect the distributiveness of the solution, but – again for cost reasons – several controllers, located in the same module, machine, area, room or building, can easily host the agents of many attached controllers. The agents still somehow work *locally*, close to the physical installation and thus the overall solutions provides redundancy, reduced latency, and near-real-time responsiveness. Step by step, as controller boards become more powerful in the coming years, the agents can be run directly on the board. This will be a smooth transition without changing the solution's core algorithms and allows one to take advantage of autonomous concepts already today.

24. Automation Under Service-Oriented Grids

Jackson He, Enrique Castro-Leon

For some companies, information technology (IT) services constitute a fundamental function without which the company could not exist. Think of UPS without the ability to electronically track every package in its system or any large bank managing millions of customer accounts without computers. IT can be capital and labor intensive, representing anywhere between 1% and 5% of a company's gross expenditures, and keeping costs commensurate with the size of the organization is a constant concern for the chief information officer (CIO)s in charge of IT.

A common strategy to keep labor costs in check today is through a deliberate *sourcing* or service procurement strategy, which may include in-sourcing using in-house resources or outsourcing, which involve the delegation of certain standardized business processes such as payroll to service companies such as ADP.

Yet another way of keeping labor costs in check with a long tradition is through the use of automation, that is, the integrated use of technology, machines, computers, and processes to reduce the cost of labor.

The convergence of three technology domains, namely virtualization, service orientation, and grid computing promises to bring the automation of provision and delivery of IT services to levels never seen before. An IT environment where these three technology domains coexist is said to be a *virtual service-oriented environment* or *VSG* environment. The cost savings are accrued through systemic reuse of resources and the ability to quickly integrate resources not just within one department, but across the whole company and beyond.

In this Chapter we will review each of the constituent technologies for a virtual service-oriented grid and examine how each contributes to the automation of delivery of IT services.

The increasing adoption of service-oriented architectures (SOAs) represents the increasing recognition by IT organizations of the need for business and technology alignment. In fact, under SOA there is no difference between the two. The unit of delivery for SOA is a service, which is usually defined in business terms.

In other words, SOA represents the up-leveling of IT, empowering IT organizations to meet the business needs of the community they serve. This up-leveling creates a gap, because for IT business requirements eventually need to be translated into technology-based solutions.

Our research indicates that this gap is being fulfilled by the resurgence of two very old technologies, namely virtualization and grid computing.

To begin with, SOA allowed the decoupling of data from applications through the magic of extensible mark-up language (XML).

A lot of work that used to be done by application developers and integrators now gets done by computers. When most data centers run at 5–10% utilization, growing and deploying more data centers is not a good solution. Virtualization technology came in very handy to address this situation, allowing the decoupling of applications from the platforms on which they run. It acts as the gearbox in a car, ensuring efficient transmission of power from the engine to the wheels.

The net effect of virtualization is that it allows utilization factors to increase to 60–70%. The technique has been applied to mainframes for decades. Deploying virtualization to tens of thousands of servers has not been easy.

Finally, grid technology has allowed very fast, on-the-fly resource management, where resources are allocated not when a physical server is provisioned, but for each instance that a program is run.

24.1 Emergence of Virtual Service-Oriented Grids

Legacy systems in many cases represent a substantial investment and the fruits of many years of refinement. To the extent that legacy applications bring business value with relatively little cost in operations and maintenance there is no reason to replace them. The adoption of virtual service-oriented grids does not imply wholesale replacement of legacy systems by any means. Newer virtual service-oriented applications will coexist with legacy systems for the foreseeable future. If anything, the adoption of a virtual service-oriented environment will create opportunities for legacy integration with the new environment through the use of web-service-based exportable interfaces. Additional value will be created for legacy systems through extended life cycles and new revenue streams through repurposing older applications.

These goals are attained through the increasing use of machine-to-machine communications during setup and operation.

To understand how the different components of virtual service-oriented grids came to be, we have to look at the evolution of its three constituent technologies: virtualization, service orientation, and grids. We also need to examine how they become integrated and interact with each other to form the core of a virtual service-oriented grid environment. This section also addresses the tools and overall architecture components that keep virtual service-oriented functions as integral business services that deliver ultimate value to businesses. Figure 24.1 depicts the abstract relationship between the three constituent technologies. Each item represents a complex technical domain of its own.

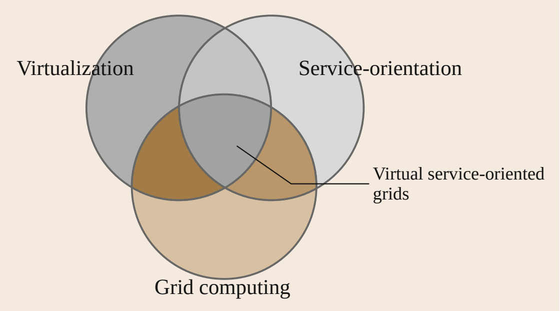

Fig. 24.1 Virtual service-oriented grids represent the confluence of three key technology domains

In the following sections, we describe how key technology components in these domains define the foundation for a virtual service-oriented grid environment, elements such as billing and metering tools, service-level agreement (SLA) management, as well as security, data integrity, etc. Further down, we discuss architecture considerations to put all these components together to deliver tangible business solutions.

24.2 Virtualization

Alan M. Turing, in his seminal 1950 article for the British psychology journal *Mind*, proposed a test for whether machines were capable of thinking by having a machine and a human behind a curtain typing text messages to a human judge [24.1]. A thinking machine would pass the test if the judge could not reliably determine whether answers from the judge's question came from the human or from the machine.

The emergence of virtualization technology poses a similar test, perhaps not as momentous as attempting to distinguish a human from a machine. Every computation result, such as a web page retrieval, a weather report, a record pulled from a database or a spreadsheet result can be ultimately traced to a series of state changes. These state changes can be represented by monkeys typing at random at a keyboard, humans scribbling numbers on a note pad, or a computer running a program. One of the drawbacks of the monkey method is the time it takes to arrive at a solution [24.2]. The *human* or manual method is also too slow for most problems of practical size today, which involve millions or billions of records.

Only machines are capable of addressing the scale of complexity of most enterprise computational problems today. In fact, their performance has progressed to such an extent that, even with large computational tasks, they are idle most of the time. This is one of the reasons for the low utilization rates for servers in data centers today. Meanwhile, this infrastructure represents a sunk cost, whether fully utilized or not.

Modern microprocessor-based computers have so much reserve capacity that they can be used to simulate other computers. This is the essence of virtualization: the use of computers to run programs that simulate computers of the same or even different architectures. In fact, machines today can be used to simulate many computers, anywhere between 1 and 30 for practical situations. If a certain machine shows a load factor of 5% when running a certain application, that machine can easily run ten virtualized instances of the same application.

Likewise, three machines of a three-tier e-commerce application can be run in a single physical machine, including a simulation of the network linking the three machines.

Virtual computers, when compared with *real* physical computers, can pass the Turing test much more easily than when humans are compared to a machine. There is essentially no difference between results of computations in a physical machine versus the computation in a virtual machine. It may take a little longer, but the results will be identical to the last bit. Whether running in a physical or a virtualized host, an application program goes through the same state transitions, and eventually presents the same results.

As we saw, *virtualization* is the creation of substitutes for real resources. These substitutes have the same functions and external interfaces as their counterparts, but differ in attributes, such as size, performance, and cost. These substitutes are called *virtual resources*. Because the computational results are identical, users are typically unaware of the substitution. As mentioned, with virtualization we can make one physical resource look like multiple virtual resources; we can also make multiple physical resources into shared pools of virtual resources, providing a convenient way of divvying up a physical resource into multiple logical resources.

In fact, the concept of virtualization has been around for a long time. Back in the mainframe days, we used to have virtual processes, virtual devices, and virtual memory [24.3–5]. We use virtual memory in most operating systems today. With virtual memory, computer software gains access to more memory than is physically installed, via the background swapping of data to disk storage. Similarly, virtualization concepts can be applied to other IT infrastructure layers including networks, storage, laptop or server hardware, operating systems, and applications. Even the notion of process is essentially an abstraction for a virtual central processing unit (CPU) running a single application.

Virtualization on x86 microprocessor-based systems is a more recent development in the long history of virtualization. This entire sector owes its existence to a single company, VMware; and in particular, to founder *Rosenblum* [24.6], a professor of operating systems at Stanford University. Rosenblum devised an intricate series of software workarounds to overcome certain intrinsic limitations of the x86 instruction set architecture in the support of virtual machines. These workarounds became the basis for VMware's early products. More recently, native support for virtualization hypervisors and virtual machines has been developed to improve the performance and stability of virtualization. An example is Intel's virtualization technology (VTx) [24.7].

To look further into the impact of virtualization on a particular platform, Fig. 24.2 illustrates a typical configuration of a single operating system (OS) platform without virtual machines (VMs) and a configuration of multiple virtual machines with virtualization. As indicated in the chart on the right, a new layer of abstraction is added, the virtual machine monitor (VMM), between physical resources and virtual resources. A VMM presents each VM on top of its virtual resources and maps virtual machine operations to physical resources. VMMs can be designed to be tightly coupled with operating systems or can be agnostic to operating systems. The latter approach provides customers with the capability to implement an OS-neutral management infrastructure.

24.2.1 Virtualization Usage Models

Virtualization is not just about increasing load factors; it brings a new level of operational flexibility and convenience to the hardware that was previously associated with software only. Virtualization allows running

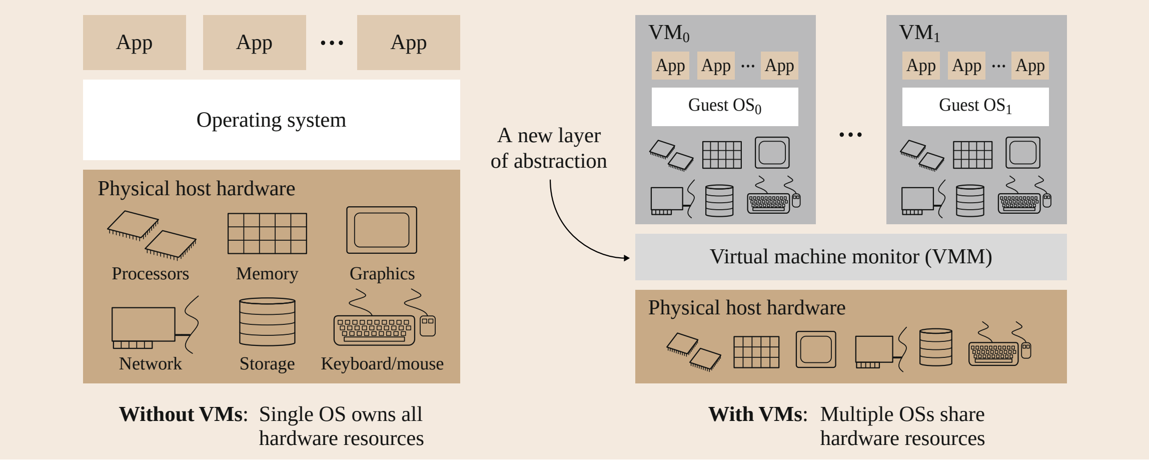

Fig. 24.2 A platform with and without virtualization

instances of virtualized machines as if they were applications. Hence, programmers can run multiple VMs with different operating systems, and test code across all configurations simultaneously. Once systems administrators started running hypervisors in test laboratories, they found a treasure trove of valuable use cases. Multiple physical servers can be consolidated onto a single, more powerful machine. The big new box still draws less energy and is easier to manage on a per-machine basis. This server consolidation model provides a good solution to *server sprawl*, the proliferation of physical servers, a side effect of deploying servers supporting a single application.

There exist additional *helper* technologies complementing and amplifying the benefits brought by virtualization; for example, extended manageability technologies will be needed to automatically track and manage the hundreds and thousands of virtual machines in the environment, especially when many of them are created and terminated dynamically in a data center or even across data centers.

Virtual resources, even though they act in lieu of physical resources, are in actuality software entities that can be scheduled and managed automatically under program control, replacing the very onerous process of physically procuring machines. The capability exists to deploy these resources on the fly instead of the weeks or months that it would take to go through physical procurement.

Grid computing technologies are needed to transparently and automatically orchestrate disparate types of physical systems to become a pool of virtual resources across the global network.

In this environment, standards-based web services become the fabric of communicate among heterogeneous systems and applications coming from different manufacturers, insourced and outsourced, legacy and new alike.

24.3 Service Orientation

Service orientation represents the natural evolution of current development and deployment models. The movement started as a programming paradigm and evolved into an application and system integration methodology with many different standards behind it. The evolution of service orientation can be traced back to the object-oriented models in the 1980s and even earlier and the component-based development model in the 1990s. As the evolution continues, service orientation retains the benefits of component-based development (self-description, encapsulation, dynamic discovery, and loading).

Service orientation brings a shift in paradigm from remotely invoking methods on objects, to one of passing messages between services. In short, service orientation can be defined as a design paradigm that specifies the creation of automation logic in the form of services based on standard messaging schemas.

Messaging schemas describe not only the structure of messages, but also behavior and semantics of acceptable message exchange patterns and policies. Service orientation promotes interoperability among heterogeneous systems, and thus becomes the fabric for systems integration, as messages can be sent from one service to another without consideration of how the service handling those messages has been implemented.

Service orientation provides an evolutionary approach to building distributed systems that facilitate loosely coupled integration and resilience to change. With the arrival of web services and WS* standards (WS* denotes the multiple standards that govern web service protocols), service-oriented architectures (SOAs) have made service orientation a feasible paradigm for the development and integration of software and hardware services.

Some advantages yielded by service orientation are described below.

Progressive and Based on Proven Principles

Service orientation is *evolutionary* (not revolutionary) and grounded in well-known information technology principles taking into account decades of experience in building real-world distributed applications. Service orientation incorporates concepts such as self-describing applications, explicit encapsulation, and dynamic loading of functionality at runtime-principles first introduced in the 1980s and 1990s through object-oriented and component-based development.

Product-Independent and Facilitating Innovation

Service orientation is a set of architectural principles supported by open industry standards independent of any particular product.

Easy to Adopt and Nondisruptive

Service orientation can and should be adopted through an incremental process. Because it follows some of the same information technology principles, service orientation is not disruptive to current IT infrastructures and can often be achieved through wrappers or adapters to legacy applications without completely redesigning the applications.

Adapt to Changes and Improved Business Agility

Service orientation promotes a loosely coupled architecture. Each of the services that compose a business solution can be developed and evolved independently.

24.3.1 Service-Oriented Architectural Tenets

The fundamental building block of service orientation is a *service*. A service is a program interacting through well-defined message exchange interfaces. The interfaces are self-describing, relatively stable over time, and versioning resilient, and shield the service from implementation details. Services are built to last while service configurations and aggregations are built for change. Some basic architectural tenets must be followed for service orientation to accomplish a successful service design and minimize the need for human intervention.

Designed for Loose Coupling

Loose coupling is a primary enabler for reuse and automatic integration. It is the key to making service-oriented solutions resilient to change. Service-oriented application architects need to spend extra effort to define clear boundaries of services and assure that services are autonomous (have fewer dependencies), to ensure that each component in a business solution is loosely coupled and easy to compose (reuse).

Encapsulation. Functional encapsulation, the process of hiding the internal workings of a service to the outside world, is a fundamental feature of service orientation.

Standard Interfaces. We need to force ubiquity at the edge of the services. Web services provide a collection of standards such as simple object access protocol (SOAP), web service definition language (WSDL), and the WS* specifications, which take anything not functionally encapsulated for conversion into reusable components. At the risk of oversimplification, in the same way the browser became the universal graphic user interface (GUI) during the emergence of the First Web in the 1990s, web services became the universal machine-to-machine interface in the Second Web of the 2000s, with the potential of automatically integrating self-describing software components without human intervention [24.8, 9].

Unified Messaging Model. By definition, service orientation enables systems to be loosely bound for both the composition of services, as well as the integration of a set of services into a business solution. Standard messaging and interfaces should be used for both service integration and composition. The use of a unified messaging model blurs the distinction between integration and composition.

Designed for Connected Virtual Environments

With advances in virtualization as discussed in the previous section, service orientation is not limited to a single physical execution environment, but rather can be applied using interconnected virtual machines (VMs). Related content on virtual network of machines is usually referred to as a *service grid*. Although the original service orientation paradigm does not mandate full resource virtualization, the combination of service orientation and a grid of virtual resources hint at the enormous potential business benefits brought by the autonomic and on-demand compute models.

Service Registration and Discovery. As services are created, and their interfaces and policies are registered and advertised, using ubiquitous formats. As more services are created and registered, a shareable service network is created.

Shared Messaging Service Fabric. In addition to networking the services, a secure and robust messaging service fabric is essential for service sharing and communication among the virtual resources.

Resource Orchestration and Resolution. Once a service is discovered, we need to have effective ways to allocate sufficient resources for the services to meet the service consumer's needs. This needs to happen dynamically and be resolved at runtime. This means special attention is placed on discovering resources at runtime and using these resources in a way that they can be automatically released and regained based on resource orchestration policies.

Designed for Manageability

The solutions and associated services should be built to be managed with sufficient interfaces to expose information for an independent management system, which by itself could be composed of a set of services, to verify that the entire loosely bound system will work as designed.

Designed for Scalability

Services are meant to scale. They should facilitate hundreds or thousands of different service consumers.

Designed for Federated Solutions

Service orientation breaks application silos. It spans traditional enterprise computing boundaries, such as network administrative boundaries, organizational and operational boundaries, and the boundaries of time and space. There are no technical barriers for crossing corporate or transnational boundaries. This means services need a high degree of built-in security, trust, and internal identity, so that they can negotiate and establish federated service relationships with other services following given policies administrated by the management system. Obviously, cohesiveness across services based on standards in a network of service is essential for service federation and to facilitate automated interactions.

24.3.2 Services Needed for Virtual Service-Oriented Grids

A set of foundation services is essential to make service-oriented grids work. These services, carried out through machine-to-machine communication, are the building blocks for a solution stack at different layers providing some of the automated functions supported by VSGs.

Fundamental services can be divided into the following categories similar to the open grid services architecture (OGSA) approach, as outlined in Fig. 24.3 and in applications in Fig. 24.4. The items are provided for conceptual clarity without an attempt to provide an exhaustive list of all the services. We highlight some example services, along with a high-level description.

Resource Management Services

Management of the physical and virtual resources (computing, storage, and networking) in a grid environment.

Asset Discovery and Management

Maintaining an automatic inventory of all connected devices, always accurate and updated on a timely basis.

Provisioning

Enabling bare metal provisioning, coordinating the configuration between server, network, and storage in a synchronous and automatic manner, making sure software gets loaded on the right physical machines, taking platforms in and out of service as required for testing, maintenance, repair or capacity expansion; remote booting a system from another system, and managing the licenses associated with software deployment.

Monitoring and Problem Diagnosis

Verifying that virtual platforms are operational, detecting error conditions and network attacks, and responding by running diagnostics, deprovisioning platforms and reprovisioning affected services, or isolating network segments to prevent the spread of malware.

Infrastructure Services

Services to manage the common infrastructure of a virtual grid environment and offering the foundation for service orientation to operate.

QoS Management

In a shared virtualized environment, making sure that sufficient resources are available and system utilization is managed at a specific quality-of-service (QoS) level as outlined in the service-level agreement (SLA).

Load Balancing

Dynamically reassigning physical devices to applications to ensure adherence to specified service (performance) levels and optimized utilization of all resources as workloads change.

Capacity Planning

Measuring and tracking the consumption of virtual resources to be able to plan when to reserve resources for certain workloads or when new equipment needs to be brought on line.

Utilization Metering

Tracking the use of particular resources as designated by management policy and SLA. The metering service could be used for chargeback and billing by higher-level software.

Execution Management Services

Execution management services are concerned with the problems of instantiating and managing to completion units of work or an application.

Business Processes Execution

Setting up generic procedure as building blocks to standardize business processes and enabling interoperability across heterogeneous system management products.

Workflow Automation

Managing a seamless flow of data as part of the business process to move from application to application. Tracking the completion of workflow and managing exceptions.

Execution Resource Allocation

In a virtualized environment, selecting optimal resources for a particular application or task to execute.

Execution Environment Provisioning

Once an execution environment is selected, dynamically provision the environment as required by the application, so that a new instance of the application can be created.

Managing Application Lifecycle

Initiate, track status of execution, and administer the end-of-life phase of a particular application

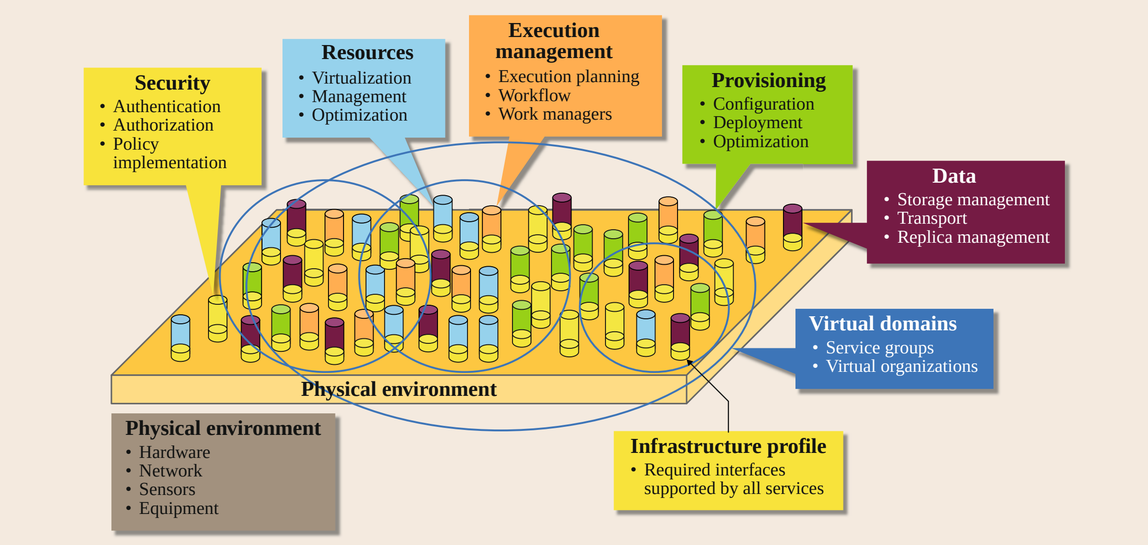

Fig. 24.3 OGSA service model from OGSA Spec 1.5, July 2006

and release virtual resources back to the resource pool.

Data Services

Moving data as required, such as data replication and updates; managing metadata, queries, and federated data resources.

Remote Access

Access remote data resources across the grid environment. The services hide the communication mechanism from the service consumer. They can also hide the exact location of the remote data.

Staging

When jobs are executed on a remote resource, the data services are often used to stage input data to that resource ready for the job to run, and then to move the result to an appropriate place.

Replication

To improve availability and to reduce latency, the same data can be stored in multiple locations across a grid environment.

Federation

Data services can integrate data from multiple data sources that are created and maintained separately.

Derivation

Data services should support the automatic generation of one data resource from another data source.

Metadata

Some data service can be used to store descriptions of data held in other data services. For example, a replicated file system may choose to store descriptions of the files in a central catalogue.

Security Services

Facilitate the enforcement of the security-related policy within a grid environment.

Authentication

Authentication is concerned with verifying proof of an asserted identity. This functionality is part of the credential validation and trust services in a grid environment.

Identity Mapping

Provide the capability of transforming an identity that exists in one identity domain into an identity within another identity domain.

Authorization

The authorization service is to resolve a policy-based access-control decision. For the resource that the service requestor requests, it resolves, based on policy, whether or not the service requestor is authorized to access the resource.

Credential Conversion

Provide credential conversion from one type of credential to another type or form of credential. This may include such tasks as reconciling group membership, privileges, attributes, and assertions associated with entities (service consumers and service providers).

Audit and Secure Logging

The audit service, similarly to the identity mapping and authorization services, is policy driven.

Security Policy Enforcement

Enforcing automatic device and software load authentication; tracing identity, access, and trust mechanisms within and across corporate boundaries to provide secure services across firewalls.

Logical Isolation and Privacy Enforcement

Ensuring that a fault in a virtual platform does not propagate to another platform in the same physical machine, and that there are no data leaks across virtual platforms which could belong to different accounts.

Self-Management Services

Reduce the cost and complexity of owning and operating a grid environment autonomously.

Self-Configuring

A set of services adapt dynamically and autonomously to changes in a grid environment, using policies provided by the grid administrators. Such changes could trigger provisioning requests leading to, for example, the deployment of new components or the removal of existing ones, maybe due to a significant increase or decrease in the workload.

Self-Healing

Detect improper operations of and by the resources and services, and initiate policy-based corrective action without disrupting the grid environment.

Self-Optimizing

Tune different elements in a grid environment to the best efficiency to meet end-user and business needs. The tuning actions could mean reallocating resources to improve overall utilization or optimization by enforcing an SLA.

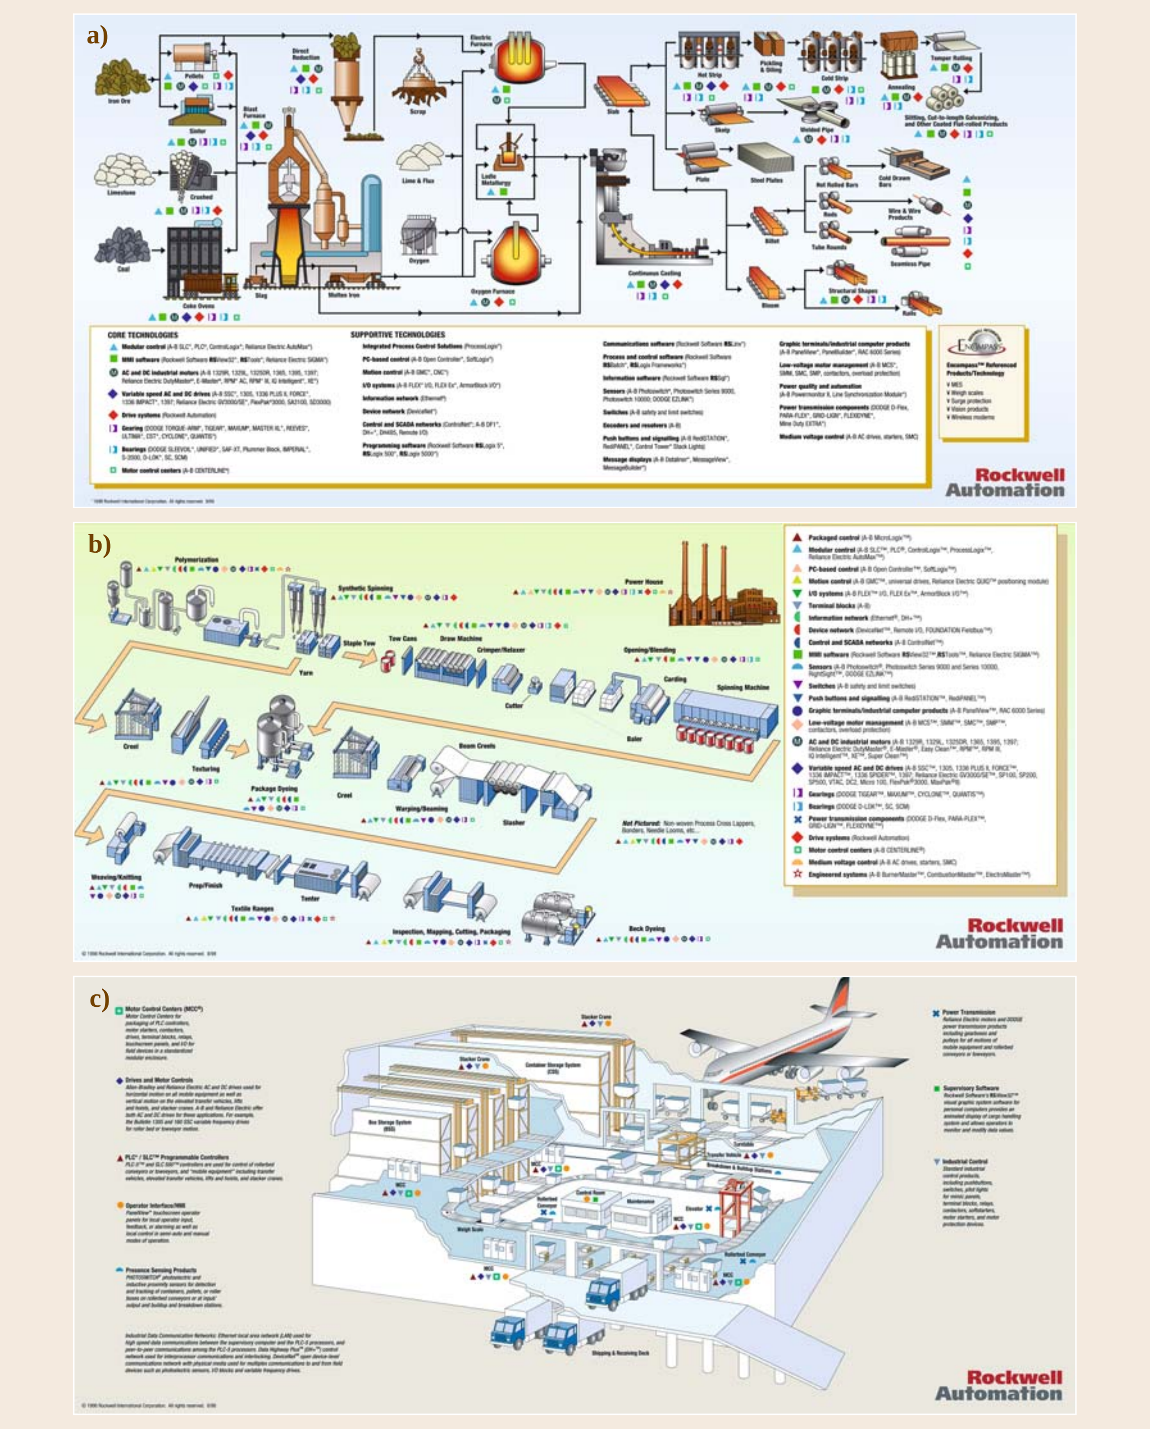

Fig. 24.4a–c Examples of applications that can benefit from virtual services as shown in Fig. 24.3. **(a)** Steel industry; **(b)** textile industry; **(c)** material handling at a cargo airport (courtesy of Rockwell Automation, Inc.)

24.4 Grid Computing

The most common description of grid computing includes an analogy to a power grid. When you plug an appliance or other object requiring electrical power into a receptacle, you expect that there is power of the correct voltage available, but the actual source of that power is not known. Your local utility company provides the interface into a complex network of generators and power sources and provides you with (in most cases) an acceptable quality of service for your energy demands. Rather than each house or neighborhood having to obtain and maintain its own generator of electricity, the power grid infrastructure provides a virtual generator. The generator is highly reliable and adapts to the power needs of the consumers based on their demand.

The vision of grid computing is similar. Once the proper grid computing infrastructure is in place, a user will have access to a *virtual computer* that is reliable and adaptable to the user's needs. This virtual computer will consist of many diverse computing resources. But these individual resources will not be visible to the user, just as the consumer of electric power is unaware of how their electricity is being generated. In a grid environment, computers are used not only to run the applications but to secure the allocation of services that will run the application. This operation is done automatically to maintain the abstraction of anonymous resources [24.10].

Because these resources are widely distributed and may belong to different organizations across many countries, there must be standards for grid computing that will allow a secure and robust infrastructure to be built. Standards such as the open grid services architecture (OGSA) and tools such as those provided by the Globus Toolkit provide the necessary framework. Initially, businesses will build their own infrastructures, but over time, these grids will become interconnected. This interconnection will be made possible by standards such as OGSA and the analogy of grid computing to the power grid will become real.

The ancestry of grids is rooted in high-performance computing (HPC) technologies, where resources are ganged together toward a single task to deliver the necessary power for intensive computing projects such as weather forecasting, oil exploration, nuclear reactor simulation, and so on. In addition to expensive HPC supercomputer centers, mostly government funded, an HPC grid emerged to link together these resources and increase utilization. In a concurrent development, grid technology was used to join not just supercomputers, but literally millions of workstations and personal computers (PCs) across the globe.

24.5 Summary and Emerging Challenges

In essence, a virtual service-oriented environment encourages the independent and automated scheduling of data resources from the applications that use the data and from the compute engines that run the applications. SOA decouples data from applications and provides the potential for automated mechanisms for aligning IT with business through business process management. Finally, grid technologies provide dynamic, on-the-fly resource management.

Most challenges in the transition to a virtualized service-oriented grid environment will likely be of both technical and nontechnical origin, for instance implementing end-to-end trust management: even if it is possible to automatically assemble applications from simpler service components, how do we ensure that these components can be trusted? How do we also ensure that, even if the applications that these components support function correctly, that they will provide satisfactory performance and that they will function reliably?

A number of service components that can be used to assemble more complex applications are available from well-known providers: Microsoft Live, Amazon.com, Google, eBay, and PayPal. The authors expect that, as technology progresses, smaller players worldwide will enter the market, fulfilling every conceivable IT need. These resources may represent business logic building blocks, storage over the network, or even computing resources in the form of virtualized servers.

The expected adoption of virtual service-oriented environments will increase the level of automation in the provisioning and delivery of IT services. Each of the constituent technologies brings a unique automation capability into the mix. Grid technology enables the automatic harnessing of geographically distributed, anonymous computing resources. Service orientation enables on-the-fly, automatic integration of the distributed resources through the use of standards-based interfaces enabled by the use of web services and XML technology. Finally, virtualization enables carving out a physical resource into a multiplicity of virtual resources, allowing the transparent (automatic) matching of the demand for a resource to the physical manifestation of the resource.

25. Human Factors in Automation Design

John D. Lee, Bobbie D. Seppelt

Designers frequently look toward automation as a way to increase system efficiency and safety by reducing human involvement. This approach often leads to disappointment because the role of people becomes more, not less, important as automation becomes more powerfull and prevalent. Developing automation without consideration of the human operator leads to new and more catastrophic failures. For automation to fulfill its promise, designers must avoid a technology-centered approach and adopt an approach that considers the joint operator–automation system. Automation-related problems arise because introducing automation changes the type and extent of feedback that operators receive, as well as the nature and structure of tasks. In addition, operators' behavioral, cognitive, and emotional responses to these changes can leave the system vulnerable to failure. Automation is not a homogenous technology. There are many types of automation and each poses different design challenges. This chapter describes how different types of automation place different demands on operators. It also presents strategies that can help designers achieve the promise of automation. The chapter concludes with future challenges in automation design.

Designers often view automation as the path toward greater efficiency and safety. In many cases, automation does deliver these benefits. In the case of the control of cargo ships and oil tankers, automation has made it possible to operate a vessel with as few as 8–12 crew members, compared with the 30–40 that were required 40 years ago [25.1]. In the case of aviation, automation has reduced flight times and increased fuel efficiency [25.2]. Similarly, automation in the form of decision-support systems has been credited with saving millions of dollars in guiding policy and production decisions [25.3]. Automation promises greater efficiency, lower workload, and fewer human errors; however, these promises are not always fulfilled.

A common fallacy is that automation can improve system performance by eliminating human variability and errors. This fallacy often leads to mishaps that surprise operators, managers, and designers. As an example, the cruise ship Royal Majesty ran aground because the global positioning system (GPS) signal was lost and the position estimation reverted to position extrapolation based on speed and heading (dead reckoning). For over 24 h the crew followed the compelling electronic chart display and did not notice that the GPS signal had been lost or that the position error had been accumulating. The crew failed to heed indications from boats in the area, lights on the shore, and even salient changes in water color that signal shoals. The surprise of the GPS failure was only discovered when the ship ran aground [25.4, 5]. As this example shows, automation does not guarantee improved efficiency and error-free performance.

For automation to fulfill its promise, designers must focus not on the design of the automation, but on the design of the joint human–automation system. Automation often fails to provide expected benefits because it does not simply replace the human in performing a task, but also transforms the job and introduces a new set of tasks [25.6].

One way to view the automation failure that led to the grounding of the Royal Majesty is that it was simply a malfunction of an otherwise well-designed system – a problem with the technical implementation. Another view is that the grounding occurred because the interface design failed to support the new navigation task and failed to counteract a general tendency for people to overrely on generally reliable automation – a problem with human–technology integration. Although it is often easiest to blame automation failures on technical problems or on human errors, many problems result from a failure to consider the challenges of designing not just automation, but a joint human–automation system.

Automation fails because the role of the person performing the task is often underestimated, particularly the need for people to compensate for the unexpected. Although automation can handle typical cases it often lacks the flexibility of humans to handle unanticipated situations. Avoiding these failures requires a design process with a focus on the joint human–automation system. In most applications, neither the human nor the automation can accommodate all situations – each has limits. Successful automation design must empower the operator to compensate for the limits of the automation and help the operator capitalize on the capabilities of the automation.

This chapter provides an overview of some of the problems frequently encountered with automation. It then describes how these problems relate to types of automation and what design strategies can help designers achieve the promise of automation. The chapter concludes with future challenges in automation design.

25.1 Automation Problems

Automation is often designed and implemented with a focus on the technical aspects of sensors, algorithms, and actuators. These are necessary but not sufficient design considerations to ensure that automation enhances system performance. Such a technology-centered approach often confronts the human operator with challenges that lead to system failures. Because automation often dramatically extends the influence of operators on the system (e.g., automation makes it possible for one person to do the work of ten), the consequences of these failures can be catastrophic. The factors underlying these failures are complex and interacting. Failures arise because introducing automation changes the type and extent of feedback that operators receive, as well as the nature and structure of tasks. In addition, operators' behavioral, cognitive, and emotional response to these changes can leave the system vulnerable to failure. A technology-centered approach to automation design often ignores these challenges, and as a consequence, fails to realize the promise of automation.

25.1.1 Problems Due to Changes in Feedback

Feedback is central to control. One reason why automation fails is that automation often dramatically changes the type and extend of the feedback the operator receives. In the context of driving a car, the driver keeps the car in the center of the lane by adjusting the steering wheel according to visual feedback regarding the position of the car on the road and haptic feedback from the forces on the steering wheel. Emerging vehicle technology may automate lane keeping. Such automation may leave the driver with the visual cues, but may remove the haptic cues. Diminished or eliminated feedback is a common occurrence with automation and it can leave people less prepared to intervene if manual control is required [25.7, 8].

Automation can replace the feedback available in manual control with qualitatively different feedback. As an example, introducing automation into paper-making plants moved operators from the plant floor and placed them in control rooms. This move distanced them from the physical process and eliminated the informal feedback associated with vibrations, sounds, and smells that many operators relied upon [25.9]. At best, this change in cues requires operators to relearn how to control the plant. At worst, the instrumentation and associated displays may not have the information needed for operators to diagnose automation failures and intervene appropriately. Automation can also qualitatively shift the feedback from raw system data to processed, integrated information. Although such integrated data can be simple and easily understood, particularly during routine situations, it may also lack the detail necessary to detect and understand system failures. As an example, the bridge of the cruise ship Royal Majesty had an electronic chart that automatically integrated inertial and GPS navigation data to show operators their position relative to their intended path. This high-level representation of the ship's position remained on the intended course even when the underlying GPS data were no longer used and the ship's actual position drifted many miles off the intended route. In this case, the lack of low-level data and of any indication of the integrated data quality left operators without the feedback they needed to diagnose and respond to the failures of the automation.

The diminished feedback that accompanies automation often has a direct influence on a mishap, as illustrated by the case of the Royal Majesty. However, diminished feedback can also act over a longer time period to undermine operators' ability to perform tasks. In situations in which the automation takes on the tasks previously assigned to the operator, the operator's skills may atrophy as they go unexercised [25.10]. Operators with substantial previous experience and well-developed mental models detect disturbances more rapidly than operators without this experience, but extended periods of monitoring automatic control may undermine skills and diminish operators' ability to generate expectations of correct behavior [25.8]. Such deskilling leaves operators without the skills to accommodate the demands of the job if they need to detect failures and assume manual control. This is a particular concern in aviation, where pilots' aircraft handling skills may degrade when they rely on the autopilot. In response, some pilots disengage the autopilot and fly the aircraft manually to maintain their skills [25.11].

Automation design requires the specification of sensor, algorithm, and actuator characteristics and their interactions. A technology-centered approach might stop there; however, automation that works effectively requires specification of the feedback to the operators. Without careful design, implementing automation can eliminate and change feedback in a way that can undermine the ability of automation to enhance system performance.

