Part D Automation Design: Theory and Methods for Integration

Automation Design: Theory and Methods for Integration. Part D After focusing in the previous part on the details, principles and practices of the methodologies for automation design, the chapters in this part cover the basic design requirements for the automation and illustrate examples of how the challenging issues can be solved for the deign and integration of automation with respect to its main purpose: Continuous and discrete processes and industries, such as chemicals, refineries, machinery, and instruments; process automation safety; automation products such as circuit breakers, motors, drives, robots, and other components for consumer products; and services, such as maintenance, logistics, upgrade and repair, remote support operations, and tools for service personnel; design issues and criteria when integrating humans with the automation; design techniques, criteria and algorithms for flow lines, such as assembly lines, transfer lines, machining lines; and the design of complex, large-scale, integrated automation. Another view of automation integration is with computer-aided design (CAD) and computer-aided engineering (CAE), which are themselves fine examples of integrated automation, and are required for the design of any automation and non-automation components, products, microelectronics, and services. Concluding this part is the design for safety of automation, and of automation for safety, as they have become an obligatory and mandatory concern of automation integrators.

31. Process Automation

Thomas F. Edgar, Juergen Hahn

The field of process automation is concerned with the analysis of dynamic behavior of chemical processes, design of automatic controllers, and associated instrumentations. Process automation as practised in the process industries has undergone significant changes since it was first introduced in the 1940s. Perhaps the most significant influence on the changes in process control technology has been the introduction of inexpensive digital computers and instruments with greater capabilities than their analog predecessors. During the past 20 years automatic control has assumed increased importance in the process industries, which has led to the application of more sophisticated techniques.

31.1 Enterprise View of Process Automation

Process automation is used in order to maximize production while maintaining a desired level of product quality and safety and making the process more economical. Because these goals apply to a variety of industries, process control systems are used in facilities for the production of chemicals, pulp and paper, metals, food, and pharmaceuticals. While the methods of production vary from industry to industry, the principles of automatic control are generic in nature and can be universally applied, regardless of the size of the plant.

In Fig. 31.1 the process automation activities are organized in the form of a hierarchy with required functions at the lower levels and desirable functions at the higher levels. The time scale for each activity is shown on the left side of Fig. 31.1. Note that the frequency of execution is much lower for the higher-level functions.

31.1.1 Measurement and Actuation (Level 1)

Measurement devices (sensors and transmitters) and actuation equipment (for example, control valves) are used to measure process variables and implement the calculated control actions. These devices are interfaced to the control system, usually digital control equipment such as a digital computer. Clearly, the measurement and actuation functions are an indispensable part of any control system.

31.1.2 Safety and Environmental/ Equipment Protection (Level 2)

The level 2 functions play a critical role by ensuring that the process is operating safely and satisfies environ-

mental regulations. Process safety relies on the principle of multiple protection layers that involve groupings of equipment and human actions. One layer includes process control functions, such as alarm management during abnormal situations, and safety instrumented systems for emergency shutdowns. The safety equipment (including sensors and control valves) operates independently of the regular instrumentation used for regulatory control in level 3a. Sensor validation techniques can be employed to confirm that the sensors are functioning properly.

31.1.3 Regulatory Control (Level 3a)

Successful operation of a process requires that key process variables such as flow rates, temperatures, pressures, and compositions be operated at, or close to, their set points. This level 3a activity, regulatory control, is achieved by applying standard feedback and feedforward control techniques. If the standard control techniques are not satisfactory, a variety of advanced control techniques are available. In recent years, there has been increased interest in monitoring control system performance.

31.1.4 Multivariable and Constraint Control (Level 3b)

Many difficult process control problems have two distinguishing characteristics: (1) significant interactions occur among key process variables, and (2) inequality constraints exist for manipulated and controlled variables. The inequality constraints include upper and lower limits; for example, each manipulated flow rate has an upper limit determined by the pump and control valve characteristics. The lower limit may be zero or a small positive value based on safety considerations. Limits on controlled variables reflect equipment constraints (for example, metallurgical limits) and the operating objectives for the process; for example, a reactor temperature may have an upper limit to avoid undesired side reactions or catalyst degradation, and a lower limit to ensure that the reaction(s) proceed.

The ability to operate a process close to a limiting constraint is an important objective for advanced process control. For many industrial processes, the optimum operating condition occurs at a constraint limit, for example, the maximum allowed impurity level in a product stream. For these situations, the set point should not be the constraint value because a process disturbance could force the controlled variable beyond the limit. Thus, the set point should be set conservatively, based on the ability of the control system to reduce the effects of disturbances.

The standard process control techniques of level 3a may not be adequate for difficult control problems that have serious process interactions and inequality constraints. For these situations, the advanced control techniques of level 3b, multivariable control and constraint control, should be considered. In particular, the model predictive control (MPC) strategy was developed to deal with both process interactions and inequality constraints.

31.1.5 Real-Time Optimization (Level 4)

The optimum operating conditions for a plant are determined as part of the process design, but during plant operations, the optimum conditions can change frequently owing to changes in equipment availability, process disturbances, and economic conditions (for example, raw materials costs and product prices). Consequently, it can be very profitable to recalculate the optimum operating conditions on a regular basis. The new optimum conditions are then implemented as set points for controlled variables.

Real-time optimization (RTO) calculations are based on a steady-state model of the plant and economic data such as costs and product values. A typical objective for the optimization is to minimize operating cost or maximize the operating profit. The RTO calculations can be performed for a single process unit and/or on a plant-wide basis.

The level 4 activities also include data analysis to ensure that the process model used in the RTO calculations is accurate for the current conditions. Thus, data reconciliation techniques can be used to ensure that steady-state mass and energy balances are satisfied. Also, the process model can be updated using parameter estimation techniques and recent plant data.

31.1.6 Planning and Scheduling (Level 5)

The highest level of the process control hierarchy is concerned with planning and scheduling operations for the entire plant. For continuous processes, the production rates of all products and intermediates must be planned and coordinated, based on equipment constraints, storage capacity, sales projections, and the operation of other plants, sometimes on a global basis. For the intermittent operation of batch and semibatch processes, the production control problem becomes a batch scheduling problem based on similar considerations. Thus, planning and scheduling activities pose large-scale optimization problems that are based on both engineering considerations and business projections.

The activities of levels 1–3a in Fig. 31.1 are required for all manufacturing plants, while the activities in levels 3b–5 are optional but can be very profitable. The decision to implement one or more of these higher-level activities depends very much on the application and the company. The decision hinges strongly on economic considerations (for example, a cost–benefit analysis), and company priorities for their limited resources, both human and financial. The immediacy of the activity decreases from level 1 to level 5 in the hierarchy. However, the amount of analysis and the computational requirements increase from the lowest to the highest level. The process control activities at different levels should be carefully coordinated and require information transfer from one level to the next. The successful implementation of these process control activities is a critical factor in making plant operation as profitable as possible.

31.2 Process Dynamics and Mathematical Models

Development of dynamic models forms a key component for process automation, as controller design and tuning is often performed by using a mathematical representation of the process. A model can be derived either from first-principles knowledge about the system or from past plant data. Once a dynamic model has been developed, it can be solved for a variety of conditions that include changes in the input variables or variations in the model parameters. The transient responses of the output variables are calculated by numerical integration after specifying both the initial conditions and the inputs as functions of time.

A large number of numerical integration techniques are available, ranging from simple techniques (e.g., the Euler and Runge–Kutta methods) to more complicated ones (e.g., the implicit Euler and Gear methods). All of these techniques represent some compromise between computational effort (computing time) and accuracy. Although a dynamic model can always be solved in principle, for some situations it may be difficult to generate useful numerical solutions. Dynamic models that exhibit a wide range of time scales (stiff equations) are quite difficult to solve accurately in a reasonable amount of computation time. Software for integrating ordinary and partial differential equations is readily available. Popular software packages include MATLAB, Mathematica, ACSL, IMSL, Mathcad, and GNU Octave.

For dynamic models that contain large numbers of algebraic and ordinary differential equations, generation of solutions using standard programs has been developed to assist in this task. A graphical user interface (GUI) allows the user to enter the algebraic and ordinary differential equations and related information such as the total integration period, error tolerances, the variables to be plotted, and so on. The simulation program then assumes responsibility for:

1. Checking to ensure that the set of equations is exactly specified
2. Sorting the equations into an appropriate sequence for iterative solution
3. Integrating the equations
4. Providing numerical and graphical output.

Examples of equation-oriented simulators used in the process industries include DASSL, ACSL, gPROMS, and Aspen Custom Modeler.

One disadvantage of equation-oriented packages is the amount of time and effort required to develop all of the equations for a complex process. An alternative approach is to use modular simulation where prewritten subroutines provide models of individual process units such as distillation columns or chemical reactors. Consequently, this type of simulator has a direct correspondence to the process flowsheet. The modular approach has the significant advantage that plant-scale simulations only require the user to identify the appropriate modules and to supply the numerical values of model parameters and initial conditions. This activity requires much less effort than writing all of the equations. Furthermore, the software is responsible for all aspects of the solution. Because each module is rather general in form, the user can simulate alternative flowsheets for a complex process, for example, different configurations of distillation towers and heat exchangers, or different types of chemical reactors. Similarly, alternative process control strategies can be quickly evaluated. Some software packages allow the user to add custom modules for novel applications.

Modular dynamic simulators have been available since the early 1970s. Several commercial products are available from Aspen Technology and Honeywell. Modelica is an example of a collaborative effort that provides modeling capability for a number of application areas. These packages also offer equation-oriented capabilities. Modular dynamic simulators are achieving a high degree of acceptance in process engineering and control studies because they allow plant dynamics, real-time optimization, and alternative control configurations to be evaluated for an existing or a new plant. They also can be used for operator training. This feature allows dynamic simulators to be integrated with software for other applications such as control system design and optimization.

While most processes can be accurately represented by a set of nonlinear differential equations, a process is usually operated within a certain neighborhood of its normal operating point (steady state), thus the process model can be closely approximated by a linearized version of the model. A linear model is beneficial because it permits the use of more convenient and compact methods for representing process dynamics, namely Laplace transforms. The main advantage of Laplace transforms is that they provide a compact representation of a dynamic system that is especially useful for the analysis of feedback control systems. The Laplace transform of a set of linear ordinary differential equations is a set of algebraic equations in the new variable s, called the Laplace variable. The Laplace transform is given by

$$F(s) = L[f(t)] = \int_0^\infty f(t)\,\mathrm{e}^{-st}\,\mathrm{d}t\,, \tag{31.1}$$

where $F(s)$ is the symbol for the Laplace transform, $f(t)$ is some function of time, and L is the Laplace operator, defined by the integral. Tables of Laplace transforms are well documented for common functions [31.1]. A linear differential equation with a single input u and single output y can be converted into a transfer function using Laplace transforms as follows

$$Y(s) = G(s)U(s)\,, \tag{31.2}$$

where $U(s)$ is the Laplace transform of the input variable $u(t)$, $Y(s)$ is the Laplace transform of the output variable $y(t)$, and $G(s)$ is the transfer function, obtained from transforming the differential equation.

The transfer function $G(s)$ describes the dynamic characteristic of the process. For linear systems it is independent of the input variable and so it can readily be applied to any time-dependent input signal. As an example, the first-order differential equation

$$\tau\frac{\mathrm{d}y(t)}{\mathrm{d}t} + y(t) = Ku(t) \tag{31.3}$$

can be Laplace-transformed to

$$Y(s) = \frac{K}{\tau s + 1}U(s)\,. \tag{31.4}$$

Note that the parameters K and τ, known as the process gain and time constant, respectively, map into the transfer function as unspecified parameters. Numerical values for parameters such as K and τ have to be determined for controller design or for simulation purposes. Several different methods for the identification of model parameters in transfer functions are available. The most common approach is to perform a step test on the process and collect the data along the trajectory until it reaches steady state. In order to identify the parameters, the form of the transfer function model needs to be postulated and the parameters of the transfer function can be estimated by using nonlinear regression. For more details on the development of various transfer functions, see [31.1].

31.3 Regulatory Control

When the components of a control system are connected, their overall dynamic behavior can be described by combining the transfer functions for each component. Each block describes how changes in the input variables of the block will affect the output variables of the block. One example is the feedback/feedforward control block diagram shown in Fig. 31.2, which contains the important components of a typical control system, namely process, controller, sensor, and final control element. Regulatory control deals with treatment of disturbances that enter the system, as shown in Fig. 31.2. These components are discussed in more detail below.

Most modern control equipment require a digital signal for displays and control algorithms, thus the analog-to-digital converter (ADC) transforms the transmitter analog signal to a digital format. Because ADCs may be relatively expensive if adequate digital resolution is required, incoming digital signals are usually multiplexed. Prior to sending the desired control action, which is often in a digital format, to the final control element in the field, the desired control action is usually transformed by a digital-to-analog (DAC) converter to an analog signal for transmission. DACs are relatively inexpensive and are not normally multiplexed. Widespread use of digital control technologies has made ADCs and DACs standard parts of the control system.

Sensors

The hardware components of a typical modern digital control loop shown in Fig. 31.2 are discussed next. The function of the process measurement device is to sense the values, or changes in values, of process variables. The actual sensing device may generate, e.g., a physical movement, a pressure signal, or a millivolt signal. A transducer transforms the measurement signal from one physical or chemical quantity to another, e.g., pressure to milliamps. The transduced signal is then transmitted to a control room through the transmission line. The transmitter is therefore a signal generator and a line driver. Often the transducer and the transmitter are contained in the same device.

The most commonly measured process variables are temperature, flow, pressure, level, and composition. When appropriate, other physical properties are also measured. The selection of the proper instrumentation for a particular application is dependent on factors such as: the type and nature of the fluid or solid involved; relevant process conditions; range, accuracy, and repeatability required; response time; installed cost; and maintainability and reliability. Various handbooks are available that can assist in selecting sensors for particular applications (e.g., [31.2]). Sensors are discussed in detail on Chap. 20.

Control Valves

Material and energy flow rates are the most commonly selected manipulated variables for control schemes. Thus, good control valve performance is an essential ingredient for achieving good control performance. A control valve consists of two principal assemblies: a valve body and an actuator. Good control valve performance requires consideration of the process characteristics and requirements such as fluid characteristics, range, shut-off, and safety, as well as control

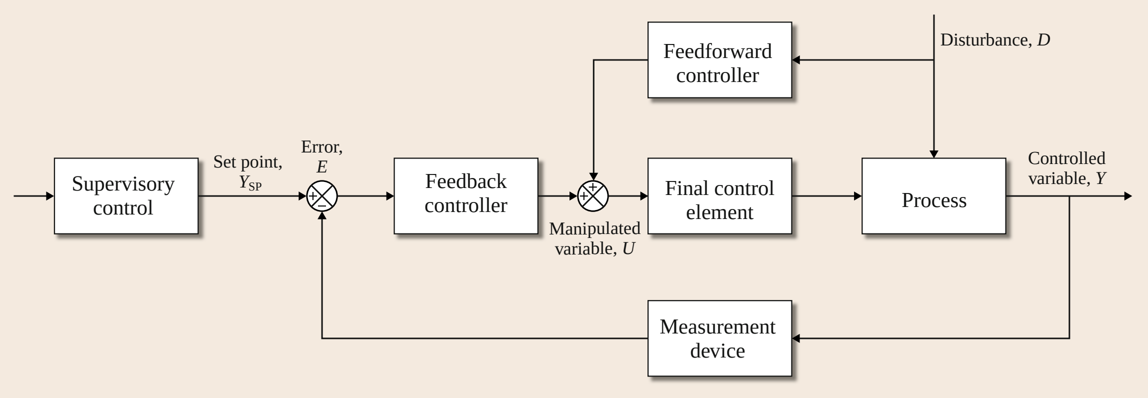

Fig. 31.2 Block diagram of a process

requirements, e.g., installed control valve characteristics and response time. The proper selection and sizing of control valves and actuators is an extensive topic in its own right [31.2].

Controllers

The most commonly employed feedback controller in the process industry is the proportional–integral (PI) controller, which can be described by the following equation

$$u(t) = \bar{u} + K_\mathrm{C}\left(e(t) + \frac{1}{\tau_\mathrm{I}}\int_0^t e(t')\,\mathrm{d}t'\right) . \tag{31.5}$$

Note that the controller includes proportional as well as integrating action. The controller has two tuning parameters: the proportional constant K_C and the integral time constant τ_I. The integral action will eliminate offset for constant load disturbances but it can potentially lead to a phenomenon known as reset windup. When there is a sustained error, the large integral term in (31.5) causes the controller output to saturate. This can occur during start-up of batch processes, or after large set point changes or large sustained disturbances.

PI controllers make up the vast majority of controllers that are currently used in the chemical process industries. If it is important to achieve a faster response that is offset-free, a PID (D = derivative) controller can be utilized, described by the following expression

$$u(t) = \bar{u} + K_\mathrm{C}\left(e(t) + \frac{1}{\tau_\mathrm{I}}\int_0^t e(t')\,\mathrm{d}t' + \tau_\mathrm{D}\frac{\mathrm{d}e(t)}{\mathrm{d}t}\right) . \tag{31.6}$$

The PID controller of (31.6) contains three tuning parameters because the derivative mode adds a third adjustable parameter τ_D. However, if the process measurement is noisy, the value of the derivative of the error may change rapidly and derivative action will amplify the noise, as a filter on the error signal can be employed. In the 21st century, digital control systems are ubiquitous in process plants, mostly employing a discrete (finite-difference) form of the PID controller equation given by

$$u_k = \bar{u} + K_\mathrm{C}\left(e_k + \frac{\Delta t}{\tau_\mathrm{I}}k\sum_{i=0}^{k} e_i + \tau_\mathrm{D}\frac{e_k - e_{k-1}}{\Delta t}\right) , \tag{31.7}$$

where Δt is the sampling period for the control calculations and k represents the current sampling time. If the process and the measurements permit to chose the sampling period Δt to be small then the behavior of the digital PID controller will essentially be the same as for an analog PID controller.

31.4 Control System Design

Traditionally, process design and control system design have been separate engineering activities. Thus, in the traditional approach, control system design is not initiated until after plant design is well underway and major pieces of equipment may even have been ordered. This approach has serious limitations because the plant design determines the process dynamics as well as the operability of the plant. In extreme situations, the process may be uncontrollable, even though the design appears satisfactory from a steady-state point of view. A more desirable approach is to consider process dynamics and control issues early in the process design.