25.1.2 Problems Due to Changes in Tasks and Task Structure

One reason for automation is that it can relieve operators of labor-intensive and error-prone tasks. Frequently, however, the situation becomes more complex in that automation does not simply relieve the operator of tasks, it changes the nature of tasks that must be performed. In most instances, this means that automation requires new skills of operators. Often automation eliminates simple physical tasks, and leaves complex cognitive tasks that appear easy. These complex, yet superficially easy, tasks often lead organizations to place less emphasis on training. On ships, training and certification unmatched to the demands of the automation have led to accidents because of the operators' misunderstanding of new radar and collision avoidance systems [25.12]. For example, on the exam used by the US Coast Guard to certify radar operators, 75% of the items assess skills that have been automated and are not required by the new technology [25.13]. The new technology makes it possible to monitor a greater number of ships, thereby enhancing the need for interpretive skills such as understanding the rules of the road that govern maritime navigation and the automation. These are the very skills that are underrepresented on the Coast Guard exam. Though automation may relieve the operator of some tasks, it often leads to new and more complex tasks that require more, not less, training.

Automation can also change the nature and structure of tasks so that easy tasks are made easier and hard tasks harder – a phenomenon referred to as clumsy automation [25.14]. As *Bainbridge* [25.15] notes, designers often leave the operator with the most difficult tasks because the designers found them difficult to automate. Because the easy tasks have been automated, the operator has less experience and an impoverished context for responding to the difficult tasks. In this situation, automation has the effect of both reducing workload during already low-workload periods and increasing it during high-workload periods; for example, a flight management system tends to make the low-workload phases of flight (e.g., straight and level flight or a routine climb) easier, but high-workload phases (e.g., the maneuvers in preparation for landing) more difficult as pilots have to share their time between landing procedures, communication, and programming the flight management system. Such effects are seen not only in aviation but also in many other domains, such as the operating room [25.16, 17].

The effects of clumsy automation often occur at the level of individual operators and over the span of several minutes, but such effects can also occur across teams of operators over hours or days of operation. Such macrolevel clumsy automation is evident in maritime operations, where automation used for open-ocean sailing reduces the task requirements of the crew, prompting reductions in the crew size. In this situation, automation can have the consequence of making the easy part of the voyage (e.g., open-ocean sailing) easier and the hard part (e.g., port activities) harder [25.18]. Avoiding clumsy automation requires a broad consideration of how automation affects the task structure of operators.

Because automation changes the task structure, new forms of human error often emerge. Ironically, managers and system designers introduce automation to eliminate human error, but new and more disastrous errors often result, in part because automation extends the scope of and reduces the redundancy of human actions. As a consequence, human errors may be more likely to go undetected and do more damage; for example, a flight-planning system for pilots can induce dramatically poor decisions because the automation assumes weather forecasts represent reality and lacks the flexibility to consider situations in which the actual weather might deviate from the forecast [25.19].

Automation-induced errors also occur because the task structure changes in a way that undermines collaboration between operators. Effective system performance involves performing both formal and informal tasks. Informal tasks enable operators to compensate for the limits of the formal task structure; for example, with paper charts mariners will check each others' work, share uncertainties, and informally train each other as positions are plotted [25.20]. Eliminating these informal tasks can make it more difficult to detect and recover from errors, such as the one that led to the grounding of the Royal Majesty. Automation can also disrupt the cooperation between operators reflected in these informal tasks. Cooperation occurs when a person acts in a way that is in the best interests of the group even when it is contrary to his or her own best interests. Most complex, multiperson systems depend on cooperation. Automation can disrupt interactions between people and undermine the ability and willingness of one operator to compensate for another. Because automation also acts on behalf of people, it can undermine cooperation by giving one operator the impression that another operator is acting in a competitive manner, even though the automation's behavior may be due to a malfunction [25.21].

Automation does not simply eliminate tasks once performed by the operator. It changes the task structure and creates new tasks that need to be supported, thereby opening the door to new types of error. Contrary to the expectations of a technology-centered approach to automation design, introducing automation makes it more rather than less important to consider the operators' tasks and role.

25.1.3 Problems Due to Operators' Cognitive and Emotional Response to Changes

Automation sometimes causes problems because it changes operators' feedback and tasks. Operators' cognitive and emotional responses to these changes can amplify these problems; for example, as automation changes the operator's task from direct control to monitoring, the operator may be more prone to direct attention away from the monitoring task, further diminishing the feedback the operator receives from the system. The tendency to trust and complacently rely on automation, particularly during multitask situations, may underlie this tendency to disengage from the monitoring task [25.22–24].

People are not passive recipients of the changes to the task structure that automation makes. Instead, people adapt to automation and this adaptation leads to a new task structure. One element of this adaptation is captured by the ideas of reliance and compliance [25.25]. Reliance refers to the degree to which operators depend on the automation to perform a function. Compliance refers to the degree to which automation changes the operators' response to a situation. Inappropriate reliance and compliance are common automation problems that occur when people rely on or comply with automation in situations where it performs poorly, or when people fail to capitalize on its capabilities [25.26].

Maladaptive adaptation generally, and inappropriate reliance specifically, depends, in part, on operators' attitudes, such as trust and self-confidence [25.27, 28]. In the context of operator reliance on automation, trust has been defined as an attitude that the automation will help achieve an operator's goals in a situation characterized by uncertainty and vulnerability [25.29]. Several studies have shown that trust is a useful concept in describing human–automation interaction, both in naturalistic [25.9] and in laboratory settings [25.30–33].

These and other studies show that people tend to rely on automation they trust and to reject automation they do not trust [25.29]. As an example, the difference in operators' trust in a route-planning aid and their self-confidence in their own ability was highly predictive of reliance on the aid [25.34]. People respond socially to technology in a way that is similar to how they respond to other people [25.35]. *Sheridan* had a similar insight, and suggested that, just as trust mediates relationships between people, it may also mediate relationships between people and automation [25.36, 37]. Because trust often has a powerful effect on mediating relationships between people, trust might exert a similarly strong effect on mediating reliance and compliance with automation [25.38–42].

Inappropriate reliance often stems from a failure of trust to match the true capabilities of the automation. Calibration refers to the correspondence between a person's trust in the automation and the automation's capabilities [25.29]. Overtrust is poor calibration in which trust exceeds system capabilities; with distrust, trust falls short of automation capabilities. Trust often responds to automation as one might expect; it increases over time as automation performs well and declines when automation fails. Importantly, however, trust does not always follow the changes in automation performance. Often, it is poorly calibrated. Trust displays inertia and changes gradually over time rather than responding immediately to changes in automation performance. After a period of unreliable performance, trust is often slow to recover, remaining low even when the automation performs well [25.43]. More surprisingly, trust sometimes depends on surface features of the system that seem unrelated to its capabilities, such as the colors and layout of the interface [25.44–46].

Attitudes such as trust and the associated influence on reliance can exacerbate automation problems such as clumsy automation. As noted earlier, clumsy automation occurs when automation makes easy tasks easier and hard tasks harder. Inappropriate trust can make automation more clumsy because it leads operators to be more willing to delegate tasks to the automation during periods of low workload, compared with periods of high workload [25.15]. This observation demonstrates that clumsy automation is not simply a problem of task structure, but one that depends on operator adaptation that is mediated by attitudes, such as trust.

The automation-related problems associated with inappropriate trust often stem from operators' shift from being a direct controller to a monitor of the automation. This shift also changes how operators receive feedback. Automation shifts people from direct involvement in the action–perception loop to supervisory control [25.47, 48]. Passive observation associated with supervisory control is qualitatively different than active monitoring associated with manual control [25.49, 50]. In manual control, perception directly supports control, and control actions guide perception [25.51]. Monitoring automation disconnects the operators' actions from actions on the system. Such disconnects can undermine the operator's mental model (i. e., their working knowledge of system dynamics, structure, and causal relationships between components), leaving the mental model inadequate to guide expectations and control [25.52, 53].

The shift from direct controller to supervisory controller can also have subtle but important effects on behavior as operators adapt to the automation. Over time automation can unexpectedly shift operators' safety norms and behavior relative to safety boundaries. Behavioral adaptation describes this effect and refers to the tendency of operators to adapt to the new capabilities of the automation in which they change their behavior so that the potential safety benefits of the technology are not realized. Automation intended by designers to enhance safety may instead lead operators to reduce effort and leave safety unaffected or even diminished. Behavioral adaptation occurs at the individual [25.54–56], organizational [25.57], and societal levels [25.58].

Antilock brake systems (ABS) for cars demonstrate behavioral adaptation. ABS automatically modulates brake pressure to maintain maximum brake force without skidding. This automation makes it possible for drivers to maintain control in extreme crash avoidance maneuvers, which should enhance safety. However, ABS has not produced the expected safety benefits. One reason is that drivers of cars with ABS tend to drive less conservatively, adopting higher speeds and shorter following distances [25.59]. Vision enhancement systems provide another example of behavioral adaption. These systems make it possible for drivers to see more at night – a potential safety enhancement; however, drivers tend to adapt to the vision systems by increasing their speed [25.60].

A related form of behavioral adaptation that undermines the benefits of automation is the phenomenon in which the presence of the automation causes a diffusion of responsibility and a tendency to exert less effort when the automation is available [25.61,62]. As a result, people tend to commit more omission errors (failing to detect events not detected by the automation) and more commission errors (incorrectly concurring with erroneous detection of events by the automation) when they work with automation. This effect parallels the adaptation of people when they work in groups; diffusion of responsibility leads people to perform more poorly when they are part of a group compared with individually [25.63].

The issues noted above have primarily addressed the direct performance problems associated with automation. Job satisfaction is another human–automation interaction issue that goes well beyond performance to consider the morale and moral implications of the worker whose job is being changed by automation [25.64]. Automation that is introduced merely because it increases the profit of the company may not necessarily be well received. Automation often has the effect of deskilling a job, making skills that operators worked for years to perfect suddenly obsolete. Properly implemented, automation should reskill workers and make it possible for them to leverage their old skills into new ones that are extended by the support of the automation. Many operators are highly skilled and proud of their craft; automation can either empower or demoralize them [25.9]. Demoralized operators may fail to capitalize on the potential of an automated system.

The cognitive and emotional response of operators to automation can also compromise operators' health. If automation creates an environment in which the demands of the work increase, but the decision latitude decreases, it may then lead to problems ranging from increased heart disease to increased incidents of depression [25.65]. However, if automation extends the capability of the operator and gives him or her greater decision latitude, job satisfaction and health can improve. As an example of improved satisfaction, night-shift operators who had greater decision latitude than day-shift operators leveraged their increased latitude to learn how to manage the automation more effectively [25.9].

Automation problems can be described independently, but they often reflect an interacting and dynamic process [25.66]. One problem can lead to another through positive feedback and vicious cycles. As an example, inadequate training may lead the operator to disengage from the monitoring task. This disengagement leads to poorly calibrated trust and overreliance, which in turn leads to skill loss and further disengagement. A similar dynamic exists between clumsy automation and automation-induced errors. Clumsy automation produces workload peaks, which increase the chance of mode and configuration errors. Recovering from these errors can further increase workload, and so on. Designing and implementing automation without regard for human capabilities and defining the human role as a byproduct is likely to initiate these negative dynamics.

25.2 Characteristics of the System and the Automation

The likelihood and consequences of automation-related problems depend on the characteristics of the automation and the system being controlled. Automation is not a homogenous technology. Instead, there are many types of automation and each poses different design challenges. As an example, automation can highlight, alert, filter, interpret, decide, and act for the operator. It can assume different degrees of control and can operate over timescales that range from milliseconds to months. The type of automation and the operating environment interact with the human to produce the problems just discussed. As an example, if only a single person manages the system then diminished cooperation and collaboration are not a concern. Some important system and automation characteristics include:

- Automation as information processing stages
- Automation authority and autonomy
- Complexity and observability
- Time-scale and multitasking demands
- Agent interdependencies
- Interaction with environment.

25.2.1 Automation as Information Processing Stages

Defining automation in terms of information processing stages describes it according to the information processing functions of the person that it supports or replaces. Automation can sense the world, analyze information, identify appropriate responses to states of the world or control actuators to change those states [25.67]. Information acquisition automation refers to technology that replaces the process of human perception. Such automation highlights targets [25.68, 69], provides alerts and warnings [25.70, 71], organizes, prioritizes, and filters information. Information analysis automation refers to technology that supplants the interpretation of a situation. An example of this type of automation is a system that critiques a diagnosis generated by the operator [25.72]. Action selection automation refers to technology that combines information in order to make decisions on behalf of the operator. Unlike information acquisition and analysis, action selection automation suggests or decides on actions using assumptions about the state of the world and the costs and values of the possible options [25.73]. Action implementation automation supplants the operators' activity in executing a response. The types of automation at each of these four stages of information process can differ according to degree of authority and autonomy.

Automation authority and autonomy concern the degree to which the automation can influence the system [25.74]. Authority reflects the extent to which the automation amplifies the influence of operators' actions and overrides the actions of other agents. One facet of authority concerns whether or not operators interact with automation by switching between manual and automatic control. With some automation, such as cruise control in cars, drivers simply engage or disengage the automation, whereas automation on the flight deck involves managing a complex network of modes that are appropriate for some situations and not for others. Interacting with such flight-deck automation requires the operator to coordinate multiple goals and strategies to select the mode of operation that fits the situation [25.75]. With such multilevel automation the idea of manual control may not be relevant, and so the issues of skill loss and other challenges with manual intervention may be of less concern. The problems with high-authority, multilevel automation are more likely to be those associated with mode confusion and configuration errors.

Autonomy reflects the degree to which automation acts without operator knowledge or opportunity to intervene. *Billings* [25.11] describes two levels of autonomy: *management by consent*, in which the automation acts only with the consent of the operator, and *management by exception*, in which automation initiates activities autonomously. As another example, automation can either highlight targets [25.68, 69], filter information, or provide alerts and warnings [25.70, 71]. Highlighting targets exemplifies a relatively low degree of autonomy because it preserves the underlying data and allows operators to guide their attention to the information they believe to be most critical. Filtering exemplifies a higher degree of autonomy because operators are forced to attend to the information the automation deems relevant. Alerts and warnings similarly exemplify a relatively high level of autonomy because they guide the operator's attention to automation-dictated information and environmental states. High levels of authority and autonomy make automation appear to act as an independent agent, even if the designers had not intended operators to perceive it as such [25.76]. High levels of these two automation characteristics are an important cause of clumsy automation and mode error and can also undermine cooperation between people [25.77].

25.2.2 Complexity and Observability

Complexity and observability refer to the degrees of freedom of the automation algorithms and how directly that complexity is revealed to the operator [25.74]. As automation becomes increasingly complex it can transition from what operators might consider a tool that they use to act on the environment to an agent that acts as a semiautonomous partner. According to the agent metaphor, the operator no longer acts directly on the environment, but acts through an intermediary agent [25.78] or intelligent associate [25.79]. As an agent, automation initiates actions that are not in direct response to operators' commands. Automation that acts as an agent is typically very complex and may or may not be observable. One of the greatest challenges with automated agents is that of mutual intelligibility. Instructing the agent to perform even simple tasks can be onerous, and agents that try to infer operators' intent and act autonomously can surprise operators who might lack accurate mental models of agent behavior. One approach is for the agents to learn and adapt to the characteristics of the operator through a process of remembering what they have been being told to do in similar situations [25.80]. After the agent completes a task it can be equally challenging to make the results observable and meaningful to the operator [25.78]. Because of these characteristics, agents are most useful for highly repetitive and simple activities, where the cost of failure is limited. In high-risk situations, constructing effective management strategies and providing feedback to clarify agent intent and communicate behavior becomes critical [25.75, 81]. The challenges associated with agents reflect a general tradeoff with automation design: more complex automation is often more capable, but less understandable. As a consequence, even though more complex automation may appear superior, the performance of resulting human–automation system may be inferior to that of a simpler, less capable version of the automation.

25.2.3 Time-Scale and Multitasking Demands

This distinction concerns the tempo of the interactions with the automation. The timescale of automation varies dramatically, from decision-support systems that guide corporate strategies over months and years to antilock brake systems that modulate brake pressure over milliseconds. These distinctions can be described in terms of strategic, tactical, and operational automation. Strategic automation concerns balancing values and costs, as well as defining goals; tactical automation, on the other hand, involves setting priorities and coordinating tasks. In contrast, operational automation concerns the moment-to-moment perception of system state and adjustment. With operational automation, operators can experience substantial time pressure as the tempo of activity, on the order of milliseconds to seconds, exceeds their capacity to monitor the automation and still respond in a timely manner to its limits [25.82, 83].

25.2.4 Agent Interdependencies

Agent interdependencies describe how tightly coupled the work of one operator or element of automation is with another [25.6, 57]. In some situations, automation might directly support work of a team of people and in other situations automation might support the activity of a person that has little interaction with others. An important source of automation-related problems is the assumption that automation affects only one person or one set of tasks, causing important interactions with other operators to be neglected. Often seemingly independent tasks may actually be coupled, and automation has a tendency to tighten this coupling. As an example, on the surface, adaptive cruise control affects only the individual driver who is using the system. Because adaptive cruise control responds to the behavior of the vehicle ahead, however, its behavior cannot be considered without taking into account the surrounding traffic dynamics. Failing to consider these interactions of intervehicle velocity changes can lead to oscillations and instabilities in the traffic speed, potentially compromising driver safety [25.84, 85]. Similar failures occur in supply chains, as well as in petrochemical processes where people and automation sometimes fail to coordinate their activities [25.86]. Designing for such situations requires a change in perspective from one centered on a single operator and a single element of automation to one that considers multi-operator–multi-automation interactions [25.87, 88].

25.2.5 Environment Interactions

Interaction with the environment refers to the degree to which the automation system is isolated from or interactive with the surrounding environment. The environmental context can affect the reliability and behavior of the automation, the operator's perception of the automation, and thus the overall effectiveness of the human–automation partnership [25.89–92]. An explicit environmental representation is necessary to understand the joint human–automation performance [25.89].

25.3 Application Examples and Approaches to Automation Design

The previous section described some important characteristics of automation and systems that contribute to automation-related problems. These distinctions help identify design approaches to minimize these problems. This section describes specific strategies for designing effective automation, which include:

- Function allocation with Fitts' list
- Operator–automation simulation and analysis
- Representation aiding and enhanced feedback
- Expectation matching and automation simplification.

25.3.1 Fitts' List and Function Allocation

Function allocation with the Fitt's list is a long-standing technique for identifying the role of operators and automation. This approach assesses each function and whether a person or automation might be best suited to performing it [25.93, 94]. Functions better performed by automation are automated and the operator remains responsible for the rest, and for compensating for the limits of the automation. The relative capability of the automation and human depend on the stage of automation [25.95].

Applying a Fitts' list to determine an appropriate allocation of function has, however, substantial weaknesses. One weakness is that any description of functions is a somewhat arbitrary decomposition of activities that can mask complex interdependencies. As a consequence, automating functions as if they were independent has the tendency to fractionate the operator's role, leaving the operator with an incoherent collection of functions that were too difficult to automate [25.15]. Another weakness is that this approach neglects the tendency for operators to use automation in unanticipated ways because automation often makes new functions possible [25.96]. Another challenge with this general approach is that it often carries the implicit assumption that automation can substitute for functions previously performed by operators and that operators do not need to be supported in performing functions allocated to the automation [25.97]. This substitution-based function allocation fails to consider the qualitative change automation can bring to the operators' work, and the adaptive nature of the operator.

As a consequence of these challenges, the Fitts' list provides only general guidance for automation design and has been widely recognized as problematic [25.73, 95, 97]. Ideally, the function allocation process should not focus on what functions should be allocated to the automation or to the human, but should identify how the human and the automation can complement each other in jointly satisfying the functions required for system success [25.98].

Although imperfect, the Fitts' list approach has some general considerations that can improve design. People tend to be effective in perceiving patterns and relationships amongst data and less so with tasks requiring precise repetition [25.64]. Human memory tends to organize large amounts of related information in a network of associations that can support effective judgments. People also adapt, improvise, and accommodate unexpected variability. For these reasons it is important to leave the *big picture* to the human and the *details* to the automation [25.64].

25.3.2 Operator–Automation Simulation

Operator–automation simulation refers to computer-based techniques that explore the space of operator–automation interaction to identify potential problems. Discrete event simulation tools commonly used to evaluate manufacturing processes are well-suited to operator–automation analysis. Such techniques provide a rough estimate of some of the consequences of introducing automation into complex dynamic systems. As an example, simulation of a supervisory control situation made it possible to assess how characteristics of the automation interacted with the operating environment to govern system performance [25.99]. This analysis showed that the time taken to engage the automation interacted with the dynamics of the environment to undermine the value of the automation such that manual control was more appropriate than engaging the automation.

Although discrete event simulation tools can incorporate cognitive mechanisms and performance constraints, developing this capacity requires substantial effort. For automation analysis that requires a detailed cognitive representation, cognitive architectures, such as adaptive control of thought-rational (ACT-R), offer a promising approach [25.100]. ACT-R is a useful tool for approximating the costs and benefits of various automation alternatives when a simple discrete event simulation does not provide a sufficiently detailed representation of the operator [25.101].

Simulation tools can be used to explore the potential behavior of the joint human–automation system, but may not be the most efficient way of identifying potential human–automation mismatches associated with inadequate mental models and automation-related errors. Network analysis techniques offer an alternative. State-transition networks can describe operator–automation behavior in terms of a finite number of states, transitions between those states, and actions. Figure 25.1 provides an example presentation, defining at a high level the behavior of adaptive cruise control (ACC). This formal modeling language makes it possible to identify automation problems that occur when the interface or the operator's mental model is inadequate to manage the automation [25.102]. Figure 25.2 shows how combining the concurrent processes of the ACC model with its internal states and transitions with the associated driver model of the ACC's behavior reveals

mismatches. These mismatches can cause automation-related errors and surprises to occur. More specifically, when the automation model enters a particular state and the operator's model does not include this state then the analysis predicts that the associated ambiguity will surprise operators and lead to errors [25.103]. Such ambiguities have been discovered in actual aircraft autopilot systems, and network analysis can identify how to avoid them with improvements to the interface and training materials [25.103].

25.3.3 Enhanced Feedback and Representation Aiding

Enhanced feedback and representation aiding can help prevent problems associated with inadequate feedback that range from developing appropriate trust and clumsy automation to the out-of-the-loop phenomenon. Automation typically lacks adequate feedback [25.104]. Providing sufficient feedback without overwhelming the operator is a critical design challenge. Poorly presented or excessive feedback can increase operator workload and undermine the benefits of the automation [25.105].

A promising approach to avoid overloading the operator is to provide feedback through sensory channels that are not otherwise used (e.g., haptic, tactile, and auditory) to prevent overload of the more commonly used visual channel. Haptic feedback (i. e., vibration on the wrist) has proven more effective in alerting pilots to mode changes of cockpit automation than visual cues [25.106]. Pilots receiving visual alerts only detected 83% of the mode changes, but those with haptic warnings detected 100% of the changes. Importantly, the haptic warnings did not interfere with performance of concurrent visual tasks. Even within the visual modality, presenting feedback in the periphery helped pilots detect uncommanded mode transitions and such feedback did not interfere with concurrent visual tasks any more than currently available automation feedback [25.107]. Similarly, *Seppelt* and *Lee* [25.108] combined a more complex array of variables in a peripheral visual display for ACC. Figure 25.3 shows how this display includes relevant variables for headway control (i. e., time headway, time-to-collision, and range rate) relative to the operating limits of the ACC. This display promoted faster failure detection and more appropriate engagement strategies compared with the standard ACC interface. Although promising, haptic, auditory and peripheral visual displays cannot convey the detail possible in visual displays, making it difficult to convey the complex relationships that some-

Driver model of ACC

Fig. 25.2 Composite of the driver and ACC models in which corresponding driver model states (*black boxes*) and ACC model states (*white boxes*) are combined into state pairs. Error states, or model mismatches, occur when a particular transition leads to discrepant states. Composite states *ACC not active* (*standby*)/*ACC off*, *ACC off*/*ACC standby*, and *ACC active*/*ACC standby* are error states. The driver is unaware of the shift of the ACC system into standby when deceleration and vehicle speed limits are reached, and of the ACC system disengaging when system faults are detected, as neither state change is clearly communicated to the driver. The state change that results from the driver depressing the brake pedal is similarly ambiguous

times govern automation behavior. An important design tradeoff emerges: provide sufficient detail regarding automation behavior, but avoid overloading and distracting the operator.

Simply enhancing the feedback operators receive regarding the automation is sometimes insufficient. Without the proper context, abstraction, and integration, feedback may not be understandable. Representation aiding capitalizes on the power of visual perception to convey this complex information; for example, graphical representations for pilots can augment the traditional airspeed indicator with target airspeeds and acceleration indicators. Integrating this information into a traditional flight instrument allows pilots to assimilate automation-related information with little additional effort [25.87]. Using a display that combines pitch, roll, altitude, airspeed, and heading can directly specify task-relevant information such as what is *too low* [25.109] as opposed to operators being required to infer such relationships from the set of variables. Integrating automation-related information with traditional displays and combining low-level data into meaningful information can help operators understand automation behavior.

In the context of process control, *Guerlain* and colleagues [25.110] identified three specific strategies for visual representation of complex process control algorithms. First, create visual forms whose emergent features correspond to higher-order relationships. Emergent features are salient symmetries or patterns that depend on the interaction of the individual data elements. A simple emergent feature is *parallelism* that can occur with a pair of lines. Higher-order relationships are combinations of the individual data elements that govern system behavior. The boiling point of water is a higher-order relationship that depends on temperature and pressure. Second, use appropriate visual features to represent the dimensional properties of the data; for example, magnitude is a dimensional property that should be displayed using position or size on a visual display, not color or texture, which are ambiguous cues as to an increase or decrease in amount. Third, place data in a meaningful context. The meaningful context for any variable depends on what comparisons need to be made. For automation, this includes the allowable ranges relative to the current control variable setting, and the output relative to its desired level. Similarly, *Dekker* and *Woods* [25.97] suggest event-based representations that highlight changes, historical representations that help operators project future states, and pattern-based representations that allow operators to synthesize complex relationships perceptually rather than through arduous mental transformations.

Representation aiding helps operators trust automation appropriately. However, trust also depends on more subtle elements of the interface [25.29]. In many cases, trust and credibility depend on surface features of the interface that have no obvious link to the true capabilities of the automation [25.111, 112]. An online survey of over 1400 people found that for web sites, credibility depends heavily on *real-world feel*, which is defined by factors such as response speed, a physical address, and photos of the organization [25.113]. Similarly, a formal photograph of the author enhanced trustworthiness of a research article, whereas an informal photograph decreased trust [25.114]. These results show that trust tends to increase when information is displayed in a way that provides concrete details that are consistent and clearly organized.

25.3.4 Expectation Matching and Simplification

Expectation matching and simplification help operators understand automation by using algorithms that are more comprehensible. One strategy is to simplify the automation by reducing the number of functions, modes, and contingencies [25.115]. Another is to match its algorithms to the operators' mental model [25.116]. Automation designed to perform in a manner consistent with operators' mental model, preferences, and expectations can make it easier for operators to recognize failures and intervene. Expectation matching and simplification are particularly effective when a technology-centered approach has created an overly complex array of modes and features.

ACC is a specific example of where matching the mental model of an operator to the automation's algorithms may be quite effective. Because ACC can only apply moderate levels of braking, drivers must intervene if the car ahead brakes heavily. If drivers must intervene, they must quickly enter the control loop because fractions of a second can make the difference in avoiding a collision. If the automation behaves in a manner consistent with drivers' expectations, drivers will be more likely to detect and respond to the operational limits of the automation quickly [25.116]. *Goodrich* and *Boer* [25.116] designed an ACC algorithm consistent with drivers' mental models such that ACC behavior was partitioned according to perceptually relevant variables of inverse time-to-collision and time headway. Inverse time-to-collision is the relative velocity divided by the distance between the vehicles. Time headway is the distance between the vehicles divided by the velocity of the driver's vehicle. Using these variables it is possible to identify a perceptually salient boundary that separates routine speed regulation and headway maintenance from active braking associated with collision avoidance.

For situations in which the metaphor for automation is an agent, the mental model people may adopt to understand the automation is that of a human collaborator. Specifically, *Miller* [25.117] suggests that computer etiquette may have an important influence on human–automation interaction. Etiquette may influence trust because category membership associated with adherence to a particular etiquette helps people to infer how the automation will perform. Some examples of automation etiquette are for the automation to make it easy for operators to override and recover from errors, to enable interaction features only when and if necessary, to explain what is being done and why, to interrupt operators only in emergency situations, and to provide information that is unique to the information known by the operator.

Developing automation etiquette could promote appropriate trust, but also has the potential to lead to inappropriate trust if people infer inappropriate category memberships and develop distorted expectations regarding the capability of the automation. Even in simple interactions with technology, people often respond as they would to another person [25.35, 118]. If anticipated, this tendency could help operators develop appropriate expectations regarding the behavior of the automation; however, unanticipated anthropomorphism could lead to surprising misunderstandings of the automation.

An important prerequisite for designing automation according to the mental model of the operator is the existence of a consistent mental model. Individual differences may lead to many different mental models and expectations. This is particularly true for automation that acts as an agent, in which a mental-model-based design must conform to complex social and cultural expectations. In addition, the mental model must be consistent with the physical constraints of the system if the automation is to work properly [25.119]. Mental models often contain misconceptions, and transferring these to the automation could lead to serious misunderstandings and automation failures. Even if an operator's mental model is consistent with the system constraints, automation based on such a mental model may not achieve the same benefits as automation based on more sophisticated algorithms. In this case, designers must consider the tradeoff between the benefits of a complex control algorithm and the costs of an operator not understanding that algorithm. Enhanced feedback and representation aiding can mitigate this tradeoff.

25.4 Future Challenges in Automation Design

The previous section outlined strategies that can make the operator–automation partnership more effective. As illustrated by the challenges in applying the Fitts' list, the application of these strategies, either individually or collectively, does not guarantee effective automation. In fact, the rapid advances in software and hardware development, combined with an ever expanding range of applications, make future problems with automation likely. The following sections highlight some of these emerging challenges. The first concerns the demands of managing swarm automation, in which many semiautonomous agents work together. The second concerns large, interconnected networks of people and automation, in which issues of cooperation and competition become critical. These examples represent some emerging challenges facing automation design.

25.4.1 Swarm Automation

Swarm automation consists of many simple, semiautonomous entities whose emergent behavior provides a robust response to environmental variability. Swarm automation has important applications in a wide range of domains, including planetary exploration, unmanned aerial vehicle reconnaissance, land-mine neutralization, and intelligence gathering; in short, it is applicable in any situation in which hundreds of simple agents might be more effective than a single, complex agent. Biology-inspired robotics provides a specific example of swarm automation. Instead of the traditional approach of relying on one or two larger robots, they employ swarms of insect robots [25.120, 121]. The swarm robot concept assumes that small robots with simple behaviors can perform important functions more reliably and with lower power and mass requirements than can larger robots [25.122–124]. Typically, the simple algorithms controlling the individual entity can elicit desirable emergent behaviors in the swarm [25.125, 126]. As an example, the collective foraging behavior of honeybees shows that agents can act as a coordinated group to locate and exploit resources without a complex central controller.

In addition to physical examples of swarm automation, swarm automation has potential in searching large complex data sets for useful information. Current approaches to searching such data sources are limited. People miss important documents, disregard data that is a significant departure from initial assumptions, misinterpret data that conflicts with an emerging understanding, and disregard more recent data that could revise interpretation [25.127]. The parameters that govern discovery and exploitation of food sources for ants might also apply to the control of software agents in their discovery and exploitation of information. Just as swarm automation might help explore physical spaces, it might also help explore information spaces [25.128].

The concept of hortatory control describes some of the challenges of controlling swarm automation. Hortatory control describes situations where the system being controlled retains a high degree of autonomy and operators must exert indirect rather than direct control [25.129]. Interacting with swarm automation requires people to consider swarm dynamics and not just the behavior of the individual agents. In these situations, it is most useful for the operator to control parameters affecting group rather than individual agents and to receive feedback about group rather than individual behavior. Parameters for control might include the degree to which each agent tends to follow successful agents (positive feedback), the degree to which they follow the emergent structure of their own behavior (stigmergy), and the amount of random variation that guides their paths [25.130]. In exploration, a greater amount of random variation will lead to a more complete search, and a greater tendency to follow successful agents will speed search and exploitation [25.131]. Swarm automation has great potential to extend human capabilities, but only if a thorough empirical and analytic investigation identifies the display requirements, viable control mechanisms, and the range of swarm dynamics that can be comprehended and controlled by humans [25.132].

25.4.2 Operator–Automation Networks

Complex operator–automation networks emerge as automation becomes more pervasive. In this situation, the appropriate unit of analysis shifts from a single operator interacting with a single element of automation to that of multiple operators interacting with multiple elements of automation. Important dynamics can only be explained with this more complex unit of analysis. The factors affecting microlevel behavior may have unexpected effects on macrolevel behavior [25.133]. As the degree of coupling increases, poor coordination between operators and inappropriate reliance on automation has greater consequences for system performance [25.6].

Supply chains represent an increasingly important example of multi-operator–multi-automation systems. A supply chain is composed of a network of suppliers, transporters, and purchasers who work together, usually as a decentralized virtual company, to convert raw materials into products. The growing popularity of supply chains reflects the general trend of companies to move away from vertical integration, where a single company converts raw materials into products. Increasingly, manufacturers rely on supply chains [25.134] and attempt to manage them with automation [25.86].

Supply chains suffer from serious problems that erode their promised benefits. One is the bullwhip effect, in which small variations in end-item demand induces large-order oscillations, excess inventory, and back-orders [25.135]. The bullwhip effect can undermine a company's efficiency and value. Automation that forecasts demands can moderate these oscillations [25.136, 137]. However, people must trust and rely on that automation, and substantial cooperation between supply-chain members must exist to share such information.

Vicious cycles also undermine supply-chain performance, through an escalating series of conflicts between members [25.138]. Vicious cycles can have dramatic negative consequences for supply chains; for example, a strategic alliance between Office Max and Ryder International Logistics devolved into a legal fight in which Office Max sued Ryder for US $21.4 million and then Ryder sued Office Max for US $75 million [25.139]. Beyond the legal costs, these breakdowns threaten competitiveness and undermine the market value of the companies involved [25.134]. Vicious cycles also undermine information sharing, which can exacerbate the bullwhip effect. Even with the substantial benefits of cooperation, supply chains frequently fall into a vicious cycle of diminishing cooperation.

Inappropriate use of automation can contribute to both vicious cycles and the bullwhip effect, but has received little attention. A recent study used a simulation model to examine how reliance on automation influences cooperation and how sharing two types of automation-related information influences cooperation between operators in the context of a two-manufacturer one-retailer supply chain [25.21]. This study used a decision field-theoretic model of the human operator [25.140, 141] to assess the effects of automation failures on cooperation and the benefit of sharing automation-related information in promoting cooperation. Sharing information regarding automation performance improved operators' reliance on automation, and the more appropriate reliance promoted cooperation by avoiding unintended competitive behaviors caused by inappropriate use of automation. Sharing information regarding the reliance on automation increased willingness to cooperate even when the other occasionally engaged in competitive behavior. Sharing information regarding the operators' reliance on automation led to a more charitable interpretation of the other's intent and therefore increased trust in the other operator. The consequence of enhanced trust is an increased chance of cooperation. Figure 25.4 shows that these two types of information sharing influence cooperation and result in an additive improvement in cooperation. This preliminary simulation study showed that cooperation depends on the appropriate use of automation and that sharing automation-related information can have a profound effect on cooperation, a result that merits verification with experiments with human subjects.

The interaction between automation, cooperation, and performance seen with supply-chain management may also apply to other domains; for example, power-grid management involves a decentralized network that makes it possible to efficiently supply the USA with power, but it can fail catastrophically when cooperation and information-sharing breaks down [25.142]. Similarly, datalink-enabled air-traffic control makes it possible for pilots to negotiate flight paths efficiently, but it can fail when pilots do not cooperate or have trouble anticipating the complex dynamics of the system [25.143, 144]. Overall, technology is creating many highly interconnected networks that have great potential, but also raise important concerns. Resolving these concerns partially depends on designing effective multi-operator–multi-automation interactions.

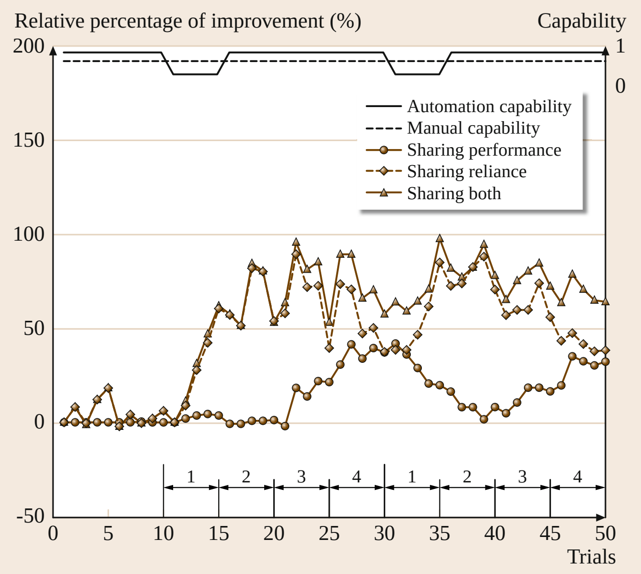

Fig. 25.4 The effect of sharing information regarding the performance of the automation and reliance on the automation [25.21]

Swarm automation and complex operator–automation networks pose challenges beyond those of traditional systems and require new design strategies. The automation design strategies described earlier, such as function allocation, operator–automation simulation, representation aiding, and expectation matching are somewhat limited in addressing the new challenges of swarm automation and complex operator–automation networks. A particular challenge in automation design is developing analytic tools, interface designs, and interaction concepts that consider issues of cooperation and coordination in operator–automation interactions. For further discussion on the automation interactions and interface design refer to Chap. 34.

26. Collaborative Human–Automation Decision Making

Mary L. Cummings, Sylvain Bruni

The development of a comprehensive collaborative human–computer decision-making model is needed that demonstrates not only what decision-making functions should or could be assigned to humans or computers, but how many functions can best be served in a mutually supportive environment in which the human and computer collaborate to arrive at a solution superior to that which either would have come to independently. To this end, we present the human–automation collaboration taxonomy (HACT), which builds on previous research by expanding the *Parasuraman* information processing model [26.1], specifically the decision-making component. Instead of defining a simple level of automation for decision making, we deconstruct the process to include three distinct roles: the moderator, generator, and decider. We propose five levels of collaboration (LOCs) for each of these roles, which form a three-tuple that can be analyzed to evaluate system collaboration, and possibly identify areas for design intervention. A resource allocation mission planning case study is presented using this framework to illustrate the benefit for system designers.

In developing any complex supervisory control system that involves the integration of human decision making with automation, the question often arises as to where, how, and how much humans should be in the decision-making loop. Allocating roles and functions between the human and the computer is critical in defining efficient and effective system architectures. However, role allocation does not necessarily need to be mutually exclusive, and instead of systems that clearly define specific roles for either human or automation, it is possible that humans and computers can collaborate in a mutually supportive decision-making environment. This is especially true for aspects of supervisory control that include planning and resource allocation (e.g., how should multiple aircraft be routed to avoid bad weather, or how to allocate ambulances in a disaster), which is the focus of this chapter. For discussion purposes, we define collaboration as *the mutual engagement of agents in a coordinated and synchronous effort to solve a problem based on a shared conception of it* [26.2, 3]. We define agents as either humans or some form of automation/computer that provides some level of interaction.

For planning and resource allocation supervisory control tasks in complex systems, the problem spaces are large with significant uncertainty, so the use of automation is clearly warranted in attempting to solve a particular problem; for example, if bad weather prevents multiple aircraft from landing at an airport, air-traffic controllers need to know right away which alternate airports are within fuel range, and of these, which have the ability to service the different aircraft types, the predicted traffic volume, routing conflicts, etc. While automation could be used to provide optimized routing recommendations quickly, computer-generated solutions are unfortunately not always the best solutions. While fast and able to handle complex computation far better than humans, computer optimization algorithms are notoriously *brittle* in that they can only take into account those quantifiable variables identified in the design stages that were deemed to be critical [26.4]. In supervisory control systems with inherent uncertainties (weather impacts, enemy movement, etc.), it is not possible to include a priori every single variable that could impact the final solution. Moreover, it is not clear exactly what characterizes an *optimal* solution in uncertain such scenarios. Often, in these domains, the need to generate an *optimal* solution should be weighed against a *satisficing* [26.5] solution. Because constraints and variables are often dynamic in complex supervisory control environments, the definition of optimal is also a constantly changing concept. In those cases of time pressure, having a solution that is good enough, robust, and quickly reached is often preferable to one that requires complex computation and extended periods of times, which may not be accurate due to incorrect assumptions.

Recognizing the need for automation to help navigate complex and large supervisory control problem spaces, it is equally important to recognize the critical role that humans play in these decision-making tasks. Optimization is a word typically associated with computers but humans are natural optimizers as well, although not necessarily in the same linear vein as computers. Because humans can reason inductively and generate conceptual representations based on both abstract and factual information, they also have the ability to optimize based on qualitative and quantitative information [26.6]. In addition, allowing operators active participation in decision-making processes provides not only safety benefits, but promotes situation awareness and also allows a human operator, and thus a system, to respond more flexibly to uncertain and unexpected events. Thus, decision support systems that leverage the collaborative strength of humans and automation in supervisory control planning and resource allocation tasks could provide substantial benefits, both in terms of human and system performance,

Unfortunately, little formal guidance exists to aid designers and engineers in the development of collaborative human–computer decision support systems. While many frameworks have been proposed that detail levels of human–automation role allocation, there has been no focus on what specifically constitutes collaboration in terms of role allocation and how this can be quantified to allow for specific system analysis as well as design guidance. Therefore, to better describe human-collaborative decision support systems in order to provide more detailed design guidance, we present the human–automation collaboration taxonomy (HACT) [26.7].

26.1 Background

There is little previous literature that attempts to classify, describe, or provide design guidance on human–automation (or computer) collaboration. Most previous efforts have generally focused on developing application-specific decision support tools that promote some open-ended form of human–computer interaction (e.g., [26.8–10]). In an attempt to categorize human–computer collaboration more formally, *Silverman* [26.11] proposed categories of human–computer interaction in terms of critiquing, although this is a relatively narrow field of human–computer collaboration. *Terveen* [26.12] attempted to seek some unified approach and more broadly define and categorize human–computer collaboration in terms of human emulation and human "complementary" [sic]. Beyond these broad definitions and categorizations of human–computer collaboration and narrow applications of specific algorithms and visualizations, there has been no underlying theory addressing how collaboration with an automated agent supports operator decision making at the most fundamental information processing level.

So while the literature on human–automation *collaboration* in decision making is sparse, the converse is true in terms of scales and taxonomies of automation levels that describe *interactions* between a human operator and a computer/automation. These levels of automation (LOAs) generally refer to the role allocation between automation and the human, particularly in the analysis and decision phases of a simplified information processing model of acquisition, analysis, decision, and action phases [26.1, 13, 14]. The originators of the concept of levels of automation, *Sheridan* and *Verplank* (SV), initially proposed that automation could range from a fully manual system with no computer intervention to a fully automated system where the human is kept completely out of the loop [26.15]. *Parasuraman* [26.1] expanded the original SV LOA to include ten levels (Table 26.1).

Table 26.1 Levels of automation (after [26.1, 15])

Automation level	Automation description
1	The computer offers no assistance: human must take all decision and actions
2	The computer offers a complete set of decision/action alternatives, or
3	Narrows the selection down to a few, or
4	Suggests one alternative, and
5	Executes that suggestion if the human approves, or
6	Allows the human a restricted time to veto before automatic execution, or
7	Executes automatically, then necessarily informs humans, and
8	Informs the human only if asked, or
9	Informs the human only if it, the computer, decides to
10	The computer decides everything and acts autonomously, ignoring the human

At the lower levels, LOAs 1–4, the human is actively involved in the decision-making process. At level 5, the automation takes on a more active role in executing decisions, while still requiring consent from the operator before doing so (known as management-by-consent). Level 6, typically referred to as management-by-exception, allows the automation a more active role in decisions, executing solutions unless vetoed by the human. For levels 7–10, humans are only allowed to accept or veto solutions presented to them. Thus, as levels increase, the human is increasingly removed from the decision-making loop, and the automation is increasingly allocated additional authority. This scale addresses primarily authority allocation, i. e., who is given the authority to make the final decision, although only to a much smaller and limited degree does it address the solution-generation aspect of decision making, which is a critical aspect of human–computer collaboration.

The solution-generation process in supervisory control planning and resource allocation tasks is critical because this is the aspect of the human–computer interaction where the variables and constraints can be manipulated to determine solution alternatives. This access creates a sensitivity analysis trade space that allows human operators the ability to cope with uncertainty and apply judgment and experience that are unavailable to computer algorithms. While the LOAs in Table 26.1 provide some indirect guidance as to how the solution-generation process can be allocated either to the human or computer, it is only tangentially inferred, and there is no level that allows for joint construction or modification of solutions.

Other LOA taxonomies have addressed the need to examine authority and solution generation LOAs, although none have addressed them in an integrated fashion; for example, *Endsley* [26.16] incorporated artificial intelligence into a five-point LOA scale, thus addressing some aspects of solution generation and authority. *Riley* [26.17] investigated the use of the level of information attribute in addition to the automation authority attribute, creating a two-dimensional scale. Another ten-point scale was created by *Endsley* and *Kaber* [26.16] where each level corresponds to a specific task behavior of the automation, going from *manual control* to *full automation*, through intermediate levels such as *blended decision making* or *supervisory control*. While all of these scales acknowledge that there are possible collaborative processes between humans and automated agents, none specifically detail how this interaction can occur, and how different attributes of a collaborative system can each have a different LOA. To address this shortcoming in the literature, we developed the human–automation collaboration taxonomy (HACT), which is detailed in the next section.

26.2 The Human–Automation Collaboration Taxonomy (HACT)

In order to better understand how human operators and automation collaborate, the four-stage information-processing flow diagram of *Parasuraman* [26.1] (with stages: information acquisition, information analysis,

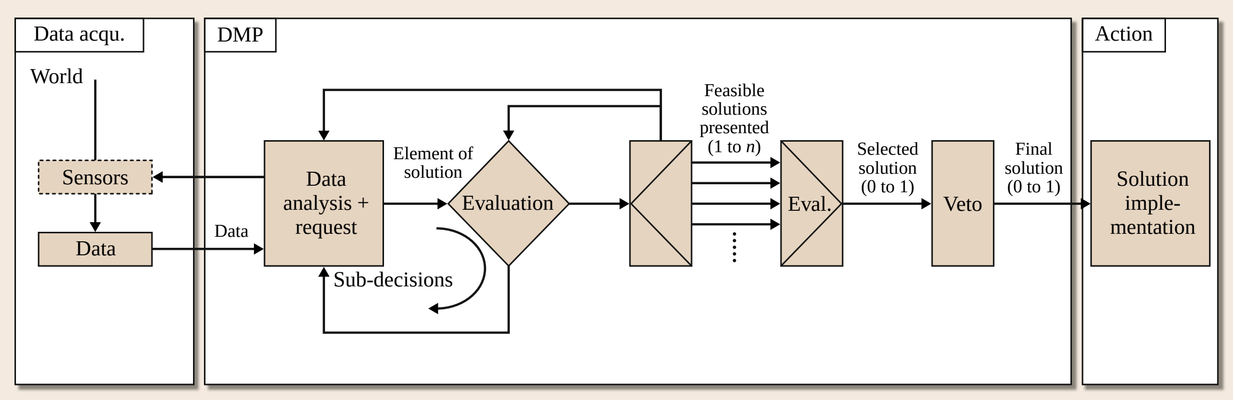

Fig. 26.1 The HACT collaborative information-processing model

decision selection, and action implementation) was modified to focus specifically on collaborative decision making. This new model, shown in Fig. 26.1, features three steps: data acquisition, decision making, and action taking. The data acquisition step is similar to that proposed by *Parasuraman* [26.1] in that sensors retrieve information from the outside world or environment, and transform it into working data. The collaborative aspect of this model occurs in the next stage, the decision-making process, which corresponds to the integration of the analysis and decision phases of the *Parasuraman* [26.1] model.

First, the data from the acquisition step is analyzed, possibly in an iterative way where requests for more data can be sent to the sensors. The data analysis outputs some elements of a solution to the problem at hand. The evaluation block estimates the appropriateness of these elements of solutions for a potential final solution. This block may initiate a recursive loop with the data analysis block; for instance, operators may request more analysis of the domain space or part thereof. At this level, subdecisions are made to orient the search and analysis process. Once the evaluation step is validated, i. e., subdecisions are made, the results are assembled to constitute one or more feasible solutions to the problem. In order to generate feasible solutions, it is possible to loop back to the previous evaluation phase, or even to the data analysis step. At some point, one or more feasible solutions are presented in a second evaluation step.

The operator or automation (depending on the level of automation) will then select one solution (or none) out of the pool of feasible solutions. After this selection procedure, a veto step is added, since it is possible for one or more of the collaborating agents to veto the solution selected (such as in management-by-exception). An agent may be a human operator or an automated computer system, also called automation. If the proposed solution is vetoed, the output of the veto step is empty, and the decision-making process starts again. If the selected solution is not vetoed, it is considered the *final solution* and is transferred to the action mechanism for implementation.

26.2.1 Three Basic Roles

Given the decision-making process (DMP) shown in Fig. 26.1, three key roles have been identified: moderator, generator, and decider. In the context of collaborative human–computer decision making, these three roles are fulfilled either by the human operator, by automation, or by a combination of both. Figure 26.2 displays how these three basic roles fit into the HACT collaborative information-processing model. The generator and the decider roles are mutually exclusive in that the domain of competency of the generator (as outlined in Fig. 26.2) does not overlap with that of the decider. However, the moderator's role subsumes the entire decision-making process. As will be discussed, each of the three roles has its own possible LOA scale.

The Moderator

The moderator is the agent(s) that keeps the decision-making process moving forward, and ensures that the various phases are executed; for instance, the moderator may initiate the decision-making process and interaction between the human and automation. The moderator may prompt or suggest that subdecisions need to be made, or evaluations need to be considered. It could also be involved keeping the decision processing within

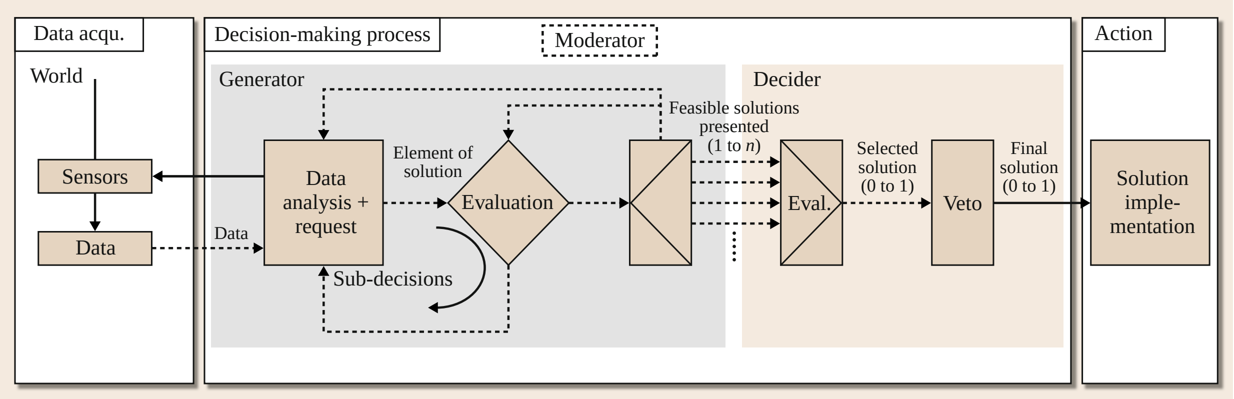

Fig. 26.2 The three collaborative decision-making process roles: moderator, generator, and decider

prespecified limits when time pressure is a concern. In relation to the ten-level SV LOA scale (Table 26.1), the step between LOA 4 and 5 implies this role, but does not address the fact that moderation can occur across multiple segments of the decision-making process and separate from the tasks of solution generation and selection.

The Generator

The generator is the agent(s) that generates feasible solutions from the data. Typically, the generator role involves searching, identifying, and creating solution(s) or parts thereof. Most of the previously discussed LOAs (e.g., [26.1, 16]) address the role of a solution generator. However, instead of focusing on only the actual solution (e.g., automation generating one or many solutions), we expand in detail the notion of the generator to include other aspects of solution generation, i. e., all the other steps within the generator box (Fig. 26.2), such as the automation analyzing data, which makes the solution generation easier for the human operator. Additionally, the role allocation for generator may not be mutually exclusive but could be shared to varying degrees between the human operator and the automation; for example, in one system the human could define multiple constraints and the automation searches for a set of possible solutions bounded by these constraints. In another system, the automation could propose a set of possible solutions and then the human operator narrows down these solutions.

Table 26.2 Moderator and generator levels

Level	Who assumes the role of generator and/or moderator?
2	Human
1	Mixed, but more human
0	Equally shared
−1	Mixed, but more automation
−2	Automation

For both the moderator and generator roles, the general LOAs can be seen in Table 26.2, which we recharacterize as LOCs (levels of collaboration). While the levels could be parsed into more specific levels, as seen in previously discussed LOAs, these five levels were chosen to reflect degrees of collaboration with the center scale reflecting balanced collaboration. At either end of the LOC scale (2 or −2), the system, in terms of moderation and generation, is not collaborative. The negative sign should not be interpreted as a critical reflection on the use of automation; it simply reflects scaling in the opposite direction. A system at LOC 0, however, is a balanced collaborative system for either the moderator and/or generator.

The Decider

The third role within the HACT collaborative decision-making process is the decider. The decider is the agent(s) that *makes the final decision*, i. e., that selects the potentially final solution out of the set of feasible solutions presented by the generator, and who has veto power over this selection decision. Veto power is a nonnegotiable attribute: once an agent vetoes a decision, the other agent cannot supersede it. This veto power is also an important attribute in other LOA scales [26.1, 16], but we have added more resolution to the possible role allocations in keeping with our collaborative approach, listed in Table 26.3. As in Table 26.2, the most balanced

Level	Who assumes the role of decider?
2	Human makes final decision, automation cannot veto
1	Human or automation can make final decision, human can veto, automation cannot veto
0	Human or automation can make final decision, human can veto, automation can veto
−1	Human or automation can make final decision, human cannot veto, automation can veto
−2	Automation makes final decision, human cannot veto

Table 26.3 Decider levels

collaboration between the human and the automation is seen at the midpoint, with the greatest lack of collaboration at the extreme levels.

The three roles, moderator, generator and decider, focus on the tasks or actions that are undertaken by the human operator, the automation, or the combination of both within the collaborative decision-making process.

26.2.2 Characterizing Human Supervisory Control System Collaboration

Given the scales outlined above, decision support systems can be categorized by the collaboration across the three different roles (moderator, generator, and decider) in the form of a three-tuple, e.g., $(2, 1, 2)$ or $(-2, -2, 1)$. In the first example of $(2, 1, 2)$, this system includes the human as both the moderator and the decider, as well as generating most of the solution, but leverages some automation for the solution generation. An example of such a system would be one where an operator needs to plan a mission route but must select not just the start and goal state, but all intermediate points in order to avoid all restricted zones and possible hazards. Automation is used to ensure fuel limits are not exceeded and to alert the operator in the case of any area violations.

This is in contrast to the highly automated $(-2, -2, 1)$ example, which is the characterization of the Patriot missile system. This antimissile missile system notifies the operator that a target has been detected, allows the operator approximately 15 s to veto the automation's solution, and then fires if the human does not intervene. Thus the automation moderates the flow, analyzes the solution space, presents a single solution, and then allows the human to veto this. Note that under the ten LOAs in Table 26.1, this system would be characterized at LOA 6, but the HACT three-tuple provides much more information. It demonstrates that the system is highly automated at the moderator and generator levels, while the human has more authority than the automation for the final decision. However, a low decider level does not guarantee a human-centered system in that the Patriot system has accidentally killed three North Atlantic Treaty Organization (NATO) airmen because operators were not able to determine in the 15 s window that the targets were actually friendly aircraft and not enemy missiles. This example illustrates that all three entries in the HACT taxonomy are important for understanding a system's collaborative potential.

26.3 HACT Application and Guidelines

In order to illustrate the application and utility of HACT, a case study is presented. Given the increased complexity, uncertainty, and time pressure of mission planning and resource allocation in command and control settings, increased automation is an obvious choice for system improvement. However just what level of automation/collaboration should be used in such an application is not so obvious. As previously mentioned, too much automation can induce complacency and loss of situation awareness, and coupled with the inherent inability of automated algorithms to be perfectly correct in dynamic command and control settings, high levels of automation are not advisable. However, low levels of automation can cause unacceptable operator workload as well as suboptimal, very inefficient solutions. Thus the resource allocation aspect of mission planning

Fig. 26.3 Interface 1

is well suited for some kind of collaborative human–computer environment. To investigate this issue, three interfaces were designed for a representative system, each with a different LOA/LOC detailed in the next section.

The general objective of this resource allocation problem is for an operator to match a set of military missions with a set of available resources, in this case Tomahawk missiles aboard ship and submarine launch platforms.

Interface 1 (Fig. 26.3) was designed to support manual matching of the missiles to the missions at a low level of collaboration. This interface provides raw data tables with all the characteristics of missions and missiles that must be matched, but only provides very limited automated support, such as basic data sorting, mission/missile assignment summaries by categories, and feedback on mission–missile incompatibility and current assignment status. Therefore, this interface mostly involves manual problem solving. As a result, interface 1 is assigned a level 2 moderator because the human operator fully controls the process. Because interface 1 only features basic automation support, the generator role is at level 1. The decider is at level 2 since only the human operator can validate a solution for further implementation, with no possible automation veto.

Interface 2 (Fig. 26.4) was designed to offer the human operator the choice to either solve the mission–missile assignment task manually as in interface 1 (note in Fig. 26.4 that the top part of interface 2 is a replica of interface 1 shown in Fig. 26.3), or to leverage automation and collaborate with the computer to generate solutions. In the latter instance, termed Automatch, the human operator can steer the search of the automated solution in the domain space by selecting and prioritizing search criteria. Then, the automation's fast computing capabilities perform a heuristic search based on the criteria defined by the human. The operator can either keep the solution output or modify it manually. The operator can also elect to modify the search criteria to get a new solution.

Therefore, for interface 2, the moderator remains at level 2 because the human operator is still in full control of the process, including which tasks are completed, at what pace, and in which order. Because of the flexibility in obtaining a solution in that the human can define the search criteria, thus orienting the automation which does the bulk of the computation, the generator is labeled 0. The decider is at level 2 since only the human operator can validate a final solution, which the automation cannot veto.

While interfaces 1 and 2 are both based on the use of raw data, interface 3 (Fig. 26.5) is completely graphical, and allows the operator to only have access to postsolution sensitivity analysis tools. For interface 2, the automated solution process is guided by the human, who also can conduct sensitivity analysis via an Au-

tomatch function; the Automatch button at the top of interface 3 is similar to that in interface 2. However, the user can only select a limited subset of information criteria by which to orient the algorithmic search, causing the operator to rely more on the automation than in interface 2. Thus the HACT three-tuple in this case

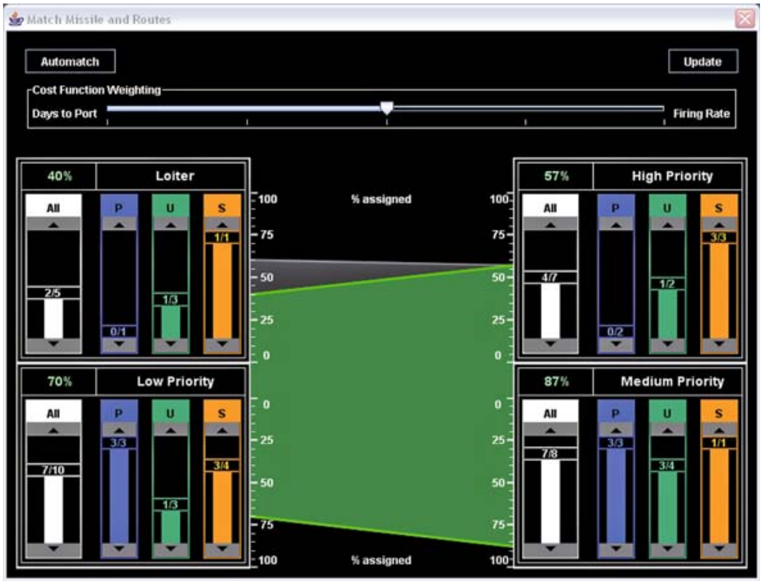

Fig. 26.5 Interface 3

is (2, −1, 2) as neither the moderator nor decider roles changed from interface 2, although the generator's did.

The three interfaces were evaluated with 20 US Navy personnel who would use such a tool in an operational setting. While the full experimental details can be found elsewhere [26.18], in terms of overall performance, operators performed the best with interfaces 1 and 2, which were not statistically different from each other ($p = 0.119$). Interface 3, the one with the predominantly automation-led collaboration, produced statistically worse performance compared with both interfaces 1 and 2 ($p = 0.011$ and 0.031 respectively). Table 26.4 summarizes the HACT categorization for the three interfaces, along with their relative performance rankings. The results indicate that, because the moderator and decider roles were held constant, the degraded performance for those operators using interface 3 was a result of the differences in the generator aspect of the decision-making process. Furthermore, the decline in performance occurred when the LOC was weighted towards the automation. When the solution process was either human-led or of equal contribution, operators performed no differently. However, when the solution generation was automation led, operators struggled.

While there are many other factors that likely affect these results (trust, visualization design, etc.), the HACT taxonomy is helpful in first deconstructing the automation components of the decision-making process. This allows for more specific analyses across different *collaboration levels* of humans and automation, which has not been articulated in other LOA scales. In addition, as demonstrated in the previous example, when comparing systems, such a categorization will also pinpoint which LOCs are helpful, or at the very least, not detrimental. In addition, while not explicitly illustrated here, the HACT taxonomy can also provides designers with some guidance on system design, i. e., to improve performance for a system; for example, in interface 3, it may be better to increase the moderator LOC instead of lowering the generator LOC.

Table 26.4 Interface performance and HACT three-tuples; M – moderator; G – generator; D – decider

	HACT three-tuple (M, G, D)	**Performance**
Interface 1	(2, 1, 2)	Best
Interface 2	(2, 0, 2)	Best
Interface 3	(2, −1, 2)	Worst

In summary, application of HACT is meant to elucidate human–computer collaboration in terms of an information processing theoretic framework. By deconstructing either a single or competing decision support systems using the HACT framework, a designer can better understand how humans and computers are collaborating across different dimensions, in order to identify possible problem areas in need of redesign; for example, in the case of the Patriot missile system with a (−2, −2, 1) three-tuple and its demonstrated poor performance, designers could change the decider role to a 2 (only the human makes the final decision, automation cannot veto), as well as move towards a more truly collaborative solution generation LOC. Because missile intercept is a time-pressured task, it is important that the automation moderate the task, but because of the inability of the automation to always correctly make recommendations, more collaboration is needed across the solution-generation role, with no automation authority in the decider role. Used in this manner, HACT aids designers in the understanding of the multiagent roles in human–computer collaboration tasks, as well as identifying areas for possible improvement across these roles.

26.4 Conclusion and Open Challenges

The human–automation collaboration taxonomy (HACT) presented here builds on previous research by expanding the *Parasuraman* [26.1] information processing model, specifically the decision-making component. Instead of defining a simple level of automation for decision making, we deconstruct the process to include three distinct roles, that of the moderator (the agent that ensures the decision-making process moves forward), the generator (the agent that is primarily responsible for generating a solution or set of possible solutions), and the decider (the agent that decides the final solution along with veto authority). These three distinct (but not necessarily mutually exclusive) roles can each be scaled across five levels indicating degrees of collaboration, with the center value of 0 in each scale representing balanced collaboration. These levels of collaboration (LOCs) form a three-tuple that can be analyzed to evaluate system collaboration, and possibly identify areas for design intervention.

As with all such levels, scales, taxonomies, etc., there are limitations. First, HACT as outlined here does not address all aspects of collaboration that could be considered when evaluating the collaborative nature of a system, such as the type and possible latencies in communication, whether or not the LOCs should be dynamic, the transparency of the automation, the type of information used (i. e., low-level detail as opposed to higher, more abstract concepts), and finally how adaptable the system is across all of these attributes. While this has been discussed in earlier work [26.7], more work is needed to incorporate this into a comprehensive yet useful application.

In addition, HACT is descriptive versus prescriptive, which means that it can describe a system and identify post hoc where designs may be problematic, but cannot indicative how the system should be designed to achieve some predicted outcome. To this end, more research is needed in the application of HACT and the interrelation of the entries within each three-tuple, as well as more general relationships across three-tuples. Regarding the within three-tuples issue, more research is needed to determine the impact and relative importance of each of the three roles; for example, if the moderator is at a high LOC but the generator is at a low LOC, are there generalizable principles that can be seen across different decision support systems? In terms of the between three-tuple issue, more research is needed to determine under what conditions certain three-tuples produce consistently poor (or superior) performance, and whether these are generalizable under particular contexts; for example, in high-risk time-critical supervisory control domains such as nuclear power plant operations, a three-tuple of $(-2, -2, -2)$ may be necessary. However, even in this case, given flawed automated algorithms such as those seen in the Patriot missile, the question could be raised of whether it is ever feasible to design a safe $(-2, -2, -2)$ system.

Despite these limitations, HACT provides more detailed information about the collaborative nature of systems than did previous level-of-automation scales, and given the increasing presence of *intelligent* automation both in complex supervisory control systems and everyday life, such as global positioning system (GPS) navigation, this sort of taxonomy can provide for more in-depth analysis and a common point of comparison across competing systems. Other future areas of research that could prove useful would be the determination of how levels of collaboration apply in the other data acquisition and action implementation information processing stages, and what the impact on human performance would be if different collaboration levels were mixed across the stages. Lastly, one area often overlooked that deserves much more attention is the ethical and social impact of human–computer collaboration. Higher levels of automation authority can reduce an operator's awareness of critical events [26.19] as well as reduce their sense of accountability [26.20]. Systems that promote collaboration with an automated agent could possibly alleviate the offloading of attention and accountability to the automation, or collaboration may further distance operators from their tasks and actions and promote these biases. There has been very little research in this area, and given the vital nature of many time-critical systems that have some degree of human–computer collaboration (e.g., air-traffic control and military command and control), the importance of the social impact of such systems should not be overlooked.

27. Teleoperation

Luis Basañez, Raúl Suárez

This chapter presents an overview of the teleoperation of robotics systems, starting with a historical background, and including the description of an up-to-date specific teleoperation scheme as a representative example to illustrate the typical components and functional modules of these systems. Some specific topics in the field are particularly discussed, for instance, control algorithms, communications channels, the use of graphical simulation and task planning, the usefulness of virtual and augmented reality, and the problem of dexterous grasping. The second part of the chapter includes a description of the most typical application fields, such as industry and construction, mining, underwater, space, surgery, assistance, humanitarian demining, and education, where some of the pioneering, significant, and latest contributions are briefly presented. Finally, some conclusions and the trends in the field close the chapter.

The topics of this chapter are closely related to the contents of other chapters such as those on *Communication in Automation, Including Networking and Wireless* (Chap. 13), *Virtual Reality and Automation* (Chap. 15), and *Collaborative Human–Automation Decision Making* (Chap. 26).

The term *teleoperation* is formed as a combination of the Greek word $\tau\eta\lambda\varepsilon$-, (*tele*-, offsite or remote), and the Latin word *operatĭo*, -*ōnis* (*operation*, something done). So, *teleoperation* means performing some work or action from some distance away. Although in this sense teleoperation could be applied to any operation performed at a distance, this term is most commonly associated with robotics and mobile robots and indicates the driving of one of these machines from a place far from the machine location.

There are of lot of topics involved in a *teleoperated robotic system*, including human–machine interaction, distributed control laws, communications, graphic simulation, task planning, virtual and augmented reality, and dexterous grasping and manipulation. Also the fields of application of these systems are very wide and teleoperation offers great possibilities for profitable applications. All these topics and applications are dealt with in some detail in this chapter.

27.1 Historical Background and Motivation

Since a long time ago, human beings have used a range of tools to increase their manipulation capabilities. In the beginning these tools were simple tree branches, which evolved to long poles with tweezers, such as blacksmith's tools that help to handle hot pieces of iron. These developments were the ancestors of master–slave robotic systems, where the slave robot reproduces the master motions controlled by a human operator. Teleoperated robotic systems allow humans to interact with robotic manipulators and vehicles and to handle objects located in a remote environment, extending human manipulation capabilities to far-off locations, allowing the execution of quite complex tasks and avoiding dangerous situations.

The beginnings of teleoperation can be traced back to the beginnings of radio communication when Nikola Tesla developed what can be considered the first teleoperated apparatus, dated 8 November 1898. This development has been reported under the US patent 613 809, *Method of and Apparatus for Controlling Mechanism of Moving Vessels or Vehicles*. However, bilateral teleoperation systems did not appear until the late 1940s. The first bilateral manipulators were developed for handling radioactive materials. Outstanding pioneers were Raymond Goertz and his colleagues at the Argonne National Laboratory outside of Chicago, and Jean Vertut at a counterpart nuclear engineering laboratory near Paris. The first mechanisms were mechanically coupled and the slave manipulator mimicked the master motions, both being very similar mechanisms (Fig. 27.1). It was not until the mid 1950s that Goertz presented the first electrically coupled master–slave manipulator (Fig. 27.2) [27.1].

In the 1960s applications were extended to underwater teleoperation, where submersible devices carried cameras and the operator could watch the remote robot and its interaction with the submerged environment. The beginnings of space teleoperation dates form the 1970s, and in this application the presence of time delay started to cause instability problems.

Technology has evolved with giant steps, resulting in better robotic manipulators and, in particular, increasing the communication means, from mechanical to electrical transmission, using optic wires, radio signals, and the Internet which practically removes any distance limitation.

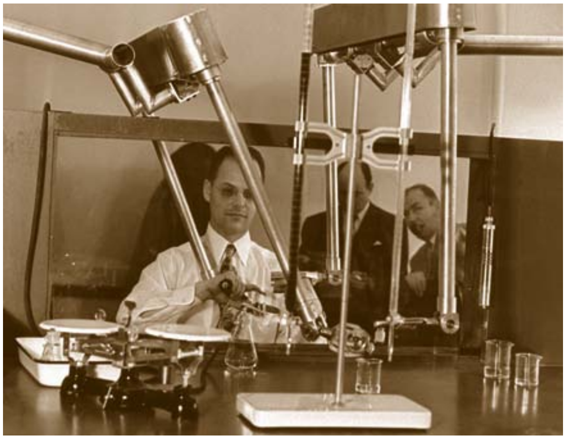

Fig. 27.1 Raymond Goertz with the first mechanically coupled teleoperator (Source: Argonne National Labs)

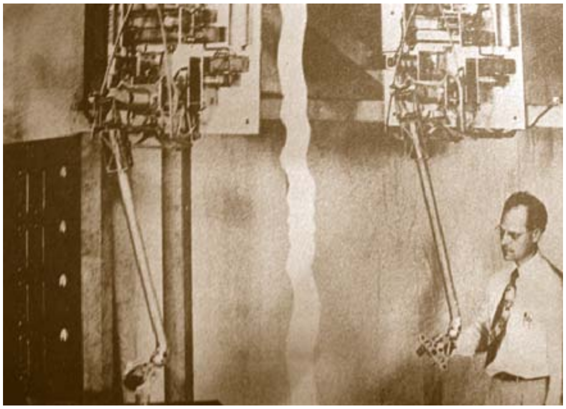

Fig. 27.2 Raymond Goertz with an electrically coupled teleoperator (Source: Argonne National Labs)

Today, the applications of teleoperation systems are found in a large number of fields. The most illustrative are space, underwater, medicine, and hazardous environments, which are described amongst others in Sect. 27.4

27.2 General Scheme and Components

A modern teleoperation system is composed of several functional modules according to the aim of the system. As a paradigm of an up-to-date teleoperated robotic system, the one developed at the Robotics Laboratory of the Institute of Industrial and Control Engineering (IOC), Technical University of Catalonia (UPC), Spain, will be described below [27.2].

The outline of the IOC teleoperation system is represented in Fig. 27.3. The diagram contains two large blocks that correspond to the local station, where the human operator and master robots (haptic devices) are located, and the remote station, which includes two industrial manipulators as slave robots. The system contains the following system modules.

Relational positioning module: This module provides the operator with a means to define geometric relationships that should be satisfied by the part manipulated by the robots with respect to the objects in the environment. These relationships can completely define the position of the manipulated part and then fix all the

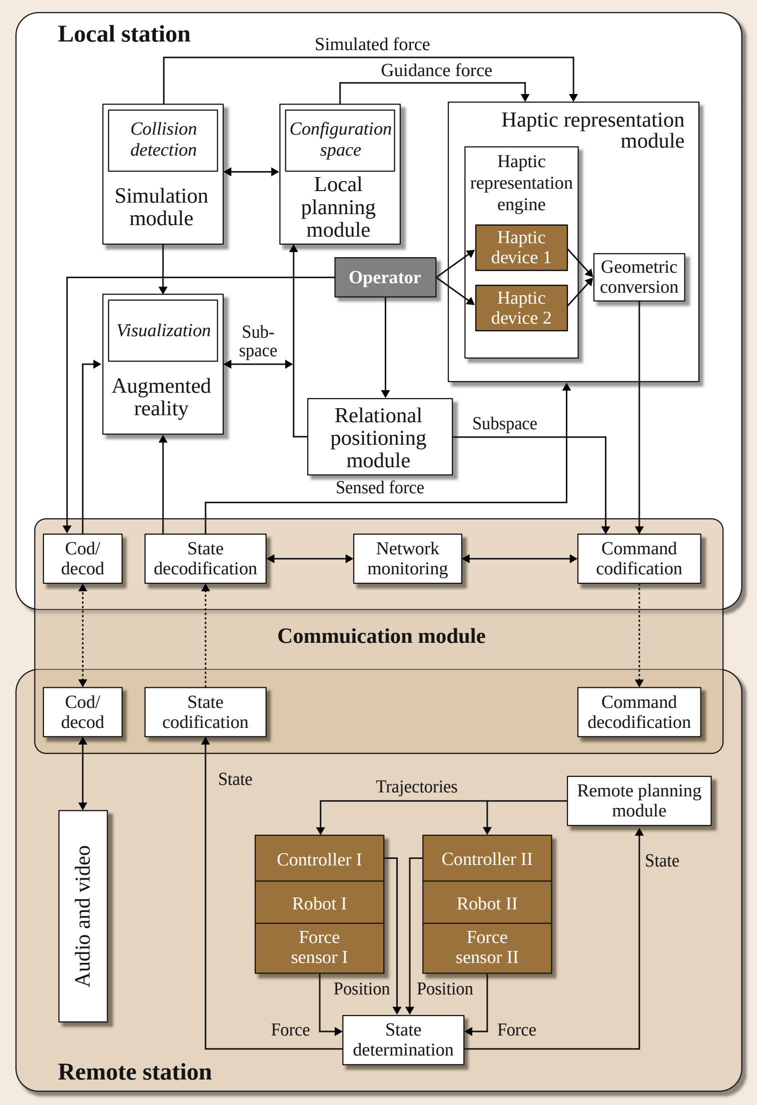

Fig. 27.3 A general scheme of a teleoperation system (courtesy of IOC-UPC)

robots' degrees of freedom (DOFs) or they can partially determine the position and orientation and therefore fix only some DOFs. In the latter case, the remaining degrees of freedom are those that the operator will be able to control by means of one or more haptic devices (master robots). Then, the output of this module is the solution subspace in which the constraints imposed by the relationships are satisfied. This output is sent to the modules of *augmented reality* (for visualization), *command codification* (to define the possible motions in the solution subspace), and *planning* (to incorporate the motion constraints to the haptic devices).

Haptic representation module: This module consists of the *haptic representation engine* and the *geometric conversion submodule*. The haptic representation engine is responsible for calculating the force to be fed back to the operator as a combination of the following forces:

- *Restriction force*: This is calculated by the *planning* module to assure that, during the manipulation of the haptic device by the operator, the motion constraints determined by the *relational positioning* module are satisfied.
- *Simulated force*: This is calculated by the *simulation* module as a reaction to the detection of potential collision situations.
- *Reflected force*: This is the force signal sent from the remote station through the *communication* module to the local station corresponding to the robots' actuators forces and those measured by the force and torque sensors in the wrist of the robots produced by the environmental interaction.

The *geometric conversion submodule* is in charge of the conversion between the coordinates of the haptic devices and those of the robots.

Augmented-reality module: This module is in charge of displaying to the user the view of the remote station, to which is added the following information:

- *Motion restrictions imposed by the operator*. This information provides the operator with the understanding and control of the unrestricted degrees of freedom can be commanded by means of the haptic device (for example, it can visualize a plane on which the motions of the robot end-effector are restricted).
- *Graphical models of the robots in their last configuration received from the cell*. This allows the operator to receive visual feedback of the robots' state from the remote station at a frequency faster than that allowed by the transmission of the whole image, since it is possible to update the robots' graphical models locally from the values of their six joint variables.

This module receives as inputs: (1) the image of the cell, (2) the state (pose) of the robots, (3) the model of the cell, and (4) the motion constraints imposed by the operator. This module is responsible for maintaining the coherence of the data and for updating the model of the cell.

Simulation module: This module is used to detect possible collisions of the robots and the manipulated pieces with the environment, and to provide feedback to the operator with the corresponding force in order to allow him to react quickly when faced with these possible collision situations.

Local planning module: The planning module of the local station computes the forces that should guide the operator to a position where the geometric relationships he has defined are satisfied, as well as the necessary forces to prevent the operator from violating the corresponding restrictions.

Remote planning module: The planning module of the remote station is in charge of reconstructing the trajectories traced by the operator with the haptic device. This module includes a feedback loop for position and force that allows safe execution of motions with compliance.

Communication module: This module is in charge of communications between the local and the remote stations through the used communication channel (e.g., Internet or Internet2). This consists of the following submodules for the information processing in the local and remote stations:

- *Command codification/decodification*: These submodules are responsible for the codification and decodification of the motion commands sent from the local station and the remote station. These commands should contain the information of the degrees of freedom constrained to satisfy the geometric relationships and the motion variables on the unrestricted ones, following the movements specified by the operator by means of the haptic devices (for instance, if the motion is constrained to be on a plane, this information will be transferred and then the commands will be the three variables that define the motion on that plane). For each robot, the following three qualitatively different situations are possible:
  - The motion subspace satisfying the constraints defined by the relationships fixed by the operator

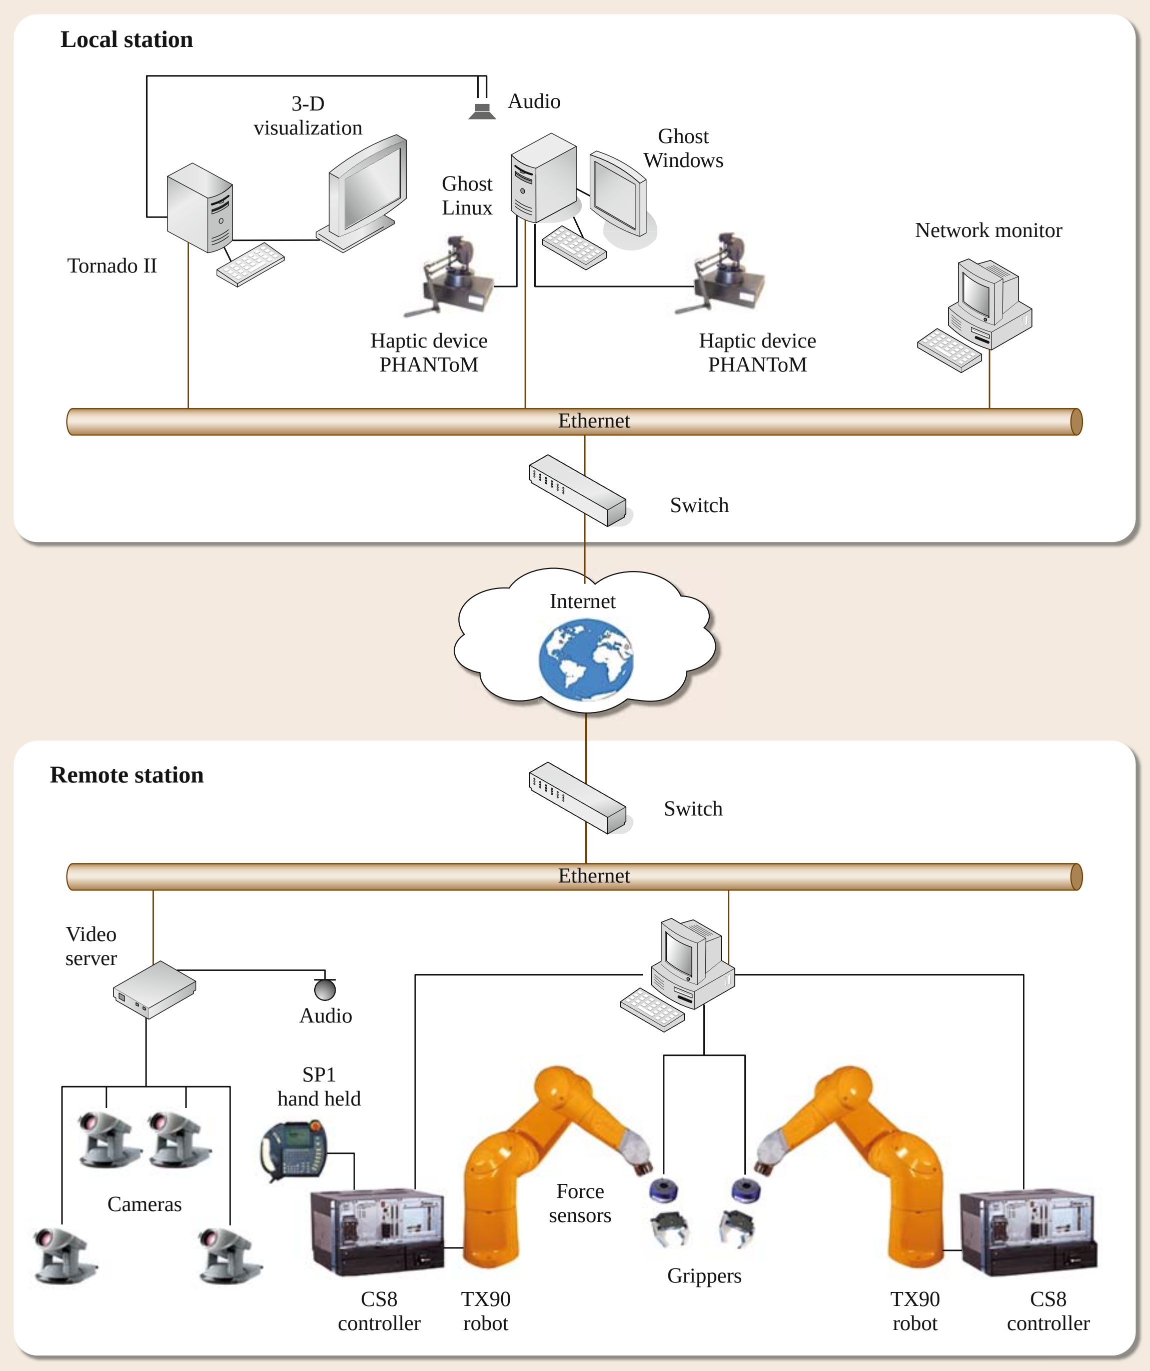

Fig. 27.4 Physical architecture of a teleoperation system (courtesy of IOC-UPC)

has dimension zero. This means that the constraints completely determine the position and orientation (pose) of the manipulated object. In this case the command is this pose.