The two general approaches to control system design are:

1. *Traditional approach*. The control strategy and control system hardware are selected based on knowledge of the process, experience, and insight. After the control system is installed in the plant, the controller settings (such as in a PID controller) are adjusted. This activity is referred to as controller tuning.
2. *Model-based approach*. A dynamic model of the process is first developed that can be helpful in at least three ways: (a) it can be used as the basis for model-based controller design methods, (b) the dynamic model can be incorporated directly in the control law (for example, model predictive control), and (c) the model can be used in a computer simulation to evaluate alternative control strategies and to determine preliminary values of the controller settings.

For many simple process control problems controller specification is relatively straightforward and a detailed analysis or an explicit model is not required. However, for complex processes, a process model is invaluable both for control system design and for an improved understanding of the process.

The major steps involved in designing and installing a control system using the model-based approach are shown in the flowchart of Fig. 31.3. The first step, formulation of the control objectives, is a critical decision. The formulation is based on the operating objectives for the plants and the process constraints; for example, in the distillation column control problem, the objective might be to regulate a key component in the distillate stream, the bottoms stream, or key components in both streams. An alternative would be to minimize energy consumption (e.g., heat input to the reboiler) while meeting product quality specifications on one or both product streams. The inequality constraints should include upper and lower limits on manipulated variables, conditions that lead to flooding or weeping in the column, and product impurity levels.

After the control objectives have been formulated, a dynamic model of the process is developed. The dynamic model can have a theoretical basis, for example, physical and chemical principles such as conservation laws and rates of reactions, or the model can be developed empirically from experimental data. If experimental data are available, the dynamic model should be validated, with the data and the model accuracy characterized. This latter information is useful for control system design and tuning.

The next step in the control system design is to devise an appropriate control strategy that will meet the control objectives while satisfying process constraints. As indicated in Fig. 31.3, this design activity is based on models and plant data. Finally the control system can be installed, with final adjustments performed once the plant is operating.

Fig. 31.3 Major steps in control system development [31.1]

31.4.1 Multivariable Control

In most industrial processes, there are a number of variables that must be controlled, and a number of variables can be manipulated. These problems are referred to as multiple-input multiple-output (MIMO) control problems. For almost all important processes, at least two variables must be controlled: product quality and throughput. Several examples of processes with two controlled variables and two manipulated variables are shown in Fig. 31.4. These examples illustrate a characteristic feature of MIMO control problems, namely, the presence of process interactions; that is, each manipulated variable can affect both controlled variables. Consider the inline blending system shown in Fig. 31.4a. Two streams containing species A and B, respectively, are to be blended to produce a produce stream with mass flow rate w and composition x, the mass fraction of A. Adjusting either manipulated flow rate, w_A or w_B, affects both w and x.

Similarly, for the distillation column in Fig. 31.4b, adjusting either reflux flow rate R or steam flow S will affect both distillate composition x_D and bottoms composition x_B. For the gas–liquid separator in Fig. 31.4c, adjusting the gas flow rate G will have a direct effect on pressure P and a slower, indirect effect on liquid level h because changing the pressure in the vessel will tend to change the liquid flow rate L and thus affect h. In contrast, adjusting the other manipulated variable L directly affects h but has only a relatively small and indirect effect on P.

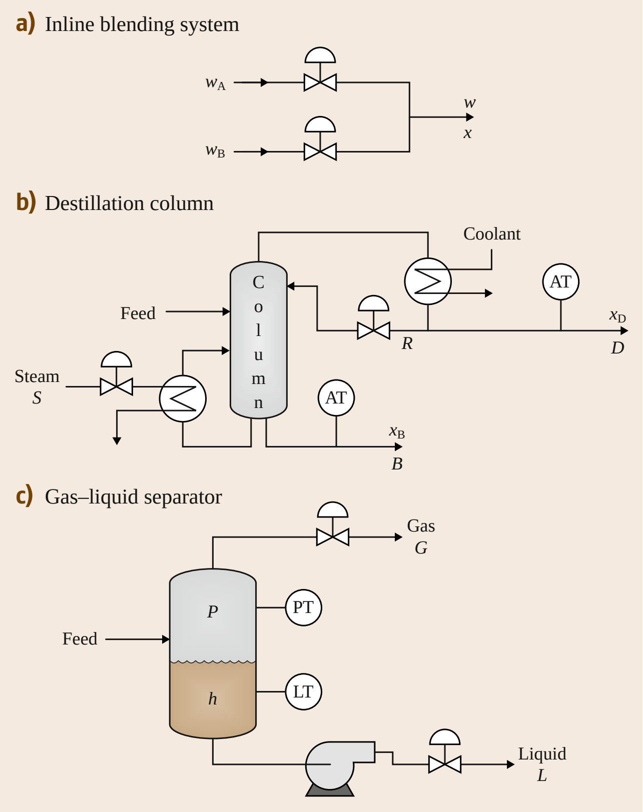

Fig. 31.4a–c Physical examples of multivariable control problems [31.1]

Pairing of a single controlled variable and a single manipulated variable via a PID feedback controller is possible, if the number of manipulated variables is equal to the number of controlled variables. On the other hand, more general multivariable control strategies do not make such restrictions. MIMO control problems are inherently more complex than single-input single-output (SISO) control problems because process interactions occur between controlled and manipulated variables. In general, a change in a manipulated variable, say u_1, will affect all of the controlled variables $y_1, y_2, \ldots, y_n$. Because of process interactions, selection of the best pairing of controlled and manipulated variables for a multiloop control scheme can be a difficult task. In particular, for a control problem with n controlled variables and n manipulated variables, there are $n!$ possible multiloop control configurations. Hence there is a growing trend to use multivariable control, in particular an approach called model predictive control (MPC).

Model predictive control offers several important advantages: (1) the process model captures the dynamic and static interactions between input, output, and disturbance variables, (2) constraints on inputs and outputs are considered in a systematic manner, (3) the control calculations can be coordinated with the calculation of optimum set points, and (4) accurate model predictions can provide early warnings of potential problems. Clearly, the success of MPC (or any other model-based approach) depends on the accuracy of the process model. Inaccurate predictions can make matters worse, instead of better.

First-generation MPC systems were developed independently in the 1970s by two pioneering industrial research groups. Dynamic matrix control (DMC) was devised by Shell Oil [31.3], and a related approach was developed by ADERSA [31.4]. Model predictive control has had a major impact on industrial practice; for example, an MPC survey by *Qin* and *Badgwell* [31.5] reported that there were over 4500 applications worldwide by the end of 1999, primarily in oil refineries and petrochemical plants. In these industries, MPC has become the method of choice for difficult multivariable control problems that include inequality constraints.

The overall objectives of an MPC controller are as follows:

1. Prevent violations of input and output constraints
2. Drive some output variables to their optimal set points, while maintaining other outputs within specified ranges
3. Prevent excessive movement of the manipulated variables
4. Control as many process variables as possible when a sensor or actuator is not available.

A block diagram of a model predictive control system is shown in Fig. 31.5. A process model is used to predict the current values of the output variables. The residuals (the differences between the actual and predicted outputs) serve as the feedback signal to a prediction block. The predictions are used in two types of MPC calculations that are performed at each sampling instant: set-point calculations and control calculations. Inequality constraints on the input and output variables, such as upper and lower limits, can be included in either type of calculation.

The model acts in parallel with the process and the residual serves as a feedback signal, however, it should be noted that the coordination of the control and set-point calculation is a unique feature of MPC.

Furthermore, MPC has had a significant impact on industrial practice because it is more suitable for constrained MIMO control problems.

The set points for the control calculations, also called targets, are calculated from an economic optimization based on a steady-state model of the process, traditionally, a linear steady-state model. Typical optimization objectives include maximizing a profit function, minimizing a cost function, or maximizing a production rate. The optimum values of set points are changed frequently owing to varying process conditions, especially changes in the inequality constraints. The constraint changes are due to variations in process conditions, equipment, and instrumentation, as well as economic data such as prices and costs. In MPC the set points are typically calculated each time the control calculations are performed.

The control calculations are based on current measurements and predictions of the future values of the outputs. The predictions are made using a dynamic model, typically a linear empirical model such as a multivariable version of the step response models that were discussed in Sect. 31.2. Alternatively, transfer function or state-space models can be employed. For very nonlinear processes, it can be advantageous to predict future output values using a nonlinear dynamic model. Both physical models and empirical models, such as neural networks, have been used in nonlinear MPC [31.5].

The objective of the MPC control calculations is to determine a sequence of control moves (that is, manipulated input changes) so that the predicted response moves to the set point in an optimal manner. The actual output y, predicted output $\hat{y}$, and manipulated input u are shown in Fig. 31.6. At the current sampling instant, denoted by k, the MPC strategy calculates a set of M values of the input $\{u\{k+i-1), i=1,2,\ldots,M\}$. The set consists of the current input $u(k)$ and $M-1$ future inputs. The input is held constant after the M control moves. The inputs are calculated so that a set of P predicted outputs $\{\hat{y}(k+i), i=1,2,\ldots,P\}$ reaches the set point in an optimal manner. The control calculations are based on optimizing an objective function. The number of predictions P is referred to as the prediction horizon while the number of control moves M is called the control horizon.

A distinguishing feature of MPC is its receding horizon approach. Although a sequence of M control moves is calculated at each sampling instant, only the first move is actually implemented. Then a new sequence is calculated at the next sampling instant, after new measurements become available; again, only the first input move is implemented. This procedure is repeated at each sampling instant.

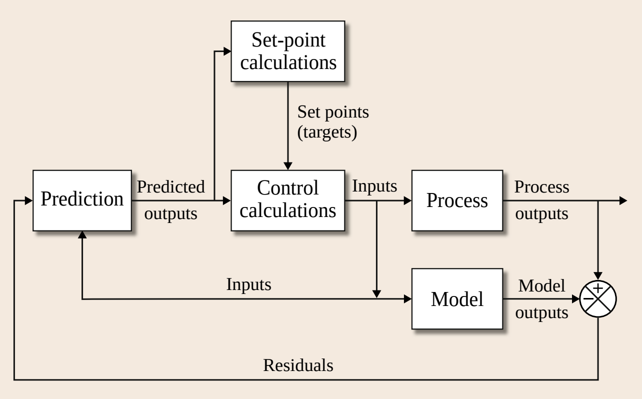

Fig. 31.5 Block diagram for model predictive control [31.1]

In MPC applications, the calculated input moves are usually implemented as set points for regulatory control loops at the distributed control system (DCS) level, such as flow control loops. If a DCS control loop has been disabled or placed in manual mode, the input variable is no longer available for control. In this situation, the control degrees of freedom are reduced by one. Even though an input variable is unavailable for control, it can serve as a disturbance variable if it is still measured.

Before each control execution, it is necessary to determine which outputs (controlled variables (CV)), inputs (manipulated variables (MV)), and disturbance variables (DVs) are currently available for the MPC

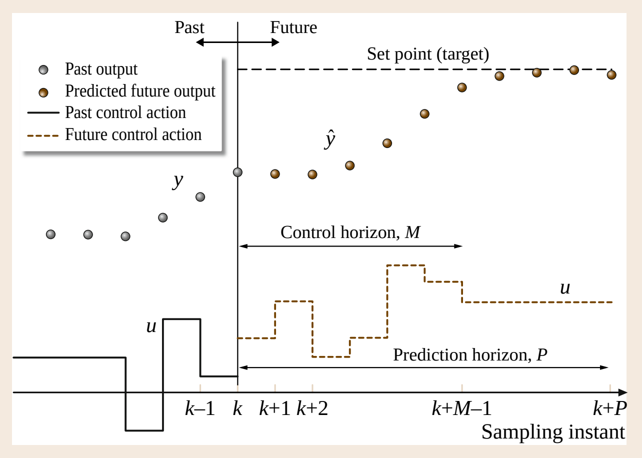

Fig. 31.6 Basic concept for model predictive control

calculations. The variables available for the control calculations can change from one control execution time to the next for a variety of reasons; for example, a sensor may not be available owing to routine maintenance or recalibration.

Inequality constraints on input and output variables are important characteristics for MPC applications. In fact, inequality constraints were a primary motivation for the early development of MPC. Input constraints occur as a result of physical limitations on plant equipment such as pumps, control valves, and heat exchangers; for example, a manipulated flow rate might have a lower limit of zero and an upper limit determined by the pump, control valve, and piping characteristics. The dynamics associated with large control valves impose rate-of-change limits on manipulated flow rates.

Constraints on output variables are a key component of the plant operating strategy; for example, a common distillation column control objective is to maximize the production rate while satisfying constraints on product quality and avoiding undesirable operating regimes such as flooding or weeping. It is convenient to make a distinction between hard and soft constraints. As the name implies, a hard constraint cannot be violated at any time. By contrast, a soft constraint can be violated, but the amount of violation is penalized by a modification of the cost function. This approach allows small constraint violations to be tolerated for short periods of time [31.1].

31.5 Batch Process Automation

Batch processing is an alternative to continuous processing. In batch processing, a sequence of one or more steps, either in a single vessel or in multiple vessels, is performed in a defined order, yielding a specific quantity of a finished product. Because the volume of product is normally small, large production runs are achieved by repeating the process steps on a predetermined schedule. In batch processing, the production amounts are usually smaller than for continuous processing; hence, it is usually not economically feasible to dedicate processing equipment to the manufacture of a single product. Instead, batch processing units are organized so that a range of products (from a few to possibly hundreds) can be manufactured with a given set of process equipment. Batch processing can be complicated by having multiple stages, multiple products made from the same equipment, or parallel processing lines. The key challenge for batch plants is to consistently manufacture each product in accordance with its specifications while maximizing the utilization of available equipment. Benefits include reduced inventories and shortened response times to make a specialty product compared with continuous processing plants. Typically, it is not possible to use blending of multiple batches in order to obtain the desired product quality, so product quality specifications must be satisfied by each batch.

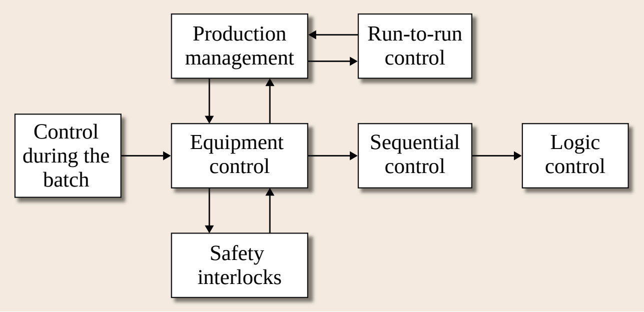

Fig. 31.7 Overview of a batch control system

Batch processing is widely used to manufacture specialty chemicals, metals, electronic materials, ceramics, polymers, food and agricultural materials, biochemicals and pharmaceuticals, multiphase materials/blends, coatings, and composites – an extremely broad range of processes and products. The unit operations in batch processing are also quite diverse, and some are analogous to operations for continuous processing.

In analogy with the different levels of plant control depicted in Fig. 31.1, batch control systems operate at various levels:

- Batch sequencing and logic controls (levels 1 and 2)
- Control during the batch (level 3)
- Run-to-run control (levels 4 and 5)
- Batch production management (level 5).

Figure 31.7 shows the interconnections of the different types of control used in a typical batch process. Run-to-run control is a type of supervisory control that resides principally in the production management block. In contrast to continuous processing, the focus of control shifts from regulation to set-point changes, and sequencing of batches and equipment takes on a much greater role.

Batch control systems must be very versatile to be able to handle pulse inputs and discrete input/output (I/O) as well as analog signals for sensors and actuators. Functional control activities are summarized as follows:

1. *Batch sequencing and logic control:* Sequencing of control steps that follow a recipe involves, for example, mixing of ingredients, heating, waiting for a reaction to complete, cooling, and discharging the resulting products. Transfer of materials to and from batch tanks or reactors includes metering of materials as they are charged (as specified by the recipe), as well as transfer of materials at the completion of the process operation. In addition to discrete logic for the control steps, logic is needed for safety interlocks to protect personnel, equipment, and the environment from unsafe conditions. Process interlocks ensure that process operations can only occur in the correct time sequence.
2. *Control during the batch:* Feedback control of flow rate, temperature, pressure, composition, and level, including advanced control strategies, falls in this category, which is also called *within-the-batch* control [31.6]. In sophisticated applications, this requires specification of an operating trajectory for the batch (that is, temperature or flow rate as a function of time). In simpler cases, it involves tracking of set points of the controlled variables, which includes ramping the controlled variables up and down and/or holding them constant for a prescribed period of time. Detection of when the batch operations should be terminated (end point) may be performed by inferential measurements of product quality, if direct measurement is not feasible.
3. *Run-to-run control:* Also called batch-to-batch control, this supervisory function is based on offline product quality measurements at the end of a run. Operating conditions and profiles for the batch are adjusted between runs to improve the product quality using tools such as optimization.
4. *Batch production management:* This activity entails advising the plant operator of process status and how to interact with the recipes and the sequential, regulatory, and discrete controls. Complete information (recipes) is maintained for manufacturing each product grade, including the names and amounts of ingredients, process variable set points, ramp rates, processing times, and sampling procedures. Other database information includes batches produced on a shift, daily, or weekly basis, as well as material and energy balances. Scheduling of process units is based on availability of raw materials and equipment and customer demand.

Recipe modifications from one run to the next are common in many batch processes. Typical examples are modifying the reaction time, feed stoichiometry, or reactor temperature. When such modifications are done at the beginning of a run (rather than during a run), the control strategy is called run-to-run control. Run-to-run control is frequently motivated by the lack of online measurements of the product quality during a batch run. In batch chemical production, online measurements are often not available during the run, but the product can be analyzed by laboratory samples at the end of the run. The process engineer must specify a recipe that contains the values of the inputs (which may be time-varying) that will meet the product requirements. The task of the run-to-run controller is to adjust the recipe after each run to reduce variability in the output product from the stated specifications.

Batch run-to-run control is particularly useful to compensate for processes where the controlled variable drifts over time; for example, in a chemical vapor deposition process the reactor walls may become fouled owing to byproduct deposition. This slow drift in the reactor chamber condition requires occasional changes to the batch recipe in order to ensure that the controlled variables remain on target. Eventually, the reactor chamber must be cleaned to remove the wall deposits, effectively causing a step disturbance to the process outputs when the inputs are held constant. Just as the run-to-run controller compensates for the drifting process, it can also return the process to target after a step disturbance change [31.7, 8].

The Instrument Society of America (ISP) SP-88 standard deals with the terminology involved in batch control [31.9]. There are a hierarchy of activities that take place in a batch processing system [31.10]. At the highest level, procedures identify how the products are made, that is, the actions to be performed (and their order) as well as the associated control requirements for these actions. Operations are equivalent to unit operations in continuous processing and include such steps as charging, reacting, separating, and discharging. Within each operation are logical points called *phases*, where processing can be interrupted by operator or computer interaction. Examples of different phases include the sequential addition of ingredients, heating a batch to a prescribed temperature, mixing, and so on. Control steps involve direct commands to final control elements, specified by individual control instructions in software.