  - The motion subspace has dimension six, i. e., the operator does not have any relationship fixed. In this case the operator can manipulate the six degrees of freedom of the haptic device and the command sent to the remote station is composed of the values of the six joint variables.
  - The motion subspace has dimension from one to five. In this case the commands are composed of the information of this subspace and the variables that describe the motion inside it, calculated from the coordinates introduced by the operator through the haptic device or determined by the local planning module.
- *State codification/decodification*: These submodules generate and interpret the messages between the remote and the local stations. The robot state is coded as the combination of the position and force information.
- *Network monitoring system*: This submodule analyzes in real time the quality of service (QoS) of the communication channel in order to properly adapt the teleoperation parameters and the sensorial feedback.

A scheme depicting the physical architecture of the whole teleoperation system is shown in Fig. 27.4.

27.2.1 Operation Principle

In order to perform a robotized task with the described teleoperation system, the operator should carry out the following steps:

- Define the motion constraints for each phase of the task, specifying the relative position of the manipulated objects or tools with respect to the environment.
- Move the haptic devices to control the motions of the robots in the subspace that satisfies the imposed constraints. The haptic devices, by means of the force feedback applied to the operator, are capable of:
  - guiding the operator motions so that they satisfy the imposed constraints
  - detecting collision situations and trying to avoid undesired impacts
- Control the realization of the task availing himself of an image of the scene visualized using three-dimensional augmented reality with additional information (like the graphical representation of the motion subspace, the graphical model of the robots updated with the last received data, and other outstanding information for the good performance of the task).

27.3 Challenges and Solutions

During the development of modern teleoperation systems, such as the one described in Sect. 27.2, a lot of challenges have to be faced. Most of these challenges now have a partial or total solution and the main ones are reviewed in the following subsections.

27.3.1 Control Algorithms

A control algorithm for a teleoperation system has two main objectives: telepresence and stability. Obviously, the minimum requirement for a control scheme is to preserve stability despite the existence of time delay and the behavior of the operator and the environment. Telepresence means that the information about the remote environment is displayed to the operator in a natural manner, which implies a feeling of presence at the remote site (immersion). Good telepresence increases the feasibility of the remote manipulation task. The degree of telepresence associated to a teleoperation system is called *transparency*.

Scattering-based control has always dominated the control field in teleoperation systems since it was first proposed by *Anderson* and *Spong* [27.3], creating the basis of modern teleoperation system control. Their approach was to render the communications passive using the analogy of a lossless transmission line with scattering theory. They showed that the scattering transformation ensures passivity of the communications despite any constant time delay. Following the former scattering approach, it was proved [27.4] that, by matching the impedances of the local and remote robot controllers with the impedance of the virtual transmission line, wave reflections are avoided. These were the beginnings of a series of developments for bilateral teleoperators. The reader may refer to [27.5, 6] for two advanced surveys on this topic.

Various control schemes for teleoperated robotic systems have been proposed in the literature. A brief description of the most representative approaches is presented below.

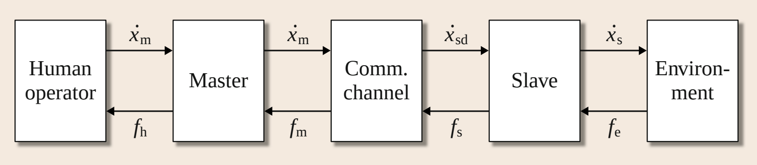

Fig. 27.5 Traditional force reflection

Traditional force reflection. This is probably the most studied and reported scheme. In this approach, the master sends position information to the slave and receives force feedback from the remote interaction of the slave with the environment (Fig. 27.5). However, it was shown that stability is compromised in systems with high time delay [27.3].

Shared compliance control. This scheme is similar to the traditional force reflection, except that on the slave side a compliance term is inserted to modify the behavior of the slave manipulator according to the interaction with the environment.

Scattering-based teleoperation. The scattering transformation (wave variables) used in the transmission of power information makes the communication channel passive even if a time delay T affects the system (Fig. 27.6). However, the scattering transformation presents a tradeoff between stability and performance. In an attempt to improve performance using the scattering transformation, several approaches have been reported, for instance, transmitting wave integrals [27.7, 8] and wave filtering and wave prediction [27.9].

Four-channel control. Velocity and force information is sent to the other side in both directions, thereby defining four channels. In both controllers a linear combination of the available force and velocity information is used to fit the specifications of the control design [27.10].

Proportional (P) and proportional–derivative (PD) controllers. It is widely known that use of the classic scattering transformation may give raise to position drift. In [27.11] position tracking is achieved by sending the local position to the remote station, and adding a proportional term to the position error in the remote controller. Following this approach, [27.12] proposed a symmetric scheme by matching the impedances and adding a proportional error term to the local and remote robots, such that the resulting control laws became simple PD-like controllers. Stability of PD-like controllers, without the scattering transformation, has been proved in [27.13] under the assumption that the human interaction with the local manipulator is passive. In [27.14] it is shown that, when the human operator applies a constant force on the local manipulator, a teleoperation system controlled with PD-like laws is stable.

Variable-time-delay schemes. In the presence of variable time delays, the basic scattering transformation cannot provide the passivity needed in the communications [27.15]. In order to solve this issue, the use of a time-varying gain that is a function of the rate of change of the time delay has been proposed [27.16]. Recently it has been shown [27.17] that, under an appropriate dissipation strategy, the communications can dissipate an amount of energy equal to the generated energy. Applying the strategy of [27.15], in [27.18] it was proven that, under power scaling factors for microteleoperation, the resulting communications remain passive.

27.3.2 Communication Channels

Communication channels can be classified in terms of two aspects: their physical nature and their mode of operation. According to the first aspect, two groups can be defined: physically connected (mechanically, electrically, optically wired, pneumatically, and hydraulically) and physically disconnected (radiofrequency and optically coupled such as via infrared). The second aspect entails the following three groups:

- *Time delay free*. The communication channel connecting the local and the remote stations does not affect the stability of the overall teleoperation system. In general this is the kind of channel present when the two stations are near to each other. Examples of these communication channels are some surgical systems, where the master and slave are lo-

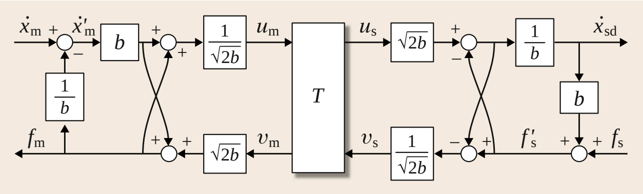

Fig. 27.6 Scattering transformation with impedance adaptation

cated in the same room and connected through wires or radio.

- *Constant time delay*. These are often associated with communications in space, underwater teleoperation using sound signals, and systems with dedicated wires across large distances.
- *Variable time delay*. This is the case, for instance, of packet-switched networks where variable time delays are caused by many reasons such as routing, acknowledge response, and packing and unpacking data.

One of the most promising teleoperation communication channels is the Internet, which is a packet-switched network, i. e., it uses protocols that divide the messages into packets before transmission. Each packet is then transmitted individually and can follow a different route to its destination. Once all packets forming a message have arrived at the destination, they are recompiled into the original message. The transmission control protocol (TCP) and user datagram protocol (UDP) work in this way and they are the Internet protocols most suitable for use in teleoperation systems.

In order to improve the performance of teleoperation systems, quality of service (QoS)-based schemes have been used to provide priorities on the communication channel. The main drawback of today's best-effort Internet service is due to network congestion. The use of high-speed networks with recently created protocols, such as the Internet protocol version 6 (IPv6), improves the performance of the whole teleoperation system [27.19].

Besides QoS, IPv6 presents other important improvements. The current 32 bit address space of IPv4 is not able to satisfy the increasing number of internet users. IPv6 quadruples this address space to 128 bits, which provides more than enough globally unique IP addresses for every network device on the planet. See Fig. 27.7 for a comparison of these protocols.

When using packet-switched networks for real-time teleoperation systems, besides bandwidth, three effects can result in decreased performance of the communication channel: packet loss, variable time delay, and in some cases, loss of order in packet arrival.

27.3.3 Sensory Interaction and Immersion

Human beings are able to perceive information from the real world in order to interact with it. However, sometimes, for engineering purposes, there is a need to interact with systems that are difficult to build in reality or that, due to their physical behavior, present unknown features or limitations. Hence, in order to allow better human interaction with such systems, as well as their evaluation and understanding, the concepts of *virtual reality* and *augmented reality* have been researched and applied to improve development cycles in engineering.

In virtual reality a nonexistent world can be simulated with a compelling sense of realism for a specific environment. So, the real world is replaced by a computer-generated world that uses input devices to interact with and obtain information from the user and capture data from the real world (e.g., using trackers and transducers), and uses output displays that represent the responses of the virtual world by means of visual, touch, aural or taste displays [e.g., haptic devices, head-mounted displays (HMD), and headphones] in order to be perceived by any of the human senses. In this context,

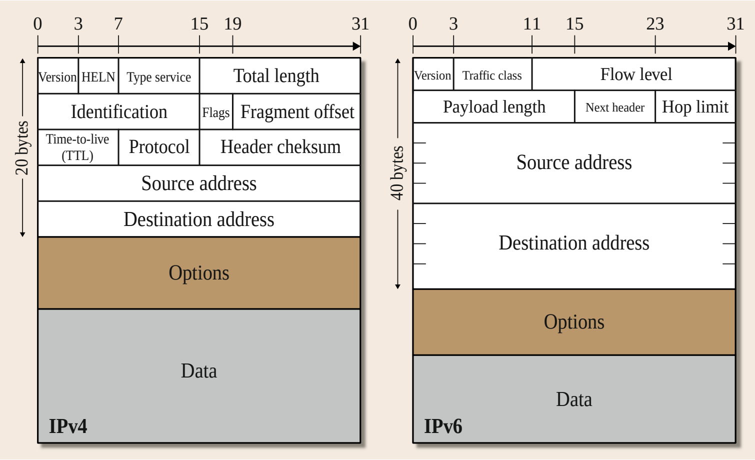

Fig. 27.7 Comparison of IPv4 and IPv6 protocols

immersion is the sensation of being in an environment that actually does not exist and that can be a purely mental state or can be accomplished through physical elements [27.20].

Augmented reality is a form of human–computer interaction (HCI) that superimposes information created by computers over a real environment. Augmented reality enriches the surrounding environment instead of replacing it as in the case of virtual reality, and it can also be applied to any of the human senses. Although some authors put attention on hearing and touch [27.21], the main augmentation route is through visual data addition. Furthermore augmented reality can remove real objects or change their appearance [27.22], operations known as diminished or mediated reality. In this case, the information that is shown and superposed depends on the context, i. e., on the observed objects.

Augmented reality can improve task performance by increasing the degree of reliability and speed of the operator due to the addition or reduction of specific information. Reality augmentation can be of two types: *modal* or *multimodal*. In the modal type, augmentation is referred to the enrichment of a particular sense (normally sight), whereas in the multimodal type augmentation includes several senses. Research done to date has focused mainly on modal systems [27.21, 23].

In teleoperation environments, augmented reality has been used to complement human sensorial perception in order to help the operator perform teleoperated tasks. In this context, augmented reality can reduce or eliminate the factors that break true perception of the remote station, such as time delays in the communication channel, poor visibility of the remote scene, and poor perception of the interaction with the remote environment.

Amongst the applications of augmented reality it is worthwhile to mention interaction between the operator and the remote site for better visualization [27.24, 25], better collaboration capacity [27.26], better path or motion planning for robots [27.27, 28], addition of specific virtual tools [27.29], and multisensorial perception enrichment [27.30].

27.3.4 Teleoperation Aids

Some of the problems arising in teleoperated systems, such as an unstructured environment, communication delays, human operator uncertainty, and safety at the remote site, amongst others, can be reduced using teleoperation aids.

Amongst the teleoperation aids aimed to diminish human operator uncertainty one can highlight virtual fixtures for guiding motion, which have recently been added in surgical teleoperation in order to improve the surgeon's repeatability and reduce his fatigue.

The trajectories to be described by a robot end-effector – either in free space or in contact with other objects – strongly depend on the task to be performed and on the topology of the environment with which it is interacting; for instance, peg-in-hole insertions require alignment between the peg and the hole, spray-painting tasks require maintenance of the nozzle at a fixed distance and orientation with respect to the surface to be painted, and assembly tasks often involve alignment or coincidence of faces, sides, and vertices of the parts to be assembled. For all these examples, virtual guides can be defined and can help the operator to perform the task.

Artificial fixtures or motion guidance can be divided into two groups, depending on how the motion constraints are created, either by software or by hardware. To the first group belong the methods that implement geometric constraints for the operator motions: points, lines, planes, spheres, and cylinders [27.2], which can usually be changed without stopping the teleoperation. An often-used method is to provide obstacles with a repulsive force field, avoiding in this way that the operator makes the robot collide with the obstacles. In the second group, specific hardware is used to guide the motion, for example, guide rails and sliders with circled rails. Figure 27.8 shows a teleoperated painting task restricted to a plane.

An example of a motion constraints generator is the PMF (positioning mobile with respect to fixed) solver [27.31]. PMF has been designed to assist execution of teleoperated tasks featuring precise or repetitive motions. By formulating an object positioning problem in terms of symbolic geometric constraints, the motion

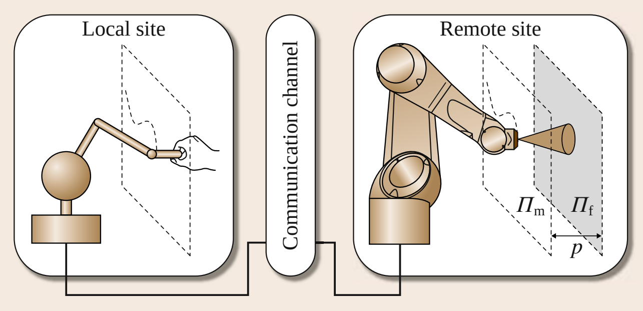

Fig. 27.8 A painting teleoperation task with a plane constraint on the local and the remote sites

of an object can be totally or partially restricted, independently of its initial configuration. PMF exploits the fact that, in geometric constraint sets, the rotational component can often be decoupled from the translational one and solved independently. Once the solution is obtained, the resulting restriction forces are fed to the operator via a haptic interface in order to guide its motions inside this subspace.

27.3.5 Dexterous Telemanipulation

A common action in robotics applications is grasping of an object, and teleoperated robotics is no exception. Grasping actions can often be found in telemanipulation tasks such as handling of dangerous material, rescue, assistance, and exploration, amongst others.

In planning a grasping action, two fundamental aspects must be considered:

1. *How to grasp the object*. This means the determination of the contact points of the grasping device on the object, or at a higher level, the determination of the relative position of the grasping device with respect to the object (e.g., [27.32–34]).
2. *The grasping forces*. This means the determination of the forces to be applied by the grasping device actuators in order to properly constrain the object (e.g., [27.35]).

These two aspects can be very simple or extremely complex depending on the type of object to be grasped, the type of grasping device, and the requirements of the task. In a teleoperated grasping system, besides the general problems associated with a teleoperation system mentioned in the previous sections, the following particular topics must be considered.

Sensing information in the local station. In telemanipulation using complex dexterous grasping devices, such as mechanical anthropomorphic hands directly commanded by the hand of the human operator, the following approaches have been used in order to capture the pose information of the operator hand:

- *Sensorized gloves*. The operator wears a glove with sensors (usually strain gauges) that identify the position of the fingers and the flexion of the palm [27.36]. These gloves allow the performance of tasks in a natural manner, but they are delicate devices and it is difficult to achieve good calibration.
- *Exoskeletons*. The operator wears over the hand an exoskeleton equipped with encoders that identify the position of the fingers [27.37]. Exoskeletons are more robust in terms of noise, but they are rather uncomfortable and reduce the accessibility of the hand in certain tasks.
- *Vision systems*. Computer vision is used to identify hand motions [27.38]. The operator does not need to wear any particular device and is therefore completely free, but some parts of the hand may easily fall outside of the field of vision of the system and recognition of hand pose from images is a difficult task.

Capturing the forces applied by the operator is a much more complex task, and only some tests using pressure sensors at the fingertips have been proposed [27.39].

Feedback information from the remote station. This can be basically of two types:

- *Visual information*. This kind of information can help the operator to realize how good (robust or stable) the remote grasp is, but only in a very simple grasp can the operator conclude if it is actually a successful grasp.
- *Haptic information*. Haptic devices allow the operator to feel the contact constraints during the grasp in the remote station. Current approaches include gloves with vibratory systems that provides a kind of tactile feeling [27.40], and exoskeletons that attached to the hand and fingers and generate constraints to their motion and provide the feeling of a contact force [27.37]. Nevertheless, these devices have limited performance and the development of more efficient haptic devices with the required num-

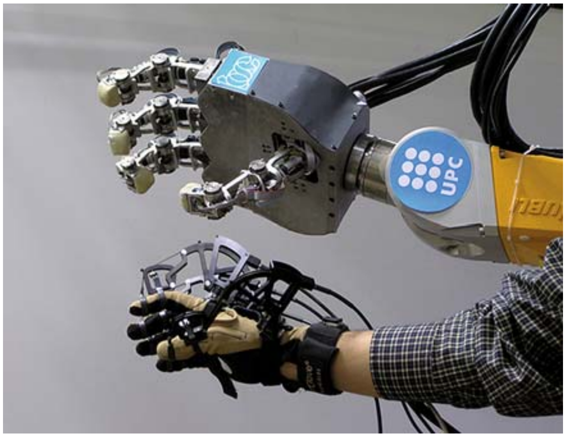

Fig. 27.9 Operator hand wearing a sensorized glove and an exoskeleton, and the anthropomorphic mechanical hand MA-I (courtesy of IOC-UPC)

ber of degrees of freedom and the configuration of the human hand is still an open problem.

Need for kinematics mapping. In real situations, the mechanical gripper or hand in the remote station will not have the same kinematics as the operator hand, even when an anthropomorphic mechanical hand is used. This means that in general the motions of the operator cannot be directly replicated by the remote grasping device, and they have to be interpreted and then adapted from one kinematics to the other, which may be computationally expensive [27.41].

Use of assistance tools. The tools developed with the aim of performing grasps in an autonomous way can be used as assistance tools in telemanipulation; for instance, grasp planners used to determine optimal grasping points automatically on different types of objects can be run considering the object to be telemanipulated and then, using augmented reality, highlight the grasping points on the object so the operator can move the fingers directly to those points. Of still greater assistance in this regard is the computation and display of independent grasping regions on the object surface [27.42] such that placing a finger on any point within each of these regions will achieve a grasp with a controlled quality [27.43].

Figure 27.9 shows an example where the operator is wearing a commercial sensorized glove and an exoskeleton in order to interact with the anthropomorphic mechanical hand MA-I [27.44].

27.4 Application Fields

The following subsections present several application fields where teleoperation plays a significant role, describing their main particular aspects and some relevant works.

27.4.1 Industry and Construction

Teleoperation in industry-related applications covers a wide range of fields. One of them is mostly oriented towards inspection, repair, and maintenance operations in places with difficult or dangerous access, particularly in power plants [27.45], as well as to manage toxic wastes [27.46]. In the nuclear industry the main reason to avoid the exposure of human workers is the existence of a continuous radioactive environment, which results in international regulations to limit the number of hours that humans can work in these conditions. This application was actually the motivation for early real telemanipulation developments, as stated in Sect. 27.1. Some typical teleoperated actions in nuclear plants are the maintenance of nuclear reactors, decommissioning and dismantling of nuclear facilities, and emergency interventions. The challenges in these tasks include operation in confined areas with high radiation levels, risk of contamination, unforeseen accidents, and manipulation of materials that can be liquid, solid or have a muddy consistency.

Another kind of application is the maintenance of electrical power lines, which require operations such as replacement of ceramic insulators or opening and reclosing bridges, which are very risky for human operators due to the height of the lines and the possibility of electric shocks, specially under poor weather conditions [27.47]. That is why electric power companies are interested in the use of robotic teleoperated systems for live-line power maintenance. Examples of these robots are the TOMCAT [27.48] and the ROBTET (Fig. 27.10) [27.49].

Another interesting application field is construction, where teleoperation can improve productivity, reliability, and safety. Typical tasks in this field are earth-moving, compaction, road construction and maintenance, and trenchless technologies [27.50]. In general, applications in this field are based on direct visual feedback. One example is radio operation of construc-

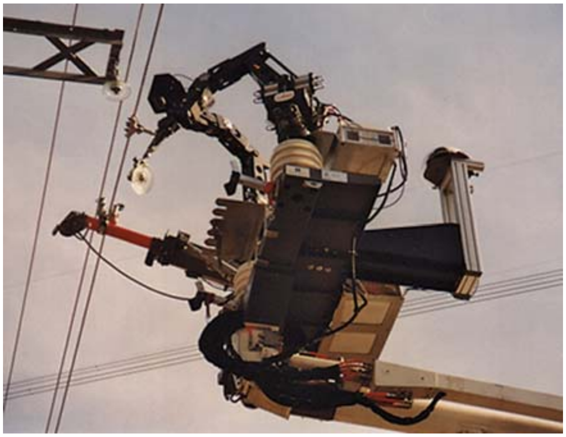

Fig. 27.10 Robot ROBTET for maintenance of electrical power lines (courtesy of DISAM, Technical University of Madrid – UPM)

tion machinery, such as bulldozers, hydraulic shovels, and crawler dump trucks, to build contention barriers against volcanic eruptions [27.51]. Another example is the use of an experimental robotized crane with a six-DOF parallel kinematic structure, to study techniques and technologies to reduce the time required to erect steel structures [27.52].

Since the tasks to be done are quite different in the different applications, the particular hardware and devices used in each case can vary a lot, ranging from a fixed remote station in the dangerous area of a nuclear plant, to a mobile remote station assembled on a truck that has to move along a electrical power line or a heavy vehicle in construction. See also Chap. 61 on *Construction Automation* and Chap. 62 on *Smart Buildings*.

27.4.2 Mining

Another interesting field of application for teleoperation is mining. The reason is quite clear: operation of a drill underground is very dangerous, and sometimes mines themselves are almost inaccessible. One of the first applications started in 1985, when the thin-seam continuous mining Jeffrey model 102HP was extensively modified by the US Bureau of Mines to be adapted for teleoperation. Communication was achieved using 0.6 inch wires, and the desired entry orientation was controlled using a laser beam [27.53]. Later, in 1991, a semiautomated haulage truck was used underground, and since then has hauled 1.5 million tons of ore without failure. The truck has an on-board personal computer (PC) and video cameras and the operator can stay on the surface and teleoperate the vehicle using an interface that simulates the dashboard of the truck [27.54]. The most common devices used for teleoperation in mining are load–haul–dump (LHD) machines, and thin-seam continuous mining (TSCM) machines, which can work in a semiautonomous and teleoperated way.

Position measurement, needed for control, is not easy to obtain when the vehicle is beneath the surface, and interference can be a problem, depending on the mine material. Moreover, for the same reason, video feedback has very poor quality. In order to overcome these problems, the use of gyroscopes, magnetic electronic compasses, and radar to locate the position of vehicles while underground has been considered [27.55]. The problems with visual feedback could be solved by integrating, for instance, data from live video, computer-aided design (CAD) mine models, and process control parameters, and presenting the operator a view of the environment with augmented reality [27.56]. In this field, in addition to information directly related to the teleoperation, the operator has to know other measurements for safety reasons, for instance, the volatile gas (like methane) concentration, to avoid explosions produced due to sparks generated by the drilling action.

Teleoperated mining is not only considered on Earth. If it is too expensive and dangerous to have a man underground operating a mining system, it is much more so for the performance of mining tasks on the Moon. As stated in Sect. 27.4.4, for space applications, in addition to the particularities of mining, the long transmission delay between the local and remote stations is a significant problem. So, the degree of autonomy has to be increased to perform the simplest tasks locally while allowing a human teleoperator to perform the complex tasks at a higher level [27.57]. When the machines in the remote station are performing automated actions, the operator can teleoperate some other machinery, thus productivity can be improved by using a multiuser schema at the local station to operate multiple mining systems at the remote station [27.58]. See also Chap. 57 on *Automation in Mining and Mineral Processing*.

27.4.3 Underwater

Underwater teleoperation is motivated by the fact that the oceans are attractive due to the abundance of living and nonliving resources, combined with the difficulty for human beings to operate in this environment. The most common applications are related to rescue missions and underwater engineering works, among other scientific and military applications. Typical tasks are: pipeline welding, seafloor mapping, inspection and reparation of underwater structures, collection of underwater objects, ship hull inspection, laying of submarine cables, sample collection from the ocean bed, and study of marine creatures.

A pioneering application was the cable-controlled undersea recovery vehicle (CURV) used by the US Army in 1966 to recover, in the Mediterranean sea south of Spain, the bombs lost due to a bomber accident [27.59]. More recent relevant applications are related to the inspection and object collection from famous sunken vessels, such as the Titanic with the ARGO robot [27.60], and to ecological disasters, such as the sealing of crevices in the hull of the oil tanker Prestige, which sank in the Atlantic in 2002 [27.61].

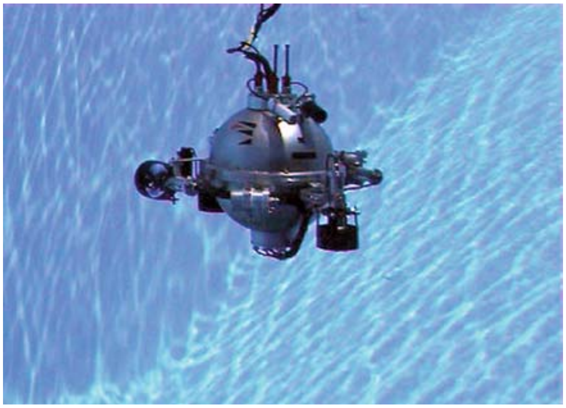

Fig. 27.11 Underwater robot Garbi III AUV (courtesy of University of Girona – UdG)

Specific problems in deep underwater environments are the high pressure, quite frequently poor visibility, and corrosion. Technological issues that must be considered include robust underwater communication, the power source, and sensors for navigation. A particular problem in several underwater applications is the position and force control of the remote actuator when it is floating without a fixed holding point.

Most common unmanned underwater robots are remotely operated vehicles (ROVs) (Fig. 27.11), which are typically commanded from a ship by an operator using joysticks. Communication between the local and remote stations is frequently achieved using an umbilical cable with coaxial cables or optic fiber, and also the power is supplied by cables. Most of these underwater vehicles carry a robotic arm manipulator (usually with hydraulic actuators), which may have negligible effects on a large vehicle, but that introduce significant perturbation on the system dynamics of a small one. Moreover, there are several sources of uncertainties, mainly due to buoyancy, inertial effects, hydrodynamic effects (of waves and currents), and drag forces [27.62], which has motivated the development of several specific control schemes to deal with these effects [27.63, 64]. The operational cost of these vehicles is very high, and their performance largely depends on the skills of the operator, because it is difficult to operate them accurately as they are always subject to undesired motion. In the oil industry, for instance, it is common to use two arms: one to provide stability by gripping a nearby structure and another to perform the assigned task.

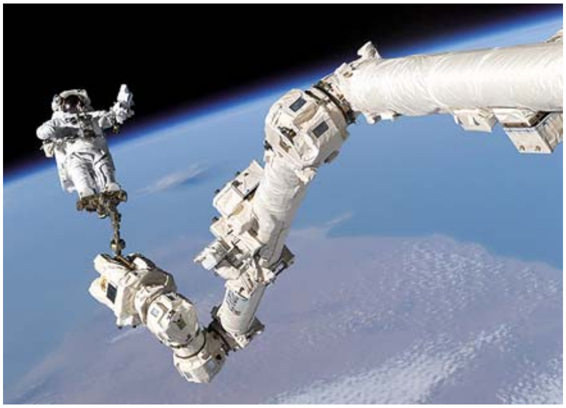

Fig. 27.12 Canadarm 2 (courtesy of NASA)

A new use of underwater robots is as a practice tool to prepare and test exploration robots for remote planets and moons [27.65].

27.4.4 Space

The main motivation for the development of space teleoperation is that, nowadays, sending a human into the space is difficult, risky, and quite expensive, while the interest in having some devices in space is continuously growing, from the practical (communications satellites) as well as the scientific point of view.

The first explorations of space were carried out by robotic spacecrafts, such as the Surveyor probes that landed on the lunar surface between 1966 and 1968. The probes transmitted to Earth images and analysis data of soil samples gathered with an extensible claw. Since then, several other ROVs have been used in space exploration, such as in the Voyager missions [27.66].

Various manipulation systems have been used in space missions. The remote manipulator system, named Canadarm after the country that built it, was installed aboard the space shuttle Columbia in 1981, and since then has been employed in a variety of tasks, mainly focused on the capture and redeployment of defective satellites, besides providing support for other crew activities. In 2001, the Canadarm 2 (Fig. 27.12) was added to the International Space Station (ISS), with more load capacity and maneuverability, to help in more sensitive tasks such as inspection and fault detection of the ISS structure itself. In 2009, the European Robotic Arm (ERA) is expected to be installed at the ISS, primarily to be used outside the ISS in service tasks requiring precise handling of components [27.67].

Control algorithms are among the main issues in this type of applications, basically due to the significant delay between the transmission of information from the local station on the Earth and the reception of the response from remote station in space (Sect. 27.3.1). A number of experimental ground-based platforms for telemanipulation such as the Ranger [27.68], the Robonaut [27.69], and the space experiment ROTEX [27.70] have demonstrated sufficient dexterity in a variety of operations such as plug/unplug tasks and tools manipulation. Another interesting experiment under development is the Autonomous Extravehicular Activity Robotic Camera Sprint (AERCam) [27.71], a teleoperated free-flying sphere to be used for remote inspection tasks. An experiment in bilateral teleoperation was developed by the National Space Development Agency of Japan (NASDA) [27.72] with the Engineering Test Satellite (ETS-VII), overcoming the significant time delay (up to 7 s was reported) in the communication channel between the robot and the ground-based control station.

Currently, most effort in planetary surface exploration is focused on Mars, and several remotely operated rovers have been sent to this planet [27.73]. In these experiments the long time delays in the control signals between Earth-based commands and Mars-based rovers is especially relevant. The aim is to avoid the effect of these delays by providing more autonomy to the rovers. So, only high-level control signals are provided by the controllers on Earth, while the rover solves low-level planning of the commanded tasks. Another possible scenario to minimize the effect of delays is teleoperation of the rovers with humans closer to them (perhaps in orbit around Mars) to guarantee a short time delay that will allow the operator to have real-time control of the rover, allowing more efficient exploration of the surface of the planet [27.74]. See also Chap. 69 on *Space and Exploration Automation* and Chap. 93 on *Collaborative Analytics for Astrophysics Explorations*.

27.4.5 Surgery

There are two reasons for using teleoperation in the surgical field. The first is the improvement or extension of the surgeon's abilities when his/her actions are mapped to the remote station, increasing, for instance, the range of position and motion of the surgical tool (motion scaling), or applying very precise small forces without oscillations; this has greatly contributed to the development of major advances in the field of microsurgery, as well as in the development of minimally invasive surgery (MIS) techniques. Using teleoperated systems, surgeries are quicker and patients suffer less than with the normal approach, also allowing faster recovery. The second reason is to exploit the expertise of very good surgeons around the world without requiring them to travel, which could waste time and fatigue these surgeons.

A basic initial step preceding teleoperation in surgical applications was telediagnostics, i. e., the motion of a device, acting as the remote station, to obtain information without working on the patient. A simple endoscope could be considered as a basic initial application in this regard, since the position of a camera is teleoperated to obtain an appropriate view inside the human body. A relevant application for telediagnostic is an endoscopic system with 3-D stereo viewing, force reflection, and aural feedback [27.75].

It is worth to highlight the first real remote telesurgery [27.76]. The scenario was as follows: the local station, i. e., the surgeon, was located in New York City, USA, and the remote station, i. e., the patient, was in Strasbourg, France. The performed surgery was a laparoscopic cholecystectomy done to a 68-year-old female, and it was called *operation Lindbergh*, based on the last name of the patient. This surgery was possible thanks to the availability of a very secure high-speed communication line, allowing a mean total time delay between the local and remote stations of 155 ms. The time needed to set up the robotic system, in this case the Zeus system [27.77], was 16 min, and the operation was done in 54 min without complications. The patient was discharged 48 h later without any particular postoperative problems.

A key problem in this application field is that someone's life is at risk, and this affects the way in which information is processed, how the system is designed, the amount of redundancy used, and any other factors that may increase safety. Also, the surgical tool design must integrate sensing and actuation on the millimeter scale.

Normally, the instruments used in MIS do not have more than four degrees of freedom, losing therefore the ability to orient the instrument tip arbitrarily, although specialized equipment such as the Da Vinci system [27.78] already incorporates a three-DOF wrist close to the instrument tip that makes the whole system benefit from seven degrees of freedom. In order to perform an operation, at least three surgical instruments are required (the usual number is four): one is an endoscope that provides the video feedback and the other two are grippers or scissors with electric scalpel functions, which should provide some tactile and/or force feedback (Fig. 27.13).

The trend now is to extend the application field of the current surgical devices so that they can be used in different types of surgical procedures, particularly including tactile feedback and virtual fixtures to minimize the effect of any imprecise motion of the surgeon [27.79]. So far, there are more than 25 surgical procedures in at least six medical fields that have been successfully performed with telerobotic techniques [27.80]. See Chap. 78 on *Medical Automation and Robotics*.

27.4.6 Assistance

The main motivation in this field is to give independence to disabled and elderly people in their daily domestic activities, increasing in this way quality of life. One of the first relevant applications in this line was seen in 1987, with the development of the Handy 1 [27.81], to enable an 11-year-old boy with cerebral palsy to gain independence at mealtimes. The main components of Handy 1 were a robotic arm, a microcomputer (used as a controller for the system), and an expanded keyboard for human–machine interface (HMI).

The most difficult part in developing assistance applications is the HMI, as it must be intuitive and appropriate for people that do not have full capabilities. In this regard different approaches are considered, such as tactile, voice recognition, joystick/haptic interfaces, buttons, and gesture recognition, among others [27.82]. Another very important issue, which is a significant difference with respect to most teleoperation scenarios, is that the local and the remote stations share the same space, i. e., the teleoperator is not isolated from the working area; on the contrary, actually he is part of it. This leads to consider the safety of the teleoperator as one of the main topics.

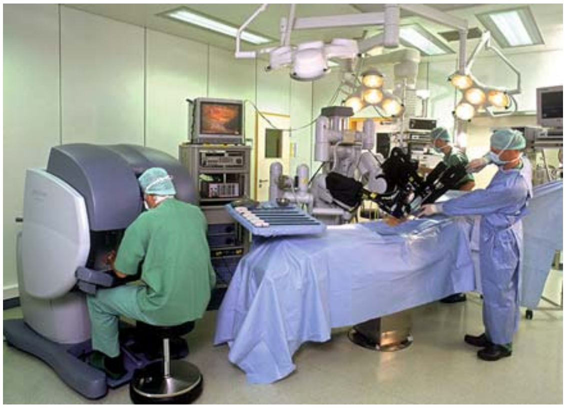

Fig. 27.13 Robotics surgery at Dresden Hospital (with permission from Intuitive Surgical, Inc. 2007)

The remote station is quite frequently composed of a mobile platform and an arm installed on it, and the whole system should be adaptable to unstructured and/or unknown environments (different houses), as it is desirable to perform actions such as going up and down stairs, opening various kinds of doors, grasping and manipulating different kind of objects, and so on. Improvements of the HMI to include different and more friendly ways of use is one of the main current challenges: the interfaces must be even more intuitive and must achieve a higher level of abstraction in terms of user commands. A typical example is understanding of an order when a voice recognition system is used [27.83].

Various physical systems are considered for teleoperation in this field, for instance, fixed devices (the disabled person has to get into the device workspace), or devices based on wheelchairs or mobile robots [27.84]; the latest are the most flexible and versatile, and therefore the most used in recently developed assistance robots, such as RobChair [27.85], ARPH [27.86], Pearl NurseBot [27.87], and ASIBOT [27.82].

27.4.7 Humanitarian Demining

This particular application is included in a separate subsection due to its relevance from the humanitarian point of view. Land mines are very easy to place but very hard to be removed. Specific robots have been developed to help in the removal of land mines, especially to reduce the high risk that exists when this task is performed by humans. Humanitarian demining differs from the mil-

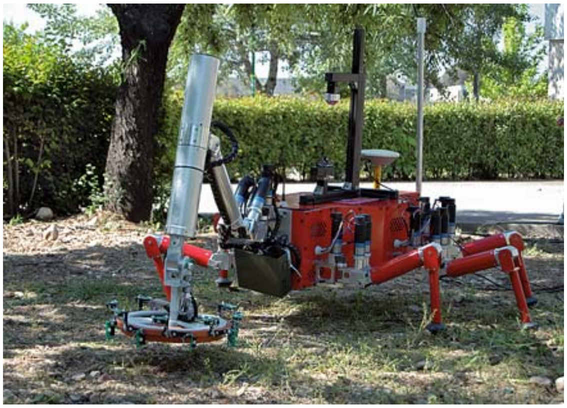

Fig. 27.14 SILO6: A six-legged robot for humanitarian demining tasks (courtesy of IAI, Spanish Council for Scientific Research – CSIC)

itary approach. In the latter it is only required to find a path through a minefield in the minimum time, while the aim in humanitarian demining is to cover the whole area to detect mines, mark them, and remove/destroy all of them. The time involved may affect the cost of the procedure, but should not affect its efficiency. One key aspect in the design of teleoperated devices for demining is that the remote station has to be robust enough to resist a mine explosion, or cheap enough to minimize the loss when the manipulation fails and the mine explodes.

The removal of a mine is quite a complex task, which is why demining tools include not only teleoperated robotic arms, but also teleoperated robotic hands [27.88]. Some proposals are based on walking machines, such as TITAN-IX [27.89] and SILO6 [27.90] (Fig. 27.14). A different method includes the use of machines to mechanically activate the mine, like the Mini Flail, Bozena 4, Tempest or Dervish, among others; many of these robotic systems have been tested and used in the removal of mines in countries such as Japan, Croatia, and Vietnam [27.91, 92].

27.4.8 Education

Recently, teleoperation has been introduced in education, and can be collated into two main types. In one of these, the professor uses teleoperation to illustrate the (theoretical) concepts to the students during the a lecture by means of the operation of a remote real plant, which obviously cannot be brought to the classroom and that would require a special visit, which would probably be expensive and time consuming. The second type of educational application is the availability of remote experimental plants where the students can carry out experiments and training, working at common facilities at the school or in their own homes at different times. In this regard, during the last 5 years, a number of remote laboratory projects have been developed to teach fundamental concepts of various engineering fields, thanks to remote operation and control of scientific facilities via the Internet. The development of e-Laboratory platforms, designed to enable distance training of students in real scenarios of robot programming, has proven useful in engineering training for mechatronic systems [27.93]. Experiments performed in these laboratories are very varied; they may go from a single user testing control algorithms in a remote real plant [27.94] to multiple users simulating and teleoperating multiple virtual and real robots in a whole production cell [27.95].

The main feature in this type of applications is the almost exclusive use of the Internet as the communication channel between the local and remote stations. Due to its ubiquitous characteristic these applications are becoming increasingly frequent.

27.5 Conclusion and Trends

Teleoperation is a highly topical subject with great potential for expansion in its scientific and technical development as well as in its applications.

The development of new wireless communication systems and the diffusion of global communication networks, such as the Internet, can tremendously facilitate the implementation of teleoperation systems. Nevertheless, at the same time, these developments give rise to new problems such as real-time requirements, delays in signal transmission, and loss of information. Research into new control algorithms that guarantee stability even with variable delays constitutes an answer to some of these problems. On the other hand, the creation of new networks, such as the Internet2, that can guarantee a quality of service can help considerably to solve the real-time necessities of teleoperated systems.

The information that the human operator receives about what is happening at the remote station is essential for good execution of teleoperated tasks. In this regard, new techniques and devices are necessary in order to facilitate immersion of the human operator in the task that he/she is carrying out. Virtual-reality, augmented-reality, haptics, and 3-D vision systems are key elements for this immersion.

The function of the human operator can also be greatly facilitated by aids to teleoperation. These aids, such as relational positioning, virtual guides, collision avoidance methods, and operation planning, can help the construction of efficient teleoperation systems.

An outstanding challenge is dexterous telemanipulation, which requires the coordination of multiple degrees of freedom and the availability of complete sensorial information.

The fields of application of teleoperation are multiple nowadays, and will become even more vast in the future, as research continues to outline new solutions to the aforementioned challenges.

28. Distributed Agent Software for Automation

Francisco P. Maturana, Dan L. Carnahan, Kenwood H. Hall

Agent-based software and hardware technologies have emerged as a major approach to organize and integrate distributed elements of complex automation. As an example, this chapter focuses on a particular situation. Composite curing, a rapidly developing industry process, generates high costs when not properly controlled. Curing autoclaves require tight control over temperature that must be uniform throughout the curing vessel. This chapter discusses how agent-based software is being implemented into the curing process by pushing control logic down to the lowest level of the control hierarchy into the process controller, i. e., the programmable logic controller (PLC). The chapter also discusses how the benefits of process survivability, diagnostics, and dynamic reconfiguration are achieved through the use of autoclave and thermocouple intelligent agents.

A general introduction and overview of agent-based automation can be found in the additional reading listed. Autoclave curing is vital to the production and support of many industries. In fact, there are so many industries that are dependent upon autoclave curing that improvements to curing production controls would lend a competitive advantage to the corporation that could deliver these improvements. While the focus of this particular work is directed predominately towards the production of composite materials, there are many other processes that could benefit from this work, with almost no differences in terms of the autoclave curing controls. This is especially true for the following products that require autoclave curing: composite materials, polymers, rubber, concrete products (e.g., sand-lime brick, asbestos, hydrous calcium silicate, cement (steam curing)), tobacco, textiles, electrical and electronics products (e.g., printed circuit boards (PCBs), ceramic substrates) chemical, medical/pharmaceutical products, wood and building products, metallurgical products, tire rethreading, glass laminating, and aircraft/aerospace products.

Much work has recently been reported for new curing methods and autoclave curing devices. This is one indication that there is a trend towards researching and developing new and better ways of curing materials. This research and development (R&D) has increased to meet market demands and technical papers regarding materials curing is proliferating. Market research studies also support the notion that there is increased demand for composite materials and that this trend will continue in the future. With increased demand comes a need for increased efficiencies in the curing production process. Composite material manufacturers, aerospace manufacturers, and manufacturers of other materials that require curing are increasing their capital expenditure budgets for the development and/or acquisition of improved autoclave manufacturing capabilities to meet this demand head-on.

Composite curing is accomplished through the proper application of heating and cooling to composite material inside autoclaves or automated ovens. Depending upon the type of composite material or the application of the composite material, a different set of curing parameters is used to control the curing process. Composite materials are cured under very stringent specifications, especially for materials that are used for aerospace applications. If composites are cured at a temperature that is too high, the material could become brittle and will be susceptible to breaking. If cured at a temperature that is too low, the material may not bond correctly and will eventually come apart.

The specifications that govern the curing process for composite materials are called recipes or profiles. Recipes/profiles differ slightly for an autoclave that has convection heaters versus an autoclave that has gas heaters. Likewise, an autoclave that has cryogenic coolers versus an autoclave that is air-cooled or fan-cooled would have slightly different control parameters within its control recipe. In the case of autoclave operations there are, generally, three profiles used to control the composite curing process: temperature, pressure, and vacuum. Of these three, temperature is the most important and the most difficult to control. As seen in Fig. 28.1, six separate periods control the temperature within the curing autoclave. Temperature increases and decreases are ramped up or down according to a particular rate of change (i. e., a slope) that is also regulated within the specification.

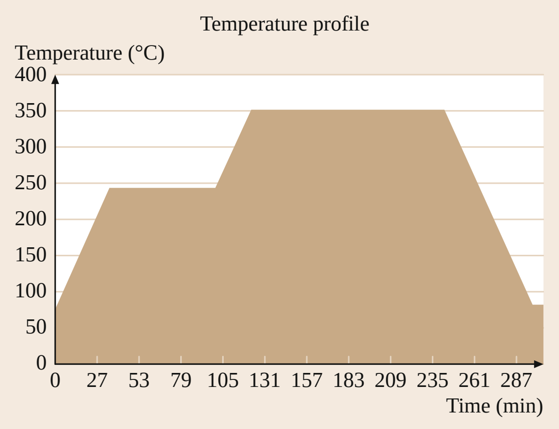

Fig. 28.1 Typical autoclave temperature profile

State-of-the-art systems use centralized material management control loops to guide the curing activity through a prescribed set of thermal, pressure, and vacuum profiles. Controlling autoclave operations so that they conform to thermal profiles is the main concern of the system and, hence, dictates the requirements for system control. For a composite material to bond properly, temperature throughout an autoclave must be maintained at a very specific level. Arrays of thermocouples provide temperature readings back to the control program through output data cards and are used to control the operation of heaters and, sometimes, coolers. One of the challenges of controlling temperature within the autoclave chamber is to keep it within a range of temperature values even when the temperature must be modified several times during the production process (as shown in Fig. 28.1). The nonlinear behaviors of a temperature profile are monitored by a *lead* thermocouple that is designated based upon its position in the autoclave, the type of material (or materials) being cured, chamber idiosyncrasies, and other production variables.

Whichever thermocouple is selected as the *lead* sensor, the feedback temperature data from that sensor will not be allowed to exceed the temperature profile temperature during heating operations. During the period of time when the thermal profile specifies a decrease in temperature (i. e., cooling operations), the *lead* thermocouple is usually used to determine the minimum temperature that will be allowed to occur. Naturally, for this type of control to be effective, network connectivity is critical to maintain high-level material state control. If a *lead* thermocouple disconnects from the composite material while the composite is being cured, the disconnection must be detected as soon as possible, and another thermocouple must be selected by the software to act as the lead. The former lead thermocouple is ignored from that point forward while the curing process continues. For cooling operations, the thermocouple that is used to control the cooling is actually called the *lag* thermocouple and temperatures are not allowed to go below that of the *lag* sensor.

On the surface of this control application, it does not seem that the requirements would be difficult to accomplish through ordinary ladder logic routines. However, there is a commercial issue that takes precedence over the control issue. Millions of dollars of composite materials could be lost during one imperfect curing process run. The survivability of the curing session must be ensured with greater probability despite perturbations in the production process.

Classical control methods suffice to monitor and control the thermal process within the autoclaves. Although the curing activity is performed in a controlled environment, there are dynamic perturbations that affect the thermocouples, which could generate unsatisfactory results, provoking complete rejection of an expensive piece of composite material. Perturbations of interest relate to potential malfunctioning in the thermocouple themselves. A malfunctioning thermocouple may appear healthy on visual inspection but its internal operations may be faulty. This is the case when thermocouples generate bogus readings. This type of problem is very difficult to detect offline and is not detected until the curing process has undergone several steps. Classical control programs that reside in the controller have limitations in terms of enabling enough reasoning to detect such problems early.

Another type of problem occurs when thermocouples detach from the material during curing. The autoclave is a sealed controlled environment that cannot be easily interrupted to reattach the sensors. The controller must be capable of reacting to the failing reader by performing corrective actions on the fly without disrupting operation.

A viable solution to the problem above is to augment the reasoning capability of the control system with more sophisticated reasoning algorithms. These augmented algorithms follow the process to generate a model from it. Condition monitoring rules can then be added to detect malfunctioning sensors. Typically, in industrial implementations, such advanced capabilities are placed in the personal computer (PC) level. A PC workstation is added to supervise the control system. This approach converts the solution into a centralized system. A centralized system suffers from other problems such as single point of failure and connectivity issues, which exacerbate the problem of maintaining a robust system for the whole duration of the process. Current trends in industry and industrial techniques show a strong tendency to move away from centralized supervisory models.

The endeavor in this work is to show a new technique to cope with the issues above. A programmable logic controller (PLC) can be designed with agent capabilities to enable for advanced reasoning at the controller level. Agents are software components that encapsulate physical equipment knowledge (rules) and properties in the form of capabilities, behaviors, and procedures [28.1–3]. The capabilities express the type of functions that an agent contributes to the well-being of the system. Each capability is a construct of behaviors. Moreover, each behavior is made of sequentially organized procedures. In the example, the agents are seamless integrated with the control algorithm inside the PLC.

The fundamental technical milestone is to eliminate the connectivity problem, and to augment the reconfiguration of the control system by moving the condition monitoring capabilities closer to the physical process, into the PLC. The PLC is the core of the control operation and therefore these devices have been widely adopted in industrial automation with the necessary redundancy to prevent losses.

The intention is to show fundamental aspects of the agent-based control technology to solve a particular composite curing application. The technology discussed is intended for general use; it is possible to use the same infrastructure to solve different applications.

The discussion will begin with a little bit of background about curing technology. Then, industrial agent technology will be discussed. The chapter concludes with an example and discussion of results on how to model the curing application with intelligent agents.

28.1 Composite Curing Background

There are several markets in which large growth in demand for autoclave cured products and materials is forecast. The carbon fiber composites market has been experiencing a growth of 12% during the last 23 years and is expected to grow to US$ 12.2 billion by 2011 [28.4, 5]. Carbon fiber reinforced thermoplastics will be improved by 37% between 2006 and 2010 [28.6]. The opportunities for continuous fiber reinforced thermoplastic composites are likewise increasing at a strong rate of growth. During 2002 alone, the growth rate was 93% [28.7, 8]. The aircraft maker Airbus has projected increases of thermoplastic composite use of 20% per year.

The natural rubber market is also seeing higher demands for its products. Rubber products have the second largest need for autoclave curing production improvements. Higher demands for natural rubber products are largely due to the spectacular economic growth in the People's Republic of China (PRC) and greater demand for consumer as well as industrial products. Production levels just within Thailand have risen from 1.805 million tons in 1995 to 2.990 million tons in 2005. Actual production exceeded 1995 demand projections by 6.25% in 2000 and 40.05% in 2005. By 2010, it is expected that 3.148 million tons of natural rubber will have to be produced. This will be more than 63% than was originally thought to be needed in 1995.

There have been many technical and scientific papers published recently that address many different methods of curing within an autoclave. In 2004, *Salagnac* et al. sought to improve the curing process through heat exchanges that were mainly free convection and radiation within a narrow-diameter autoclave [28.9, 10]. Transient thermal modeling of in situ curing during the tape winding of composite cylinders was attempted and successfully executed by *Kim* et al. at the University of Texas at Austin in 2002 [28.11]. *Chang* et al. studied the optimal design of the cure cycle for the consolidation of thick composite laminates in 1996 at the National Cheng-Kung University in Taiwan [28.12]. Smart autoclave processing of thermoset resin matrix composites that were based upon temperature and internal strain monitoring was studied by *Jinno* et al. in 2003 [28.13]. Their work looked at the control of temperature ramp rate so that the peak temperature predicted by Springer's thermochemical model is kept below an allowable value. Cure completion was determined by a cure rate equation, and internal strain monitoring with embedded optical-fiber sensors [28.13]. In 2003, a report was performed by *Mawardi* and *Pitchumani* at the University of Connecticut [28.14]. Their work was depicted as the development of optimal temperature and current cycles for the curing of composites using embedded resistive heating elements. Heating and cooling was controlled internal to the materials rather than through external heating and cooling equipment.

To get to a better understanding of the curing process *Thomas* et al. performed experimental characterizations of autoclave-cured glass–epoxy composite laminates at Washington University in St. Louis, MO [28.15]. From the results of over 100 experimental autoclave curing runs in 1996, the study team sought to verify shrinking horizon model predictive control (SHMPC) to predict and control the thickness and void content of their composite materials. At the Korea Advanced Institute of Science and Technology, *Kim* and *Lee* reported the results from their experiments with composites to reduce fabrication thermal residue stress of hybrid co-cured structures through the use of dielectrometry [28.16]. *Ghasemi-Nejhad* reported in 2005 his method of manufacturing and testing of active composite panels with embedded piezoelectric sensors and actuators [28.17]. The embedded sensors and actuators were used to minimize the problems associated with layering composites such as voids and weak bonds. *Pantelelis* et al. of the National Technical University of Athens presented a computer simulation tool in 2004 that was coupled with a numerical optimization method developed for use in the optimal design of cure cycles in the production of thermoset-matrix composite parts [28.18]. The presenters, *Georg* et al. from Boeing, *Madsen* and *Teng* from Northrup Grumman, and *Courdji* from Convergent Manufacturing, discussed the exploration of composites processing and producibility by analysis [28.19]. The discussion centered predominately on accelerated insertion of materials-composites (AIM-C) processing and producibility modules and the results that could be achieve by linking it with the robust design computation system (RDCS). AIM-C was being conducted jointly by the Naval Air Systems Command (NASC) and the Defense Advance Research Projects Agency (DARPA). In particular, AIM-C sought to significantly reduce the time and cost of inserting new materials.

For more than 10 years, the University of Delaware has been formulating advanced curing controls in its Department of Chemical Engineering and Center for Composite Materials. A team consisting of *Pillai*, *Beris*, and *Dhurjati* developed an expert system tool in 1997 to operate an autoclave for the intelligent curing of composite materials [28.20]. At the same facility in 2002, *Michaud* et al. developed a robust, simulation-based optimization and control method methodology to identify and implement the optimal curing conditions for thick-sectioned resin transfer molding (RTM) composite manufacturing [28.21].

To get better validation results for the curing process, *Arms* et al. developed a technique for remote powering and bidirectional communication with a network of micro-miniature, multichannel addressable sensing modules [28.22]. Use of the embedded sensors sought to eliminate the damage that is commonly incurred when removing thermocouples from composite materials in the post-curing phase of production. *Uryasev* and *Trindade* also studied methods to achieve better validation results and settled on a method combining an analytical model and experimental test data for optimal determination of failure tolerance limits [28.23].

Alternative curing schemes are also being developed. Electron beam (EB) curing is a technique that researchers at Acsion in Manitoba, Canada say could have a massive impact in the aerospace and defense industries, especially for the composite materials used in aircraft wings [28.24]. In electron beam curing, the incoming high-speed electrons knock off other electrons in the polymer resin, causing the material to cure. X-rays generated from the high-energy beams can penetrate even deeper into the composite, yielding a uniform cure in material several centimeters thick. The process takes only minutes compared with hours for conventional autoclave curing. Eight independent studies have shown potential manufacturing cost savings of 26–65% for prototyping alone. This could rise to as much as 90–95% [28.24]. The National Aeronautics and Space Administration (NASA) encouraged the advancement of the EB curing process through a small business innovation research (SBIR) grant awarded to Science Research Laboratory (SRL), Inc. As a result of the work conducted, a new curing method was produced that used automated tape placement with the electron beam. The new method is known as in situ electron beam curing and the SRL-devised system is being utilized at the NASA Marshall Space Flight Center [28.25].

Commercial interests have been developing other methods and products to supplement the curing controls that have already been put into use in the factory. The Blair Rubber Company of Seville, OH has developed very precise process specifications for vulcanizing rubber products in curing autoclaves. Multichannel communications modules are in common use with thermocouples. In particular, Data Translation, Inc. has universal serial bus (USB) thermocouple measurement modules that can monitor several thermocouple devices simultaneously. Flexible thermocouple management programs have been developed to minimize the costs associated with thermocouple wear and tear. Thermocouples are reworked and/or recalibrated and returned to service through this type of program. Other thermocouple management programs are involved with manual and automatic device slaving, intelligent thermocouples that protect against ground fault current, automatic compensation, and automatic swapping of lead thermocouples [28.26–30].

Even the design and manufacture of thermocouples has become specialized. Customized wiring is provided within thermocouples by manufacturers depending upon the industrial application and/or the environment in which the sensors will be placed. Within autoclave-based composite applications, there are at least seven types of thermocouples.

28.2 Industrial Agent Architecture

Industrial agents have been designed to execute on programmable logic controllers (PLCs). The agents are built on workstations, compiled, and then downloaded to the PLCs [28.31–33]. The downloading of the agents is directed by central management software that executes an agent assignment script. A decision was made to expand the PLC firmware to enable for the programming of advanced decision-making engines.

The agents have three main parts:

1. Reasoning
2. Data table interface
3. Execution control.

The first part is the actual brain of the agent. The brain is composed of behaviors, which execute as needed, as prescribed in the process operations. Dynamically generated events trigger the execution of behaviors in the agent to follow a particular sequence of procedures. An industrial agent is essentially reactive, but its software infrastructure permits the incorporation of proactive behaviors. The data table interface serves as the repository of control and agent data. The reasoning part sets values in the data table to estimable the control loops. The control part is the control execution level. This part is in charge of executing control loops in a periodic or continuous fashion to maintain steady-state conditions during the execution of the operations.

As shown in Fig. 28.2, a hierarchical library of interrelated agents represents the composite curing application. Each node of the library corresponds to an agent of a given type such as a thermocouple or autoclave. Each agent will expose a set of user-configurable attributes to give it a personality and operational ranges.

The interagent communication is based on the FIPA (Foundation for Intelligent Physical Agents) [28.34] language specification. The content of the agent message is written in a job description language

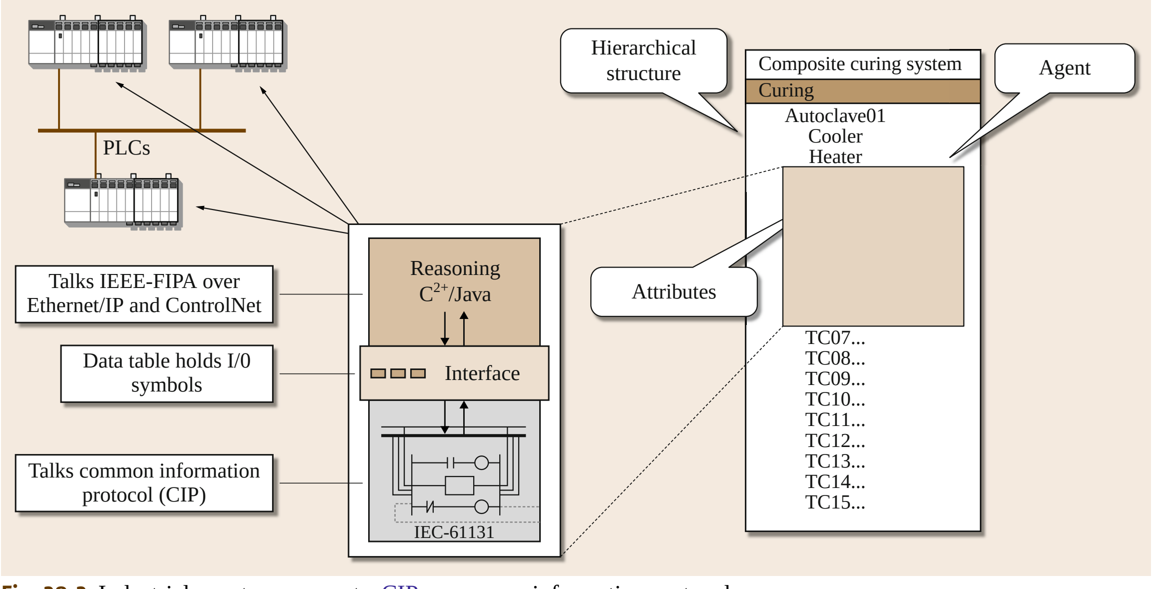

Fig. 28.2 Industrial agent components. CIP – common information protocol

(JDL) [28.31–33]. The industrial platform is based on Rockwell Automation's PLCs and NetLinx networking.

28.2.1 Agent Design and Partitioning Perspective

The benefits of using agents can be observed in three main technological aspects:

1. System design
2. Upgrading
3. Runtime.

For an appropriate system design technique, the effects of changing components (adding, removing, and altering) must be measured. The agent technology provides new techniques to design truly distributed systems by using libraries of functionality where the designers specify the components and their corresponding behaviors in generic terms. The libraries of functionality augment the system design capabilities by eliminating the need to redesign the whole system when changes are made.

System upgradability is traditionally a difficult task in industrial systems due to the hard-coupled dependencies among the controlled components (tightly coupled systems). In a nonagent system, the logical dependencies among the components must be hard-coded into the software during design time. Therefore, the effect of changing one component cascades throughout the system, forcing the modification of other components, and so on. In an agent-based system, one attempts to eliminate this cascading effect by emphasizing loosely coupled relationships among the controlled components. Agents generate dynamic interconnections with counterparts via agent messages. The dynamically emerging interconnectivity effects the agents' behaviors by locally changing their world view.

The runtime perspective of agent-based systems is helped by the agent's capability (or service) of infrastructure discovery. Using the dynamic discovery infrastructure, an agent can initiate the discovery of other agents than can help in responding to a particular event. As opposed to having a specific set of predefined plans or agents to talk to under particular circumstances, the agents opt to discover their associates that can currently supply a solution. This distributed nature of agent technology opens the door to creating a more survivable system by eliminating single points of failure.

A very significant aspect of the agent-based control technology is system scalability. An agent solution can be scaled up and down to fit different system sizes.

A powerful feature of agents is the ability for interagent communications to detect, isolate, and accommodate component failures. In the case of a multithermocouple system, agent-to-agent communication is directed at validating normative temperature readings. Any variations from the group's tendency are quickly detected and assessed by the individual agents that are affected by such variations. Inconsistency between observed temperatures provides the basis to suspect, detect, and further isolate the faulty element. Fault detection and diagnosis are key enabling features of the agent infrastructure that drive the processes of configuration and planning. Dynamic reconfiguration may include changing the operating state of a group of system devices in a coordinated manner as well as dynamically changing the control for system elements.

28.2.2 Agent Tool

The technological advantage provided by the agents is the ability to create agent components in industrial commercial off-the-shelf PLCs without having to create specialized hardware and programming tools. The advantage of using PLC devices as the primary control and agent-hosting platform is the reliability of its operating system, hardware components, and packaging, which are readily available for industrial use.

By embedding the agents directly into the controller, it is possible for the agent to interoperate with the control programs faster. This embodiment eliminates the potential loss of controllability due to a lost connection between a controlling device and the supervising computer. Control programs ensure the hard, real-time response required by many control applications and an agent part ensures high-level coordination and flexibility. This synergy of agent and control inside the PLC and in combination with smaller PLCs has made it possible to transform a physical machine into an intelligent machine by localizing the intelligence.

The changes made to the PLC firmware include software extensions to the tasking model of the controller, object instantiation and retention during power cycles, and a more general communication layer. Great effort took place initially to make the PLC an agent-hosting device with the capability to absorb executable agent code via object downloading. The extensions to the communication layer covered the generation and parsing of FIPA-based messages. With this feature, the control-based agents talk to other agents that comply with the FIPA specifications, even those that may have been implemented using a different infrastructure.

To make the agent system scalable and manageable in terms of software for agent development, it was necessary to create a development environment for the programming of agent libraries [28.35]. There are five main phases of agent development:

1. Template library design
2. Facility editor
3. Control system editor
4. Assignment wizard
5. Control code generator.

In the template library editor, a collection of components to represent the physical system is identified and built with control and reasoning parts. These components are generic, without referring to specific instances or devices. The library of components is then instantiated and arranged in a specific tree to represent the hierarchical order and attributes of the components that will be part of a specific system. This is where parameters of controlled devices and locations are added. The control system editor helps in the selection of the control and communication network equipment. In addition, it helps in the assignment of the input and output (I/O) points.

Once the pieces above are defined, the control and reasoning components defined within the application (in the facility editor) are assigned to specific controllers (PLCs). After the assignment, the executable code is generated and downloaded to the controllers.

28.3 Building Agents for the Curing System

The purpose of modeling the composite process using industrial agents is to increase the degree of survivability, diagnostics, and reconfigurability of the system [28.36]. Survivability of the control system is very important since it is directly related to safety and the creation of scrap material.

Curing is a long process and therefore there is a greater time span during which disruption may occur. Situations such as power shutdowns and network discontinuity are of critical importance and these must be handled in a timely way to sustain high process integrity. Since the curing process consists of applying heat and cooling to composite material inside a sealed autoclave, a reliable system to operate on top of the temperature sensors is fundamental. The thermocouples read the temperature of the composite material at differ-

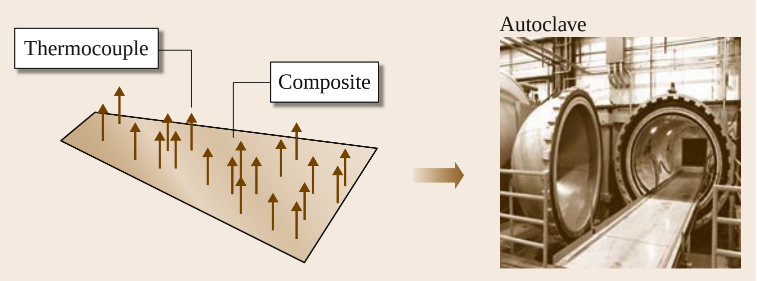

Fig. 28.3 Composite curing

ent locations. Moreover, since these constitute a group of logically interconnected sensors, the thermocouples are treated as a multisensor problem. Figure 28.3 illustrates how a composite material part is populated with the multisensor array prior to its placement inside the autoclave furnace. Thermocouple agents will be created to represent the thermocouple devices in the controller. The agents will use their social skills to organize the array into a smart and highly reconfigurable logical structure.

Given that the process operates in a controlled vacuum, it is not possible to stop the process to adjust a loose thermocouple, for example. Therefore, the autodiagnosability of the process is a critical factor that is made a part of the decision-making roles of the agents. As a consequence, both the supervisory and control roles must be able to detect problems and reconfigure the physical system to cope with such eventualities in order to enable continuous, uninterrupted activity.

Factors such as nonlinearities of the process and material (exothermal reactions provoking thermal spikes) must be considered in the modeling of the supervisory intelligence. The agent technology discussed herein allows for an incremental implementation of the necessary rules. The agent's decision power resides in rules, which are encapsulated in the behaviors. A validation framework based on simulation helps to create a virtual model for testing and enhancing the curing control rules and loops of the agents and control algorithms.

The agent software that is downloaded to the PLC is associated with a control-level driver (IEC-61131 control programs). The agent directs the control system using a lightweight supervisory strategy. Agents do not perform direct control. The device drivers carry out direct control upon the equipment. Thus, to avoid decision collisions and misinterpretation of the world, the sphere of influence of each agent must be defined with respect to its associated physical device.

The distribution of the agents throughout specific sections of the application is a necessary partitioning of responsibility that needs to take place before programming the rules. In the current case, the application is made of a single machine (autoclave) with a multisensor array (thermocouples).

There are three partitioning criteria to model the system:

1. One-to-one
2. One-to-many
3. Many-to-one.

One-to-one portioning exists in physical devices that can be isolated and classified as independent work units. Typical examples of such a case are a valve, switch, or breaker. In this case, one agent per physical device is enough. A one-to-many case appears in complex systems, where there is still an easy classification of the work units. This type of partitioning happens in equipment grouping situations, whereby one agent can be associated with a group of related physical devices. A rarer case is many-to-one partitioning, in which multiple agents are associated with a single or grouped

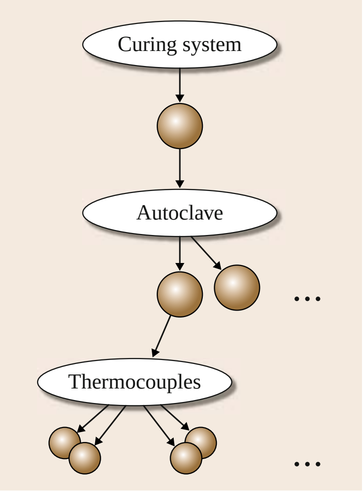

Fig. 28.4 Agent classification for curing system

physical device. A typical situation of this type occurs when a single agent cannot cope with too many concurrent processes. Efficiency of the decision-making process is then measured in terms of communication latencies and decision-making convergence. A system with too many agents and processes has many more messages on the network. The network may become overwhelmed with too many packets and communication latencies may increase. Since agents collaborate with their peers through the exchange of information, they heavily depend on timely arrival of information during the group decision process. Thus, it may occur that the agents begin dropping out of the conversation without concluding a decision process. In this case, agents would retry communication, causing more messages and therefore problems in convergence. Thus, special care must be taken to obtain a good partitioning of agent functionality.

The composite curing system corresponds to a three-tier one-to-one system. As shown in Fig. 28.4, the top-level tier has one agent to represent the overall curing system. The second tier represents the autoclave machinery that will be part of the curing system. There is one autoclave agent per autoclave machine. The third tier represents the thermocouple sensor level. There is one agent per thermocouple.

28.4 Autoclave and Thermocouple Agents

A bottom-up design (from the simplest part of operation to the more complex behavior) of the components takes place to build the curing system. Each component is associated with a piece of equipment or a particular process as an agent. Figure 28.5 shows a group of curing components. Most of the components are control-oriented drivers. However, autoclave and thermocouple components are agents.

The left-hand side of Fig. 28.5 shows the component list. The upper-right part shows the low-level programming blocks of the component. The lower-right part shows the list of control parameters of the component, such as input and output (I/O) variables.

28.4.1 Autoclave Agent

The autoclave agent contains curing artifacts such as cooler, heater, pressure compressor, and thermocouples. Thermocouple agents have their own temperature monitoring system and personality. Depending on the stage of the curing process, an autoclave agent periodically requests a reorganization of the thermocouples to se-

lect a leading and a lagging thermocouple. The nominal behaviors given to an autoclave agent consist of the following:

- *cNetTCTemp*: This behavior generates a multicast message to all dependent thermocouples (TC1–TC16 in Fig. 28.2 to have them summarize their current temperature trends. Asynchronous responses are sent by the thermocouple agents to report their temperature information.
- *SetNewLeaTC*: In this behavior, the autoclave agent applies process-specific criteria to generate a list of leading and lagging thermocouples. The autoclave agent uses a min–max selection mechanism. The process recipe and the stage of curing determine the temperature boundaries (upper and lower).
- *startCuringProcess*: This behavior contains the startup sequence of the autoclave.
- *stopCuringProcess*: This behavior contains the shutdown sequence of the autoclave.

The aggregation of capabilities into the agent behavior creates the rules of the agent incrementally. In Fig. 28.6 all autoclave agents have the *CuringEvent* capability, which implements a set of template behaviors. Each behavior is associated with a set of procedures.

28.4.2 Thermocouple Agent

A thermocouple agent has two essential behaviors to monitor the temperature of the process and the sensor condition and trending using the following behaviors

- *getTemperature*: This behavior uses a sampling algorithm to calculate temperature average and standard deviations. This behavior allows for continuous adjustment of temperature measurement to compensate for natural jitter.
- *provideTemperatureTrend*: This behavior enables the detection of temperature variations outside the nominal ranges. The feasible range allows for the detection of extreme deviations from nominal trends. These events are reported to the autoclave agent as events.

Each thermocouple carries out continuous sampling of the temperature. This information is processed statistically. Temperature sampling is an internal-to-thermocouple action, which corresponds to an interagent communication. The thermocouple agents receive requests from the autoclave agent to transmit their temperature trends in the form of agent messages in a periodic fashion.

28.5 Agent-Based Simulation

Simulation is made up of two parts: the machine and the material. Machine simulation covers the autoclave machine itself with its mechanical devices (such as heater, cooler, and compressor) and thermocouples. Material simulation mimics the behavior of the composite material. A finite-difference mesh simulates the thermal dissipation throughout the material. The model represents a single piece of composite material of square shape with arbitrary sides and thickness.

The control process takes place in a PLC. However, for the purpose of the simulation, a soft controller PLC (Rockwell Automation, SoftLogix 5800) with firmware extensions to support the agents was used. The Simulink/Matlab engine was used as the simulation toolset. To mimic the physical process, a simulation of the material, thermocouples, and material was created. The agents use the simulation as the process model instead of the actual machine and material.

In Fig. 28.7 there are horizontally and vertically arranged gray rectangular boxes. These boxes contain heat transfer differential equations to calculate the accumulation and dissipation of heat on a specific node of the finite-difference mesh. The heat transfer model is subjected to anisotropic properties to mimic the heat

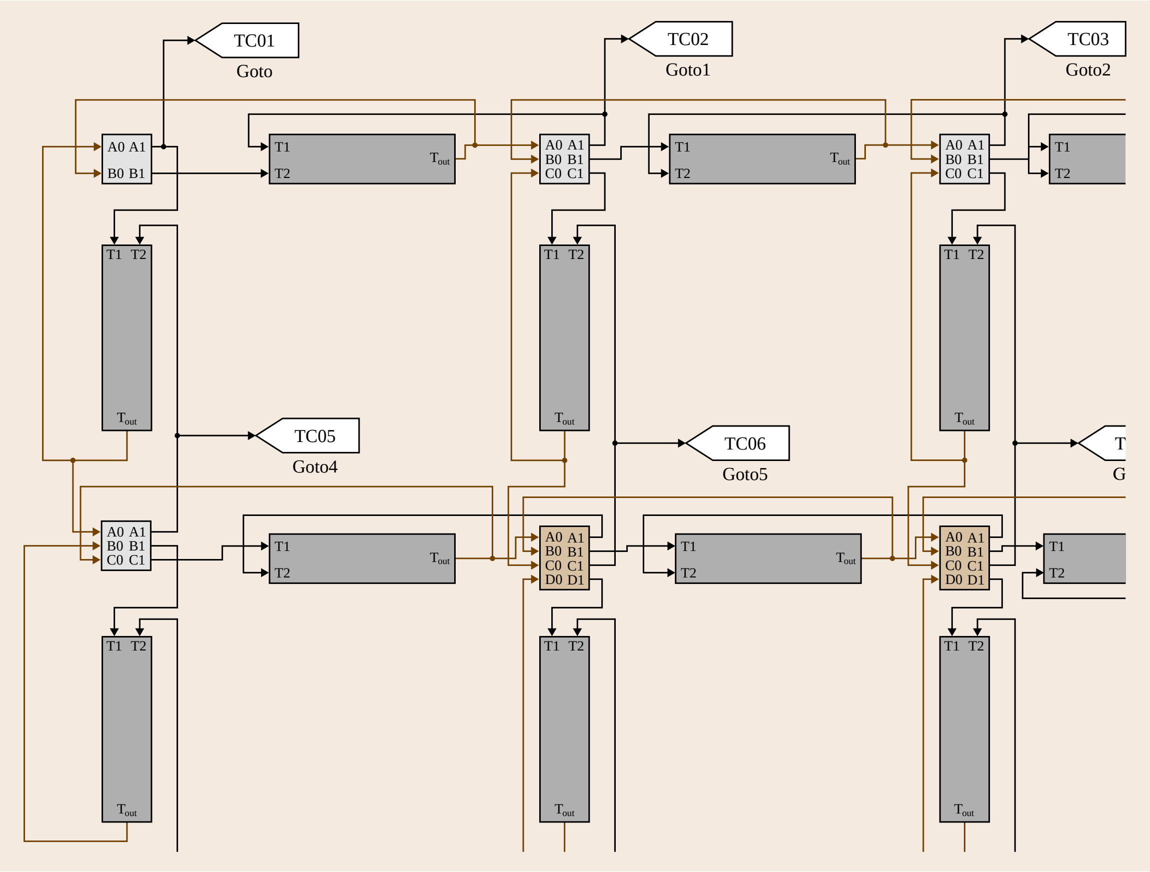

Fig. 28.7 Composite material simulation

dissipation rates throughout the material. The chemical composition of the resin affects the heat transfer, making it vary with location and direction of propagation.

The square boxes represent finite-difference nodes (concentration nodes) to calculate the average temperature of the material at the specific location of measurement. Figure 28.7 shows just a small section of the finite-difference mesh. In the actual model, there are 16 concentration points and 16 thermocouples. The thermocouple sensors are scattered throughout the material to measure the temperature of the composite at each node. The temperature readings are sent to the PLC as an input array of temperatures to be further interpreted by the thermocouple control drivers.

Figure 28.8 shows the simulation blocks that contain the autoclave and autoclave's inner atmosphere. The autoclave agent connects to the simulation throughout six inputs parameters (heaterIsOn, coolerIsOn, coolerIsEnabled, heaterIsEnabled, heatingRate, coolingRate) to control the autoclave. The maximum and minimum heating and cooling rates are provided in the curing recipe. Heating and cooling rates are used as the control variables to control the amount of heat that is applied to the material. Table 28.1 shows an example of the command that initiates a heating-up phase in the simulation.

Control commands drive the simulation in desired directions to achieve a particular curing profile. All 16 thermocouple readings must be maintained within the curing envelope (refer to Fig. 28.1 for the profile shape).

Deviations from the curing envelop are regulated by the cooperative actions of the agents. The agents continuously monitor the health of the thermocouples using temperature trending and standard deviations. When a thermocouple fails, the agent that represents that thermocouple decides to dismiss itself from the monitoring array. This decision is taken autonomously at the lowest level. The dismissal cascades up the hierarchy, inducing

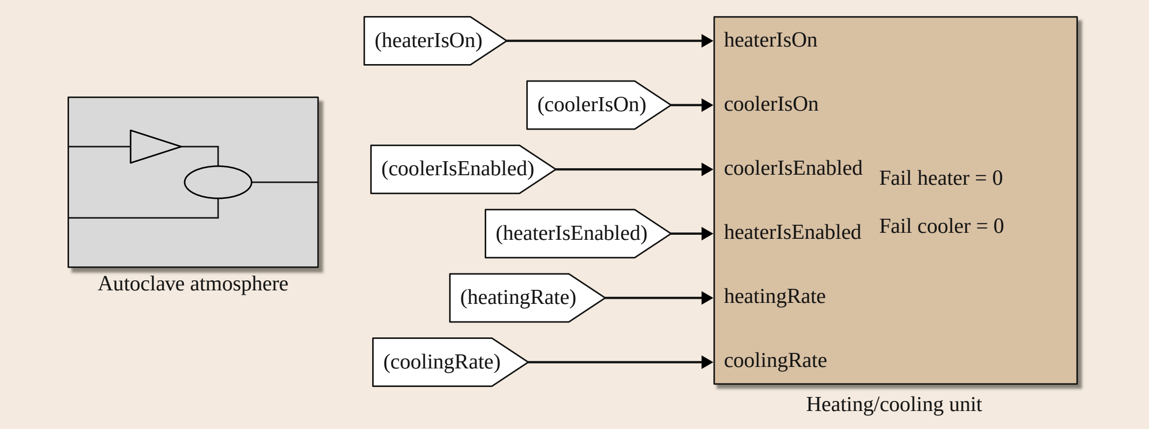

Fig. 28.8 Autoclave and autoclave atmosphere simulation

a reorganization of the sensor array to adjust to the new reading set.

If a departing thermocouple was operating as a leading or lagging thermocouple, the current stage of curing is at high risk since the autoclave agent loses its window into the process variable. The reorganization of the sensor arrays implies a discovery of new leading and/or lagging thermocouples to reestablish the process variable. While the agents reorganize the system, the control must continue its normal activity by maintaining all temperatures within the nominal ranges as prescribed in the recipe, but this fall-back position can only be sustained for a short period until the new process variable is reestablished. This reorganization activity is the core benefit of the multiagent system. Agents are intended to handle these dynamic decisions.

Variable name	Value
heaterIsEnabled	true
coolerIsEnabled	false
coolerIsOn	false
heaterIsOn	true
heatingRate	%.%
coolingRate	%.%

28.6 Composite Curing Results and Recommendations

The composite curing process begins with downloading of the agents and device drivers into the PLC. Next, the process simulation is started and connected to the soft controller throughout and automation proxy. The role of the automation proxy is to exchange I/O data between the controller and the simulation, as well as the synchronization of their clocks.

There are several aspects of interest that can be extracted from this technology. First, there is a permanent learning process associated with the encapsulation of the behaviors into particular agents, as well as the partitioning of the domain into regions.