As an example, for {operation = charge reactant} and {phase = add ingredient B}, the control steps would be: (1) open the B supply valve, (2) total the flow of B over a period of time until the prescribed amount has been added, and (3) close the B supply valve.

The term *recipe* has a range of definitions in batch processing, but in general a recipe is a procedure with the set of data, operations, and control steps required to manufacture a particular grade of product. A *formula* is the list of recipe parameters, which includes the raw materials, processing parameters, and product outputs. A recipe *procedure* has operations for both normal and abnormal conditions. Each operation contains resource requests for certain ingredients (and their amounts). The *operations* in the recipe can adjust set points and turn equipment on and off. The complete production run for a specific recipe is called a *campaign* (multiple batches).

In multigrade batch processing, the instructions remain the same from batch to batch, but the formula can be changed to yield modest variations in the product; for example, in emulsion polymerization, different grades of polymers are manufactured by changing the formula. In flexible batch processing, both the formula (recipe parameters) and the processing instructions can change from batch to batch. The recipe for each product must specify both the raw materials required and how conditions within the reactor are to be sequenced in order to make the desired product.

Many batch plants, especially those used to manufacture pharmaceuticals, are certified by the International Standards Organization (ISO). ISO 9000 (and the related ISO standards 9001–9004) state that every manufactured product should have an established, documented procedure, and the manufacturer should be able to document that the procedure was followed. Companies must pass periodic audits to main ISO 9000 status. Both ISO 9000 and the US Food and Drug Administration (FDA) require that only a certified recipe be used. Thus, if the operation of a batch becomes *abnormal*, performing any unusual corrective action to bring it back within the normal limits is not an option. In addition, if a slight change in the recipe apparently produces superior batches, the improvement cannot be implemented unless the entire recipe is recertified. The FDA typically requires product and raw materials tracking, so that product abnormalities can be traced back to their sources.

Recently, in an effort to increase the safety, efficiency, and affordability of medicines, the FDA has proposed a new framework for the regulation of pharmaceutical development, manufacturing, and quality assurance. The primary focus of the initiative is to reduce variability through a better understanding of processes than can be obtained by the traditional approach. Process analytical technology (PAT) has become an acronym in the pharmaceutical industry for designing, analyzing, and controlling manufacturing through timely measurements (i. e., during processing) of critical quality and performance attributes of raw and in-process materials and processes, with the goal of ensuring final product quality. Process variations that could possibly contribute to patient risk are determined through modeling and timely measurements of critical quality attributes, which are then addressed by process control. In this manner processes can be developed and controlled in such a way that quality of product is guaranteed.

Semiconductor manufacturing is an example of a large-volume batch process [31.7]. In semiconductor manufacturing an integrated circuit consists of several layers of carefully patterned thin films, each chemically altered to achieve desired electrical characteristics. These devices are manufactured through a series of physical and/or chemical batch unit operations similar to the way in which speciality chemicals are made. From 30 to 300 process steps are typically required to construct a set of circuits on a single-crystalline substrate called a wafer. The wafers are 4 to 4–12 inch (100–300 mm) in diameter, 400–700 μm thick, and serve as the substrate upon which microelectronic circuits (devices) are built. Circuits are constructed by depositing the thin films (0.01–10 μm) of material of carefully controlled composition in specific patterns and then etching these films to exacting geometries (0.35–10 μm).

The main unit operations in semiconductor manufacturing are crystal growth, oxidation, deposition (dielectrics, silicon, metals), physical vapor deposition, dopant diffusion, dopant-ion implantation, photolithography, etch, and chemical–mechanical polishing. Most processes in semiconductor manufacturing are semi-batch; for example, in a single-wafer processing tool the following steps are carried out:

1. A robotic arm loads the boat of wafers
2. The machine transfers a single wafer into the processing chamber
3. Gases flow continuously and reaction occurs
4. The machine removes the wafer
5. The next wafer is processed.

When all wafers are finished processing, the operator takes the boat of wafers to the next machine. All of these steps are carried out in a clean room designed to minimize device damage by particulate matter.

For a given tool or unit operation a specified number of wafers are processed together in a lot, which is carried in a boat. There is usually an extra slot in the boat for a pilot wafer, which is used for metrology reasons. A cluster tool refers to equipment which has several single-wafer processing chambers. The chambers may carry out the same process or different processes; some vendors base their chamber designs on series operation, while others utilize parallel processing schemes.

The recipe for the batch consists of the regulatory set points and parameters for the real-time controllers on the equipment. The equipment controllers are normally not capable of receiving a continuous set-point trajectory. Only furnaces and rapid thermal processing tools are able to ramp up, hold, and ramp down their temperature or power supply. A recipe can consist of several steps; each step processes a different film based on specific chemistry. The same recipe on the same type of chamber may produce different results, due to different processes used in the chamber previously. This lack of repeatability across chambers is a big problem with cluster tools or when a fabrication plant (fab) has multiple machines of the same type, because it requires that a fab keep track of different recipes for each chamber. The controller translates the desired specs into a machine recipe. Thus, the fab supervisory controller only keeps track of the product specifications.

Factory automation in semiconductor manufacturing integrates the individual equipment into higher levels of automation, in order to reduce the total cycle time, increase fab productivity, and increase product yield [31.8]. The major functions provided by the automation system include:

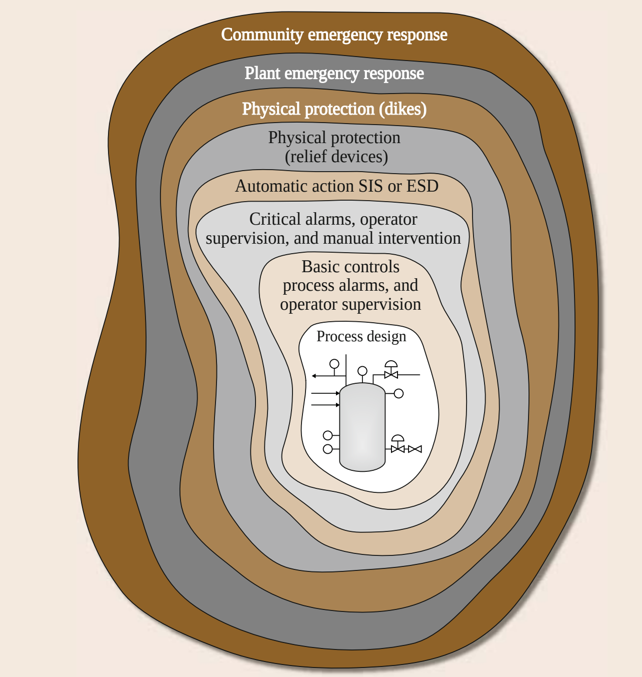
1. Planning of factory operation from order entry through wafer production
2. Scheduling of factory resources to meet the production plan
3. Modeling and simulation of factory operation
4. Generation and maintenance of process and product specification and recipes
5. Tracking of work-in-progress (WIP)
6. Monitoring of factory performance
7. Machine monitoring, control, and diagnosis
8. Process monitoring, control, and diagnosis.

Automation of semiconductor manufacturing in the future will consist of meeting a range of technological challenges. These include the need for faster yield ramp, increasing cost pressures that compel productivity improvements, environmental safety and health concerns, and shrinking device dimensions and chip size. The development of 300 mm platforms in the last few years has spawned equipment with new software systems and capabilities. These systems will allow smart data collection, storage, and processing on the equipment, and transfer of data and information in a more efficient manner. Smart data management implies that data are collected as needed and based upon events and metrology results. As a result of immediate and automatic processing of data, a larger fraction of data can be analyzed, and more decisions are data driven. New software platforms provide the biggest opportunity for a control paradigm shift seen in the industry since the introduction of statistical process control.

31.6 Automation and Process Safety

In modern chemical plants, process safety relies on the principle of multiple protection layers. A typical configuration is shown in Fig. 31.8. Each layer of protection consists of a grouping of equipment and/or human actions. The protection layers are shown in the order of activation that occurs as a plant incident develops. In the inner layer, the process design itself provides the first level of protection. The next two layers consist of the basic process control system (BPCS) augmented with two levels of alarms and operator supervision or intervention. An alarm indicates that a measurement has exceeded its specified limits and may require operator action.

The fourth layer consists of a safety interlock system (SIS), which is also referred to as a safety instrumented system or as an emergency shutdown (ESD) system. The SIS automatically takes corrective action when the process and BPCS layers are unable to handle an emergency; for example, the SIS could automatically turn off the reactant pumps after a high-temperature alarm occurs for a chemical reactor. Relief devices such as rupture discs and relief valves provide physical protection by venting a gas or vapor if overpressurization occurs. As a last resort, dikes are located around process units and storage tanks to contain liquid spills. Emergency response plans are used



Community emergency response
Plant emergency response
Physical protection (dikes)
Physical protection (relief devices)
Automatic action SIS or ESD
Critical alarms, operator supervision, and manual intervention
Basic controls process alarms, and operator supervision
Process design

Note:
Protection layers for a typical process are shown in the order of activation expected as a hazardous condition is approached
ESD = Emergency shutdown; SIS = Safety interlock system

Fig. 31.8 Typical layers of protection in a modern chemical plant [31.11]

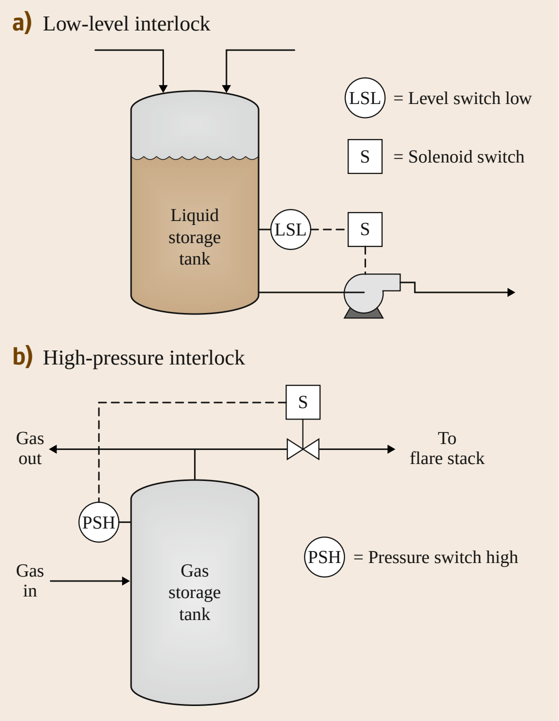


Fig. 31.9a,b Two interlock configurations [31.1]

to address emergency situations and to inform the community.

The functioning of the multiple layer protection system can be summarized as follows [31.11]:

> *Most failures in well-designed and operated chemical processes are contained by the first one or two protection layers. The middle levels guard against major releases and the outermost layers provide mitigation response to very unlikely major events. For major hazard potential, even more layers may be necessary.*

It is evident from Fig. 31.8 that automation plays an important role in ensuring process safety. In particular, many of the protection layers in Fig. 31.8 involve instrumentation and control equipment. The SIS operation is designed to provide automatic responses after alarms indicate potentially hazardous situations. The objective is to have the process reach a safe condition. The automatic responses are implemented via interlocks and automatic shutdown and start-up systems. Distinctions are sometimes made between safety interlocks and process interlocks; process interlocks are used for less critical situations to provide protection against minor equipment damage and undesirable process conditions such as the production of off-specification product.

Two simple interlock systems are shown in Fig. 31.9. For the liquid storage system, the liquid level must stay above a minimum value in order to avoid pump damage such as cavitation. If the level drops below the specified limit, the low-level switch (LSL) triggers both an alarm and a solenoid (S), which acts as a relay and turns the pump off. For the gas storage system in Fig. 31.9b, the solenoid-operated valve is normally closed. However, if the pressure of the hydrocarbon gas in the storage tank exceeds a specified limit, the high-pressure switch (PSH) activates an alarm and causes the valve to open fully, thus reducing the pressure in the tank. For interlock and other safety systems, a switch can be replaced by a transmitter if the measurement is required. Also, transmitters tend to be more reliable.

The SIS in Fig. 31.9 serves as an emergency backup system for the BPCS. The SIS automatically starts when a critical process variable exceeds specified alarm limits that define the allowable operating region. Its initiation results in a drastic action such as starting or stopping a pump or shutting down a process unit. Consequently, it is used only as a last resort to prevent injury to people or equipment.

It is very important that the SIS function independently of the BPCS; otherwise emergency protection will be unavailable during periods when the BPCS is not operating (e.g., due to a malfunction or power failure). Thus, the SIS should be physically separated from the BPCS and have its own sensors and actuators. Sometimes redundant sensors and actuators are utilized; for example, triply redundant sensors are used for critical measurements, with SIS actions based on the median of the three measurements. This strategy prevents a single sensor failure from crippling SIS operation. The SIS also has a separate set of alarms so that the operator can be notified when the SIS initiates an action (e.g., turning on an emergency cooling pump), even if the BPCS is not operational.

31.7 Emerging Trends

Main emerging trends in process automation have to do with process integration, information integration, and engineering integration. The theme across all of these is the need for a greater degree of integration of all components of the process. A thorough discussion on the implications of these trends and their challenges on process automation can be found in this Handbook in Chap. 8.

32. Product Automation

Friedrich Pinnekamp

The combined effects of rapidly growing computational power, and the shrinking of the associated hardware in recent decades, mean that almost all products used in industry have acquired some form of *intelligence*, and can perform at least part of their functions automatically.

The influence of this development on global society is breathtaking. Today, only 50 years after the first indication of automation, the life of individuals and the way industries work has been transformed fundamentally.

The automation of a product requires the ability to achieve unsupervised interaction between the device's various sensors and actuators, and ultimately the ability to communicate and interact with other units.

This chapter gives an overview of the requirements to be fulfilled in the automation of products, and gives a flavor of today's state of the art by presenting typical examples of automated products from a wide range of industrial applications. These examples cover automation in instrumentation, motors, circuit breakers, drives, robots, and embedded systems.

32.1 Historical Background

Some 50 years ago the term *product automation* was not even known. The door opener to the automation of individual devices, components or *products* was a tiny electronic circuit, commercially introduced by Fairchild Semiconductors and Texas Instruments in 1961: the microprocessor.

Already 5 years later the trend towards progressive miniaturization, known as Moore's law, was initiated and is still ongoing.

In the 1970s the development of the microprocessors geared up and led to the RISC (reduced instruction set computer) processors and very-large-scale integration (VLSI) in the 1980s. In the 1980s the step from 32 to 64 bit processors was taken.

In 1992, DEC introduced the Alpha 21064 at a speed of 200 MHz. The superscalar, superpipelined 64 bit processor design was pure RISC, but it outperformed the other chips and was referred to by DEC as the world's fastest processor.

Today in 2007 the flagships of microprocessors are built in 65 nm technology, have about 170 million transistors, and tact frequencies of 2000 MHz.

With such a powerful *brain* embedded in a device, automation has almost unlimited potential.

The enormous impact of this revolutionary technical development on society is obvious. It changed the daily life of almost all people in the world. The personal computer (PC) is based on microprocessors, transforming the way of working in offices and factories fundamentally. Microprocessors *crept* into almost all devices and made the use of machines much more convenient (at least after all the manuals themselves have developed into embedded systems).

Production of goods boosted to new productivity levels with microprocessors and there is hardly a single niche in our life that is not covered by automation devices today.

32.2 Definition of Product Automation

Product automation is a notation that can easily be confused with *production automation* or *automation products*, all names used in industry. To add to the confusion, the individual terms *product* and *automation* have a wide range of meanings themselves. Before we discuss *product automation* it seems to be appropriate to clearly describe what we understand by this.

Production automation is the automation of individual steps or the whole chain of steps necessary to produce. The otherwise manual part of the *manufacturing* is therefore carried out or supported by tools, machines or other devices.

Industries that produce such tools or machines call their devices *products*. Products used to automate production can be called *automation products*. Examples are numerical controlled machines, robots or sorting devices. These automation products serve individual steps or support the infrastructure of an automated production line.

To be able to do this, these products or devices must possess a certain degree of automation themselves. A motor that drives the arm of a robot, for example, must be able to receive signals for its operation and must have some mechanism to start its operation on request. Thus a motor, to use this example, must itself be automated.

When we talk about *product automation* we have in mind the automation of devices that fulfill various tasks in industry, not necessarily only tasks in production processes. A device with automation capabilities can also be used as a stand-alone unit to serve individual functions.

Thus *product automation* is the attempt to equip products with functionality so that they can fulfill their tasks fully or partly in an automated way.

In this chapter we want to describe the state of the art and the trends in automating products.

The functions required to transform a simple tool, say a hammer, into an automated product – in this case it may be a robot executing the same movement with the hammer as we would do with our arm – are very different, both in nature and complexity.

From the large variety of combinations of these functions we select a dozen typical applications or product examples to give a feeling of the status of implementation of automation on the product level.

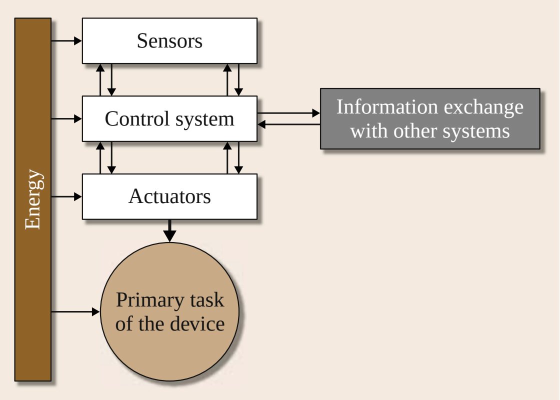
Further examples can be found in [32.1]

32.3 The Functions of Product Automation

The hammer mentioned above is a good example of a whole class of *products* (or devices) with the task of providing a mechanical impulse to another object (in most cases a nail). This hammer is useless if no one is taking it and using it as a tool.

To make a simple hammer an automated hammer, we need an additional system that provides at least the functions a person would apply to the hammer in order to make it useful.

We have to give the hammer a target (hit that specific nail), we need a force (an actuator) to move the hammer, and we have to control the movement in various aspects: acceleration, direction, speed, angle of impact, precision of the path. We have to inform the



Sensors
Control system
Information exchange with other systems
Actuators
Energy
Primary task of the device

Fig. 32.1 The functional blocks required for automating a device

control system (the brain) that the task is executed and we have to put the hammer back into a default position after the hit. In addition, we need an energy source to provide the power for the operation and we need some sensors (eyes, ears, fingers) to inform the control system about the status of the hammer and its position during the action.