28.6.1 Designing the Validation System

The system designer carries out preliminary verifications to test the agent behaviors. It is natural to see some chaotic results in the initial iterations. The designer adjusts the agent and control functions to make the prototype stable and observable using an interactive process.

The design of the agent is based on templates [28.35]; for instance, only one thermocouple agent template is built for all 16 thermocouples. Likewise, in object-oriented programming, agent programming allows for the creation of agent instances from a single agent template. Thus, all thermocouple agents share the same reasoning rules but vary in personality (name, location, ranges, etc.).

Another consideration is the speed of the simulation. The real curing process takes hours to complete. However, during the modeling and validation phase it is not affordable to spend so much time waiting for events and changes in the process, so the simulation has to be accelerated to compress the total time. This requirement adds complexity to the model since the controller cycles must be in real time to mimic actual control. Time compression is factored into the control timers to make events observable in shorter time spans. In this curing model, ideal time spans during the validation phase *d* should not exceed 30 min/cycle. Once the overall model is ready, tests begin to check the control/agent responses against the system dynamics.

28.6.2 Modeling Process Dynamics

A critical requirement in agent-based engineering is the interdisciplinary attitude of the engineers. The creation of these sophisticated models requires more than one design perspective to create valid results. The designer transits from sole software engineer into a control engineer who understands the dynamics of the process.

Figure 28.9 shows the distribution of temperature for one of the test runs. The colored regions represent isothermals for heating and cooling. The isothermals change in shape and size as the curing process evolves. The curing profile is shown in the lower half of Fig. 28.9. The temperature distribution is not uniform due to the properties of the material. The thermal reaction of the composite makes hot and cold spots change location and size over time. The control system must maintain all temperatures within the upper and lower

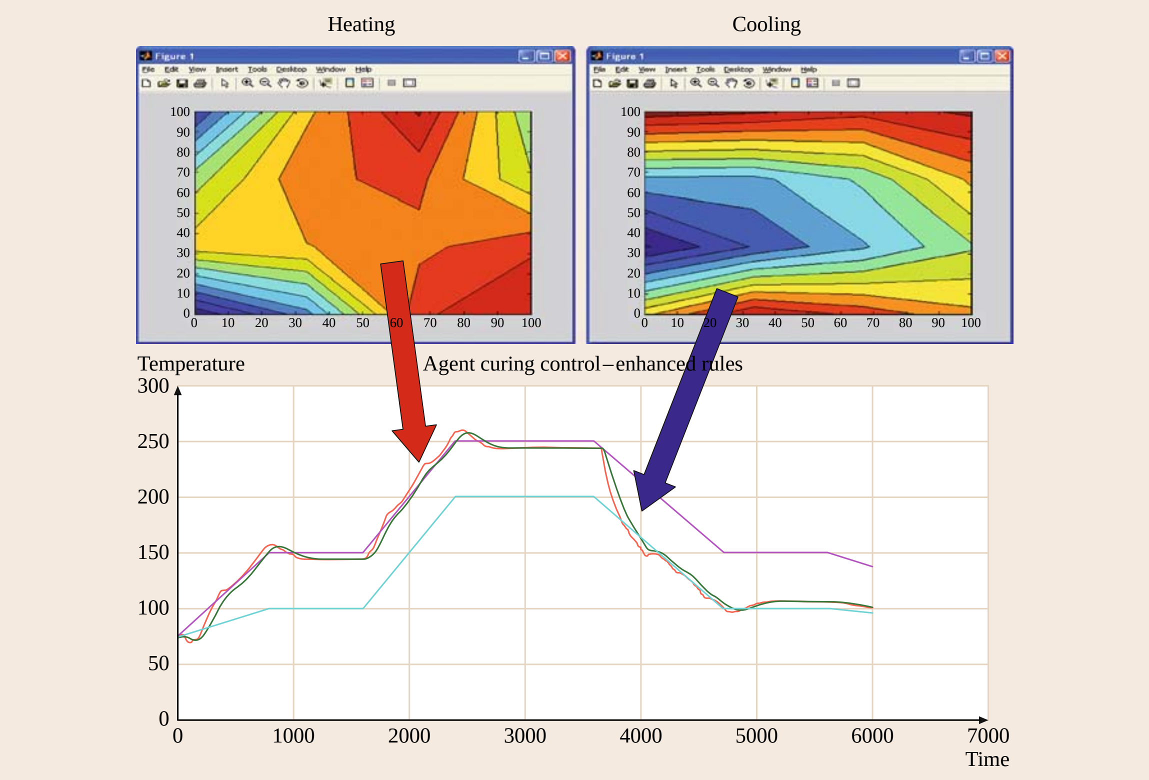

Fig. 28.9 Heating and cooling simulation

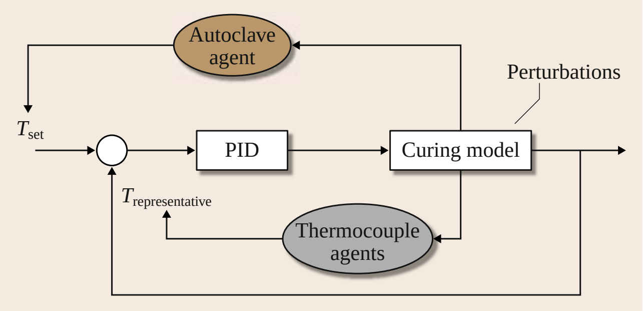

Fig. 28.10 Agents and control cooperation

bound of the curing envelope. The profile introduces abrupt changes in the temperature slopes when moving from a neutral stage into a heating or cooling stage. The control system must regulate the overshooting amplitude while maintaining a good configuration of the thermocouple. There is overshooting in the process but the recipe allows for some operation outside the boundaries for short periods.

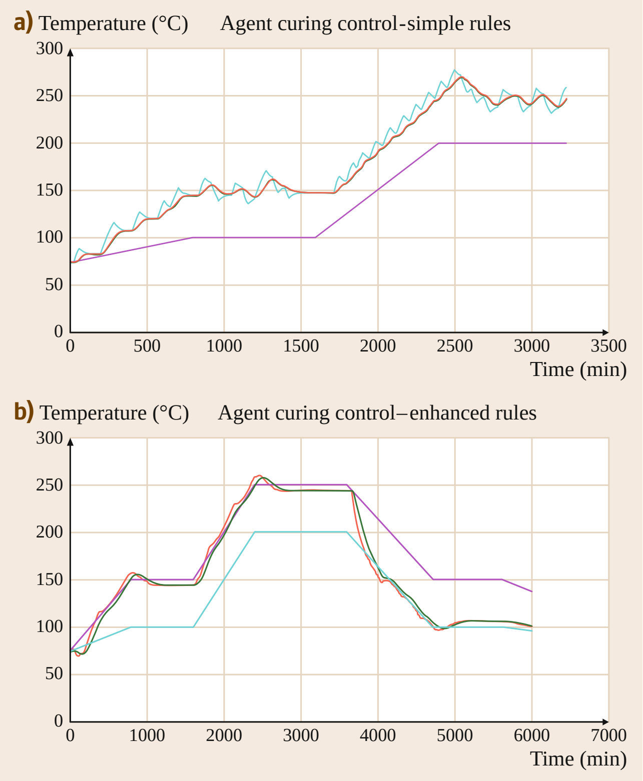

Fig. 28.11 (a) Control response for large look-ahead factor. **(b)** Control response for small look-ahead factor

The core activity is to observe and diagnose the thermocouple readings to select the representative temperature of the process as the process variable. Cooperation among the thermocouples helps in determining this information autonomously. It is very important that the agents maintain close inspection of the temperature sensors and ensure correct selection of the representative temperatures to be able to set the heating and cooling rates, as the material is very susceptible to these rates.

The control system has been implemented as a combination of a proportional–integral–derivative (PID) block with agents, as shown in Fig. 28.10. The combined operations of PID and agents constitute the main control loop to generate heating and cooling rates as the control response. The agents interact with the PID in two main ways. First, to execute an accurate control response, the agents select the lead temperature for the particular stage of the process, which could be heating, cooling or neutral. The autoclave agent calculates the temperature set-point (T_{set}) as an input to the PID block. The temperature set-point is calculated to be in the proximity of the upper or lower bound of the profile depending on the stage of curing. Second, the thermocouple agents collect data from the curing model (simulation) to select $T_{\text{representative}}$. The PID block ensures that the process variable is driven closer to the set-point value.

The PID block requires empirical calibration to adjust the proportional, integral, and derivative coefficients of the equation. The tuning is performed online while running the simulation and controller (for more information on how to tune PID coefficients please refer to the control system design literature). The shape of the curing profile introduces too drastic inflections, making it harder to maintain the steady-state condition. Nevertheless, the introduction of the agents into the loop allows for quicker and better utilization of the system variables to cope with such changes.

The ability to look ahead into the future (greater than 60 s) was introduced into the agents to learn future inflections in the curing profile. The intention was to adjust the set-point to begin compensation early to prevent overshoot. However, it was learned that the resultant control response constrained the PID action by provoking oscillation, as shown in Fig. 28.11a. Throughout experimentation, it was learned that the extent of the look-ahead factor played a critical role in the instability observations. The look-ahead factor was reduced to a less than 30 s horizon to make the PID filtering more dominant in the control of the overshooting, as shown in Fig. 28.11b. Nonetheless, the inflexion points are still a difficult aspect to handle using the discussed agent control algorithm. Without agent support, the inflexion points that are introduced by the curing profile will be confined to a PID loop fine-tuning task. By expanding and contracting the look-ahead factor of the agents, it is possible to perceive the effect of the agent reasoning on the PID loop response. Ideally, agents will act rapidly with a very short look-ahead factor to provide better input to the PID loop. However, agents are not intended to carry out control; they are designed to influence the control algorithm in a beneficial direction. An important lesson from this experiment is the notion of role separation: that which belongs to control must be in the control layer. How to define this boundary is still an art rather than a science.

Figure 28.11b shows an improved response, where the temperature profile follows the recipe with no oscillations. According to specifications, the resultant cured material from this experimental trial would be considered of high quality. To obtain an optimum solution further adjustments to the PID coefficients and agent actions are required and perhaps an expansion of the agent intelligence. Nevertheless, these improvements fall outside the scope of this chapter.

During the agent cooperation, the agents talk to each other using the FIPA/JDL messaging protocol. Figure 28.12 shows an example agent communication. The observer can trace the agent transactions to learn what decisions have been made. The transactions show the information that the agents exchanged to arrive at a control decision. In Fig. 28.12 a multicasting example is shown, where a single agent contacts multiple agents in a two-way transaction. In multiagent systems, interagent communication consists of request/inform transactions, where an agent transmits a request for information to one or a group of agents. The receiving agents process the request locally but may initiate consultation with other agents as well by using similar request/inform transactions. Once the receiving agent has finished preparing its response, it uses an inform message to send the information back to the requester. The requester then receives multiple responses from the agents. Each response provides a different perspective of the situation under consultation. The requester must select the most valuable information or a combination of it to conclude its own decision-making cycle.

Fig. 28.12 Agent communication

The distributed nature of agent messaging allows for a realistic expansion of the system to add/remove functionality as desired.

In the current implementation, all agents reside within one controller, but the agents can be distributed in any desired topology. The distribution topology is a design decision that must comply with the application's characteristics and requirements. A rule of thumb to decide on the agent distribution is to weigh the desired degree of survivability, diagnosability, and reconfigurability of the system.

In a distributed agent implementation, agents reside in separate platforms. The distribution of the agents depends on the partitioning criteria selected for the application. The partitioning criteria takes under considerations the number of messages used in negotiation. The idea is to use a reduced number of messages. A poor division of functionality among the agents will result in more messaging among them. Message traffic and bandwidth utilization are good metrics to define optimum partitioning.

28.6.3 Timing and Stability Criteria

The multiagent system guarantees an exhaust search for an optimum configuration within a specific time horizon. For small systems (< 100 agents), it is fairly simply to establish the time horizon required by the agents to accomplish a complete search of configurations. The time horizon estimation is established by injecting various conditions into the simulation model so the system designer can observe what time is required to search for and converge to a solution. Once this time horizon is estimated, each agent is given a factored time limit to participate in a particular negotiation process. An infinite time horizon is never given to the agents to avoid deadlocks. Unknown singularities could generate deadlocks in the system. It is guaranteed that the agents will find a solution within the predefined time horizon. However, the value of the solution will fluctuate within optimum and-near optimum performances, depending on the complexity of the emergent search space.

28.7 Conclusions

This chapter has shown how to use industrial agent technology to solve a composite curing application. It has also shown some of the technology requirements and implications of extending industrial PLCs with agent firmware. An example application was used to show the design and modeling phases and the validation of the solution using simulation. Important results and recommendations can be extracted from this to help the modernization of curing technology. Using interagent messaging and the ability to cooperate on the creation and assessment of thermocouple configurations, the agents enable a dynamic learning system, always adapting to current conditions.

The PLC firmware provides for a multitasking priority-based executive control cycle. Agents on built as user level tasks to execute at a low priority. Fundamental tasks in the PLC that manage the PLC's integrity are never interrupted by the agent tasks. User-defined tasks such as stand-alone periodic and continuous control loops compete with agent tasks, but based on their priority levels. Among these, periodic tasks are higher order than agents, but never higher than the executive functions.

The extent of learning depends on the sophistication of the rules given to the agents. This aspect is a user-defined characteristic of the system. Agent programming provides for this type of flexibility. It has been learned that loosely coupled agents and control components ease the scalability of the control solution. Finally, this chapter has shown how survivability, diagnostics, and reconfiguration of a control system can be achieved with component-level intelligence in a more compact manner.

29. Evolutionary Techniques for Automation

Mitsuo Gen, Lin Lin

In this chapter, evolutionary techniques (ETs) will be introduced for treating automation problems in factory, manufacturing, planning and scheduling, and logistics and transportation systems. ET is the most popular metaheuristic method for solving NP-hard optimization problems. In the past few years, ETs have been exploited to solve design automation problems. Concurrently, the field of ET reveals a significant interest in evolvable hardware and problems such as routing, placement or test pattern generation.

The rest of this chapter is organized as follows. First the background developments of evolutionary techniques are described. Then basic schemes and working mechanism of genetic algorithms (GAs) will be given, and multiobjective evolutionary algorithms for treating optimization problems with multiple and conflicting objectives are presented. Lastly, automation and the challenges for applying evolutionary techniques are specified.

Next, the various applications based on ETs for solving factory automation (FA) problems will be surveyed, covering planning and scheduling problems, nonlinear optimization problems in manufacturing systems, and optimal design problems in logistics and transportation systems.

Finally, among those applications based on ETs, detailed case studies will be introduced. The first case study covers dispatching of automated guided vehicles (AGV) and machine scheduling in a flexible manufacturing system (FMS). The second ET case study for treating automation problems is the robot-based assembly line balancing (ALB) problem. Numerical experiments for various scales of AGV dispatching problems and robot-based ALB problems will be described to show the effectiveness of the proposed approaches with greater search capability that improves the quality of solutions and enhances the rate of convergence over existing approaches.

29.1 Evolutionary Techniques

Evolutionary techniques (ET) is a subfield of artificial intelligence (AI), and refers to a synthesis of methodologies from fuzzy logic (FL), neural networks, genetic algorithm (GA), and other evolutionary algorithms (EAs). ET uses the evolutionary process within a computer to provide a means for addressing complex engineering problems involving chaotic disturbances, randomness, and complex nonlinear dynamics that traditional algorithms have been unable to conquer (Fig. 29.1).

Computer simulations of evolution started as early as in 1954; however most publications were not widely noticed. From these beginnings, computer simulation of evolution by biologists became more common in the early 1960s. Evolution strategies (ES) was introduced by *Rechenberg* in the 1960s and early 1970s, and it was able to solve complex engineering problems [29.2]. Another approach was the evolutionary programming (EP) of *Fogel* [29.3], which was proposed for generating artificial intelligence. EP originally used finite state machines for predicting environments, and used variation and selection to optimize the predictive logic. Genetic algorithms (GAs) in particular became popular through the work of *Holland* in the early

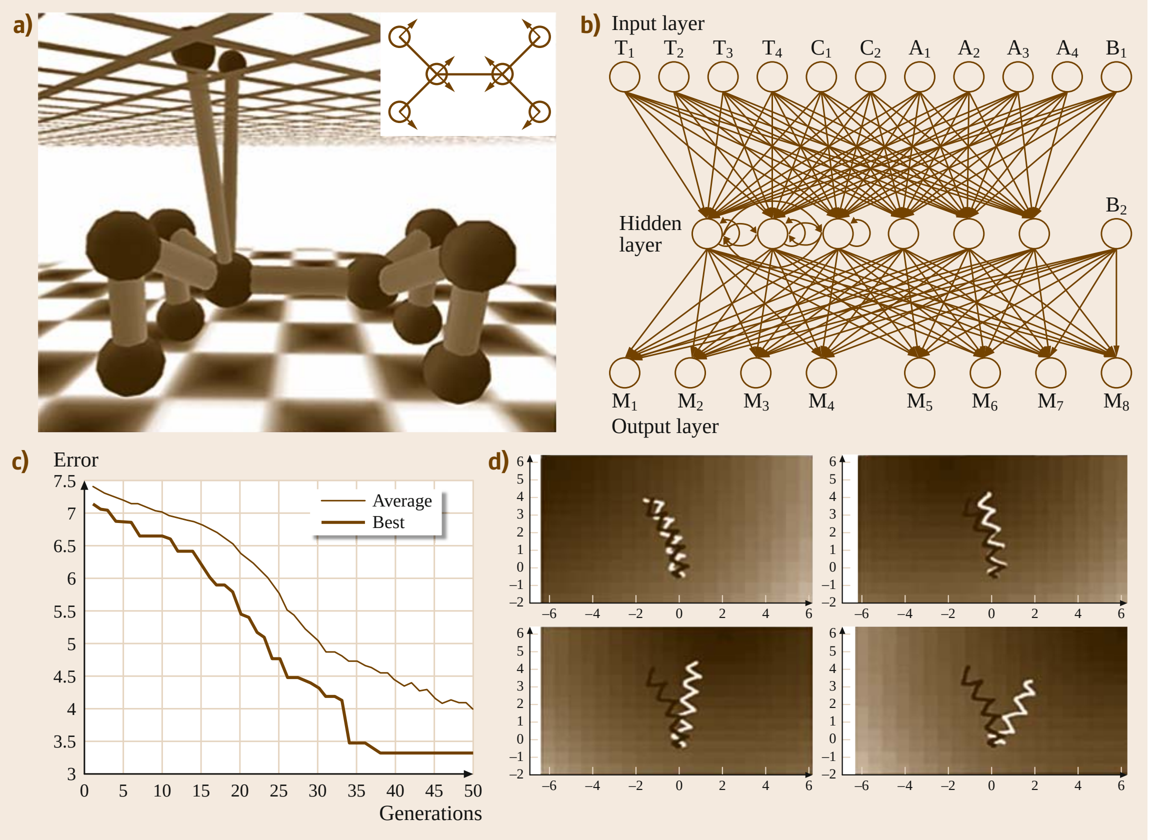

Fig. 29.1a–d Evolving a controller for a fixed morphology: **(a)** The morphology of the machine contains four legs actuated with eight motors, four ground-touch sensors, four angle sensors, and two chemical sensors. **(b)** The machine is controlled by a recurrent neural net whose inputs are connected to the sensors and whose outputs are connected to the motors. **(c)** Evolutionary progress shows how the target misalignment error reduces over generations. **(d)** *White trails* show the motion of the machine towards high concentration (*darker area*). *Black trails* show tracks when the chemical sensors are turned off (after [29.1])

1970s [29.4]. His work originated with studies of cellular automata, conducted by Holland and his students at the University of Michigan [29.5]. Holland introduced a formalized framework for predicting the quality of the next generation, known as Holland's schema theorem. Research in GAs remained largely theoretical until the mid-1980s. Genetic programming (GP) is an extended technique of GA popularized by *Koza* in which computer programs, rather than function parameters, are optimized [29.6]. Genetic programming often uses tree-based internal data structures to represent the computer programs for adaptation instead of the list structures typical of genetic algorithms. As academic interest grew, the dramatic increase in desktop computational power allowed for practical application of the new technique [29.7–11]. Evolutionary techniques are generic population-based metaheuristic optimization algorithms, summarized in Table 29.1.

Several conferences and workshops have been held to provide an international forum for exchanging new ideas, progress or experience on ETs and to promote better understanding and collaborations between the theorists and practitioners in this field. The major meetings are the Genetic and Evolutionary Computation Conference (GECCO), the IEEE Congress on Evolutionary Computation (CEC), Parallel Problem Solving from Nature (PPSN), the Foundations of Genetic Algorithms (FOGA) workshop, the Workshop on Ant Colony optimization and Swarm Intelligence (ANTS) and the Evo* and EuroGP workshops etc. The major journals are *Evolutionary Computation*, *IEEE Transactions on Evolutionary Computation*, *Genetic Programming*, and *Evolvable Machines*.

29.1.1 Genetic Algorithm

Among evolutionary techniques (ETs), genetic algorithms (GA) are the most widely known type of ETs today. GA includes the common essential elements of ETs, and has wide real-world applications. The original form of GA was described by *Goldberg* [29.5]. GA is a stochastic search technique based on the mechanism of natural selection and natural genetics. The central theme of research on GA is to keep a balance between exploitation and exploration in its search to the optimal solution for survival in many different environments. Features for self-repair, self-guidance, and reproduction are the rules in biological systems, whereas they barely exist in the most sophisticated artificial systems. GA has been theoretically and empirically proven to provide a robust search in complex search spaces.

GA, differing from conventional search techniques, starts with an initial set of random solutions called the *population*. Each individual in the population is called a *chromosome*, representing a solution to the problem at hand. A chromosome is a string of symbols, usually but not necessarily, a binary bit string. The chromosomes *evolve* through successive iterations, called *generations*. During each generation, the chromosomes are *evaluated*, using some measures of *fitness*. To create the next generation, new chromosomes, called *offspring*, are generated by either merging two chromosomes from the current generation using a *crossover* operator and/or modifying a chromosome using a *mutation* operator. A new generation is formed by selecting some of the parents, according to the fitness values, and offspring, and rejecting others so as to keep the *population size* constant. Fitter chromosomes have higher probabilities of being selected. After several generations, the algorithms converge to the best chromosome, which hopefully represents the optimum or suboptimal solution to the problem. In general, GA has five basic components, as summarized by *Michalewicz* [29.8]:

1. A genetic representation of potential solutions to the problem
2. A way to create a population (an initial set of potential solutions)
3. An evaluation function rating solutions in terms of their fitness
4. Genetic operators that alter the genetic composition of offspring (crossover, mutation, selection, etc.)
5. Parameter values that genetic algorithms use (population size, probabilities of applying genetic operators, etc.).

Figure 29.2 shows a general structure of GA, where $P(t)$ and $C(t)$ are parents and offspring in the current generation t.

29.1.2 Multiobjective Evolutionary Algorithm

Multiple objective problems arise in the design, modeling, and planning of many complex real systems in the areas of industrial production, urban transportation, capital budgeting, forest management, reservoir management, layout and landscaping of new cities, energy distribution, etc. It is easy to find that almost every important real-world decision problem involves multiple and conflicting objectives which need to be tackled while respecting various constraints, leading to overwhelming problem complexity. Since the 1990s, EAs have been received considerable attention as a novel approach to multiobjective optimization problems, resulting in a fresh body of research and applications known as evolutionary multiobjective optimization (EMO).

Features of Genetic Search

The inherent characteristics of EAs demonstrate why genetic search is well suited for multiple-objective op-

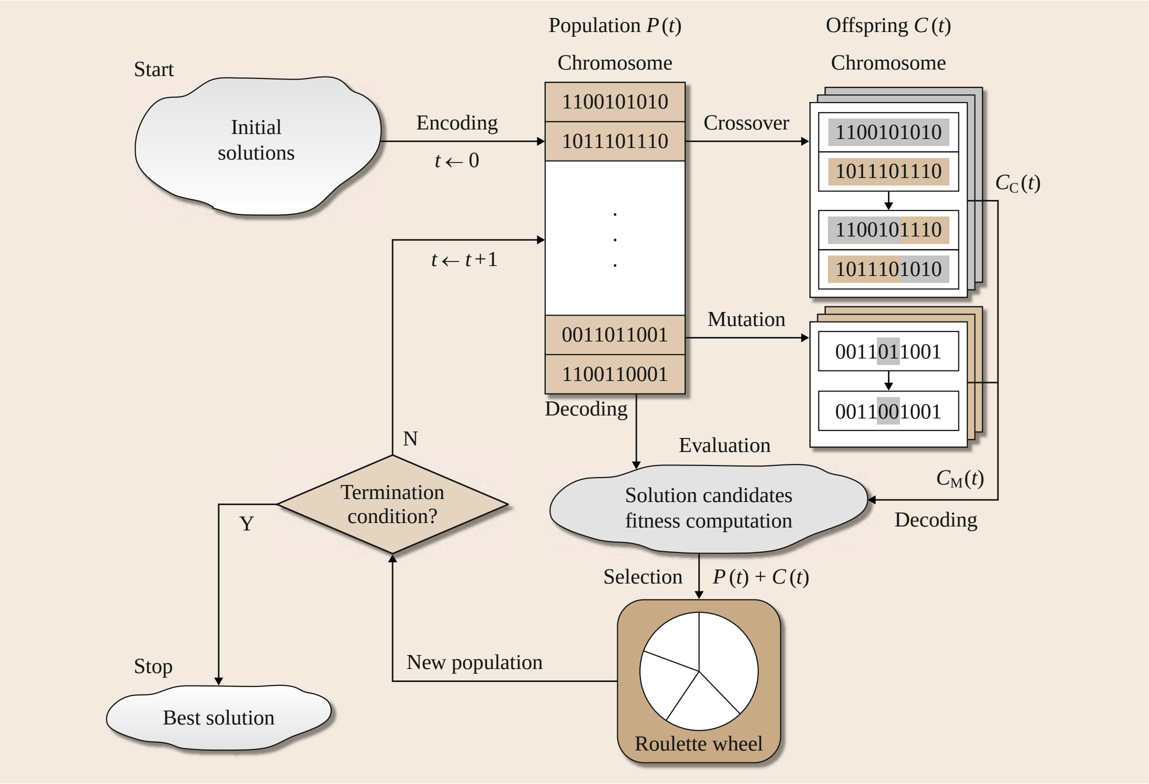

Fig. 29.2 The general structure of genetic algorithms

timization problems. The basic feature of the EAs is multiple-directional and global search by maintaining a population of potential solutions from generation to generation. It is hoped that the population-to-population approach will explore all Pareto solutions.

EAs do not have much mathematical requirements about the problems, and can handle any kind of objective functions and constraints. Due to their evolutionary nature, EAs can search for solutions without regard to the specific internal workings of the problem. Therefore, it is hopeful to solve complex problem by using the evolutionary algorithms.

Because evolutionary algorithms, as a kind of metaheuristics, provide us with great flexibility to hybridize conventional methods into their main framework, we can take advantage of both evolutionary algorithms and conventional methods to make much more efficient implementations. The growing research on applying EAs to multiple-objective optimization problems presents a formidable theoretical and practical challenge to the mathematical community [29.10].

Fitness Assignment Mechanism

A special issue in the multiobjective optimization problem is the fitness assignment mechanism. Since the 1980s, several fitness assignment mechanisms have been proposed and applied to multiobjective optimization problems. Although most fitness assignment mechanisms are just different approaches and are applicable to different cases of multiobjective optimization problems. In order to understanding the development of EMO, we classify the fitness assignment mechanisms by according to the published year.

Type 1: Vector evaluation approach. The vector evaluated genetic algorithm (veGA) was the first notable work to solve multiobjective problems in which a vector fitness measure is used to create the next generation [29.13].

Type 2: Pareto ranking + diversity: *Fonseca* and *Fleming* proposed a multiobjective genetic algorithm (moGA) in which the rank of a certain individual corresponds to the number of individuals in the current population that dominate it [29.14]. *Srinivas* and *Deb* also developed a Pareto-ranking-based fitness assignment and called it the nondominated sorting genetic algorithm (nsGA) [29.15]. In each method, the nondominated solutions constituting a nondominated front are assigned the same dummy fitness value.

Type 3: Weighted sum + elitist preserve: *Ishibuchi* and *Murata* proposed a weighted-sum-based fitness assignment method, called the random-weight genetic algorithm (rwGA), to obtain a variable search direction toward the Pareto frontier [29.16]. The weighted-sum approach can be viewed as an extension of methods used in the multiobjective optimizations to GAs. It assigns weights to each objective function and combines the weighted objectives into a single objective function. *Gen* et al. proposed another weight-sum-based fitness assignment method called the adaptive-weight genetic algorithm (awGA), which readjusts weights for each objective based on the values of nondominated solutions in the current population to obtain fitness values combined with the weights toward the Pareto frontier [29.11]. *Zitzler* and *Thiele* proposed the strength Pareto evolutionary algorithm (spEA) [29.16] and an extended version spEA II [29.17, 18] that combines several features of previous multiobjective genetic algorithms (moGA) in a unique manner. *Deb* suggested a nondominated sorting-based approach called the nondominated sorting genetic algorithm II (nsGA II) [29.10], which alleviates three difficulties: computational complexity, nonelitism approach, and the need to specify a sharing parameter. nsGA II was advanced from its origin, nsGA. *Gen* et al. proposed an interactive adaptive-weight genetic algorithm (i-awGA), which is an improved adaptive-weight fitness assignment approach with consideration of the disadvantages of the weighted-sum and Pareto-ranking-based approaches [29.11].

29.1.3 Evolutionary Design Automation

Automation is the use of control systems such as computers to control industrial machinery and processes, replacing human operators. In the scope of industrialization, it is a step beyond mechanization. Whereas mechanization provided human operators with machinery to assist them with the physical requirements of work, automation greatly reduces the need for human sensory and mental requirements as well. Processes and systems can also be automated.

Automation plays an increasingly important role in the global economy and in daily experience. Engineers strive to combine automated devices with mathematical and organizational tools to create complex systems for a rapidly expanding range of applications and human activities.

Evolutionary algorithms (EAs) have received considerable attention regarding their potential as novel optimization techniques. There are three major advantages when applying EA to design automation:

1. *Adaptability*: EAs do not have many mathematical requirements regarding the optimization problem. Due to their evolutionary nature, EAs will search for solutions without regard to the specific internal workings of the problem. EAs can handle any kind of objective functions and any kind of constraints (i. e., linear or nonlinear, defined on discrete, continuous or mixed search spaces).
2. *Robustness*: The use of evolution operators makes EA very effective in performing global search (in probability), while most conventional heuristics usually perform local search. It has been proven by many studies that EA is more efficient and more robust at locating optimal solution and reducing computational effort than other conventional heuristics.
3. *Flexibility*: EAs provide great flexibility to hybridize with domain-dependent heuristics to make an efficient implementation for a specific problem.

However, to exploit the benefits of an effective EA to solve design automation problems, it is usually necessary to examine whether we can build an effective genetic search with the encoding. Several principles were proposed to evaluate effectiveness [29.11]:

Property 1 (*Space*): Chromosomes should not require extravagant amounts of memory.

Property 2 (*Time*): The time required for executing evaluation, recombination, and mutation on chromosomes should not be great.

Property 3 (*Feasibility*): A chromosome corresponds to a feasible solution.

Property 4 (*Legality*): Any permutation of a chromosome corresponds to a solution.

Property 5 (*Completeness*): Any solution has a corresponding chromosome.

Property 6 (*Uniqueness*): The mapping from chromosomes to solutions (decoding) may belong to one of the following three cases (Fig. 29.5): 1-to-1 mapping, n-to-1 mapping, and 1-to-n mapping. The 1-to-1 mapping is the best among the three cases, and 1-to-n mapping is the most undesirable.

Property 7 (*Heritability*): Offspring of simple crossover (i. e., one-cut-point crossover) should correspond to solutions which combine the basic features of their parents.

Property 8 (*Locality*): A small change in a chromosome should imply a small change in its corresponding solution.

29.2 Evolutionary Techniques for Industrial Automation

Currently, for manufacturing, the purpose of automation has shifted from increasing productivity and reducing costs to broader issues, such as increasing quality and flexibility in the manufacturing process. For example, automobile and truck pistons used to be installed into engines manually. This is rapidly being transitioned to automated machine installation, because the error rate for manual installment was around 1–1.5%, but has been reduced to 0.00001% with automation. Hazardous operations, such as oil refining, manufacturing of industrial chemicals, and all forms of metal working, were always early contenders for automation.

However, many applications of automation, such as optimizations and automatic controls, are formulated with complex structures, complex constraints, and multiple objects simultaneously, which makes the problem intractable to traditional approaches. In recent years, the evolutionary techniques community has turned much of its attention toward applications in industrial automation.

29.2.1 Factory Automation

In a manufacturing system, layout design is concerned with the optimum arrangement of physical facilities, such as departments or machines, in a certain area. Usually the design criterion is considered to be minimizing material-handling costs. Because of the combinatorial nature of the facility layout problem, the heuristic technique is the most promising approach for solving practical-size layout problems. The interest in application of ETs to facility layout design has been growing rapidly. *Tate* and *Smith* applied GA to the shape-constrained unequal-area facility layout problem [29.19]. *Cohoon* et al. proposed a distributed GA for the floorplan design problem [29.20]. *Tam* reported his experiences of applying genetic algorithms to the facility layout problem [29.21].

A flexible machining system is one of the forms of factory automation. The design of a flexible machining system (FMS) involves the layout of machine and workstations. *Kusiak* and *Heragu* wrote a survey paper on the machine layout problem [29.22]. The layout of machines in a FMS is typically determined by the type of material-handling devices used. The most used material-handling devices are: material-handling robot, automated guided vehicle (AGV), and gantry robot. *Gen* and *Cheng* provide various GA approaches for the machine layout and facility layout problems [29.9].

29.2.2 Planning and Scheduling Automation

The planning and scheduling of manufacturing systems always require resource capacity constraints, disjunctive constraints, and precedence constraints, owing to the tight due dates, multiple customer-specific orders, and flexible process strategies. Here, some hot topics of applications of ETs in advanced planning and scheduling (APS) are introduced. These models mainly support the integrated, constraint-based planning of the manufacturing system to reduce lead times, lower inventories, increase throughput, etc.

The flexible jobshop problem (fJSP) is a generalization of the jobshop and parallel machine environment [29.23], which provides a closer approximation to a wide range of real manufacturing systems. *Kacem* et al. proposed the operations machine-based GA approach [29.24], which is based on a traditional representation called the schemata theorem representation. *Zhang* and *Gen* proposed a multistage operation-based encoding for fJSP [29.25].

The objective of the resource-constrained project scheduling problem (rcPSP) is to schedule activities such that precedence and resource constraints are obeyed and the makespan of the project is to be minimized. *Gen* and *Cheng* adopted priority-based encoding for this rcPSP [29.9]. In order to improve the effectiveness of priority-based GA approach for an extended resource constrained multiple project scheduling problem, *Kim* et al. combined priority dispatching rules in priority-based encoding process [29.26].

The advanced planning and scheduling (APS) model includes a range of capabilities from finite capacity planning at the plant floor level through constraint-based planning to the latest applications of advanced logic for supply-chain planning and collaboration [29.27]. Several related works by *Moon* et al. [29.28] and *Moon* and *Seo* [29.29] have reported a GA approach especially for solving such kinds of APS problems.

29.2.3 Manufacturing Automation

Assembly-line balancing problems (ALB) consist of distributing work required to assemble a product in mass or series production on an assembly line among a set of workstations. Several constraints and different objectives may be considered. The simple assembly-line balancing problem consists of assigning tasks to workstations such that precedence relations between tasks and zoning or other constraints are met. The objective is to make the work content at each station most balanced. GAs have been applied to solve various assembly-line balancing problems [29.30–32]. *Gao* et al. proposed an innovative GA hybridized with local search for a robotic-based ALB problem [29.33]. Based on different neighborhood structures, five local search procedures are developed to enhance the search ability of GA.

An automated guided vehicle (AGV) is a mobile robot used widely in industrial applications to move materials from point to point. AGVs help to reduce costs of manufacturing and increase efficiency in a manufacturing system. For a recent review of AGV problems and issues the reader is referred to [29.34–37]. *Lin* et al. adopted priority-based encoding for solving the AGV dispatching problem in an FMS [29.38].

29.2.4 Logistics and Transportation Automation

Logistics is the last frontier for cost reduction and the third profit source of enterprises [29.39]. The interest in developing effective logistics system design models and efficient optimization methods has been stimulated by high costs of logistics and the potential for securing considerable savings. One of the most important topics of logistics and transportation automation is automated container terminals.

Handling equipment scheduling (HES) is important for scheduling different types of handing equipment in order to improve the productivity of automated container terminals. Lau and Zhao give a mixed-integer programming model, which considers various constraints related to the integrated operations between different types of handling equipment. This study proposes a multilayer GA to obtain the near-optimal solution of the integrated scheduling problem [29.39].

Berth allocation planning (BAP) is to allocate space along the quayside to incoming ships at a container terminal in order to minimize some objective function.

Imai et al. introduce a formulation for the simultaneous berth and crane allocation problem and employed GA to find an approximate solution for the problem [29.40].

The aim of storage locations planning (SLP) is to determine the optimal storage strategy for various container-handling schedules. *Preston* and *Kozan* developed a container location model and proposed a GA approach with analyses of different resource levels and a comparison with current practice at the Port of Brisbane [29.41].

29.3 AGV Dispatching in Manufacturing System

Automated material handling has been called the key to integrated manufacturing. An integrated system is useless without a fully integrated, automated material handling system. In the manufacturing environment, there are many automated material handling possibilities. Currently, automated guided vehicles systems (AGV systems), which include automated guided vehicles (AGVs), are the state of the art, and are often used to facilitate automatic storage and retrieval systems (AS/RS).

Traditionally, AGV systems were mostly used in manufacturing systems. In manufacturing areas, AGVs are used to transport all types of materials related to the manufacturing process. The transportation network connects all stationary installations (e.g., machines) in the center. At stations, pickup and delivery points are installed that operate as interfaces between the production/storage system and the transportation system of the center. At these points a load is transferred by, for example, a conveyor from the station to the AGV and vice versa. AGVs travel from one pickup and delivery point to another on fixed or free paths. Guide paths are determined by, for example, wires in the ground or markings on the floor. More recent technologies allow AGVs to operate without physical guide paths.

29.3.1 Network Modeling for AGV Dispatching

In this Subsection, we introduce simultaneous scheduling and routing of AGVs in a flexible manufacturing system (FMS) [29.38]. An FMS environment requires a flexible and adaptable material handling system. AGVs provide such a system. An AGV is a material-handling equipment that travels on a network of guide paths. The FMS is composed of various cells, also called workstations (or machines), each with a specific operation such as milling, washing or assembly. Each cell is connected to the guide path network by a pickup/delivery (P/D) point where pallets are transferred from/to the AGVs. Pallets of products are moved between the cells by the AGVs. Assumptions considered are as follows:

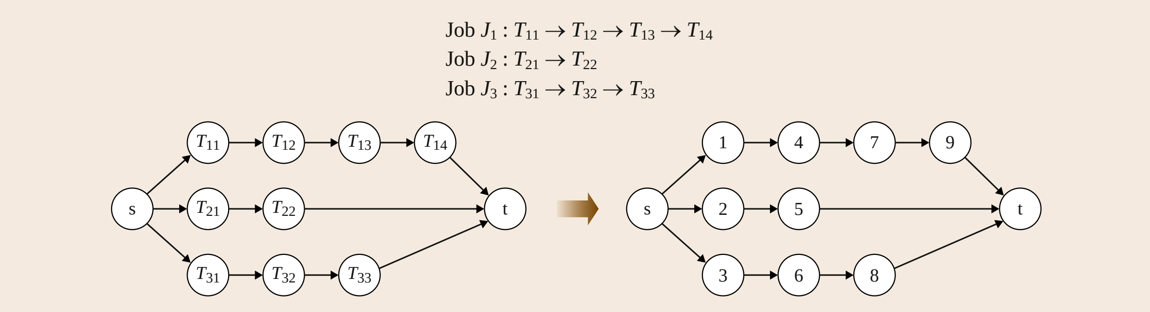
1. AGVs only carry one kind of products at a time.
2. A network of guide paths is defined in advance, and the guide paths have to pass through all pickup/delivery points.
3. The vehicles are assumed to travel at a constant speed.
4. The vehicles can just travel forward, not backward.
5. As many vehicles travel on the guide path simultaneously, collisions are avoided by hardware and are not considered herein.
6. At each workstation, there is pickup space to store the operated material and delivery space to store the material for the next operation.
7. The operation can be started any time after an AGV took the material to come. And also the AGV can transport the operated material from the pickup point to the next delivery point any time.

Definition 1: A node is defined as task T_{ij}, which represents a transition task of the j-th process of job J_i for moving from the pickup point of machine $M_{i,j-1}$ to the delivering point of machine M_{ij}.