In a more schematic way the requirements for automation look like the following.

32.4 Sensors

To automate a device, sensors are required to inspect the environment and provide information about the subsequent reaction of the device.

It depends very much on the task to be carried out with the *product* which type of sensor is adequate (see Chap. 20 in this handbook and [32.2, 3]).

Table 32.1 gives an overview on the physical parameters to be measured by the sensor when specific properties are applicable.

Table 32.1 Physical parameters to be measured by a sensor

Mechanical properties	Distance, speed, acceleration, position, angle, mass flow, level, tension, movement, vibration
Thermodynamic properties	Temperature, pressure, composition, density, energy content
Electrical properties	Voltage, current, phase, frequency, phase angle, conductivity
Magnetic properties	Magnetic field
Electromagnetic properties	Radiation intensity, light fluctuations, parameters of light propagation
Other properties	Radioactivity

32.5 Control Systems

The signals from the sensors, in either analog or digital form, have to be interpreted and compared with a model of the device task in order to initiate the actuators. The control system therefore contains all algorithms to provide a proper operation of the device.

Simple logical controllers are used for on–off functions. Sequence controllers are used for time-dependent operations of the devices (Chap. 9 on control theory and [32.4–6]).

Proportional–integral–derivative (PID) controllers are widely used for parameter control, and the even more sophisticated model-based control systems see use in device control. For example, the starter of a motor to close a valve may need to adjust its current ramp-up curve according to the behavior of the overall system in which this valve and its automated motor are embedded.

32.6 Actuators

Actuators are the devices through which a controller acts on the system. As in the case of sensors, the specific type of the actuator depends very much on the application [32.7, 8].

Mechanical movements are introduced by spring mechanisms, hydraulic and/or pneumatic devices, magnetic forces, valves or thermal energy. Changes of thermodynamic properties are introduced through heating or cooling or pressure variations, for example.

Electrical properties are modified by charging or discharging capacitors or application of voltage and current, just to mention a few.

32.7 Energy Supply

Energy is required to perform the primary function of the device. It can be supplied in various forms such as mechanical, electrical or thermal.

Energy is also required to operate the sensors, actuators, and control systems as well as the communication channels within or to the outside of the device.

Energy (in most cases electrical energy) can be supplied from remote sources, either via cables or without a wired connection (for example, transmitted through electromagnetic fields), or taken from device internal storage systems, mostly batteries (in rare cases also fuel cells).

In the long term, the energy supply for systems that must operate in remote locations for long periods without intervention will develop into a design issue – for example, through suitable storage mechanisms.

32.8 Information Exchange with Other Systems

To operate in an automatic way, a device often has to communicate with its environment. For stand-alone devices, this information exchange is provided through sensors that observe the external parameters. In the majority of cases, however, the automated device must communicate with peer devices or with a superordinate control system.

Basic information for the function of the device has to be transferred and, if necessary, updated. Such updates can affect anything from operating data to the master program for the operation.

It may be necessary for an operator to communicate with the device, thus a man–machine interface is required.

Other devices or higher control systems may require information exchange in both directions, to activate the device, get a status report or synchronize with other devices in a larger system.

A language for the communication has to be defined and here several standards have been developed over the years as automation was spreading across industry.

32.9 Elements for Product Automation

The overview above covers the broad spectrum of aspects and applications in product automation. In the following, some prominent examples of state-of-the-art implementation of the related technologies are given.

32.9.1 Sensors and Instrumentation

Instrumentation is a crucial element in product automation. The information required to effectively automate a product has to be gathered in an adequate way. The state of the art in sensor technology shall be demonstrated with a few examples only, characterizing the level of technology required in modern sensors.

Figure 32.1 shows both a pressure and a temperature sensor. In both cases the probe itself is the crucial but is by far a minor part of the whole system. Most of the technology is located in the electronic part that serves as data evaluation and signal transmission.

Fig. 32.1 Examples of pressure and temperature sensors (after [32.9, 10])

Signal transmission takes place via a communication protocol.

A further critical element is the human–machine interface, which is becoming more intuitive in its use. The user is provided only a few *simple* buttons to check or modify the settings of the sensors.

A high degree of automation is put into the peripheral aspects of the sensors after the primary measurement system of the physical parameters have been developed to perfection.

Other sensors are built on new sensing technology, perfecting physical effects such as the influence of a magnetic field on the polarization of light waves propagating in this field. Figure 32.3 shows such a sensor for measuring the direct-current (DC) in a foundry.

The sensor as such consists of an optical fiber wound around the current-carrying bar. The magnetic field generated by the current influences the light propagation in the fiber, from which the amplitude of the current can be derived.

Arrangement of the displacement body in a paramagnetic oxygen sensor

Planar micro-electromechanical system (MEMS) sensor chip (inner volume approximately 100 mm^3)

Fig. 32.4 Micro-electromechanical oxygen sensor (after [32.12])

The electronic processing of the transformed light signal occupies the central part of the sensor.

Making use of micro-electromechanical systems (MEMS) technology, the sensors themselves become more accurate and easier to manufacture [32.13, 14].

An example of this development towards silicon-based systems is the oxygen sensor head shown in Fig. 32.4.

Compared with other gases, oxygen shows a high magnetic susceptibility, and this is used to detect it in a gas flow. The sensor consists of a displacement body located in a strong magnetic field gradient. The torque of this body is a measure of the concentration of the magnetic oxygen gas. With silicon manufacturing technology these delicate mechanical devices can be cut out on chips and integrated into the overall measuring system.

32.9.2 Circuit Breakers

Circuit breakers are devices that connect or disconnect electrical energy to a user and, in addition, interrupt a short-circuit current in case of emergency (Fig. 32.5) [32.15].

While the primary mechanism for this function is the mechanical movement of metal contacts, modern versions of this product show a very high degree of automation.

State-of-the-art circuit breakers therefore have a quick and user-friendly way of setting trip parameters – preferably a method that can be instantiated offline and before installation of the circuit breaker. In addition, they offer a complete indication of why a trip occurs, and a data-logger function to record all electrical quantities surrounding the tripping event. Accessing

Fig. 32.5 Automated circuit breakers for different power levels

this information quickly and from anywhere, without the need to plug a direct physical connections between the trip unit and the PC or personal digital assistant (PDA) are also features of modern products.

An important element in any circuit breaker is a current sensor. In low-voltage circuit breakers, which are fitted with electronic trip units, these sensors are not only used for current measurement, but they must also provide sufficient energy to power the electronics.

A commonly used sensor is a Rogowsky coil that provides a signal proportional to the derivative of the current – this signal needs to be integrated. This is done digitally with a powerful digital signal processor (DSP), which is part of the overall multiprocessor architecture, and essentially the heart of the trip unit. In fact, this DSP is used to carry out other functions, for example, communications, that in previous designs required separate hardware components.

The elimination of these hardware components combined with a simplified trip unit input stage means that a single printed circuit board (PCB) is all that is required for the unit's electronics. This is a vast improvement on previous designs where four PCBs were needed to provide the same functionality.

The circuit breaker shown in Fig. 32.6 also has an integrated human–machine interface (HMI) [32.15]. A high-definition, low-power-consuming graphical display makes data easier to read. And, because of an energy-storing capacitor, a description of the alarms can be displayed for up to 48 h without the need for an auxiliary power supply. Nevertheless, these alarm descriptions are saved and can be viewed long after this 48 h period has elapsed by simply powering the trip unit.

A wireless link, based on Bluetooth technology, connects the trip unit to a portable PC, PDA or laptop. This enables users to operate in a desktop environment familiar to them. From this environment operators can use electric network dimensioning support programs to ensure optimal adjustment of the protection functions. In addition, users can print reports, save data on different media, or send data by e-Mail to other parties from the comfort of their own desk.

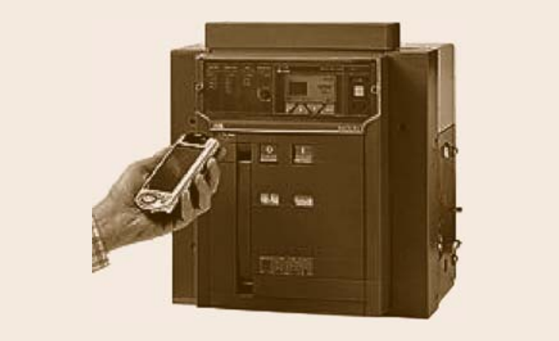

Fig. 32.6 HMI of a circuit breaker

The use of fieldbus plug devices allows a choice of fieldbus (e.g., DeviceNet or Profibus DP) that best suits the user's specific needs when connecting the circuit breakers to an overall system.

32.9.3 Motors

Motors are the most common devices in production automation, being part of production lines or of robots [32.16]. The need to automate the motors themselves is therefore very high, but also motors in stand-alone application have automation features built in for various reasons.

To avoid negative influence on the electrical supply system when motors are switched on, the most common automation device is the *soft starter*: when a certain motor power output is required, the optimal solution (depending on the power network conditions and requirements) becomes a frequency converter start, also called a soft start. This allows the motor to be started at high torque without causing any voltage drop on the power network.

The converter brings the motor up to speed. Upon reaching nominal speed and after being synchronized to the network, the circuit breaker between the converter and the power network is opened. The breaker between the motor and the network is then closed. Finally, the breaker between the motor and the converter is opened.

The control systems to manage the motor come in two basic varieties. Closed-loop control systems have encoders in the motor to report its status. This is used as feedback information for the control algorithm. Open-loop systems are simpler because these encoders are omitted, but at the price of a lower control accuracy. With model-based control, however, the accuracy of a closed-loop is achieved without encoders. ABB's direct torque control technology is an example for this modern approach: it uses mathematical functions to predict the motor status. The accuracy and repeatability delivered is comparable to closed-loop systems, but with the added bonus of a higher responsiveness (up to ten times as fast).

Direct torque control (DTC) is a control method that gives electronic variable-speed motor controllers [alternating-current (AC) drives] an excellent torque response time. For AC induction machines, it deliv-

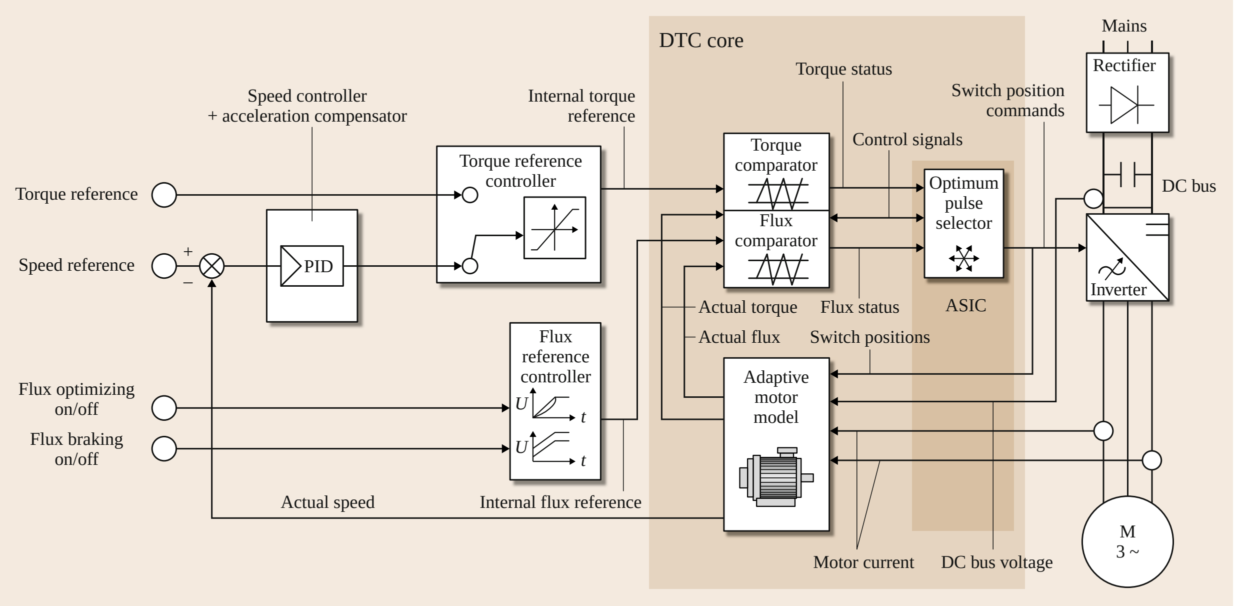

Fig. 32.7 Block diagram of DTC (after [32.17])

ers levels of performance and responsiveness reaching the machine's theoretical limits in terms of torque and speed control (Fig. 32.7).

DTC uses a control algorithm that is implemented on a microcontroller embedded in the drive. The technology was first used commercially in 1995, and rapidly became the preferred control scheme for AC drives, especially for demanding or critical applications, where the quality of the control system could not be compromised.

32.9.4 Drives

In the above example of motor automation, soft starters for smaller motors are often integrated into the motor itself.

The control systems to manage larger motors become large in themselves – like their smaller counterparts, they are equipped with power electronic components as well as control processors and peripheral systems, but the size of these rises with their power capability.

Such units are called drives. Today drive units can power motors of up to 50 MW. The continuing decrease in size and increase in power in such units is driven by improvements in power electronics and microelectronics.

When we look at a drive device as a product in itself, the automation of this product is mainly by two growing requirements: a simplified man–machine interface and communication issues within a system of which the drive is part.

Intelligent drives are certain to benefit from the growth of Ethernet communications by becoming an integral part of control, maintenance, and monitoring systems. Decentralized control systems will be created in which multiple drives share control functions, with one taking over in the event of a fault or error in another drive. The advantage of this is that reliance on costly

Fig. 32.8 Assistant control panels allow easy programming of standard drives (after [32.18])

programmable logic controllers (PLC) is greatly reduced and automation reliability improves dramatically.

The modern drive is programmed via a control panel that is similar in look, feel, and functionality to a mobile phone. A large graphical display and soft keys make it extremely easy to navigate. This detachable, multilingual alphanumeric control panel, as shown in Fig. 32.8, allows access to various *assistants* and a built-in help function to guide the user during start-up, maintenance, and diagnostics. For example, a real-time clock assists in rapid fault diagnostics. When a fault is detected, a diagnostic assistant will suggest ways to fix the problem. Drive setup and configuration data can be copied from one motor controller to another to ensure that, in the event of a drive failure, there is no need to start the setup process from the beginning.

Today, mid-range drives can store five times the amount of information compared with typical drives from the 1980s. In addition, drives with increased processing power and memory enable configurations that are better suited to an application.

In industry today, software modifications are the most useful and cost-effective way of modifying a drive. This is because developments in software have given drives increased capability with less hardware; for example, a drive controlling a conveyor belt in a biscuit factory can be programmed to operate in many different ways, such as starting and stopping at certain intervals or advancing a certain distance. The same drive used in a ventilation system can be programmed to maintain constant air pressure in a ventilation duct.

Software developments are also leading to drives with adaptive programming. Adaptive programming enables the user to freely program the drive with a set of predefined software blocks with predefined functions.

32.9.5 Robots

Robots are the prototype of product automation as they present the impression of a self-determined machine in the most visible way.

The classical application of robots is found in car manufacturing, where hundreds of devices perform movements, grinding, welding, painting, assembly, and other operations in the flow production (see Chap. 21 and [32.19, 20]).

Other applications of robotic support are less well known but are entering the market on a broad base.

The FlexPicker from ABB (Fig. 32.9) is one such example: It is a parallel kinematics robot that offers a great combination of speed and flexibility [32.21].

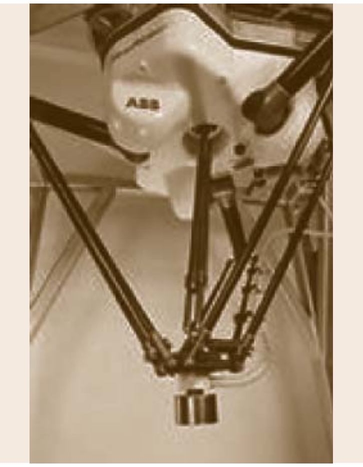

Fig. 32.9 The FlexPicker robot achieves accelerations of 10 g and handles up to 120 item/min

The gripper can pick items with picking rates exceeding 120 items per minute. The products can be picked and placed one by one. Since all the motors and gears are fixed on the base of the robot, the mass of the moving arms is limited to a few kilograms. This means that accelerations above 10 g can be achieved. Automation of this fast movement puts different requirements on the automation system of the device than, for example, the slow welding of a car roof.

While the primary automation of the robot movement is fully developed (the world's first electrically driven robot was introduced as early as 1974), the

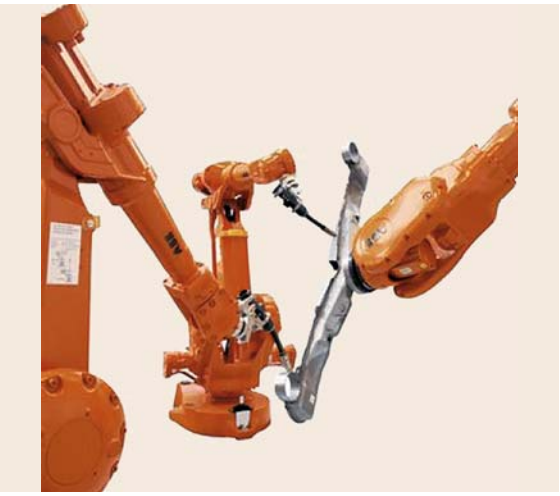

Fig. 32.10 The MultiMove function, which is embedded into the IRC5 software, allows up to four robots and their work-positioners or other devices to work in full coordination

further improvements come, such as in the drives examples, from better coordination of several robots, a simplified man–machine interface, and easier programming methods for the robot systems.

The recently launched robot controller IRC5 from ABB, presenting the fifth generation of robot controllers, introduces MultiMove (Fig. 32.10). MultiMove is a function embedded into the IRC5 software that allows up to four robots and their work-positioners or other devices to work in full coordination. This advanced functionality has been made possible by the processing power and modularity of the IRC5 control module, which is capable of calculating the paths of up to 36 servo axes [32.22].

The FlexPendant (Fig. 32.11) [32.22] is a handheld robot–user interface for use with the IRC5 controller. It is used for manually controlling or programming a robot, or for making modifications or changing settings during operation. The FlexPendant can jog a robot through its program, or jog any of its axes to drive the robot to a desired position, and save and recall learnt positions and actions.

The ergonomically designed unit weighs less than 1.3 kg. It has a large color touchscreen, eight keys, a joystick, and an emergency stop button. The user-friendly interface is based on Microsoft's CE.NET system. It can display information in 12 languages of which 3 can be made active simultaneously, meaning languages can be changed during operation. This is useful when staff from different countries work in the same factory. The display can be flipped by 180° to make the FlexPendant suitable for left- or right-handed operators. The options can be customized to suit the robot application.

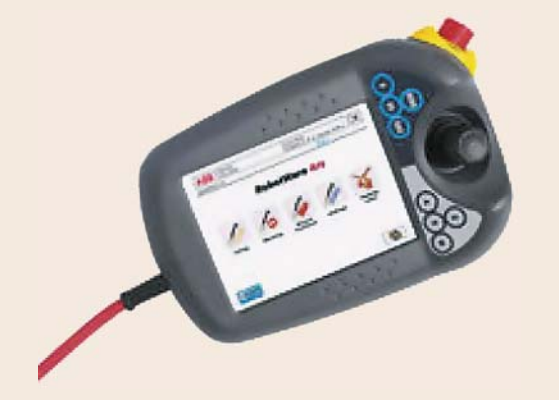

Fig. 32.11 Handheld programming

Programming of robots to fulfill their sometimes quite complicated task requires a lot of time and can in most cases be done by specialists only. However, considerable progress has been made by virtual robot programming that allows offline programming with models. Recently these systems can also be directly connected to the robots, which is especially useful to set up a new robot installation. Background software programs and the use of templates significantly facilitate this programming work.

32.10 Embedded Systems

Most of the examples given in Sect. 32.9 have the automation function embedded in the product, making embedded system a common feature for product automation.

Embedded systems are special-purpose computer systems that are totally integrated and enclosed by the devices that they serve or control – hence the term *embedded systems*. While this is a generally accepted definition of embedded systems, it does not give many clues as to the special characteristics the systems possess. The use of general-purpose computers, such as PCs, would be far too costly for the majority of products that incorporate some form of embedded system technology. A general-purpose solution might also fail to meet a number of functional or performance requirements such as constraints in power consumption, size limitations, reliability or real-time performance.

Most present product automation could not have been conceived without embedded system technology. Examples are distributed control systems (DCS) that can safely automate and control large and complex industrial plants, such as oil refineries, power plants, and paper mills. In the early days of industrial automation, relay logic was used to perform simple control functions. With the advent of integrated circuits and the first commercial microcontrollers in the 1970s and 1980s, programmable industrial controllers were introduced to perform more complex control logic.

Industrial requirements vary enormously from application to application, but special industrial requirements typically include:

- Availability and reliability
- Safety

- Real-time, deterministic response
- Power consumption
- Lifetime

Automated products as well as automation and power systems must have very high availability and be extremely reliable. Economic security and personal safety depend on high-integrity systems. Embedded systems play a critical role in such mission-critical configurations.

Real time is a term often associated with embedded systems. Because these systems are used to control or monitor real-time processes, they must be able to perform certain tasks reliably within a given time. The response time associated with this *real time* varies with the application and can range from seconds to microseconds. Embedded systems must operate with as little power consumption as possible. For this reason various *power-harvesting* technologies are often included in the design.

Yet another requirement that is frequently imposed on industrial embedded systems is a long lifetime of the product itself and the lifecycle of the product family. While modern consumer electronics may be expected to last for less than 5 years, most industrial devices are expected to work in the field for 20 years or more. This imposes challenges not only on the robustness of the electronics, but also on how the product should be handled throughout its lifecycle: Hardware components, operating systems, and development tools are constantly evolving and individual products eventually become obsolete.

The key issues in developing embedded systems are complexity, connectivity, and usability. While the steadily increasing transistor density and speeds of integrated circuits offer tremendous opportunities, these improvements also present huge challenges to handle the complexity: a modern embedded system can consist of hundreds of thousands of lines of software code.

Before the widespread deployment of digital communication, most embedded systems operated in a stand-alone mode (Fig. 32.12). They may have had some capabilities for remote supervision and control, but, by and large, most functions were performed autonomously. This is changing rapidly. Embedded systems are now often part of sophisticated distributed networks. Simple sensors with basic transmitter electronics have been replaced by complex, intelligent field devices. As a consequence, individual products can no longer be automated in isolation; they must have common components. Communication has gone from being a small part of a system to being a significant function. Where serial peer-to-peer communication was once the only way to connect a device to a control system, fieldbuses are now able to integrate large numbers of complex devices. The need to connect different applications within a system to information and services in field devices drives the introduction of standard information and communication technologies (ICT) such as Ethernet and web services.

Complex field devices are often programmable or configurable. Today's pressure transmitters can contain several hundred parameters. The interaction with a device – either from a built-in panel or from a software

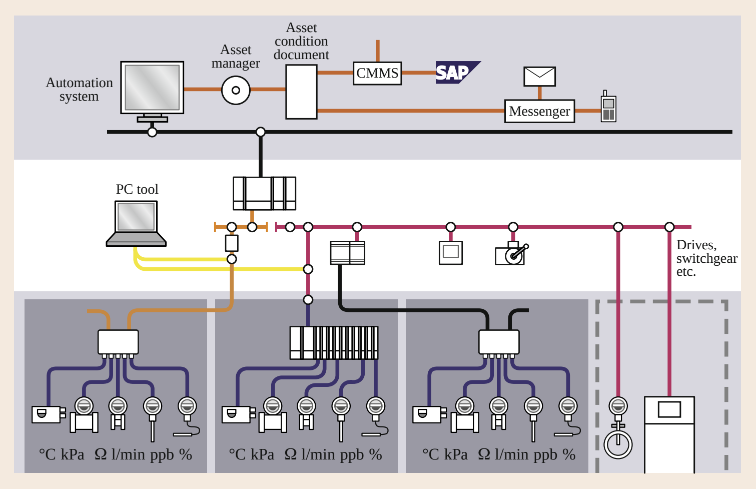

Fig. 32.12 Automated products like instruments as part of a control network (after [32.23])

application in the system – has become more complex. The task of hiding this complexity from the user through the creation of a user-friendly device has sometimes been underestimated. Most other requirements are easily quantifiable or absolute, but *usability* is somewhat harder to define.

The emergence of system-on-chip (SoC) technology has enabled extremely powerful systems to run on configurable platforms that contain all the building blocks of an embedded system: microprocessors, digital signal processors (DSP), programmable hardware logic, memory, communication processors, and display drivers, to give but a few examples. A further important aspect of the evolution of embedded systems is the trend towards networking of embedded nodes using specialized network technologies, frequently referred to as networked embedded systems (NES).

SoC can be defined as a complex integrated circuit, or integrated chipset, that combines the main functional elements or subsystems of a complete end product in a single entity (Fig. 32.13). Nowadays, the most challenging SoC designs include at least one programmable processor, and very often a combination of at least one RISC (reduced instruction set computing) control processor and one DSP. They also include on-chip communications structures – processor bus(es), peripheral bus(es), and sometimes a high-speed system bus. A hierarchy of on-chip memory units, as well as links to off-chip memory, is especially important for SoC processors. For most signal-processing applications, some degree of hardware-based accelerating functional unit is provided, offering higher performance and lower energy consumption. For interfacing to the external world, SoC design includes a number of peripheral processing blocks consisting of analogue components as well as digital interfaces (for example, to system buses at board or backplane level). Future SoC may incorporate MEMS-based (microelectromechanical system) sensors and actuators or chemical processing (lab-on-a-chip).

Recently, the scope of SoC has broadened. From implementations using custom integrated circuits (ICs),

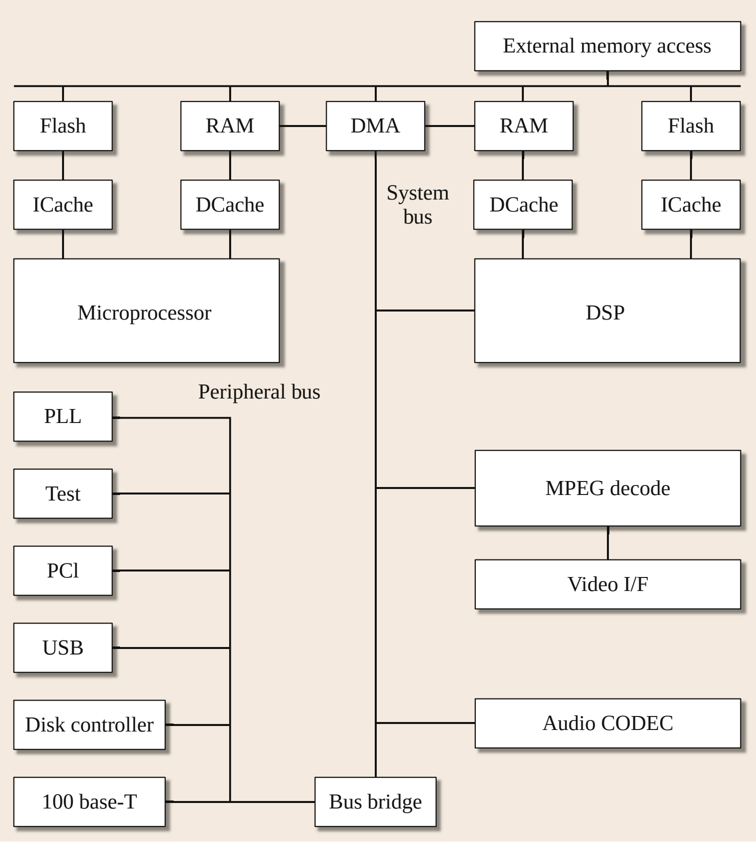

Fig. 32.13 Typical SoC system for consumer applications (after [32.24]). USB – universal serial bus, PLL – phase locked loop, PCI – peripherical component interconnect, DMA – direct memory access, I/F – interface

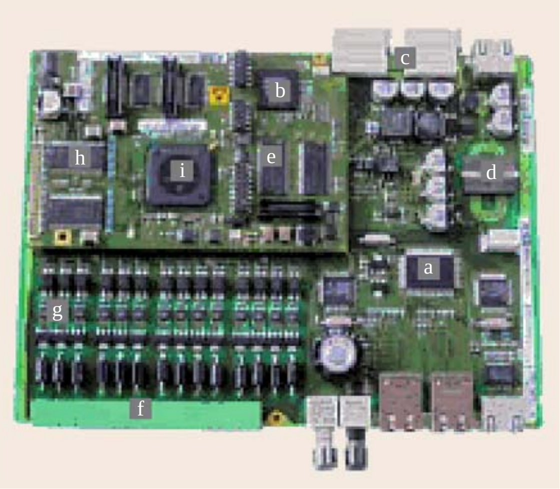

Fig. 32.14 Fully fledged board for the automation of a substation in an electric grid: (a) EPROM, (b) signal preprocessing FPGA, (c) device internal 100 bit/s serial communication, (d) power supply, (e) multiport Ethernet switch with optical and electrical 100 Mbit/s Ethernet media access, (f) 18–300 V binary inputs, (g) binary input processing ASIC, (h) RAM, (i) PowerPC microcontroller (after [32.25])

application-specific IC (ASIC) or application-specific standard part (ASSP), the approach now includes the design and use of complex reconfigurable logic parts with embedded processors. In addition other application-oriented blocks of intellectual property, such as processors, memories or special-purpose functions from third parties are incorporated into unique designs.

These complex field-programmable gate arrays (FPGAs) are offered by several vendors. The guiding principle behind this approach to SoC is to combine large amounts of reconfigurable logic with embedded RISC processors, in order to enable highly flexible and tailorable combinations of hardware and software processing to be applied to a design problem. Algorithms that contain significant amounts of control logic, plus large quantities of dataflow processing, can be partitioned into the control RISC processor with reconfigurable logic for hardware acceleration.

Another important facet of the evolution of embedded systems is the emergence of distributed embedded systems, frequently termed networked embedded systems, where the word *networked* signifies the importance of the networking infrastructure and communication protocol. A networked embedded system is a collection of spatially and functionally distributed embedded nodes, interconnected by means of wired and/or wireless communication infrastructure and protocols, and interacting with the environment (via sensor/actuator elements) and with each other. Within the system, a master node can also be included to coordinate computing and communication, in order to achieve specific objectives.

Early implementation of numerical power system protection and control devices used specialized digital signal processing (DSP) units. Today's implementations are leveraging the vast computing power available in general-purpose central processing units (CPU). As such, PowerPC microcontrollers deliver high computing power at low power consumption and, therefore, low power dissipation. Random-access memory (RAM) is utilized for the program execution memory and erasable read-only memory (EPROM) stores program and configuration information. A typical configuration can include a 400 MHz PowerPC, 64 MB of EPROM, and 64 MB of RAM. The CPU can be complemented with field-programmable gate arrays (FPGAs) that integrate logic and signal preprocessing functionality. An automation device usually includes a number of printed circuit board assemblies (PCBA), accommodating requirements for the diversity and number of different input and output circuitry. High-speed serial communication is built in for intermodule communication that enables the CPU to send and acquire data from the input and output modules. Application-specific circuits are designed to optimize overall technical and economical objectives. Figure 32.14 shows a sample of a high-performance CPU module, connected to a binary input and Ethernet communication module.

32.11 Summary and Emerging Trends

Product automation is a highly dynamic and interdisciplinary field of technology.

The attempt to automate almost all individual devices from consumer products to large machines and systems is an ongoing trend.

It is driven by the advances in miniaturization, cost, and performance of electronic components and the standardization of cross-device functions such as communication.

The broad application range of product automation requires both general understanding of the development of electronics and software as well as specific knowledge of the tasks of the products to be automated.

With a higher degree of standardization and modularization of embedded systems the implementation of product automation will continue with high speed.

To facilitate an efficient implementation of embedded systems as the heart of product automation future research will focus on three areas:

- Reference designs and architecture
- Seamless connectivity and middleware
- System design methods and tools

The target will be a generic platform of abstract components with high reusability for the applications. This platform shall facilitate a standardized interface to the environment and allow for the addition of application-specific modules. An overriding feature here is the lowest possible power consumption of the embedded systems.

Further steps will deal with the self-configuration and self-organization of components that form the product automation system. There is a clear trend towards ubiquitous connectivity schemes and networks for those systems.

Last not least, design methods and tools must be further developed addressing the various levels of the complex systems. This set of methods will include open interface standards, automatic validation and testing as well as simulation. We will also see progress in the rapid design and prototyping of complex systems.

33. Service Automation

Friedrich Pinnekamp

A fast and effective industrial service, supporting plants with a broad spectrum of assistance from preventive maintenance to emergency repair, rests on two legs: the physical transport of people and equipment, and the provision of the vast variety of information required by service personnel. While the automation of physical movement is limited, data management for efficient servicing, including optimized logistics for transport, is increasingly expanding throughout the service industry.

This chapter discusses the basic requirements for the automation of service and gives examples of how the challenging issues involved can be solved.

33.1 Definition of Service Automation

To be able to describe the automation of service, we must first define what we mean by *service*. While it is obvious that in the context of this Handbook we are not talking about public religious worship or the act of putting a ball into play in a tennis match, the wide application of the word *service* still requires a stricter definition.

Service in general is an act of helpful activity, but in the context of this chapter we shall restrict ourselves to considering the provision of the activities that industry requires. In particular, we want to address organized systems of apparatus, appliances, employees, etc. for providing supportive activities to industrial operations.

In this narrower sense we will discuss how industrial service is automated. Other types of service automation are discussed in more detail in Chaps. 62, 65, 66, 68 and 71–74 of this Handbook.

33.2 Life Cycle of a Plant

Every physical object in use shows signs of wear once in operation. This is true for cars, airplanes, ships, computers, and combining many individual devices, for plants.

Operators of an industrial plant are well aware of this *natural* behavior of equipment and react accordingly to avoid deterioration of plant performance.

The value of the installation is decreasing, the reason for the depreciation, and there are different strategies for countermeasures.

Figure 33.1 shows an overview of the main strategies to extend the useful life cycle of an industrial plant.

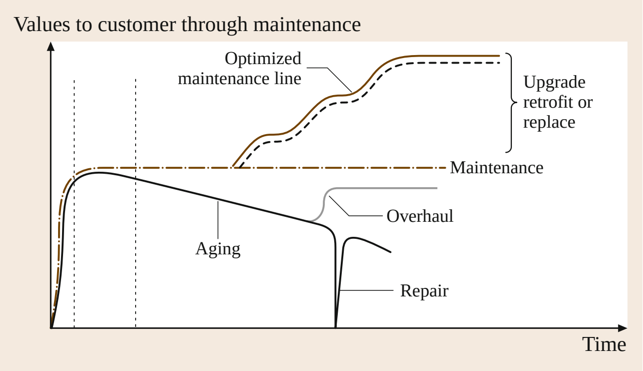

Fig. 33.1 Various approaches to maintenance during the lifecycle of an industrial plant [33.5]

Continuous maintenance is a way to keep performance at a high level, while overhaul is done at regular intervals and repair in case of need (see Chap. 42 on *Reliability, Maintenance and Safety*, and [33.1–4]). When retrofit and replacement is combined with a performance upgrade, the value of the plant can even be increased.

Performance of maintenance, overhaul, repair or upgrade has an associated cost and which strategy is most beneficial depends very much on the plant concerned. A car manufacturer with a robotized workflow and high production rate cannot afford the outage of a line due to a malfunctioning robot, and the cost of a standing line can easily be calculated. However, a factory in batch operation with long delays in production may be less sensitive to an outage.

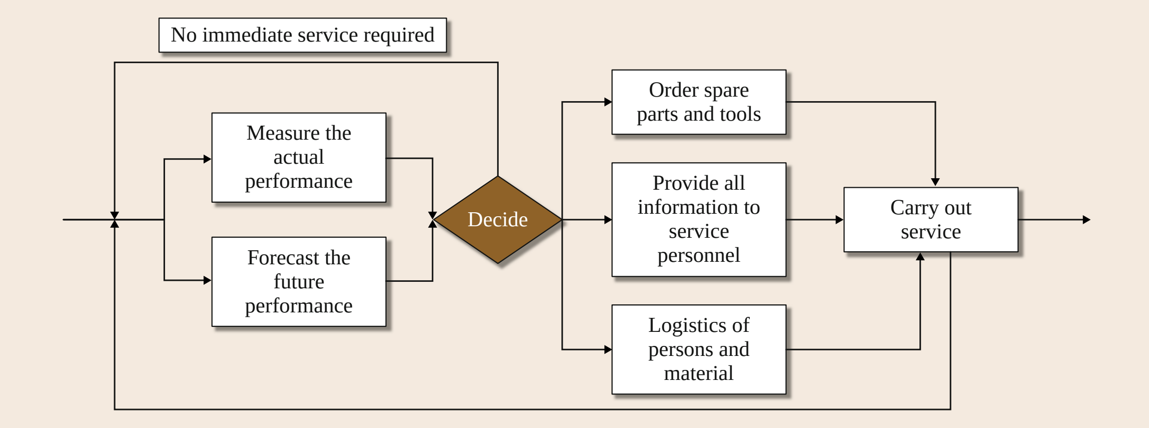
In any case the cost of service shall be as low as possible to provide a positive balance to the economic equation. Cost of service has three main elements: the parts that have to be replaced, the man-hours for performing the service, and last but not least, the cost of interrupted production, the latter being proportional to time of outage.