Definition 2: An arc can be defined as many decision variables, such as, capacity of AGVs, precedence constraints among the tasks, or costs of movement. Lin et al. defined an arc as a precedence constraint, and give a transition time $c_{jj'}$ from the delivery point of machine M_{ij} to the pickup point of machine $M_{i'j'}$ on the arc.

Definition 3: We define the task precedence for each job; for example, task precedence for three jobs is shown in Fig. 29.3.

The notation used in this Chapter is summarized as follows. Indices: i, i': index of jobs, $i, i' = 1, 2, \ldots, n$; j, j': index of processes, $j, j' = 1, 2, \ldots, n$. Parameters: n: total number of jobs, m: total number of machines, n_i: total number of operations of job i, o_{ij}: the j-th operation of job i, p_{ij}: processing time of operation o_{ij}, M_{ij}: machine assigned for operation o_{ij}, T_{ij}:



Job $J_1 : T_{11} \to T_{12} \to T_{13} \to T_{14}$
Job $J_2 : T_{21} \to T_{22}$
Job $J_3 : T_{31} \to T_{32} \to T_{33}$

Fig. 29.3 Illustration of the network structure of the example

transition task for operation o_{ij}, t_{ij}: transition time from $M_{i,j-1}$ to M_{ij}. Decision variables: x_{ij}: assigned AGV number for task T_{ij}, t^{S}_{ij}: starting time of task T_{ij}, c^{S}_{ij}: starting time of operation o_{ij}.

The objective functions are to minimize the time required to complete all jobs (i. e., the makespan) t_{MS} and the number of AGVs n_{AGV}, and the problem can be formulated as follows:

$$\min t_{\mathrm{MS}} = \max_i \left\{ t^{\mathrm{S}}_{i,n_i} + t_{M_{i,n_i},0} \right\} , \tag{29.1}$$

$$\min n_{\mathrm{AGV}} = \max_{i,j} \left\{ x_{ij} \right\} , \tag{29.2}$$

$$\text{s.t. } c^{\mathrm{S}}_{ij} - c^{\mathrm{S}}_{i,j-1} \geq p_{i,j-1} + t_{ij} , \quad \forall i,\ j = 2, \ldots, n_i , \tag{29.3}$$

$$\begin{aligned} &\left(c^{\mathrm{S}}_{ij} - c^{\mathrm{S}}_{i'j'} - p_{i'j'} + \Gamma \left| M_{ij} - M_{i'j'} \right| \geq 0 \right) \\ &\quad \vee \left(c^{\mathrm{S}}_{i'j'} - c^{\mathrm{S}}_{ij} - p_{ij} + \Gamma \left| M_{ij} - M_{i'j'} \right| \geq 0 \right) , \\ &\quad \forall (i,\ j), (i',\ j') , \end{aligned} \tag{29.4}$$

$$\begin{aligned} &\left(t^{\mathrm{S}}_{ij} - t^{\mathrm{S}}_{i'j'} - t_{i'j'} + \Gamma \left| x_{ij} - x_{i'j'} \right| \geq 0 \right) \\ &\quad \vee \left(t^{\mathrm{S}}_{i'j'} - t^{\mathrm{S}}_{ij} - t_{ij} + \Gamma \left| x_{ij} - x_{i'j'} \right| \geq 0 \right) , \\ &\quad \forall (i,\ j), (i',\ j') , \end{aligned} \tag{29.5}$$

$$\begin{aligned} &\left(t^{\mathrm{S}}_{i,n_i} - t^{\mathrm{S}}_{i'j'} - t_{i'j'} + \Gamma \left| x_{ij} - x_{i'j'} \right| \geq 0 \right) \\ &\quad \vee \left(t^{\mathrm{S}}_{i'j'} - t^{\mathrm{S}}_{i,n_i} - t_i + \Gamma \left| x_{ij} - x_{i'j'} \right| \geq 0 \right) , \\ &\quad \forall (i, n_i), (i',\ j') , \end{aligned} \tag{29.6}$$

$$c^{\mathrm{S}}_{ij} \geq t^{\mathrm{S}}_{i,j+1} - p_{ij} , \tag{29.7}$$

$$x_{ij} \geq 0 , \quad \forall i,\ j , \tag{29.8}$$

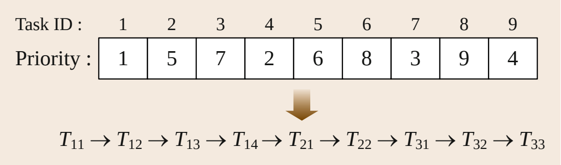
$$t^{\mathrm{S}}_{ij} \geq 0 , \quad \forall i,\ j , \tag{29.9}$$

where Γ is a very large number, and t_i is the transition time from the pickup point of machine M_{in} to the delivery point of loading/unloading. Constraint (29.3) describes the operation precedence constraints. In (29.4)–(29.6), since one or the other constraint must hold, it is called disjunctive constraint. This represents the operation nonoverlapping constraint (29.4) and the AGV nonoverlapping constraint (29.5, 29.6).

29.3.2 Evolutionary Approach: Priority-Based GA

For solving the AGV dispatching problem in FMS, the special difficulty arises from (1) that the task sequencing is *NP-hard problem*, and (2) that a random sequence of AGV dispatching usually does not satisfy the operation precedence constraint and routing constraint.

Firstly, we give a priority-based encoding method that is an indirect approach, encoding some guiding information to construct a sequence of all tasks. As is known, a gene in a chromosome is characterized by two factors: the locus, i. e., the position of the gene within the structure of the chromosome, and the allele, i. e., the value the gene takes. In this encoding method, the position of a gene is used to represent the ID which mapping the task in Fig. 29.3 and its value is used to represent the priority of the task for constructing a sequence among candidates. A feasible sequence can be uniquely determined from this encoding with consideration of the operation precedence constraint. An example of a gen-



Task ID :	1	2	3	4	5	6	7	8	9
Priority :	1	5	7	2	6	8	3	9	4

$T_{11} \to T_{12} \to T_{13} \to T_{14} \to T_{21} \to T_{22} \to T_{31} \to T_{32} \to T_{33}$

Fig. 29.4 Example generated chromosome and its decoded task sequence

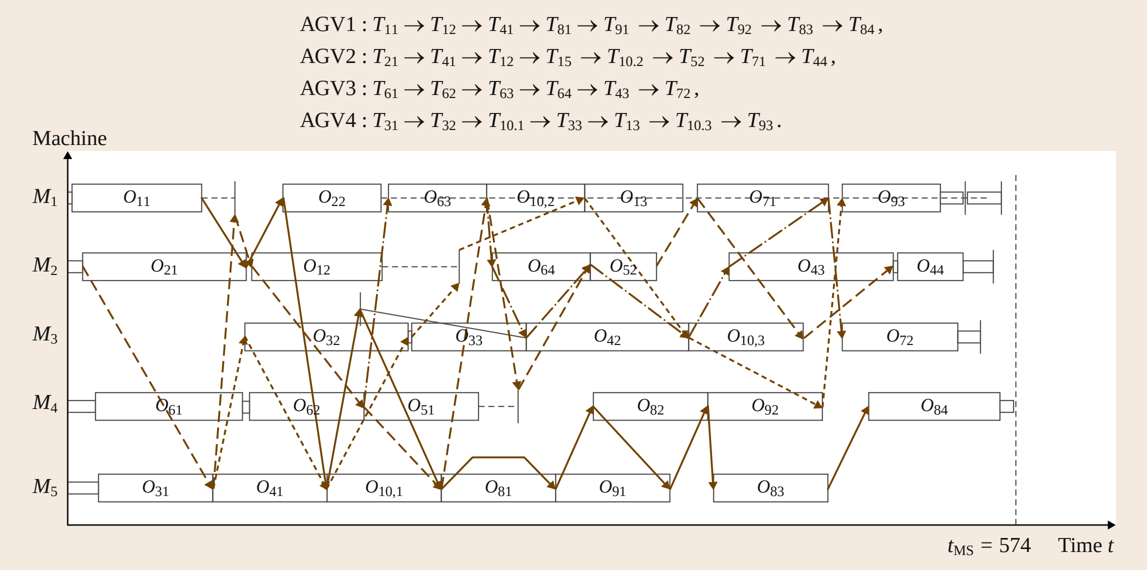


Fig. 29.5 Gantt chart of the schedule of the case study considering AGVs routing (after [29.1], by permission of Macmillan Nature 2004)

erated chromosome and its decoded path is shown in Fig. 29.4 for the network structure of Fig. 29.3.

After generating the task sequence, we separate tasks into several groups for assigning different AGVs. We find the breakpoints, which the tasks are the final transport of job i from pickup point of operation O_{in} to delivery point of loading/unloading. Then we separate the part of tasks sequence by the breakpoints. An example of grouping is shown as follows, using the chromosome (Fig. 29.4):

$$\begin{aligned}&\mathrm{AGV1}\colon\ T_{11} \to T_{12} \to T_{13} \to T_{14}\\&\mathrm{AGV2}\colon\ T_{21} \to T_{22}\\&\mathrm{AGV3}\colon\ T_{31} \to T_{32} \to T_{33}\ .\end{aligned}$$

As genetic operators, we combine a weight mapping crossover (WMX), insertion mutation, and immigration operator based on the characteristic of this representation, and adopt an interactive adaptive-weight fitness assignment mechanism that assigns weights to each objective and combines the weighted objectives into a single objective function. The detailed procedures are showed in [29.38].

29.3.3 Case Study

For evaluating the efficiency of the AGV dispatching algorithm suggested in the case study, a simulation program was developed using Java on a Pentium IV processor (3.2 GHz clock). The detailed test data is given by *Yang* [29.42] and *Kim* et al. [29.43]. GA parameter settings were taken as follows: population size, *popSize* = 20; crossover probability, $p_{\mathrm{C}} = 0.70$; mutation probability, $p_{\mathrm{M}} = 0.50$; immigration rate, $\mu = 0.15$. In an FMS case study, ten jobs are to be scheduled on five machines. The maximum number of processes for the operations is four. The detailed date sets are shown in [29.44].

We can draw a network depended on the precedence constraints among tasks $\{T_{ij}\}$ of the case study. The best result is shown in Fig. 29.5. The final time required to complete all jobs (i. e., the makespan) is 574, and four AGVs are used. Figure 29.5 shows the result on a Gantt chart. As discussed above, the AGV dispatching problem is a difficult problem to solve by conventional heuristics. Adaptability, robustness, and flexibility make EA very effective for such automation problems.

29.4 Robot-Based Assembly-Line System

Assembly lines are flow-oriented production systems which are still typical in the industrial production of high-quantity standardized commodities and are even gaining importance in low-volume production of customized products. Usually, specific tooling is developed to perform the activities needed at each station. Such tooling is attached to the robot at the station. In order to avoid the wasted time required for tool change, the design of the tooling can take place only after the line has been balanced. Different robot types may exist at the assembly facility. Each robot type may have different capabilities and efficiencies for various elements of the assembly tasks. Hence, allocating the most appropriate robot for each station is critical for the performance of robotic assembly lines.

29.4.1 Assembly-Line Balancing Problems

This problem concerns how to assign the tasks to stations and how to allocate the available robots for each station in order to minimize cycle time under the constraint of precedence relationships. Let us consider a simple example to describe the problem, in which ten tasks are to be assigned to four workstations, and four robots are to be equipped on the four stations. Figure 29.6 shows the precedence constraints for the ten tasks, and Table 29.2 gives the processing time for each of the tasks processed by each robot. We show a feasible solution for this example in Fig. 29.7.

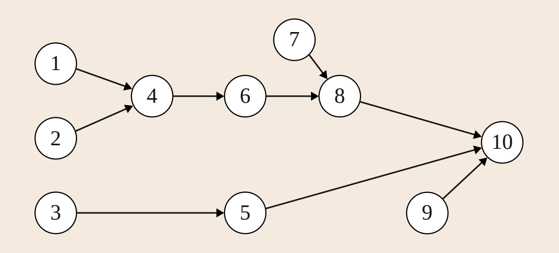

Fig. 29.6 Precedence graph of the example problem

Table 29.2 Data for the example

i	Suc(*i*)	R_1	R_2	R_3	R_4
1	4	17	22	19	13
2	4	21	22	16	20
3	5	12	25	27	15
4	6	29	21	19	16
5	10	31	25	26	22
6	8	28	18	20	21
7	8	42	28	23	34
8	10	27	33	40	25
9	10	19	13	17	34
10	–	26	27	35	26

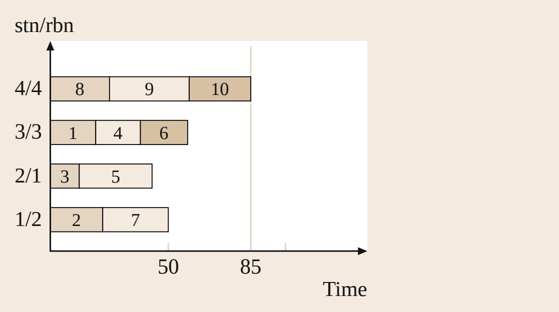

Fig. 29.7 The feasible solution for the example (stn – workstation number, rbn – robot number)

The balancing chart for the solution can be drawn to analyze the solution. Figure 29.7 shows that the idle time of stations 1–3 is very large, which means that this line is not balanced for production. In the real world, an assembly line is not just used for producing one unit of the product; it should produce several units. So we give the Gantt chart for three units to analyze the solution, as shown in Fig. 29.8.

29.4.2 Robot-Based Assembly-Line Model

The following assumptions are stated to clarify the setting in which the problem arises:

1. The precedence relationship among assembly activities is known and invariable.
2. The duration of an activity is deterministic. Activities cannot be subdivided.

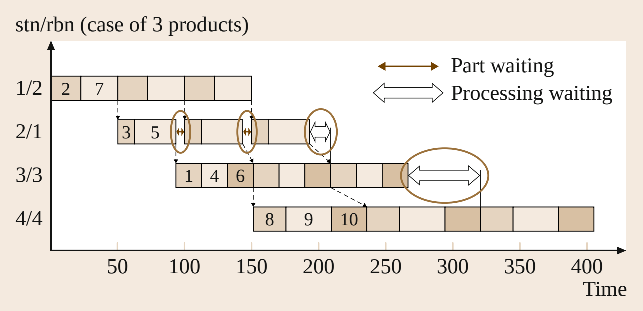

Fig. 29.8 Gantt chart for producing three units

3. The duration of an activity depends on the assigned robot.
4. There are no limitations on the assignment of an activities or a robot to any station. If a task cannot be processed on a robot, the assembly time of the task on the robot is set to a very large number.
5. A single robot is assigned to each station.
6. Material handling, loading, and unloading times, as well as setup and tool changing times are negligible, or are included in the activity times. This assumption is realistic on a single model assembly line that works on the single product for which it is balanced. Tooling on such a robotic line is usually designed such that tool changes are minimized within a station. If tool change or other type of setup activity is necessary, it can be included in the activity time, since the transfer lot size on such line is of a single product.
7. The number of workstations is determined by the number of robots, since the problem aims to maximize the productivity by using all robots at hand.
8. The line is balanced for a single product.

The notation used in this section can be summarized as follows. Indices: i, j: index of assembly tasks, $i, j = 1, 2, \ldots, n$; k: index of workstations, $k = 1, 2, \ldots, m$; l: index of robots, $l = 1, 2, \ldots, m$. Parameters: n: total number of assembly tasks, m: total number of workstations (robots), t_{il}: processing time of the i-th task by robot l, pre(i): the set of predecessor of task i in the precedence diagram. Decision variables

$$x_{jk} = \begin{cases} 1 & \text{if task } j \text{ is assigned to workstation } k \\ 0 & \text{otherwise}\,, \end{cases}$$

$$y_{kl} = \begin{cases} 1 & \text{if robot } l \text{ is allocated to workstation } k \\ 0 & \text{otherwise}\,. \end{cases}$$

	Locus	1	2	3	4	5	6	7	8	9	10
Phase 1:	Task sequence (v_1)	2	1	3	4	9	6	5	7	8	10

	Locus: station	1	2	3	4
Phase 2:	Robot assignment (v_2)	1	2	3	4

Fig. 29.9 Solution representation of a sample problem

Problem formulation

$$\min C_{\mathrm{T}} = \max_{1\le k\le m} \left\{ \sum_{i=1}^{n} \sum_{l=1}^{m} t_{il} x_{ik} y_{kl} \right\}\,, \tag{29.10}$$

$$\text{s.t.} \sum_{k=1}^{m} k x_{jk} - \sum_{k=1}^{m} k x_{ik} \ge 0,\ \forall i,\ j \in \mathrm{pre}(i)\,, \tag{29.11}$$

$$\sum_{k=1}^{m} x_{ik} = 1\,, \quad \forall i\,, \tag{29.12}$$

$$\sum_{l=1}^{m} y_{kl} = 1\,, \quad \forall k\,, \tag{29.13}$$

$$\sum_{k=1}^{m} y_{kl} = 1\,, \quad \forall l\,, \tag{29.14}$$

$$x_{ik} \in \{0, 1\} \quad \forall k, i\,, \tag{29.15}$$

$$y_{kl} \in \{0, 1\} \quad \forall l, k\,. \tag{29.16}$$

The objective (29.10) is to minimize the cycle time, C_{T}. Constraint (29.11) represents the precedence constraints. It ensures that, for each pair of assembly activities, the precedent cannot be assigned to a station before the station of the successor if there is precedence between the two activities. Constraint (29.12) ensures that each task has to be assigned to one station. Constraint (29.13) ensures that each station is equipped with one robot. Constraint (29.14) ensures that each robot can only be assigned to one station.

29.4.3 Hybrid Genetic Algorithm

Order encoding for task sequence: A GA's structure and parameter settings affect its performance. However, the primary determinants of a GA's success or failure are the coding by which its genotypes represent candidate solutions, and the interaction of the coding with the GA's recombination and mutation operators.

A solution of the robot-based assembly line balancing (rALB) problem can be represented by two integer vectors: the task sequence vector, v_1, which contains a permutation of assembly tasks ordered according to their technological precedence sequence, and the robot assignment vector, v_2. The solution representation method is illustrated in Fig. 29.9. The detailed processes of decoding the task sequence and assigning robots to workstations are shown in [29.34].

In the real world, an assembly line is not just for producing one unit of the product; tt should produce several units. So we give the Gantt chart

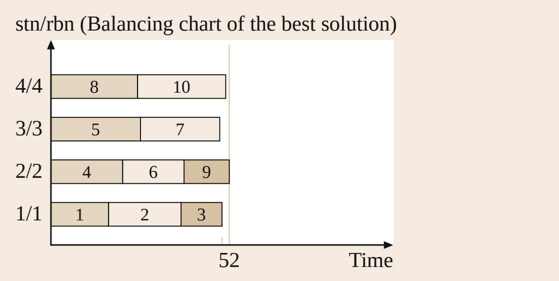

Fig. 29.10 The balancing chart of the best solution (stn – workstation number, rbn – robot number)

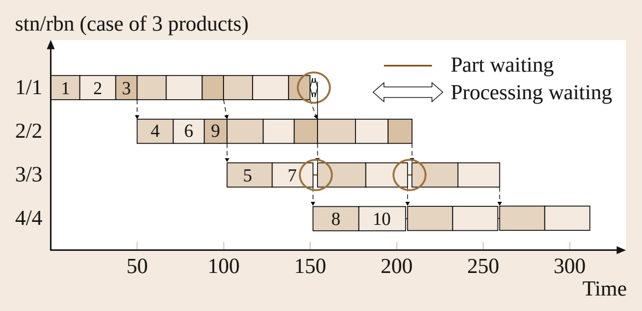

Fig. 29.11 Gantt chart for producing three units

Table 29.3 Performance of the proposed algorithm

Test problem			Cycle time (C_T)		
No. of tasks	No. of stations	WEST ratio	Levitin et al. recursive	Levitin et al. consecutive	Proposed approach

	38	7.82	442	348	344
	50	5.94	363	275	256

with three units for analyzing the solution as in Fig. 29.11. We can see the solution reduce the waiting time for the line by comparing with the feasible solution from Fig. 29.8. This also means that the better solution improved the assembly-line balancing.

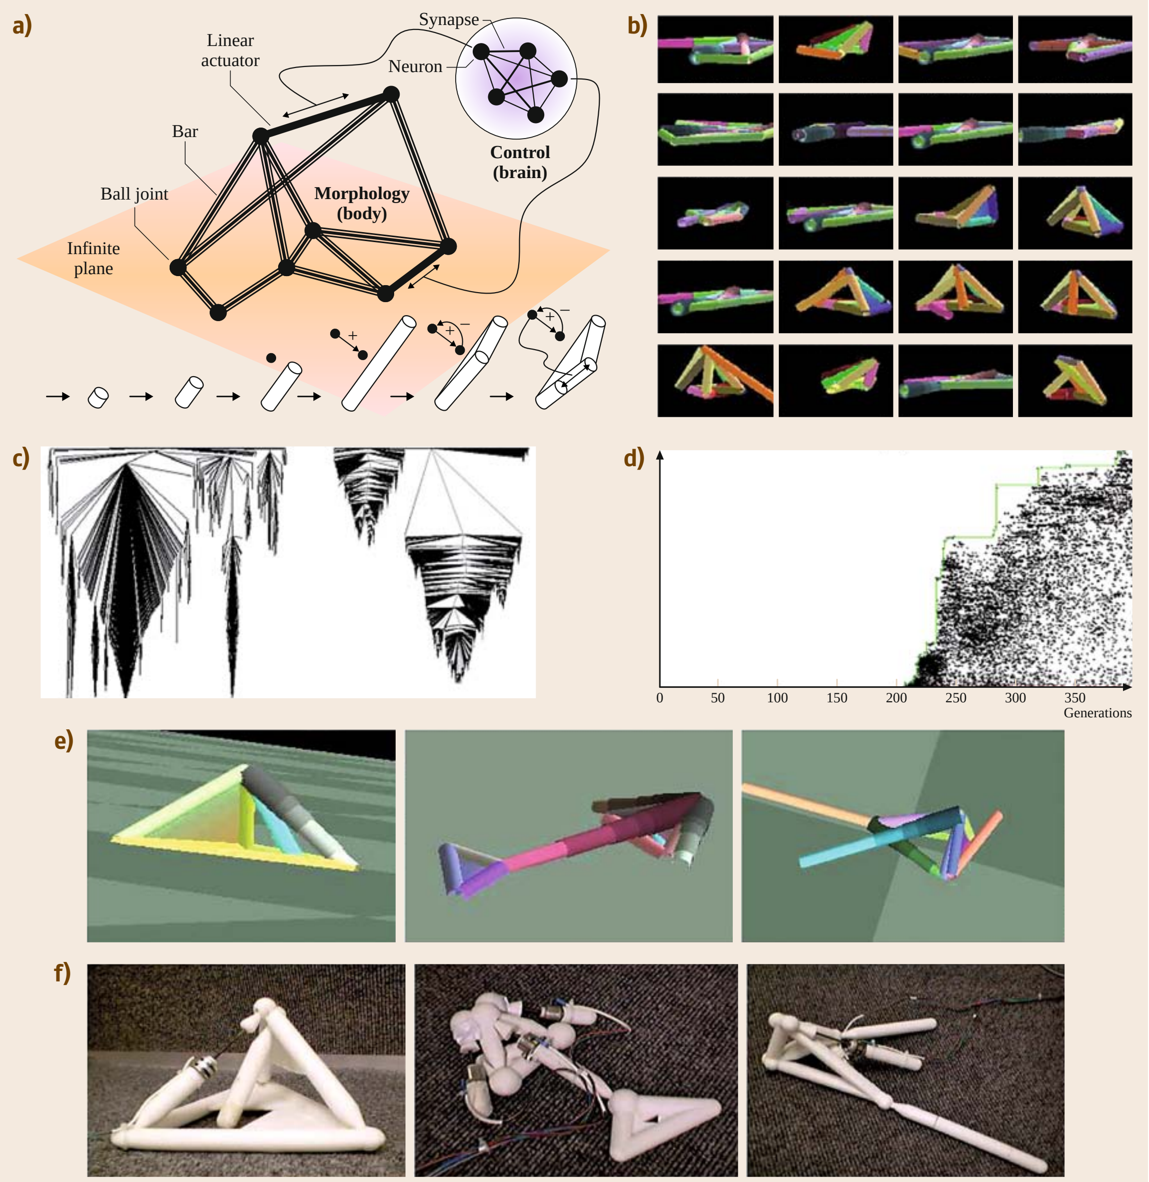

Fig. 29.12a–f Evolving bodies and brains. **(a)** Schematic illustration of an evolvable robot. **(b)** An arbitrarily sampled instance of an entire generation, thinned down to show only significantly different individuals. **(c)** Phylogenetic trees of two different evolutionary runs, showing instances of speciation and massive extinctions. **(d)** Progress of fitness versus generation for one of the runs. 29.4.4 Case Study

In order to evaluate the performance of the proposed method, a large set of problems were tested. In the literature, no benchmark data sets are available for rALB. There are eight representative precedence graphs [29.45], used in the simple assembly line balancing (sALB) literature [29.46]. These precedence graphs contain 25–297 tasks.

Table 29.3 shows the experiment results of Levitin et al.'s two algorithms and proposed approach for 32 different scale test problems [29.47]. As depicted in Table 29.3, all of the results by the proposed approach are better than Levitin et al.'s recursive assignment method, and most results of the proposed approach are better than Levitin et al.'s consecutive assignment method, except for tests 25-3, 35-7, and 111-17. Depending on the experiment results, the way in which a solution of the automation problem is encoded into a chromosome is a key issue for applying the evolutionary algorithm.

29.5 Conclusions and Emerging Trends

The techniques presented in this Chapter are bioinspired and their influence on factory, planning and scheduling, manufacturing, logistics and transportation is discussed. Emerging trends will continue to follow bioinspired control and automation, such as the development of evolvable robots to better meet the needs of evolving and flexible lines (Fig. 29.12). For a related discussion refer to Chap. 14 in an earlier section of this Handbook.

30. Automating Errors and Conflicts Prognostics and Prevention

Xin W. Chen, Shimon Y. Nof

Errors and conflicts exist in many systems. A fundamental question from industries is How can errors and conflicts in systems be eliminated by automation, or can we at least use automation to minimize their damage? The purpose of this chapter is to illustrate a theoretical background and applications of how to automatically prevent errors and conflicts with various devices, technologies, methods, and systems. Eight key functions to prevent errors and conflicts are identified and their theoretical background and applications in both production and service are explained with examples. As systems and networks become larger and more complex, such as global enterprises and the Internet, error and conflict prognostics and prevention become more important and challenging; the focus is shifting from passive response to proactive prognostics and prevention. Additional theoretical developments and implementation efforts are needed to advance the prognostics and prevention of errors and conflicts in many real-world applications.

30.1 Definitions

All humans commit errors ("To err is human") and encounter conflicts. In the context of automation, there are two main questions: (1) Does automation commit errors and encounter conflicts? (2) Can automation help humans prevent errors and eliminate conflicts? All human-made automation includes human-committed errors and conflicts, for example, human programming errors, design errors, and conflicts between

Table 30.1 Examples of errors and conflicts in production automation

Error	Conflict
● A robot drops a circuit board while moving it between two locations ● A machine punches two holes on a metal sheet while only one is needed, because the size of the metal sheet is recognized incorrectly by the vision system ● A lathe stops processing a shaft due to power outage ● The server of a computer-integrated manufacturing system crashes due to high temperature ● A facility layout generated by a software program cannot be implemented due to irregular shapes	● Two numerically controlled machines request help from the same operator at the same time ● Three different software packages are used to generate optimal schedule of jobs for a production facility; the schedules generated are totally different ● Two automated guided vehicles collide ● A DWG (drawing) file prepared by an engineer with AutoCAD cannot be opened by another engineer with the same software ● Overlapping workspace defined by two cooperating robots

human planners. Two automation systems, designed separately by different human teams, will encounter conflicts when they are expected to collaborate, for instance, the need for communication protocol standards to enable computers to interact automatically. Some errors and conflicts are inherent to automation, similar to all human-made creations, for instance, a robot mechanical structure that collapses under weight overload.

An error is any input, output or intermediate result that has occurred or will occur in a system and does not meet system specification, expectation or comparison objective. A conflict is an inconsistency between different units' goals, plans, tasks or other activities in a system. A system usually has multiple units, some of which collaborate, cooperate, and/or coordinate to complete tasks. The most important difference between an error and a conflict is that an error can involve only one unit, whereas a conflict involves two or more units in a system. An error at a unit may cause other errors or conflicts, for instance, a workstation that cannot provide the required number of products to an assembly line (a conflict) because one machine at the workstation breaks down (an error). Similarly, a conflict may cause other errors and conflicts, for instance, a machine that did not receive required products (an error) because the automated guided vehicles that carry the products collided when they were moving toward each other on the same path (a conflict). These phenomena, errors leading to other errors or conflicts, and conflicts leading to other errors or conflicts, are called *error and conflict propagation*.

Errors and conflicts are different but related. The definition of the two terms is often subject to the understanding and modeling of a system and its units. Mathematical equations can help define errors and con-

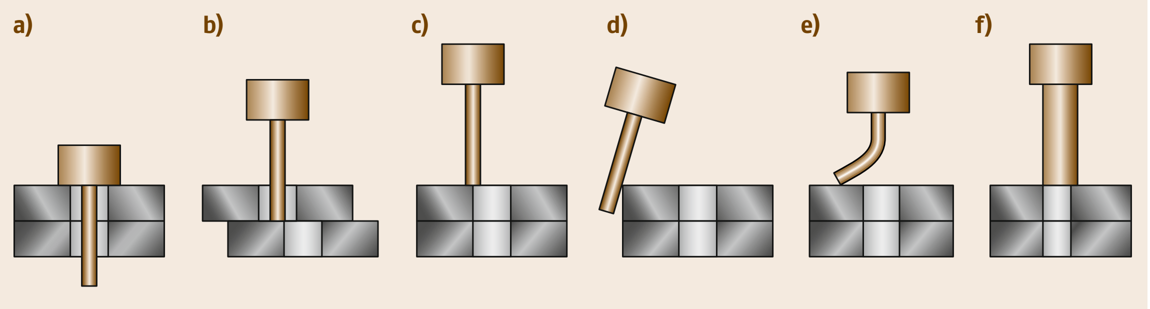

Fig. 30.1a–f Errors and conflicts in a pin insertion task: **(a)** successful insertion; **(b–f)** are unsuccessful insertion with (1) errors if the pin and the two other components are considered as one unit in a system, or (2) conflicts if the pin is a unit and the two other components are considered as another unit in a system [30.1]

Table 30.2 Examples of errors and conflicts in service automation

Error	Conflict
● The engine of an airplane shuts down unexpectedly during the flight ● A patient's electronic medical records are accidently deleted during system recovery ● A pacemaker stops working ● Traffic lights go off due to lightening ● A vending machine does not deliver drinks or snacks after the payment ● Automatic doors do not open ● An elevator stops between two floors ● A cellphone automatically initiates phone calls due to a software glitch	● The time between two flights in an itinerary generated by an online booking system is too short for transition from one flight to the other ● A ticket machine sells more tickets than the number of available seats ● An ATM machine dispenses $ 250 when a customer withdraws $ 260 ● A translation software incorrectly interprets text ● Two surgeries are scheduled in the same room due to a glitch in a sensor that determines if the room is empty

flicts. An error is defined as

$$\exists E\left[u_{r,i}(t)\right]\ , \quad \text{if } \vartheta_i(t) \xrightarrow{\text{Dissatisfy}} \text{con}_r(t)\ . \tag{30.1}$$

$E\left[u_{r,i}(t)\right]$ is an error, $u_i(t)$ is unit i in a system at time t, $\vartheta_i(t)$ is unit i's state at time t that describes what has occurred with unit i by time t, $\text{con}_r(t)$ denotes constraint r in the system at time t, and $\xrightarrow{\text{Dissatisfy}}$ denotes that a constraint is not satisfied. Similarly, a conflict is defined as

$$\exists C\left[n_r(t)\right]\ , \quad \text{if } \theta_i(t) \xrightarrow{\text{Dissatisfy}} \text{con}_r(t)\ . \tag{30.2}$$

$C\left[n_r(t)\right]$ is a conflict and $n_r(t)$ is a network of units that need to satisfy $\text{con}_r(t)$ at time t. The use of constraints helps define errors and conflicts unambiguously. A constraint is the system specification, expectation, comparison objective or acceptable difference between different units' goals, plans, tasks or other activities. Tables 30.1 and 30.2 illustrate errors and conflicts in automation with some typical examples. There are also human errors and conflicts that exist in automation systems. Figure 30.1 describes the difference between errors and conflicts in pin insertion.

This Chapter provides a theoretical background and illustrates applications of how to prevent errors and conflicts automatically in production and service. Different terms have been used to describe the concept of errors and conflicts, for instance, failure (e.g., [30.2–5]), fault (e.g., [30.4, 6]), exception (e.g., [30.7]), and flaw (e.g., [30.8]). *Error* and *conflict* are the most popular terms appearing in literature (e.g., [30.3,4,6,9–15]). The related terms listed here are also useful descriptions of errors and conflicts. Depending on the context, some of these terms are interchangeable with error; some are interchangeable with conflict; and the rest refer to both error and conflict.

Eight key functions have been identified as useful to prevent errors and conflicts automatically as described below [30.16–19]. Functions 5–8 prevent errors and conflicts with the support of functions 1–4. Functions 6–8 prevent errors and conflicts by managing those that have already occurred. Function 5, *prognostics*, is the only function that actively determines which errors and conflicts will occur, and prevents them. All other seven functions are designed to manage errors and conflicts that have already occurred, although as a result they can prevent future errors and conflicts directly or indirectly. Figure 30.2 describes error and conflict propagation and their relationship with the eight functions:

1. Detection is a procedure to determine if an error or a conflict has occurred.
2. Identification is a procedure to identify the observation variables most relevant to diagnosing an error or conflict; it answers the question: Which of them has already occurred?
3. Isolation is a procedure to determine the exact location of an error or conflict. Isolation provides more information than identification function, in which only the observation variables associated with the error or conflict are determined. Isolation does not provide as much information as the diagnostics function, however, in which the type, magnitude,

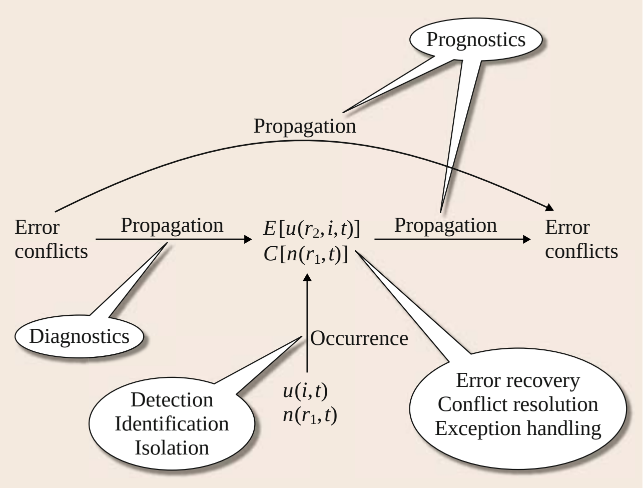

Fig. 30.2 Error and conflict propagation and eight functions to prevent errors and conflicts

and time of the error or conflict are determined. Isolation answers the question: Where has an error or conflict occurred?

4. Diagnostics is a procedure to determine which error or conflict has occurred, what their specific characteristics are, or the cause of the observed out-of-control status.
5. Prognostics is a procedure to prevent errors and conflicts through analysis and prediction of error and conflict propagation.
6. Error recovery is a procedure to remove or mitigate the effect of an error.
7. Conflict resolution is a procedure to resolve a conflict.
8. Exception handling is a procedure to manage exceptions. Exceptions are deviations from an ideal process that uses the available resources to achieve the task requirement (goal) in an optimal way.

There has been extensive research on the eight functions, except prognostics. Various models, methods, tools, and algorithms have been developed to automate the management of errors and conflicts in production and service. Their main limitation is that most of them are designed for a specific application area, or even a specific error or conflict. The main challenge of automating the management of errors and conflicts is how to prevent them through prognostics, which is supported by the other seven functions and requires substantial research and developments.

30.2 Error Prognostics and Prevention Applications

30.2.1 Error Detection in Assembly and Inspection

As the first step to prevent errors, error detection has attracted much attention, especially in assembly and inspection; for instance, researchers [30.3] have studied an integrated sensor-based control system for a flexible assembly cell which includes error detection function. An error knowledge base has been developed to store information about previous errors that had occurred in assembly operations, and corresponding recovery programs which had been used to correct them. The knowledge base provides support for both error detection and recovery. In addition, a similar machine-learning approach to error detection and recovery in assembly has been discussed. To realize error recovery, failure diagnostics has been emphasized as a necessary step after the detection and before the recovery. It is noted that, in assembly, error detection and recovery are often integrated.

Automatic inspection has been applied in various manufacturing processes to detect, identify, and isolate errors or defects with computer vision. It is mostly used to detect defects on printed circuit board [30.20–22] and dirt in paper pulps [30.23, 24]. The use of robots has enabled automatic inspection of hazardous materials (e.g., [30.25]) and in environments that human operators cannot access, e.g., pipelines [30.26]. Automatic inspection has also been adopted to detect errors in many other products such as fuel pellets [30.27], printing the contents of soft drink cans [30.28], oranges [30.29], aircraft components [30.30], and microdrills [30.31]. The key technologies involved in automatic inspection include but are not limited to computer or machine vision, feature extraction, and pattern recognition [30.32–34].

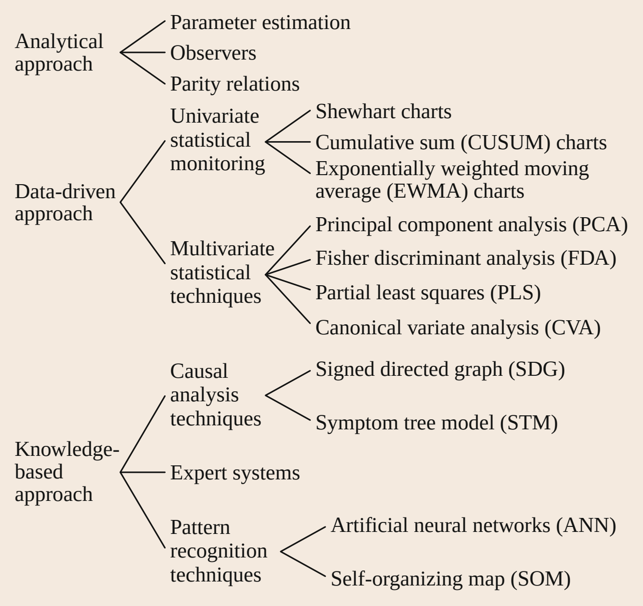
30.2.2 Process Monitoring and Error Management

Process monitoring, or fault detection and diagnostics in industrial systems, has become a new subdiscipline within the broad subject of control and signal processing [30.35]. Three approaches to manage faults for process monitoring are summarized in Fig. 30.3. The analytical approach generates features using detailed mathematical models. Faults can be detected and diagnosed by comparing the observed features with the features associated with normal operating conditions directly or after some transformation [30.19]. The data-driven approach applies statistical tools on large amount of data obtained from complex systems. Many quality control methods are examples of the data-driven approach. The knowledge-based approach uses qualitative models to detect and analyze faults. It is especially suited for systems in which detailed mathematical models are not available. Among these three approaches, the data-driven approach is considered most promising because of its solid theoretical foundation compared with the knowledge-based approach and its ability to deal with large amount of data compared with the analytical approach. The knowledge-based approach, however, has gained much attention recently. Many errors and conflicts can be detected and diagnosed only by experts who have extensive knowledge and experience, which need to be modeled and captured to automate error and conflict prognostics and prevention.

30.2.3 Hardware Testing Algorithms

The three fault management approaches discussed in Sect. 30.2.2 can also be classified according to the way that a system is modeled. In the analytical approach, quantitative models are used which require the complete specification of system components, state variables, observed variables, and functional relationships among them for the purpose of fault management. The data-driven approach can be considered as the effort to develop qualitative models in which previous and current data obtained from a system are used. Qualitative models usually require less information about a system than do quantitative models. The knowledge-based approach uses qualitative models and other types of models; for instance, pattern recognition techniques use multivariate statistical tools and employ qualitative models, whereas the signed directed graph is a typical dependence model which represents the cause–effect relationships in the form of a directed graph [30.36].

Similar to algorithms used in quantitative and qualitative models, optimal and near-optimal test sequences have been developed to diagnose faults in hardware [30.36–45]. The goal of the test sequencing problem is to design a test algorithm that is able to unambiguously identify the occurrence of any system state (faulty or fault-free state) using the test in the test set and minimizes the expected testing cost [30.37].