Thus time and cost efficiency are the critical factors of any service and are the main driving forces to automate the task to the highest possible extent. In this sense service is following the trend of implementing information technology (IT) to speed up and rationalize its performance, as is done in office work or production.

33.3 Key Tasks and Features of Industrial Service

Before we discuss the automation of industrial services, we must describe the aspects and tasks of industrial service in order to understand the different approaches to automation in this area. Service comes onto the stage after an industrial plant or subsystems of plants or even individual products in an industrial operation have been installed and placed into operation.

For the operator of an industrial plant, it is of utmost important that the equipment is available with optimum performance at any time that it is needed. For some systems in a plant this means 24 h a day and 365 days a year, whereas for others this may apply for only a few weeks spread over the year.



No immediate service required
Measure the actual performance
Forecast the future performance
Decide
Order spare parts and tools
Provide all information to service personnel
Logistics of persons and material
Carry out service

Fig. 33.2 Major steps in industrial service

Even though industrial plants prefer to have equipment that does not require any service, maintenance or repair, planned outage for overhaul is generally accepted and sometimes unavoidable. A large rotating kiln in a cement plant, for example, must usually be fitted with a new liner every year, stopping production for a short time. Mostly unacceptable, however, are unplanned outages due to malfunction of equipment.

The better prepared a supplier of this equipment is to react to these unplanned events, the more appreciated this service will be.

Taking this into account, industrial service must strive to:

- Keep equipment at maximum performance all the time
- Provide well-planned service at times of planned outage
- Restore optimum performance as quickly and effectively as possible after unplanned outages.

Figure 33.2 shows the major steps to be taken for any service action. As we can see in this figure, there is a layer of information gathering, analyzing, and exchange and a logistic element, including the physical transport. Both elements can be automated and it is obvious that the information-related aspect has attracted the highest degree of automation to date.

In a more detailed view, the following aspects have to be considered:

- The actual performance of the equipment must be known.
- A forecast of possible changes in the performance must be available.
- Detailed knowledge of the scheduled use of the equipment is necessary.
- Efficient, real-time communication about disturbances must exist.
- Optimum logistics must enable fast and effective service action.

In more technical terms, an optimum service is based on:

- Real-time performance monitoring of the equipment
- Knowledge-based extrapolation of future performance
- Knowledge about use of the equipment in the industrial environment

Fig. 33.5 Structured view of devices in a plant with some aspects related to them [33.7]

In order to keep a plant in optimum operation, all devices must work properly; this means that their performance must be monitored. This can be done by regular inspection by service personnel, or in an automated way, i. e., by equipping each device with adequate sensors [33.8–10].

In Chap. 20 the sensors suitable for the automation of the functions of a product are described in more detail. As an illustrative example of the automation of service, we have chosen a motor, which is a typical example in industry with motors accounting for more than 60% of the electrical energy consumed by industry.

Figure 33.4 shows a real-time measurement of five motors in a plant. Here the specific aspect of efficiency is displayed, composed from sensors that measure current, voltage, heat, and torque. Information of this type is a useful indicator of the motor's performance and, together with other motor data, for example, the vibration level and its frequency spectrum, can be used to judge whether intervention is required.

With an efficient data structure (Sect. 33.6) similar real-time performance can be displayed for all the devices in a plant, provided that they are equipped with suitable sensors. Figure 33.5 shows a display in which the operator can easily view relevant information from all aspects and systems in his plant. In this view, the functional structure of the plant is displayed and, for each physical object, a number of aspects, shown in the right menu, are listed. In this example, the plant operator can obtain information about the product data of the motor or energy losses.

All these data are valuable for the service task, based on which predictions about future performance of the parts can be made.

33.5 Analysis of Performance

An experienced plant operator or service engineer can use device performance information measured in real time to determine further actions. Modern IT systems support this task. The various data are analyzed and knowledge-based systems propose further actions, which may for example include the replacement of a component, a scheduled service within a certain interval or some other preventive intervention. When more background knowledge is considered in the programming, these systems can also include the financial and environmental consequences of a replacement, as shown in Fig. 33.6.

The example given in Fig. 33.6 also shows that information from different functions, here engineering, service, and finances, are increasingly being combined to provide a consistent view of the whole industrial operation.

This accumulated knowledge and experience helps engineers to decide what equipment needs to be inspected and when, as well as to establish where failure would be least acceptable and cause the most problems. This makes it easier to see where effort has to be focused in order to maximize return. It facilitates the optimization of examination intervals whilst at the same time identifying equipment for which noninvasive examinations would be equally effective.

More innovative automation in this direction can be expected in the future.

Motor Data
Nominal Power 30 kW — Recommended: 18 kW incl. 10 % safety margin
Motor Voltage 400 V
Nominal Efficiency 96.0 %

Drive Data
Nominal Efficiency 97.0 % — Recommended: ACS 401-0030-3

Economic Data
Currency Unit EUR
Energy Price 0.05 EUR/kWh
Investment Cost 5,000 EUR
Interest Rate 10%
Service Life 10 years

Results
Annual Energy Saving 55,918 kWh
Annual CO₂ Reduction 27,959 kg
CO₂ Emission Per Unit 0.5 kg/kWh
Annual Money Saving 2,796 EUR
Payback Period 1.8 years
Net Present Value 12,180 EUR
Profitability Index 2.4
Estimated Cut in Energy Costs: 44.0 %

Environmental evaluation
Country/Region electricity: Britain
Environmental evaluation: Global warming potential
Annual impact reduction 38369.52 kg CO2-equivalents
Service life impact reduction 383695.2 kg CO2-equivalents

Explanation environmental evaluation
Global warming potential: Estimated greenhouse effect in a 100 years perspective. GWP is based on the degree to which a mass unit of a specific substance can absorb infrared radiation relative to CO2. Some emissions can be converted into an equivalent quantity of CO2 that would cause an equal greenhouse effect.

33.6 Information Required for Effective and Efficient Service

The amount of data and background information that a service engineer requires to enable a fast reaction is enormous; the list below describes the major aspects:

- Location of the equipment and description of how to reach it, including local access procedures
- Technical data, including drawings and part lists
- Purpose of the equipment and expected performance
- Connection of equipment to other parts of the installation
- Security issues in handling the equipment
- Historical data for the equipment, including previous service actions

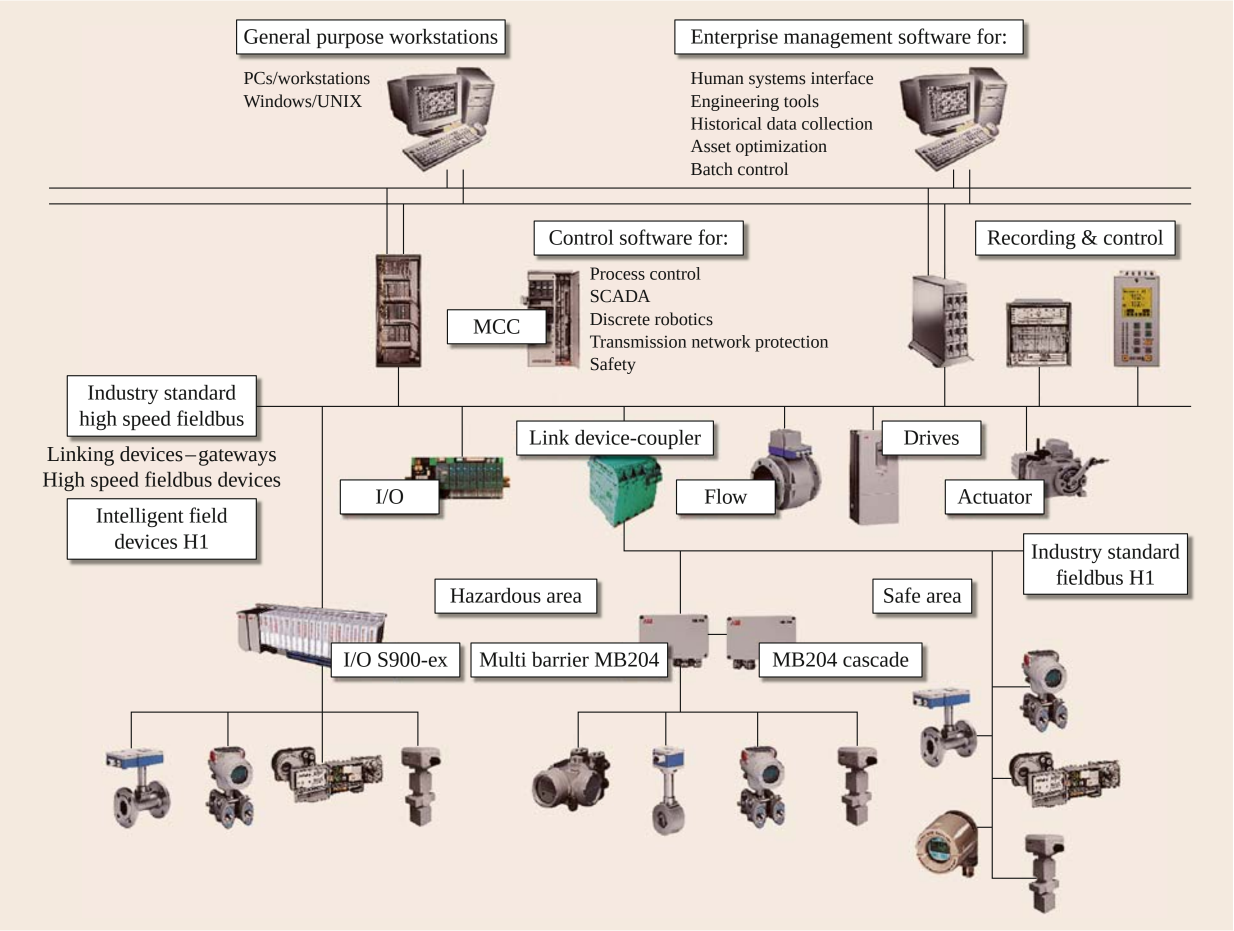

Fig. 33.9 Architecture of a plant with control and information flow down to the field device level [33.13] (MCC: motor control center; I/O: input/output; SCADA: supervisory control and data acquisition)

- Failure reports
- Proposed service actions
- Detailed advice of how to carry out these actions, including required tools
- Information about spare parts, and their availability and location
- Information about urgency and time constraints
- Data for administrative procedures.

Most of this information can be supplied automatically to service personnel if it is available in a form that allows digital data transfer.

This availability is the major bottleneck for the automation of service. Drawings of equipment may be difficult to come by and/or the original supplier of this equipment may no longer be available.

Drawings, for example, may be available but not scanned, so that only physical copies can be used by service personnel.

Gradually, suppliers of industrial equipment are transferring their data to platforms allowing various forms of access, a trend already established for many consumer goods such as cars or washing machines, for example.

Figure 33.7 shows the example of a data set used in the service of transmission systems, where a failure in the grid has to be located and identified, and the service crew has to be sent to the correct location for repair. In this multilayer view, geographical data, taken from global position system (GPS) systems are combined with detailed technical information, failure reports, and historical aspects of the devices to be serviced.

The way in which these different data are stored and prepared for fast and easy retrieval is important for an efficient service. Figure 33.8 shows a multidimensional structure, in which, for each physical object of an installation – in this example a flow meter – a large number of views are available: so called aspects of the equipment. These aspects cover the items in the long list above.

The service engineer can either look at the aspects of interest by opening the corresponding view or can be supported by automated systems that collect and prepare the relevant data for the task.

Obviously, for full use to be made of the data, it is necessary that the data are available in the first place. Service automation yields the highest benefit when the automation architecture in the plant is adequate and communication capabilities and products for all asset-related information are possible.

Figure 33.9 shows an example of such an architecture that provides this information from the field instrument level to the highest control level of a plant. The data are recorded and analyzed in several distributed data management systems.

33.7 Logistics Support

Logistics is a support function whose objective is guaranteeing the availability of required hardware when service is performed. Such hardware is primarily spare parts, but also includes maintenance parts and tools [33.14–17]. The logistics function includes inventory management and warehousing (stocking), transportation planning and execution, including both transportation to the customer site (or site where service is performed), and the return of material (reverse logistics). The challenge of this function is to optimize the use of inventory and associated investment, while providing the service level required by service operations.

Automating the logistics support function is enabled through information technology, integrating: information about spare parts for products and systems through an online catalogue with inventory status, availability information through warehouse management systems (WMS) ordering, order status information through order managements systems (OMS) [33.18], and specific delivery and shipment status information through track-and-trace systems.

In the environment of a large corporation with many different products and systems serving a global market, it is possible to establish an integrated global logistics network enabling support of servicing all products and systems to all customers worldwide. Such a network could be organized as shown in Fig. 33.10. The product services center (PSC) is responsible for product support, and supply of spare parts (and other service related products). The DC (distribution center) represents

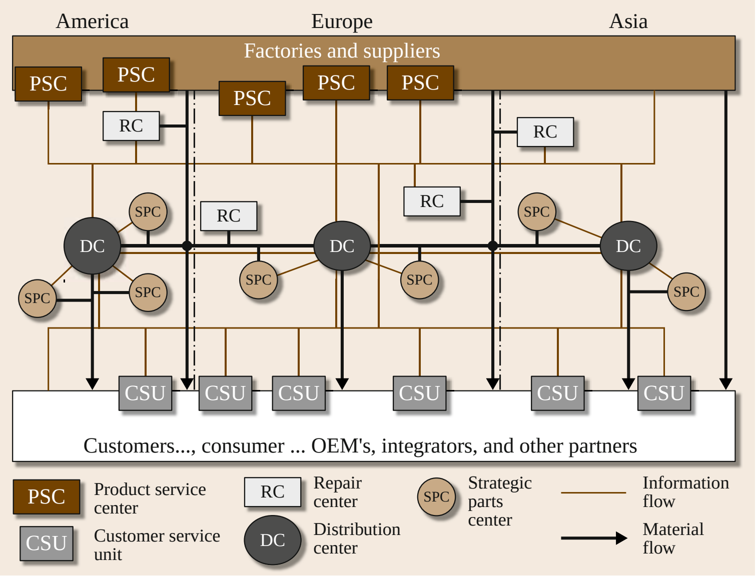

Fig. 33.10 A network to deliver fast and effective service to a widely distributed customer base. OEM, original equipment manufacturer

cost-based operations focused on distribution, providing logistics services to different units. The DCs provide all logistics services, including warehousing and shipping, and are strategically located. In an efficient network most spare part orders are directly shipped to end customers from the central DCs. The DC will handle delivery of parts in a specified time window depending on where the customer is located in relation to the DC.

Other approaches to efficient logistics may have critical parts stocked at a customer site, with all movements of parts tracked and automatic replenishment done based on parameter settings. When a part has to be removed, the integrated network will generate the replacement order automatically.

Customer support units (CSUs) are close to the sites at which service may be required. The CSU works with customers to ensure they have access to the right spare parts. Proactive support might enable customers to directly access the CSU to order parts online, for example, or ask for technical and order information.

The repair center (RC) is another important function in the service network. Customers are not only interested in replacement of faulty parts but could require repair or reconditioning as an alternative. The suppliers of this service are the RCs, providing the repair function itself, and the *reverse logistics*. Administration of product warranty often requires return of faulty parts, which is an element of the reverse logistics flow.

33.8 Remote Service

Remote service [33.19] is an umbrella term for a variety of technologies that have one concept in common: bringing the problem to the expert rather than bringing the expert to the problem.

Remote services use existing and cutting-edge technologies to support field engineers, irrespective of location, in ways only dreamt of as little as 5 years ago. The Internet, together with advances in communications and encryption techniques, has contributed enormously to this end. Remote service developments are a direct result of the changing needs of plant operators expecting more support at lower costs. Remote services are designed to maximize knowledge bases in the most cost-effective manner. The result ensures that the best knowledge is in the right place, at the right time. With a large number of different types of devices in a plant, this can be a complex undertaking.

Generally equipment (control systems, sensors, motors etc.) is accessible from a remote location primarily via the Internet or a telephone line. Several advantages are obvious:

- Support can be given in a shorter period of time.
- The right experts support the local service personnel.
- Cost may be reduced by avoiding travel.

One of many examples where remote service is introduced is robots. Robots play a crucial role in the high productivity and availability of a production line. Any problem or reduced performance of a robot has a direct negative influence on the output of the line. The operator's expectation is to avoid delays and disturbances during production.

Recently, Asea Brown Boveri (ABB) developed a communication module that can easily be plugged into the robot controller for both old and new robot generations [33.20]. This module reads the data from the controller and sends them directly to a remote service center, where the data are automatically analyzed. This is another example of the ever-growing application of machine-to-machine technology, which has now been applied to the world of robots. By accessing all relevant information on the conditions, the support expert can remotely identify the cause of a failure and provide fast support to the end user to restart the system. Many issues can hence be solved without a field intervention. In a case where a field intervention is necessary, the resolution at the site will be rapid and minimal, supported by the preceding remote diagnostics.

This automatic analysis not only provides an alert when a failure with the robot occurs but also predicts a difficulty that may present itself in the future. To achieve this, performance of the robot is regularly analyzed and the support team is automatically notified of any condition deviation.

The degree of automation of a remote service is again limited by the fact that personnel have to be present at the location where the service is required.

Even though the replacement of people by service robots is possible in principle, practical implementation of this approach is hardly feasible.

33.9 Tools for Service Personnel

The service task is, like almost all industrial operations, an administrative process with many steps that need to be organized, executed, and monitored. To support this administrative work, a number of software solutions are available on the market. These tools help to oversee and order the steps to be taken by analyzing the situation down to execution of the service on site.

Besides this administrative element of service there is another level of organization, which is more difficult to manage. When service personnel arrive at the location where the service is needed, they should already have all necessary information about the repair or maintenance. If this is not possible (because the automation level was too low) the information has to be collected on site – a costly and time-consuming process.

Devices with a data port and a self-analysis system can be connected and may help service personnel to find the optimum approach for the task. In connection to the back office, the service person is supplied with documentation such as handbooks, drawings, guidelines for maintenance etc. via various communication channels. While the availability of communication channels and portable devices to handle the data are not a major bottleneck today, the access to all the information, preferably in digital form, is the limiting factor.

To alleviate this, increasing amounts of data related to the specific device are stored together with the hardware, for example, in form of radiofrequency identification (RFID) [33.21, 22] or built-in direct Internet connection.

Future tools could integrate technologies of *augmented reality*. These tools combine the real picture of a device with displayed information about the object inspected. Looking at a valve in a plant, for example, the system would display the data of last inspection, the present performance status, analyzed by a background system, the scheduled maintenance interval, etc. Drawings of the part can be displayed and maintenance instructions can be given.

In a number of very specific applications such as surgery, the defense industry or aircraft, for example, head-up devices are in use. Due to the need for integrated data from many different sources in the service application, it will take some time until this technology will get wider use in service.

33.10 Emerging Trends: Towards a Fully Automated Service

While industrial service has various branches, from preventive maintenance to scheduled repair, we take emergency repair as an example to paint the future of service automation.

What is currently state of the art in many consumer products and some industrial devices will spread through the whole industry in the form of products and systems with self-monitoring capability and self-diagnostic features to detect a performance problem and analyze the probable cause.

These devices will be equipped with communication functions to report their status to a higher-level data management system, which will then automatically initiate the necessary steps: further analysis of the case and comparison with previous events, thereby implementing a knowledge-based repair strategy. It will collect the necessary documents for efficient repair according to the chosen strategy and provide these to the service personnel, who will have been alerted automatically. It will provide access information to the service staff and inform the personnel at the location about the details of the subsequent repair.

The system will furthermore automatically order the spare parts or any special tools needed for the service and initiate their delivery to the site.

Once the service personnel is on site the system will give automated advice related to the service and, if needed, connect to a back-up engineer who will have full access to all data and the actual situation on site.

In the far future robots installed or transported to the site of service may take over the manual work of service engineers: as a first step with direct remote control, but in the future as independent service robots.

While the automated functions can be carried out with almost no time delay, the transport of people and hardware required to execute the repair will be the time-limiting factor. In this regard improvements in warehousing and transportation logistics, for example, with the help of GPS systems, will drive future development.

Service automation is one of the fastest-growing disciplines in industry. Ideally, it makes utmost use of information and communication technology. It will however take some time for the valuable tools already installed in some parts of industry to penetrate fully into industrial service. Service automation requires close cooperation of many experts working in the areas of embedded systems, sensors, knowledge management, logistics, communication, data architecture, control systems, etc.

We can expect major steps in the future towards more effective and faster industrial service.

34. Integrated Human and Automation Systems

Dieter Spath, Martin Braun, Wilhelm Bauer

Over the last few decades, automation has developed into a central technological strategy. Automation technologies augment human life in many different fields. However, after having an unrealistic vision of fully automated production, we came to the realization that automation would never be able to replace man completely, but rather support him in his work. A contemporary model is the human-oriented design of an automated man–machine system. Here, the technology helps man to accomplish his tasks and enables him at the same time to expand his capacities.

In addition to traditional usage in industrial process automation nowadays automation technology supports man through the help of *smarter*, so to speak, better linked, efficient, miniaturized systems. In order to facilitate the interaction taking place between man and machine, functionality and usability are stressed.

In addition to basic knowledge, examples of use, and development prospects, this chapter will present strategies, procedures, methods, and rules regarding human-oriented and integrative design of automated man–machine systems.

Within the last decades automation has become a central technological strategy. Automation technologies have penetrated into several fields of application, for example, industrial production of goods, selling of tickets in the field of public transport, and light control in the domestic environment, where it has shaped our daily life and work situation.

Work automatons have liberated man from processing dangerous or inadequate work, on the one hand. Since automatons continue to accomplish more demanding functions, which had previously been accomplished by man himself, the meaning of human work is challenged, on the other. This question has already been elaborated on at the beginning of the endeavor of industrial automation. Nowadays we hardly discuss the necessity of the application of automated systems anymore. We rather discuss their human-oriented design.

Progress within the field of information technology is one reason for increased automation. A characteristic of modern automation technologies is the miniaturization of components and the decentralization of systems. In addition to applications of industrial process automation, which are strongly influenced by mechanical engineering, information and automation technology allows for the design of *smarter*, more efficient assisting systems – such as personal digital assisting systems or ambient intelligent systems – whose technical components the user often does not see anymore.

In the past, technical progress became a synonym for replacement of man by a technical system. When working systems were developed rationally, the role of human work and its contribution to the overall result often only found partial consideration.

Following the rationalization and automation of work with the aim of increasing production, we risk increasing dissolution of the relation between individual and work. However, we have to realize that the human contribution will always influence the performance and quality of any work system.

After visionary illusions of an entirely automated and deserted factory based on mass production, the notion that automation technologies could not entirely replace man became increasingly dominant. An increasing number of individualized products demand a high degree of production flexibility and dependability, a requirement that an entirely automated system cannot fulfill. These demands can be accomplished by hybrid automation, which appropriately integrates the specific strengths of man and technology.

The contemporary approach is the human-oriented design of a man–machine system. Instead of subordinating man to the technical-organizational conditions of any work process, this approach contributes to humane conditions, which helps man to accomplish his tasks and supports the expansion of his capacities. The special meaning of a human-oriented work environment results from the fact that man is the agent of his own manpower. Consequently, individual, work process, and work result are closely linked with each other. Only if the process of automation – in addition to every necessary rationalization – also serves the humanization of the working conditions can it fulfill functional and economical expectations.

The interaction of man and technology is the focus when developing a human-oriented automated man–machine system.

In order to apply human resources in an optimal way and to use them synergetically, we need an integrative approach for the development of a man–machine system.

According to an integrated procedure regarding the development of (partly) automated man–machine systems, the present chapter will first elaborate some basics and definitions (Sect. 34.1). In Sect. 34.2 we present practical knowledge of the technology of automation regarding its usage in different life circumstances and fields of work and establish the relation between automation and man.

In Sect. 34.3 we present successful rules of development and processes of automated systems. The presentation will end with an outlook of future development and its implication for man (Sect. 34.4).

The main focus will be on the interaction of man and technology. Specific methods and instruments for the development of technical and technological aspects of automated work systems will be presented in this Handbook in the corresponding chapters.

34.1 Basics and Definitions

The development of an automated man–machine system demands relevant basic knowledge as well as well-chosen definitions of some individual terms.

34.1.1 Work Design

The goal of work design is adjustment of work and man so that functional organization with regard to human effectiveness and needs can be realized. Thus, the goal is to achieve good interaction between the working man, the technical object, and the work tools (see Sect. 34.1.8). Goals of the work design are:

- *Humanization*, which means human-friendly design of a work system regarding its demands and effects on the working human being.

- *Rationalization*, which means the increase of effectiveness or efficiency of the human or technical work in relation to the work product, for example, the amount, quality, dependability, and security, or avoiding of failure. The goal is to gain the same effect with less means, or a better effect with the same means.
- *Cost effectiveness*, expressing the relation between cost and gain; it will be codetermined by the two other target areas.

The work design encompasses ergonomic, organizational, and technical conditions of work systems and work processes in order to achieve the main design requirements.

Ergonomic Work Design

The object of ergonomic design is adjustment of work to the characteristics and capacities of man [34.1]. With the help of human-oriented design of the workplace and working conditions we want to achieve the following for the worker to enable productive and efficient working processes:

- Harmless, accomplishable, tolerable, and undisturbed working conditions
- Standards of social adequacy according to work content, work task, work environment as well as salary and cooperation
- Capacities in order to fulfill learning tasks that can support and develop the worker's personality [34.2].

The basis of ergonomic design of the workplace is the *anthropometry*, which defines the doctrine of dimensions, proportions, and measurements in relation to the human body. The goal of the anthropometrical design of the workplace is the adjustment of the workplace according to human dimensions. This can be realized by including spatial dimensions and functions of the human body (Sect. 34.3.4).

This physiological design of the workplace takes into consideration human factors engineering as well as the work plan and work process, which are adapted to the physiological demand of the worker (Sect. 34.1.8).

Software usability engineering aims for optimization of the various elements of the man–machine interface and communication between man and machine. The term *usability engineering* implies the development, analyses, and evaluation of information systems, so that man with his demands and capacities is the center of interest. The adjustment of software–technical application and user is supposed to increase productivity, flexibility, and quality within the work system.

Usability aims at the optimization of the different procedures, which enables the user to accomplish a certain task with the help of a technical product. The main goals are: easy handling, learning ability, and optimal usage. Usability is not only a characteristic of a product, but rather an attribute of the interaction between a group of users and a product within a certain context [34.3].

Organizational Work Design

Organizational work design aims at the coordination of division of labor, meaning the appropriate segmentation of a task into subtasks and their goal-oriented adjustment. Organizational work can pursue different goals, for example:

- Addressing economic problems (deficient flexibility, poor capacity utilization, inappropriate quality)
- Addressing personal problems (for example, dissatisfaction, high fluctuation)
- Reshaping of the technical system.

Regarding the notion of humanization, organizational development contributes to good matching of work content and conditions to the capacities and interests of each individual worker [34.4].

From an economical point of view, organizational development aims for efficient application of scant resources, so that the final goal can be achieved. When competing for scant resources, the form of organization that provides smooth handling of the division of labor prevails.

34.1.2 Technical and Technological Work Design

The *technological design* of a work system is based on the selection of a certain class of technologies. It refers to the work procedure, that is to say, the basic decision of how to achieve a change of the work object [34.5]. From a technological point of view we have to increase the reliability and efficiency of the work system. The tasks of the technological work design are the constructive design of the technical tangible means (for example, equipment and facility) and the design of the man–machine interface (see Sect. 34.1.3).

Further technical development will modify the technological work design. The *technical work design* will define the functional separation of man and technical

Table 34.1 Level of technologies and functional division between man and technical system [34.5]

Technical level	Energy supply	Process control
Manual realization	Man	Man
Mechanical realization	Technical system	Man
Automated realization	Technical system	Technical system

tangible means, as shown in the level of technology of the particular work system [34.1]. Table 34.1 presents schematically the relation between the different levels of technology and the functional separation between man and technical system.

34.1.3 Work System

We understand human work within the realm of a work system, in which the worker functions with a goal in mind. A work system consists of the three elements: *man*, *technical tangible means* (for example, machines), and the *environment*, and is characterized by a task. Tasks are understood as either a change in the configuration of the work object (for example, to process material, to change energy, to inform men) or in place (for example, transportation of goods, energy, information or men). These elements of the work system are all connected by the time of activity.

Man does not always have a direct influence on the work object; very often man exercises the influence indirectly through a means he uses at work, such as a tool, machine, vehicle, and computer. The influence of man on the object is then characterized by the mechanization of this applied means [34.6].

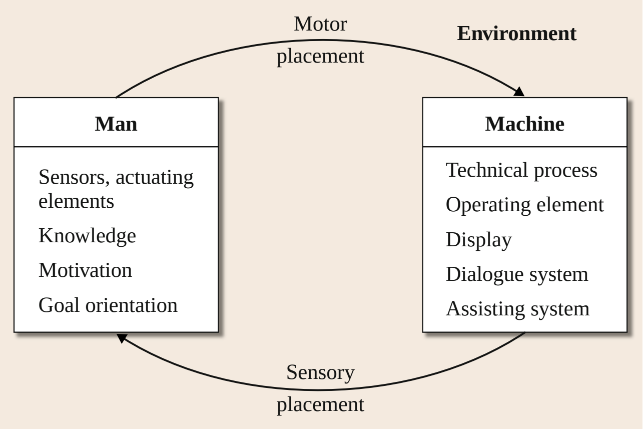

Fig. 34.1 General structure of a man–machine system

34.1.4 Man–Machine System

A man–machine system (MMS) is one specific form of a work system. It is understood as a functional abstraction when analyzing, designing, and evaluating the many forms of goal-oriented exchange of information between man and the technical system in order to fulfill the work task. All man–machine systems comprise man, interface, and the according technical system. The term *machine* is used for all technical shapes. Important components of a machine are display and control units, automated subunits, and computerized assistant systems [34.7].

Processes of human or physical-technical data processing characterize the conduct of a man–machine system. The general structure of a MMS (Fig. 34.1) is a feedback control system, where man, according to his goal, the information he has received, and the work task, decides and, thus, exercises control of the technical system.

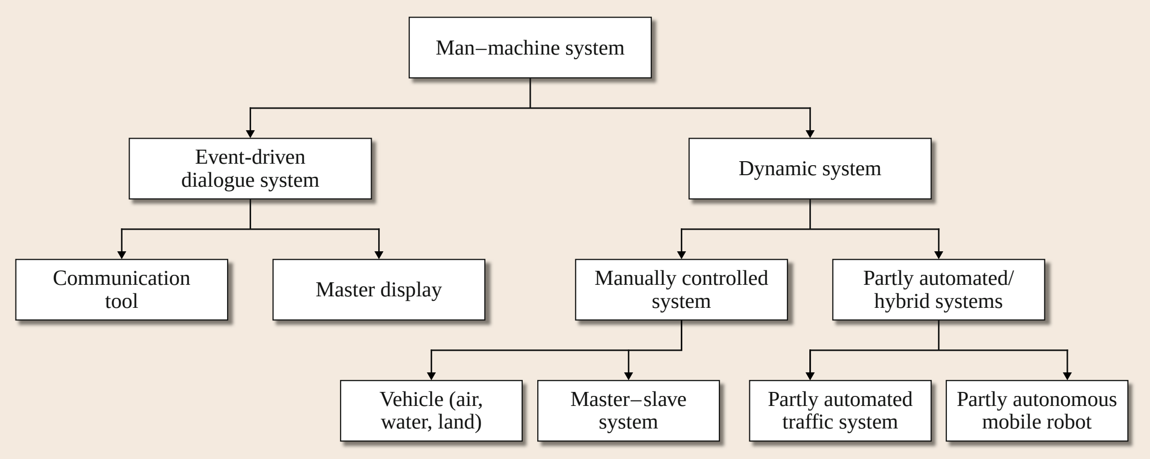
We can differentiate between man–machine-systems that show goal-oriented dialog systems and dynamic systems. Further subcategorizations are shown in Fig. 34.2.

The spectrum of goal-oriented dialog systems comprises end devices belonging to information technology, mobile communication technology, consumer electronics, medical technology, domestic appliance technology, service automatons (Fig. 34.3), and process control workstations.

Dialogue systems are interactive, goal-oriented systems from information technology, which react on external input.

Dynamic systems are characterized by a continuously changeable variable. The condition of a manual control system is called *man in the loop*, while the condition of an automated control system is called *man out of the loop*.

We find manual control systems in all kinds of vehicles, on the water, in the air, and on the ground. Man has the following tasks in a manually control system [34.8]:



Man–machine system
Event-driven dialogue system
Dynamic system
Communication tool
Master display
Manually controlled system
Partly automated/ hybrid systems
Vehicle (air, water, land)
Master–slave system
Partly automated traffic system
Partly autonomous mobile robot

Fig. 34.2 Types of man–machine systems [34.8]

- *Communication:* Creation of communication interfaces as well as sending and reception of information
- *Scanning and evaluation of the situation:* Scanning of state variables of the system and the environment, directly via the natural senses or indirectly via technical sensors and displays
- *Planning:* Determination of distance from start to destination
- *Navigation:* Compliance with the planned distance and estimation
- *Stabilization:* Maintenance of necessary positions (for example, machine direction control on the street)
- *System management:* Utilization and supply of subsystems as well as error diagnosis and elimination.

Fig. 34.3 Ticket machine as an event-driven dialogue system

Another application range with manual control is the master–slave system used for telepresence, i. e., the enhancement of man's sensorial and manipulation capacities in order to work further away. The teleoperator benefits from sensors, actuating elements, and multimodal channels of communication to and from the human user. This creates a telepresence from a teleworkplace for the operation in a nonadmissible physical environment – for example, over large distances or in microworlds [34.9].

We sometimes find automatic regulation of state variables (Sect. 34.1.5) in *partly automated systems*. During automated processing, the worker is placed outside of the closed loop, but nevertheless supervises the automated process and handles disturbances.

Hybrid systems characterize a simultaneous situation- and function-oriented combination of manual or automated processing of the task within a collective work system. Due to flexible adaptation of the degree of automation, we aim for optimal usage of the specific and supplementary capacities or characteristics of man and machine [34.10].

Planes and cars are representatives of partly automated systems. As we do not want to rely solely on automaton when using *partly automated transportation systems*, a human observer is assigned to the system. In this way intervention is guaranteed in case of breakdown.

Another category of man–machine systems is partly automated robots. Here, the human being undertakes mission management by transmitting goals to a removed, partly automated robot, controls its actions, and compensates for its errors. The user retrieves information from the system, for example, information about the which tasks to accomplish, difficulties, the robot, and the distant application environment.

34.1.5 Man–Machine Interaction

The interaction between man and machine deals with the user-friendly design of interactive systems and their man–machine interface in general. Man interacts with the technical system (Sect. 34.1.3) via the man–machine interface.

Usability is an essential criterion for the man–machine interaction. The design of a man–machine interaction takes account of aspects of usability engineering, context analyses, and information design [34.11]. To provide the user with programs, which the untrained worker is able to learn quickly and the professional can use in a productive and accurate way, is the goal of software ergonomic technologies.

Computer-based word-processing systems are a good example of a man–machine interaction. In the past, computer systems often used text-based man–machine interfaces. In the meantime, the graphical desktop has become the main interface; even language and gesture identification are becoming increasingly important.

34.1.6 Automation

To assign functions to a machine, which once were accomplished by man, is the goal of automation. The degree of automation is determined by how many subfunctions are done by man or by the machine. Automation is also characterized by process control, which beyond mechanization is also a result of the technical system [34.12]. Depending on the complexity of the control tasks, we differentiate between complete and semiautomatic functions:

- *A complete automated system* of a machine does not need any human support. The machine completely relieves man from work. Complete automation is appropriate or functional when the worker cannot complete his work precisely enough, when he is not able to complete it at all, or when the working task, for example, is too dangerous for him.
- *Semiautomation* is a work characteristic of a machine that only needs some degree of support from man. In contrast to a completely automated system, semiautomation does not achieve complete relief from work for the worker. The control of the individual functions is usually achieved by the technical system. Program control, which means the start, end, and succession of the individual functions, is accomplished by man.