Analytical approach

Fig. 30.3 Techniques of fault management in process monitoring

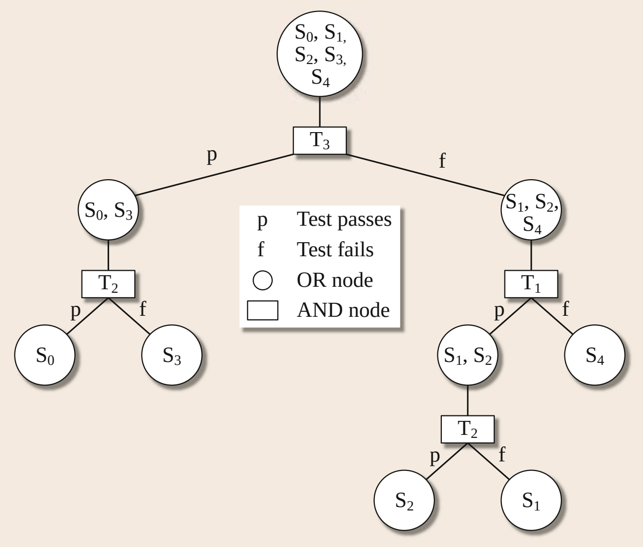

Fig. 30.4 Single-fault test strategy

The test sequencing problem belongs to the general class of binary identification problems. The problem to diagnose single fault is a perfectly observed Markov decision problem (MDP). The solution to the MDP is a deterministic AND/OR binary decision tree with OR nodes labeled by the suspect set of system states and AND nodes denoting tests (decisions) (Fig. 30.4). It is

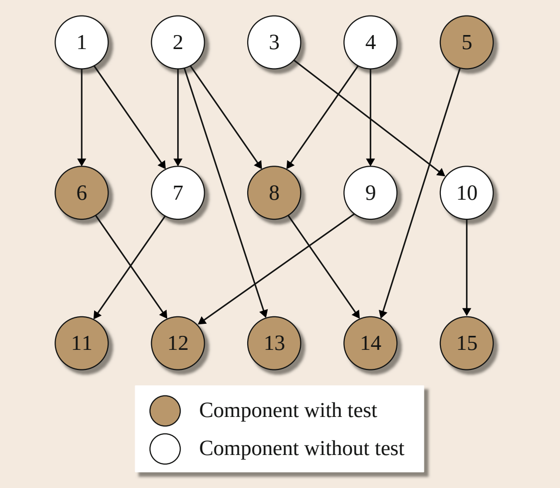

Fig. 30.5 Digraph model of an example system

well known that the construction of the optimal decision tree is an NP-complete problem [30.37].

To subdue the computational explosion of the optimal test sequencing problem, algorithms that integrate concepts from information theory and heuristic search have been developed and were first used to diagnose faults in electronic and electromechanical systems with a single fault [30.37]. An X-Windows-based software tool, the testability engineering and maintenance system (TEAMS), has been developed for testability analysis of large systems containing as many as 50 000 faults and 45 000 test points [30.36]. TEAMS can be used to model individual systems and generate near-optimal diagnostic procedures. Research on test sequencing then expanded to diagnose multiple faults [30.41–45] in various real-world systems including the Space Shuttle's main propulsion system. Test sequencing algorithms with unreliable tests [30.40] and multivalued tests [30.45] have also been studied.

To diagnose a single fault in a system, the relationship between the faulty states and tests can be modeled by directed graph (digraph model) (Fig. 30.5). Once a system is described in a diagraph model, the full order dependences among failure states and tests can be captured by a binary test matrix, also called a dependency matrix (D-matrix, Table 30.3). Other researchers have used digraph model to diagnose faults in hypercube microprocessors [30.46]. The directed graph is a powerful tool to describe dependences among system components and tests.

Three important issues have been brought to light by extensive research on test sequencing problem and should be considered when diagnosing faults for hardware:

1. The order of dependences. The first-order cause–effect dependence between two nodes, i. e., how a faulty node affects another node directly, is the simplest dependence relationship between two nodes. Earlier research did not consider the dependences among nodes [30.37, 38], whereas in

Table 30.3 D-matrix of the example system derived from Fig. 30.5

State/test	$T_1(5)$	$T_2(6)$	$T_3(8)$	$T_4(11)$	$T_5(12)$	$T_6(13)$	$T_7(14)$	$T_8(15)$
$S_1(1)$	0	1	0	1	1	0	0	0
$S_2(2)$	0	0	1	1	0	1	1	0
$S_3(3)$	0	0	0	0	0	0	0	1
$S_4(4)$	0	0	1	0	1	0	1	0
$S_5(5)$	1	0	0	0	0	0	1	0
$S_6(6)$	0	1	0	0	1	0	0	0
$S_7(7)$	0	0	0	1	0	0	0	0
$S_8(8)$	0	0	1	0	0	0	1	0
$S_9(9)$	0	0	0	0	1	0	0	0
$S_{10}(10)$	0	0	0	0	0	0	0	1
$S_{11}(11)$	0	0	0	1	0	0	0	0
$S_{12}(12)$	0	0	0	0	1	0	0	0
$S_{13}(13)$	0	0	0	0	0	1	0	0
$S_{14}(14)$	0	0	0	0	0	0	1	0
$S_{15}(15)$	0	0	0	0	0	0	0	1

most recent research different algorithms and test strategies have been developed with the consideration of not only the first-order, but also high-order dependences among nodes [30.43–45]. The high-order dependences describe relationships between nodes that are related to each other through other nodes.

2. Types of faults. Faults can be classified into two categories: functional faults and general faults. A component or unit in a complex system may have more than one function. Each function may become faulty. A component may therefore have one or more functional faults, each of which involves only one function of the component. General faults are those faults that cause faults in all functions of a component. If a component has a general fault, all its functions are faulty. Models that describe only general faults are often called *worst-case* models [30.36] because of their poor diagnosing ability;
3. Fault propagation time. Systems can be classified into two categories: zero-time and nonzero-time systems [30.45]. Fault propagation in zero-time systems is instantaneous to an observer, whereas in nonzero-time systems it is several orders of magnitude slower than the response time of the observer. Zero-time systems can be abstracted by taking the propagation times to be zero.

Another interesting aspect of the test sequencing problem is the list of assumptions that have been discussed in several articles, which are useful guidelines for the development of algorithms for hardware testing:

1. At most one faulty state (component or unit) in a system at any time [30.37]. This may be achieved if the system is tested frequently enough [30.42].
2. All faults are permanent faults [30.37].
3. Tests can identify system states unambiguously [30.37]. In other words, a faulty state is either identified or not identified. There is not a situation such as: There is a 60% probability that a faulty state has occurred.
4. Tests are 100% reliable [30.40, 45]. Both false positive and false negative rates are zero.
5. Tests do not have common setup operations [30.42]. This assumption has been proposed to simplify the cost comparison among tests.
6. Faults are independent [30.42].
7. Failure states that are replaced/repaired are 100% functional [30.42].
8. Systems are zero-time systems [30.45].

Note the critical difference between assumptions 3 and 4. Assumption 3 is related to diagnostics ability. When an unambiguous test detects a fault, the conclusion is that the fault has definitely occurred with 100% probability. Nevertheless, this conclusion could be wrong if the false positive rate is not zero. This is the test (diagnostics) reliability described in assumption 4. When an unambiguous test does not detect a fault, the conclusion is that the fault has not occurred with 100% probability. Similarly, this conclusion could be wrong if the false negative rate is not zero. Unambiguous tests have better diagnostics ability than ambiguous tests. If a fault has occurred, ambiguous tests conclude that the fault has occurred with a probability less than one. Similarly, if the fault has not occurred, ambiguous tests conclude that the fault has not occurred with a probability less than one. In summary, if assumption 3 is true, a test gives only two results: a fault has occurred or has not occurred, always with probability 1. If both assumptions 3 and 4 are true, (1) a fault must have occurred if the test concludes that it has occurred, and (2) a fault must have not occurred if the test concludes that it has not occurred.

30.2.4 Error Detection in Software Design

The most prevalent method to detect errors in software is model checking. As *Clarke* et al. [30.47] state, *model checking* is a method to verify algorithmically if the model of software or hardware design satisfies given requirements and specifications through exhaustive enumeration of all the states reachable by the system and the behaviors that traverse them. Model checking has been successfully applied to identify incorrect hardware and protocol designs, and recently there has been a surge in work on applying it to reason about a wide variety of software artifacts; for example, model checking frameworks have been applied to reason about software process models, (e.g., [30.48]), different families of software requirements models (e.g., [30.49]), architectural frameworks (e.g., [30.50]), design models (e.g., [30.51]), and system implementations (e.g., [30.52–55]). The potential of model checking technology for (1) detecting coding errors that are hard to detect using existing quality assurance methods, e.g., bugs that arise from unanticipated interleavings in concurrent programs, and (2) verifying that system models and implementations satisfy crucial temporal properties and other lightweight specifications has led a number of international corporations and government research laboratories such as Microsoft, IBM, Lucent, NEC, the National Aeronautics and Space Administration (NASA), and the Jet Propulsion Laboratory (JPL) to fund their own software model checking projects.

A drawback of model checking is the state-explosion problem. Software tends to be less structured than hardware and is considered as a concurrent but asynchronous system. In other words, two independent processes in software executing concurrently in either order result in the same global state [30.47]. Failing to execute checking because of too many states is a particularly serious problem for software. Several methods, including symbolic representation, partial order reduction, compositional reasoning, abstraction, symmetry, and induction, have been developed either to decrease the number of states in the model or to accommodate more states, although none of them has been able to solve the problem by allowing a general number of states in the system.

Based on the observation that software model checking has been particularly successful when it can be optimized by taking into account properties of a specific application domain, *Hatcliff* and colleagues have developed Bogor [30.56], which is a highly modular model-checking framework that can be tailored to specific domains. Bogor's extensible modeling language allows new modeling primitives that correspond to domain properties to be incorporated into the modeling language as first-class citizens. Bogor's modular architecture enables its core model-checking algorithms to be replaced by optimized domain-specific algorithms. Bogor has been incorporated into Cadena and tailored to checking avionics designs in the common object request broker architecture (CORBA) component model (CCM), yielding orders of magnitude reduction in verification costs. Specifically, Bogor's modeling language has been extended with primitives to capture CCM interfaces and a real-time CORBA (RT-CORBA) event channel interface, and Bogor's scheduling and state-space exploration algorithms were replaced with a scheduling algorithm that captures the particular scheduling strategy of the RT-CORBA event channel and a customized state-space storage strategy that takes advantage of the periodic computation of avionics software.

Despite this successful customizable strategy, there are additional issues that need to be addressed when incorporating model checking into an overall design/development methodology. A basic problem concerns incorrect or incomplete specifications: before verification, specifications in some logical formalism (usually temporal logic) need to be extracted from design requirements (properties). Model checking can verify if a model of the design satisfies a given specification. It is impossible, however, to determine if the derived specifications are consistent with or cover all design properties that the system should satisfy. That is, it is unknown if the design satisfies any unspecified properties, which are often assumed by designers. Even if all necessary properties are verified through model checking, code generated to implement the design is not guaranteed to meet design specifications, or more importantly, design properties. Model-based software testing is being studied to connect the two ends in software design: requirements and code.

The detection of design errors in software engineering has received much attention. In addition to model checking and software testing, for instance, *Miceli* et al. [30.8] has proposed a metric-based technique for design flaw detection and correction. In parallel computing, synchronization errors are major problems and a nonintrusive detection method for synchronization errors using execution replay has been developed [30.14]. Besides, concurrent error detection (CED) is well known for detecting errors in distributed computing systems and its use of duplications [30.9, 57], which is sometimes considered a drawback.

30.2.5 Error Detection and Diagnostics in Discrete-Event Systems

Recently, Petri nets have been applied in fault detection and diagnostics [30.58–60] and fault analysis [30.61–63]. Petri nets are formal modeling and analysis tool for discrete-event or asynchronous systems. For hybrid systems that have both event-driven and time-driven (synchronous) elements, Petri nets can be extended to global Petri nets to model both discrete-time and event elements. To detect and diagnose faults in discrete-event systems (DES), Petri nets can be used together with finite-state machines (FSM) [30.64, 65]. The notion of diagnosability and a construction procedure for the diagnoser have been developed to detect faults in diagnosable systems [30.64]. A summary of the use of Petri nets in error detection and recovery before the 1990s can be found in the work of *Zhou* and *DiCesare* [30.66].

To detect and diagnose faults with Petri nets, some of the places in a Petri net are assumed observable and others are not. All transitions in the Petri net are also unobservable. Unobservable places, i. e., faults, indicate that the number of tokens in those places is not observable, whereas unobservable transitions indicate that their occurrences cannot be observed [30.58, 60]. The objective of the detection and diagnostics is to identify the occurrence and type of a fault based on observable places within finite steps of observation after the occurrence of the fault. It is clear that to detect and diagnose faults with Petri nets, system modeling is complex and time consuming because faulty transitions and places must be included in a model. Research on this subject has mainly involved the extension of previous work using FSM and has made limited progress.

Faults in discrete-event systems can be diagnosed with the decentralized approach [30.67]. Distributed diagnostics can be performed by either diagnosers communicating with each other directly or through a coordinator. Alternatively, diagnostics decisions can be made completely locally without combining the information gathered [30.67]. The decentralized approach is a viable direction for error detection and diagnostics in large and complex systems.

30.2.6 Error Detection in Service and Healthcare Industries

Errors tend to occur frequently in certain service industries that involve intensive human operations. As the use of computers and other automation devices, e.g., handwriting recognition and sorting machines in postal service, becomes increasingly popular, errors can be effectively and automatically prevented and reduced to minimum in many service industries including delivery, transportation, e-Business, and e-Commerce. In some other service industries, especially in healthcare systems, error detection is critical and limited research has been conducted to help develop systems that can automatically detect human errors and other types of errors [30.68–72]. Several systems and modeling tools have been studied and applied to detect errors in health industries with the help of automation devices (e.g., [30.73–76]). Much more research needs to be conducted to advance the development of automated error detection in service industries.

30.2.7 Error Detection and Prevention Algorithms for Production and Service Automation

The fundamental work system has evolved from manual power, human–machine system, computer-aided and computer-integrated systems, and then to e-Work [30.77], which enables distributed and decentralized operations where errors and conflicts propagate and affect not only the local workstation, but the entire production/service network. Agent-based algorithms, e.g., (30.3), have been developed to detect and prevent errors in the process of providing a single product/service in a sequential production/service line [30.78, 79]. Q_i is the performance of unit i. U'_m and L'_m are the upper limit and lower limit, respectively, of the acceptable performance of unit m. U_m and L_m are the upper limit and lower limit, respectively, of the acceptable level of the quality of a product/service after the operation of unit m. Units 1 through $m-1$ complete their operation on a product/service before unit m starts its operation on the same product/service. An agent deployed at unit m executes (30.3) to prevent errors

$$\exists E(u_m)\,, \quad \text{if } \left\{U_m - L'_m < \sum_{i=1}^{m-1} Q_i\right\} \cup \left\{L_m - U'_m > \sum_{i=1}^{m-1} Q_i\right\} . \tag{30.3}$$

In the process of providing multiple products/services, traditionally, the centralized algorithm (30.4) is used to predict errors in a sequential production/service line. $I_i(0)$ is the quantity of available raw materials for unit i at time 0. η_i is the probability a product/service is within specifications after being operated by unit i, assuming the product/service is within specifications before being operated by unit i. $\varphi_m(t)$ is the needed number of qualified products/services after the operation of unit m at time t. Equation (30.4) predicts at time 0 the potential errors that may occur at unit m at time t. Equation (30.4) is executed by a central control unit that is aware of $I_i(0)$ and η_i of all units. Equation (30.4) often has low reliability, i. e., high false positive rates (errors are predicted but do not occur), or low preventability, i. e., high false negative rate (errors occur but are not predicted), because it is difficult to obtain accurate η_i when there are many units in the system.

$$\exists E[u_m(t)]\,, \quad \text{if } \min_{i=1}^{m}\left\{I_i\,(0) \times \prod_{i}^{m} \eta_i\right\} < \varphi_m(t) \tag{30.4}$$

To improve reliability and preventability, agent-based error prevention algorithms, e.g., (30.5), have been de-

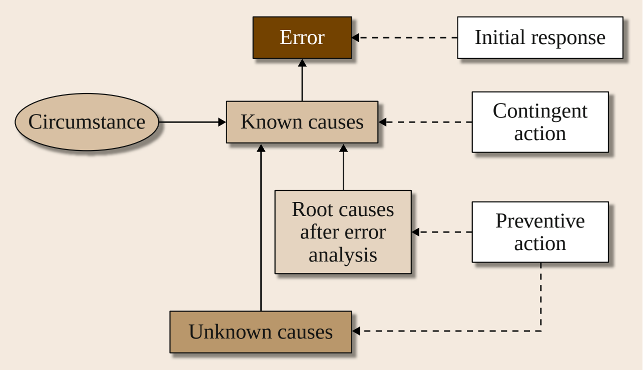

Fig. 30.6 Incident mapping

veloped to prevent errors in the process of providing multiple products/services [30.80]. $C_m(t')$ is the number of cumulative conformities produced by unit m by time t'. $N_m(t')$ is the number of cumulative nonconformities produced by unit m by time t'. An agent deployed at unit m executes (30.5) by using information about unit $m-1$, i. e., $I_{m-1}(t')$, η_{m-1}, and $C_{m-1}(t')$ to prevent errors that may occur at time t, $t' < t$. Multiple agents deployed at different units can execute (30.5) simultaneously to prevent errors. Each agent can have its own attitude, i. e., optimistic or pessimistic, toward the possible occurrence of errors. Additional details about agent-based error prevention algorithms can be found in the work by *Chen* and *Nof* [30.80]:

$$\begin{aligned}\exists E[u_m(t)] \quad \text{if } \min\big[&I_m(t'), I_{m-1}(t') \times \eta_{m-1} \\ &+ C_{m-1}(t') - N_m(t') \\ &- C_m(t')\big] \times \eta_m + C_m(t') \\ &< \varphi_m(t), \quad t' < t\,. \end{aligned} \qquad (30.5)$$

30.2.8 Error-Prevention Culture (EPC)

To prevent errors effectively, an organization is expected to cultivate an enduring error-prevention culture (EPC) [30.81], i. e., the organization knows what to do to prevent errors when no one is telling it what to do. The EPC model has five components [30.81]:

1. Performance management: the human performance system helps manage valuable assets and involves five key areas: (a) an environment to minimize errors, (b) human resources that are capable of performing tasks, (c) task monitoring to audit work, (d) feedback provided by individuals or teams through collaboration, and (e) consequences provided to encourage or discourage people for their behaviors.
2. System alignment: an organization's operating systems must be aligned to get work done with discipline, routines, and best practices.
3. Technical excellence: an organization must promote shared technical and operational understanding of how a process, system or asset should technically perform.
4. Standardization: standardization supports error prevention with a balanced combination of good manufacturing practices.
5. Problem-resolution skills: an organization needs people with effective statistical diagnostics and issue-resolution skills to address operational process challenges.

Not all errors can be prevented manually and/or by automation systems. When an error does occur, incident mapping (Fig. 30.6) [30.81] as one of the exception-handling tools can be used to analyze the error and proactively prevent future errors.

30.3 Conflict Prognostics and Prevention

Conflicts can be categorized into three classes [30.82]: goal conflicts, plan conflicts, and belief conflicts. Goals of an agent are modeled with an intended goal structure (IGS; e.g., Fig. 30.7), which is extended from a goal structure tree [30.83]. Plans of an agent are modeled with the extended project estimation and review technique (E-PERT) diagram (e.g., Fig. 30.8). An agent has (1) a set of goals which are represented by circles (Fig. 30.7), or circles containing a number (Fig. 30.8), (2) activities such as Act 1 and Act 2 to achieve the goals, (3) the time needed to complete an activity, e.g., T1, and (4) resources, e.g., R1 and R2 (Fig. 30.8). Goal conflicts are detected by comparing goals by agents. Each agent has a PERT diagram and plan conflicts are detected if agents fail to merge PERT diagrams or the merged PERT diagrams violate certain rules [30.82].

The three classes of conflicts can also be modeled by Petri nets with the help of four basic modules [30.84]: sequence, parallel, decision, and decision-free, to detect conflicts in a multiagent system. Each agent's goal and plan are modeled by separate Petri nets [30.85], and many Petri nets are integrated using a bottom-up approach [30.66, 84] with three types of operations [30.85]: AND, OR, and precedence. The synthesized Petri net is analyzed to detect conflicts. Only normal transitions and places are modeled in Petri nets for conflict detection. The Petri-net-based approach for conflict detection developed so far has been rather limited. It has emphasized more the modeling of a system and its agents than the analysis process through which conflicts are detected.

The three common characteristics of available conflict detection approaches are: (1) they use the agent concept because a conflict involves at least two units in a system; (2) an agent is modeled for multiple times because each agent has at least two distinct attributes: goal and plan; and (3) they not only detect, but mainly prevent conflicts because goals and plans are determined before agents start any activities to achieve them. The main difference between the IGS and PERT approach, and the Petri net approach is that agents communicate with each other to detect conflicts in the former approach whereas a centralized control unit analyzes the integrated Petri net to detect conflicts in the latter approach [30.85]. The Petri net approach does not detect conflicts using agents, although systems are modeled with agent technology. Conflict detection has been mostly applied in collaborative design [30.86–88]. The ability to detect conflicts in distributed design activities is vital to their success because multiple designers tend to pursue individual (local) goals prior to considering common (global) goals.

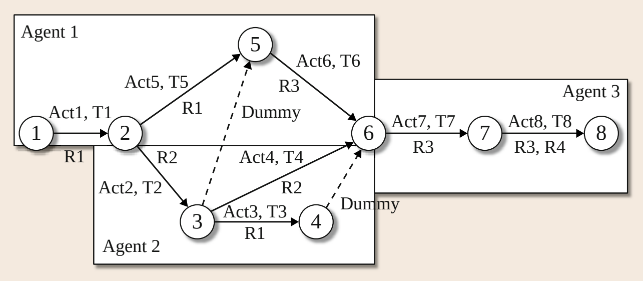

Fig. 30.8 Merged project estimation and review technique (PERT) diagram

30.4 Integrated Error and Conflict Prognostics and Prevention

30.4.1 Active Middleware

Middleware was originally defined as software that connects two separate applications or separate products and serves as the glue between two applications; for example, in Fig. 30.9, middleware can link several different database systems to several different web servers. The middleware allows users to request data from any database system that is connected to the middleware using the form displayed on the web browser of one of the web servers.

Active middleware is one of the four circles of the "e-" in e-Work as defined by the PRISM Center (Production, Robotics, and Integration Software for Manufacturing & Management) at Purdue University [30.77]. Six major components in active middleware have been identified [30.89, 90]: modeling tool, workflows, task/activity database, decision support system (DSS), multiagent system (MAS), and collaborative work protocols. Active middleware has been developed to optimize the performance of interactions in heterogeneous, autonomous, and distributed (HAD) environments, and is able to provide an e-Work platform and enables a universal model for error and conflict prognostics and prevention in a distributed environment. Figure 30.10 shows the structure

of the active middleware; each component is described below:

1. *Modeling tool*: The goal of a modeling tool is to create a representation model for a multiagent system. The model can be transformed to next-level models, which will be the base of the system implementation.
2. *Workflows*: Workflows describe the sequence and relations of tasks in a system. Workflows store the answer to two questions: (1) Which agent will benefit from the task when it is completed by one or more given agents? (2) Which task must be finished before other tasks can begin? The workflows are specific to the given system, and can be managed by a workflow management system (WFMS).
3. *Task/activity database*: This database is used to record and help allocate tasks. There are many tasks in a large system such as those applied in automotive industries. Certain tasks are performed by several agents, and others are performed by one agent. The database records all task information and the progress of tasks (activity) and helps allocate and reallocate tasks if required.
4. *Decision support system* (DSS): DSS for the active middleware is like the operating system for a computer. In addition, DSS already has programs running for monitoring, analysis, and optimization. It can allocate/delete/create tasks, bring in or take off agents, and change workflows.
5. *Multiagent system* (MAS): MAS includes all agents in a system. It stores information about each agent, for example, capacity and number of agents, functions of an agent, working time, and effective date and expiry date of the agent.
6. *Cooperative work protocols*: Cooperative work protocols define communication and interaction protocols between components of active middleware. It is noted that communication between agents also includes communication between components because active middleware includes all agents in a system.

30.4.2 Conflict and Error Detection Model

A conflict and error detection model (CEDM; Fig. 30.11) that is supported by the conflict and error detection protocol (CEDP, part of collaborative work protocols) and conflict and error detection agents (CEDAs, part of MAS) has been developed [30.91] to detect errors and conflicts in different network topologies. The CEDM integrates CEDP, CEDAs, and four error and conflict detection components (Fig. 30.11). A CEDA is deployed at each unit of a system to (1) detect errors and conflicts by three components (detection policy generation, error detection, and conflict evaluation), which interact with and are supported by error knowledge base, and (2) communicate with other CEDAs to send and receive error and conflict announcements with the support of CEDP. The CEDM has been applied to four different network topologies and the results show that the performance of CEDM is sometimes counterintuitive, i. e., it performs better on networks that seem more complex. To be able to detect both errors and conflicts is desired when they exist in the same system. Because errors are different from conflicts, the activities to detect them are often different and need to be integrated.

30.4.3 Performance Measures

Performance measures are necessary for the evaluation and comparison of various error and conflict prognostics and prevention methods. Several measures have already been defined and developed in previous research:

1. Detection latency: The time between the instant that an error occurs and the instant that the error is detected [30.10, 91].
2. Error coverage: The percentage of detected errors with respect to the total number of errors [30.10].
3. Cost: The overhead caused by including error detection capability with respect to the system without the capability [30.10].
4. Conflict severity: The severity of a conflict. It is the sum of the severity caused by the conflict at each involving unit [30.91].
5. Detectability: The ability of a detection method. It is a function of detection accuracy, cost, and time [30.92].
6. Preventability: The ratio of the number of errors prevented divided by the total number of errors [30.80].
7. Reliability: The ratio of the number of errors prevented divided by the number of errors identified or predicted, or the ratio of the number of errors detected divided by the total number of errors [30.40, 45, 80].

Other performance measures, e.g., total damage and cost–benefit ratio, can be developed to compare different methods. Appropriate performance measures help determine how a specific method performs in different situations and are often required when there are multiple methods available.

30.5 Error Recovery and Conflict Resolution

When an error or a conflict occurs and is detected, identified, isolated or diagnosed, there are three possible consequences: (1) other errors or conflicts that are caused by the error or conflict have occurred; (2) other errors or conflicts that are caused by the error or conflict will (probably) occur; (3) other errors or conflicts, or the same error or conflict, will (probably) occur if the current error or conflict is not recovered or resolved, respectively. One of the objectives of error recovery and conflict resolution is to avoid the third consequence when an error or a conflict occurs. They are therefore part of error and conflict prognostics and prevention.

There has been extensive research on automated error recovery and conflict resolution, which are often domain specific. Many methods have been developed and applied in various real-world applications in which the main objective of error recovery and conflict resolution is to keep the production or service flowing; for instance, Fig. 30.12 shows a recovery tree for rheostat pick-up and insertion, which is programmed for automatic error recovery. Traditionally, error recovery and conflict resolution are not considered as an approach to prevent errors and conflicts. In the next two Sections, we describe two examples, error recovery in robotics [30.93] and conflict resolution in collaborative facility design [30.88, 94], to illustrate how to perform these two functions automatically.

30.5.1 Error Recovery

Error recovery cannot be avoided when using robots because errors are an inherent characteristic of robotic applications [30.95] that are often not fault tolerant. Most error recovery applications implement preprogrammed nonintelligent corrective actions [30.95–98]. Due to the large number of possible errors and the

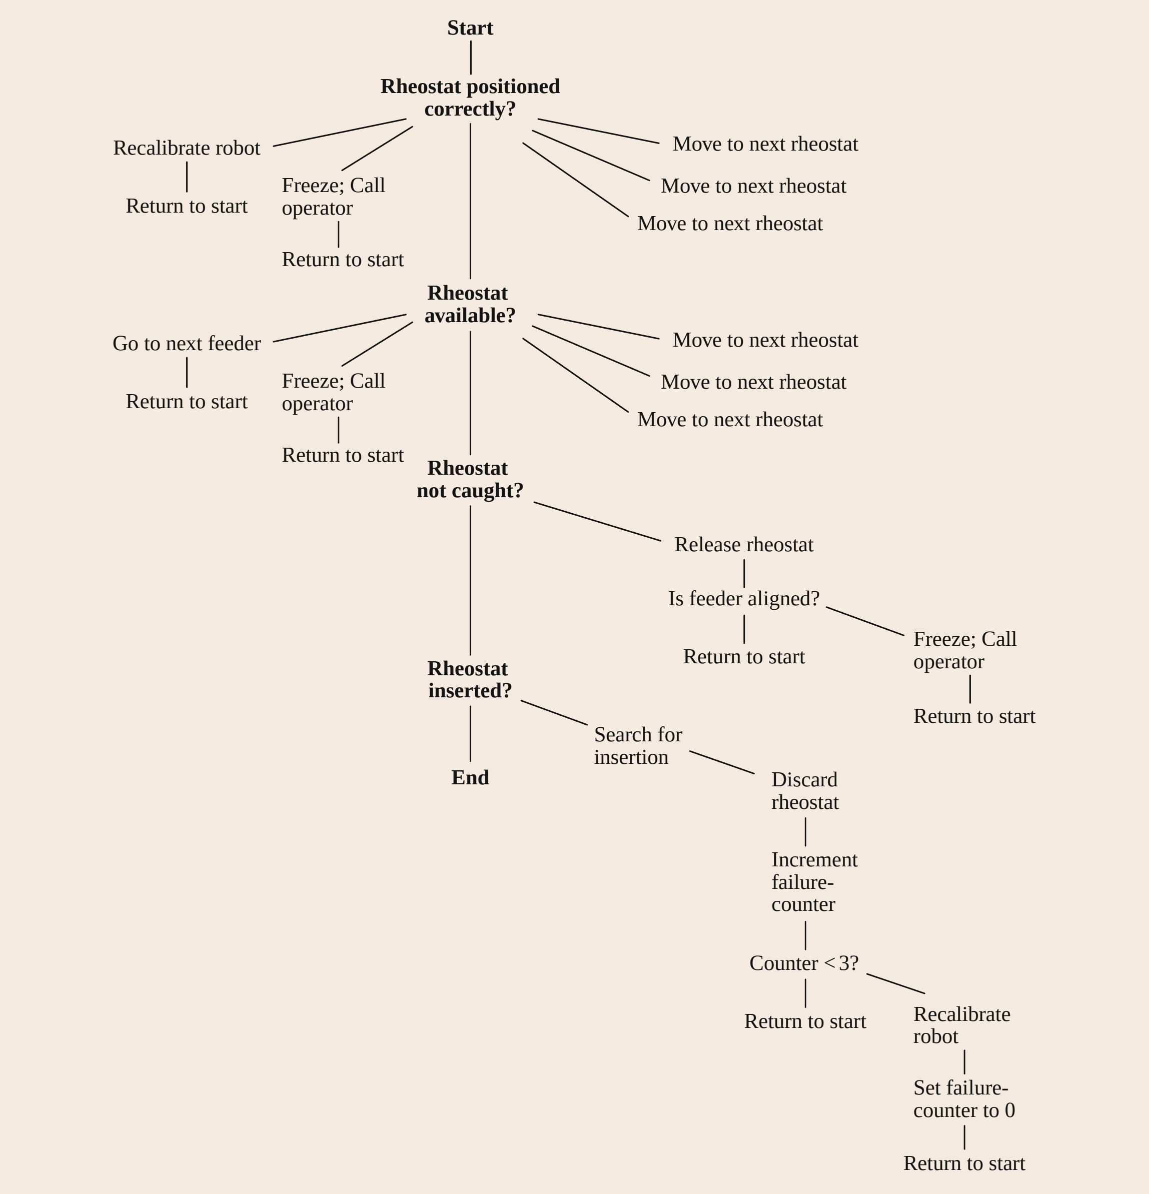

Fig. 30.12 Recovery tree for rheostat pick-up and insertion recovery. A branch may only be entered once; on success branch downward; on failure branch to right if possible, otherwise branch left; when the end of a branch is reached, unless otherwise specified return to last sensing position; "?" signifies sensing position where sensors or variables are evaluated (after [30.1])

inherent complexity of recovery actions, to automate error recovery fully without human interventions is difficult. The emerging trend in error recovery is to equip

systems with human intelligence so that they can correct errors through reasoning and high-level decision making. An example of an intelligent error recovery system is the neural-fuzzy system for error recovery (NEFUSER) [30.93]).

The NEFUSER is both an intelligent system and a design tool of fuzzy logic and neural-fuzzy models for error detection and recovery. The NEFUSER has been applied to a single robot working in an assembly cell. The NEFUSER enables interactions among the robot, the operator, and computer-supported applications. It interprets data and information collected by the robot and provided by the operator, analyzes data and information with fuzzy logic and/or neural-fuzzy models, and makes appropriate error recovery decisions. The NEFUSER has learning ability to im-

prove corrective actions and adapt to different errors. The NEFUSER therefore increases the level of automation by decreasing the number of times that the robot has to stop and the operator has to intervene due to errors.

Figure 30.13 shows the interactions between the robot, the operator, and computer-supported applications. The NEFUSER is the error recovery brain and is programmed and run on MATLAB, which provides a friendly windows-oriented fuzzy inference system (FIS) that incorporates the graphical user interface tools of the fuzzy logic toolbox [30.103]. The example in Fig. 30.13 includes a robot and an operator in an assembly cell. In general, the NEFUSER design for error

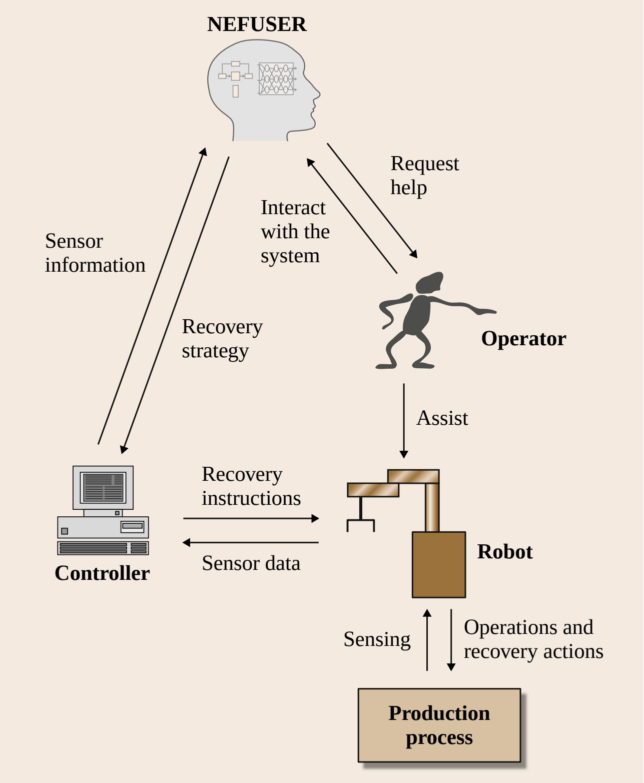

Fig. 30.13 Interactions with NEFUSER (after [30.93])

recovery includes three main tasks: (1) design the FIS, (2) manage and evaluate information, and (3) train the FIS with real data and information.

30.5.2 Conflict Resolution

There is a growing demand for knowledge-intensive collaboration in distributed design [30.94, 113, 114]. Conflict detection has been studied extensively in collaborative design, as has conflict resolution, which is often the next step after a conflict is detected. There has been extensive research on conflict resolution (e.g., [30.105–110]). Recently, a multiapproach method to conflict resolution in collaborative design has been introduced with the development of the facility description language–conflict resolution (FDL-CR) [30.88]. The critical role of computer-supported conflict resolution in distributed organizations has been discussed in great detail [30.77, 104, 111, 112]. In addition, *Ceroni* and *Velasquez* [30.86] have developed the conflict detection and management system (CDMS) and their work shows that both product complexity and number of participating designers have a statistically significant effect on the ratio of conflicts resolved to those detected, but that only complexity had a statistically significant effect on design duration.

Based on the previous work, most recently, a new method, Mcr (Table 30.4), has been developed to automatically resolve conflict situations common in collaborative facility design using computer-support tools [30.88, 94]. The method uses both traditional human conflict-resolution approaches that have been used successfully by others and principles of conflict prevention to improve design performance and apply computer-based learning to improve usefulness. A graph model for conflict resolution is used to facilitate conflict modeling and analysis. The performance of the new method has been validated by implementing its conflict resolution capabilities in the FDL, a computer tool for collaborative facility design, and by applying FDL-CR, to resolve typical conflict situations. Table 30.4 describes the Mcr structure.

Table 30.5 summarizes error and conflict prognostics and prevention methods and technologies in various production and service applications.

30.6 Emerging Trends

30.6.1 Decentralized and Agent-Based Error and Conflict Prognostics and Prevention

Most error and conflict prognostics and prevention methods developed so far are centralized approaches (Table 30.5) in which a central control unit controls data and information and executes some or all eight functions to prevent errors and conflicts. The centralized approach often requires substantial time to execute various functions and the central control unit often possesses incomplete or incorrect data and information [30.80]. These disadvantages become apparent when a system has many units that need to be examined for errors and conflicts.

To overcome the disadvantages of the centralized approach, the decentralized approach that takes advantage of the parallel activities of multiple agents has been developed [30.16, 67, 79, 80, 91]. In the decentralized approach, distributed agents detect, identify or isolate errors and conflicts at individual units of a system, and communicate with each other to diagnose and prevent errors and conflicts. The main challenge of the decentralized approach is to develop robust protocols that can ensure effective communications between agents. Further research is needed to develop and improve decentralized approaches for implementation in various applications.

30.6.2 Intelligent Error and Conflict Prognostics and Prevention

Compared with humans, automation systems perform better when they are used to prevent errors and conflicts through the violation of specifications or violation in comparisons [30.13]. Humans, however, have the ability to prevent errors and conflicts through the violation of expectations, i. e., with tacit knowledge and high-level decision making. To increase the effectiveness degree of automation of error and conflict prognostics and prevention, it is necessary to equip automation systems with human intelligence through appropriate modeling techniques such as fuzzy logic, pattern recognition, and artificial neural networks. There has been some preliminary work to incorporate high-level human intelligence in error detection and recovery (e.g., [30.3, 93]) and conflict resolution [30.88, 94]. Additional work is needed to develop self-learning, self-improving artificial intelligence systems for error and conflict prognostics and prevention.

30.6.3 Graph and Network Theories

The performance of an error and conflict prognostics and prevention method is significantly influenced by the number of units in a system and their relationship. A system can be viewed as a graph or a network with many nodes, each of which represents a unit in the system. The relationship between units is represented by the link between nodes. The study of network topologies has a long history stretching back at least to the 1730s. The classic model of a network, the random network, was first discussed in the early 1950s [30.115] and was rediscovered and analyzed in a series of papers published in the late 1950s and early 1960s [30.116–118]. Most recently, several network models have been discovered and extensively studied, for instance, the small-world network (e.g., [30.119]), the scale-free network (e.g., [30.120–123]), and the Bose–Einstein condensation network [30.124]. Bioinspired network models for collaborative control have recently been studied by *Nof* [30.125] (see also Chap. 75 for more details).

Because the same prognostics and prevention method may perform quite differently on networks with different topologies and attributes, or with the same network topology and attributes but with different parameters, it is imperative to study the performance of prognostics and prevention methods with respect to different networks for the best match between methods and networks. There is ample room for research, development, and implementation of error and conflict prognostics and prevention methods supported by graph and network theories.

30.6.4 Financial Models for Prognostics Economy

Most errors and conflicts must be detected, isolated, identified, diagnosed or prevented. Certain errors and conflicts, however, may be tolerable in certain systems, i. e., fault-tolerant systems. Also, the cost of automating some or all eight functions of error and conflict prognostics and prevention may far exceed the damages caused by certain errors and conflicts. In both situations, cost–benefit analyses can be used to determine if an error or a conflict needs to be dealt with. In general, financial models are used to analyze the economy of prognostics and prevention methods for specific errors and conflicts, to help decide which of the eight functions will be executed and how they will be executed, e.g., the frequency. There has been limited research on how to use financial models to help justify the automation of error and conflict prognostics and prevention [30.92, 126]. One of the challenges is how to appropriately evaluate or assess the damage of errors and conflicts, e.g., short-term damage, long-term damage, and intangible damage. Additional research is needed to address these economical decisions.

30.7 Conclusion

In this Chapter we have discussed the eight functions that automate error and conflict prognostics and prevention and their applications in various production and service areas. Prognostics and prevention methods for errors and conflicts are developed based on extensive theoretical advancements in many science and engineering domains, and have been successfully applied to various real-world problems. As systems and networks become larger and more complex, such as global enterprises and the Internet, error and conflict prognostics and prevention become more important and the focus is shifting from passive response to active prognostics and prevention.