Numerical controlled machines can switch between semi- and complete automation while working. Solutions for automated systems have to correspond to human and economical criteria. Automated workplaces can lead to work relief and decrease of physical strain due to the elimination or limitation of certain situations and their necessary adaptations. Automation can free the worker from hazardous work tasks, which could influence his health. Good examples for this case are automatic handling machines. In relation to humanization, the following criteria promote automation:

- Abolition of monotone work
- Abolition of difficult physical strain due to unfavorable body position and exertion, for example, lifting heavy parts
- Abolition of unfavorable environmental impact, for example, provoked by heat, dirt, and noise
- Reduction of risk of accident [34.4].

The design of complete work tasks creates better work conditions. To reach this goal we need qualitative job enrichment based on new combinations of work tasks as well as the realization of new work functions.

Problem shifting can occur as well. Automation changes the job requirement in terms of attention, concentration, reaction rate and reliability, combination capacity, and distinct optical and acoustical perceptual capacity [34.13].

Due to the combination of manual and automated functions, we aim for adequate and practical application of specific human/engine capacity resources in hybrid systems [34.14].

34.1.7 Automation Technology

Automation technology refers to the use of strategies, methods, and appliances (hardware and software), which are able to fulfill predetermined goals mostly automatically and without constant human interference [34.15]. Automation technology addresses the conceptualization and development of automatons or other automatically elapsing and technical processes in the following areas:

- Engine construction, automotive engineering, air and space technology, robotics

- Automation of factories and buildings
- Computer process control of chemical and procedural machines
- Traffic control.

Process automation (during continuous processes such as power generation) and *production automation* (for discrete processes such as assembly of machines or controlling of machine tools) are main application areas in the field of automation technology.

34.1.8 Assisting Systems

Assisting systems are components of man–machine communication (Sect. 34.3.4). Assisting systems do not substitute a human being, but support him occasionally while accomplishing tasks that overburden or do not challenge him enough. An assisting system should:

- Reduce the subjectively felt complexity of a technical system
- Facilitate the spontaneous use of a technical system
- Enable fast learning of the functions or handling of the system
- Make the use of the system more reliable and secure.

Assistance creates a connection between the demands, capabilities, and capacities of the user on the one hand, and the functions of the interactive system on the other. The following assisting functions seem relevant [34.16]:

- Motivation, activation, and goal orientation (i. e., activation, orientation, and warning assistance)
- Information reception, and perception of signals of interactive systems and of environmental information (i. e., display, amplifier, and repetition assistance)
- Information integration and production of situational consciousness (i. e., presentation, translation, and explanation assistance)
- Decisiveness to take action, to decide and choose a course of action (i. e., offer, filter, proposition, and acceptance assistance; informative and silent construction assistance)
- To take action or carry out an operation (i. e., power and limit assistance; input assistance)
- Processing of system feedback or of a situation (i. e., feedback assistance).

As an example, we use assisting systems through personal computer (PC) software, automatic copilots in planes and vehicles, in the form of personal digital assistants (PDAs), or as part of smart-home concepts.

Assisting systems can be differentiated according to their adaptation of different user profiles, tasks, and situational conditions [34.17]:

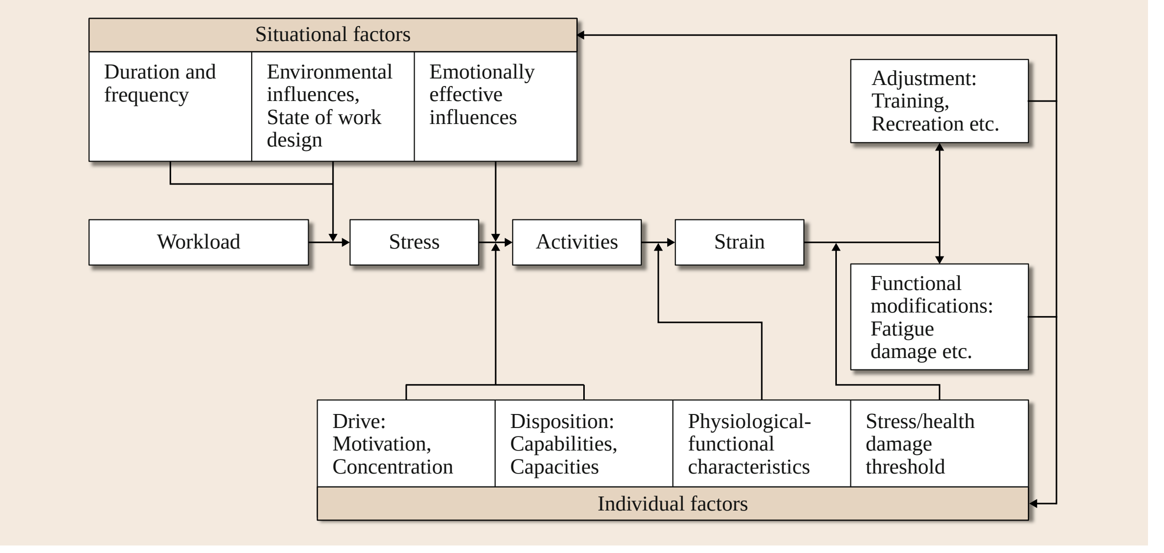
- *Constant assisting systems* always show the same conduct, independent of the operator or situation. Their advantage is consistency and transparency. However, these systems are inflexible; the provided support does not always suit the user nor the situation.
- *Assisting systems designed according to user specification* adjusted to the needs of certain users and their tasks in specific contexts. This kind of adjustment proves to be problematic when, for example, the context of usage changes.
- *Adaptable assisting systems* can be adjusted by the user to specific needs, tasks, and situations of use. The calibration of assisting systems occurs via selection or adjustment of parameters. The user takes the initiative to adjust the system.
- Changes of *adaptive assisting systems* do not occur on the basis of explicit guidelines given by the user, but through the system's evaluation of actual and saved context characteristics. Adaptive systems autonomously adjust assistance to the user, his preferences, and needs in certain situations.

34.1.9 The Working Man

The development and evaluation of human-oriented work (Sect. 34.1.1) requires knowledge about the human factors. Selected work-scientific concepts are described below.

Concept of Stress and Strain. All human requirements, which evolve from workplace, work object, work organization, and environmental influences, are part of the notion of *stress and strain*, which concept describes the defined reaction of the individual body to external stress (or workload). Individual capability is the factor connecting impact and stress [34.1]. The workload and individual capabilities are decisive for the strain factor.

The higher the impact of the workload, the more the worker has to use his individual capabilities in order to fulfill the task effectively. Figure 34.4 shows an ergonomic *stress–strain* model. This *stress–strain* concept has been primarily described for the field of physical labor, but can also be used when talking about psychological stress.



Situational factors
Duration and frequency
Environmental influences, State of work design
Emotionally effective influences
Adjustment: Training, Recreation etc.
Workload
Stress
Activities
Strain
Functional modifications: Fatigue damage etc.
Drive: Motivation, Concentration
Disposition: Capabilities, Capacities
Physiological-functional characteristics
Stress/health damage threshold
Individual factors

Fig. 34.4 Stress–strain model (according to [34.18])

Prerequisites for Performance. The entirety of information processing and energy transformation, which leads to the achievement of a goal, is defined as work performance. In order to be work efficient, we need human and objective prerequisites of performance (i. e., work organization and technical facilities). Human prerequisites for performance refer to capability and motivation (Fig. 34.5).

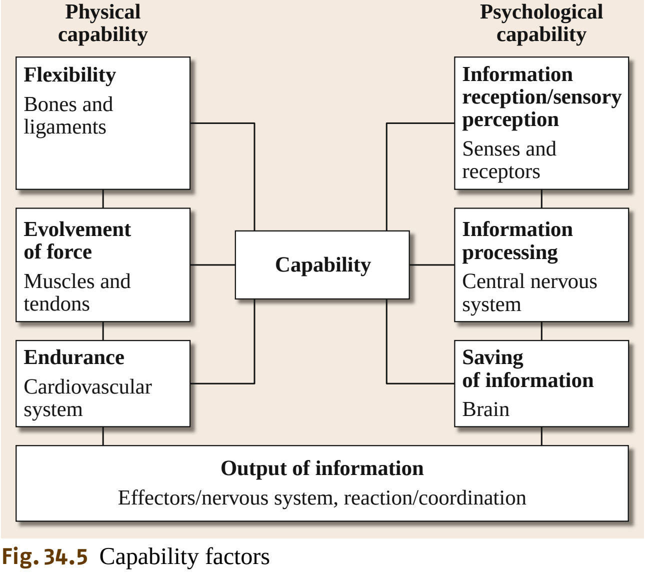


Fig. 34.5 Capability factors

The term *physical motivation* comprises the sum of all biological body activity. It is limited to physical aspects. Work performance is not a constant factor, but undergoes changes. In order to be efficient, physical performance requires several psychological performance prerequisites, such as motivation, willingness of effort, and cognitive understanding of the task. These factors are called psychological motivation.

Stress. *Task-related stress* results mainly from the comprehension and processing of information, the movement of the body, and the release of muscle power when using work equipment. Comprehension and processing of information occurs through sensor and discriminatory work. Perception stresses our visual, auditory, haptics/tactile, and proprioceptive sense organs. Discriminating work leads to stress, based on recognition and identification of signals. The intensity of stress, which results from the work function, depends on:

- The duration and frequency of the task
- The complexity of the task itself and of different work processes
- The dynamics of the processes that need to be controlled
- The expected precision of the accomplishment of the task
- The level of concentration required while working

- The specific characteristics of appearing signals
- Flexibility of comprehension of the information.

Stress that results from the *work environment* can result from a physical, chemical or social cause that may affect factors such as lighting, sound, climate, and mechanical vibration. Bodily stress can be provoked by manual handling of heavy loads or work equipment due to inappropriate body movement and enforced body position. Workplace conditions that demand a static body position are very stressful for the body as the circulation of blood is negatively affected.

Stress from *work organization* can result from regulation of the work schedule (for example, shift work), operating speed, the succession of tasks, inappropriate amounts of work during peak times, lack of influence on one's work, strict control, and uniform tasks. We also speak of stress when a task demands constant willingness of action, even though human interference is only necessary in exceptional cases [34.19].

The operation of *information* (for example, complex information or information deficits) can also provoke further situations of stress.

Strain. We differentiate between physical and psychological strain. Consequences of strain present themselves on a muscular–vegetative or cognitive–emotional level. Disturbances of the psychophysical balance are provoked by either excessive or unchallenging situations. Both of these situations imply that the individual prerequisite of performance does not correspond to the corresponding performance condition. In the case of an excessively challenging situation operational demands exceed the individual's capability and motivation. Unchallenging situations are characterized by the fact that individual capabilities and needs are not sufficiently taken into consideration. Both situations can lead to reversible disturbance of the individual performance prerequisite, such as tiredness, monotony, stress, and psychological saturation. On the level of performance, they can cause changes in work processing (e.g., output and quality). These disturbances can be eliminated by a change of physical and psychological performance functions, as well as by implementing phases of recovery time. Nevertheless, disaccord between strain and recovery can only be tolerated for a limited period of time [34.20].

34.2 Use of Automation Technology

Automation technology can be found in many fields at work as well as in public and private life. Examples of automation technologies are:

- Assembly automation (factory automation)
- Process automation in chemical and procedural facilities
- Automation of office work
- Building automation
- Traffic control
- Vehicle and aeronautical technology.

Increasing functional and economical demands as well as technical development will lead to ongoing automation of technical systems in many different walks of life and work – from the office to factory level. Regarding automation effort we can identify two developing trends [34.21]:

- Increase of *complexity* of automation solutions via enhancement and process-oriented integration of functionalities: linked and standardized control systems are increasingly replacing often proprietary isolated applications. The continuous automation of processes and work systems leads to an increase of effectiveness and quality as well as to a decrease of costs in industrial processes of value creation.
- The increasing effectiveness of automation and control techniques and miniaturization of components leads to decentralization of control systems and their integration on-site. Next to process automation, more and more often, we also find product automation.

Information technology, which continues to produce more powerful hardware components, is a driving force for this development. Selected areas of application, which are characterized by a high degree of interaction between man and technology, will be presented in the following sections. Partly automated systems and assisting systems will be one focus of the following elaboration.

34.2.1 Production Automation

Production automation is a discipline within the field of automation technology that aims at the automation of discontinuous processes (i. e., discrete parts manufacturing) using technical automatons. Production automation is engaged in the entirety of control, closed-loop control devices, and optimization equipment in the space of production facilities [34.22].

Through history, production automation shows several levels of development, starting with automation related to the working process and ending with complex assembly automation. In the early days of automation, extensive complete processing of specific work objects was the focus. This development started with numerically controlled (NC) machine tools, following by mechanical workstations, reaching the level of flexible processing systems.

Flexible production systems are based on the material and informational linking of automated machines. They are characterized by the integration of the functions of transportation, storing, handling, and operating, and comprise the following subsystems:

- Technical system
- Flow of material, maintenance, and disposal system
- Storage system and application system
- Information and energy system
- Equipment system, machine system, and inspection equipment system
- Maintenance system.

Flexible production systems are designed for an assortment of geometrical and technological work equipment. Due to the marginal effort required for their adjustment they can be fitted to changing production tasks as well as to fluctuating capacity loads. Control of the corresponding subsystems can be realized by a linked computer system, which takes into account machining situations, storage, and transport systems among others, and which receives requirements from a central processing control. The computer system controls usage of the appropriate machines, appropriation of the technical control programs, availability and progress controls, logging of production, and information from the maintenance service. An agent can influence the system in case of disturbance. Figure 34.6 summarizes the different levels of the respective machines up to the flexible production system.

A main technical component of production automation is the industrial robot. An industrial robot is a universally usable automaton with at least three axes, which have claws or tools, and whose movements are programmable without mechanical interaction. The main application areas of industrial robots are welding, assembling, and handling of tools.

The present level of development of production automation exhibits process-related integration of computer-based construction (computer-aided design, CAD) and production (computer-aided manufacturing, CAM). Process-oriented CAD/CAM solutions result in a continuous information processing system during the preparation and execution of production, in

which data is produced and managed automatically and is circulated to other fields of operation (for example, systems of merchandise management). During the complex and continuous process of automation, development and production as well as the corresponding business fields are informationally and materially linked with each other. Continuous solutions are the basis of an automated plant, which at first only captures selected production areas, but then entire companies [34.23].

An extreme degree of automation is not always the perfect solution for manufacturing technology. If fewer pieces and complex tasks determine the production, the usage of less automated systems is a better solution [34.24]. Robots reach their limit if the execution of the task demands a high degree of perception, skill, or decisiveness, which cannot be realized in a robust or cost-effective way.

Unpredictable production range and volume as well as higher costs and quality demands increase the area of conflict between flexibility and automation in the production. Due to progress in the field of man–machine interaction and robotics, the field of hybrid systems has become established, in which mobile or stationary assisting robots represent the most economical form of production [34.25]. Assisting robots support flexible manual positions by accomplishing tasks together with the human being.

Man's sensory capabilities, knowledge, and skill are thus combined with the advantages of a robot (e.g., power, endurance, speed, and preciseness). Assisting robots can now not only handle special tasks, but also cover a broad spectrum of assistance of widely different tasks. Figure 34.7 shows an exemplary utilization of an assisting robot while assembling.

An assisting robot can either be installed stationary at the workplace or used in a mobile way at different locations. In both cases the movement and workplace of man and robot overlap. In order to make it possible for man and robot to cooperate efficiently in complex situations, it is necessary that the robot system has a sensory survey of the environment and an understanding of the job definition.

34.2.2 Process Automation

Chemical and procedural industries use automation, first and foremost, for monitoring and control of autonomous processes. This can usually be realized by the application of process computers, which are directly connected to the technical process. They collect situational data, analyze errors, and control and optimize the process.

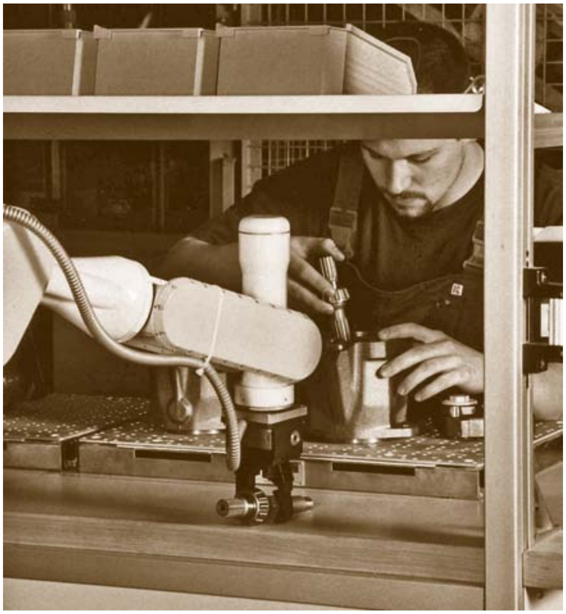

Fig. 34.7 Hybrid system during assembly (photo was taken with permission of Fraunhofer IPA)

Interaction of man and technology is limited to man–machine communication when using process computers and control equipment. Section 34.3.4 will elaborate on these aspects in more detail.

34.2.3 Automation of Office Work

In this regard, we can differentiate between *informational* and *manual office work*. Manual office work can especially be found in the infrastructure sector. The use of decentralized computer technologies close to the workplace accelerates the automation of algorithmic office work with manual and informational character.

Automation of office processes aims to increase work efficiency. Some business processes can only be realized by use of technology. The comprehensive information offered by the Internet is, for example, only usable by computer-based search algorithms.

Workflow systems are important for the automation of *infrastructural office* work. They use optimized structures of organization for the automation of work processes. They influence the work process of each individual worker [34.26] by allocating individual procedure steps and forwarding them after processing.

Workflow systems support among others the following functions:

- Classification, excavation, and removal of information carriers in an archive
- Physical transport of information carriers
- Recognition of documents and transmission to the appropriate agent
- Connecting of incoming documents with previous information (for example, an incoming document will be connected with previously saved data about the client)
- Deadline monitoring and resubmission, capacity exchange in case of employer absence (for example, forwarding systems)
- Updating of data in the course of the process of individual processing steps (e.g., verification of the inventory when sending out orders).

Moreover, the use of automated work tools in the form of copy technology, microfilm technology, word-processing systems, and information transfer technology contributes to an increase of efficiency in the field of office work.

A characteristic of *informational office work* is tight connection of creative and processing work phases. The human being creates ideas, processes the task, and evaluates the results of the work. As organizational task are algorithmatized and delegated to the computer, the machine can support the working man [34.27]. Man has the possibility to intervene in the process by correcting, modifying, evaluating, and controlling it. Computer-based work connects the advantages of a computer, for example, high-speed operations and manipulation of extended data, with man's decision-making ability in an optimal way. Computer-based work does not eliminate man's creativity, but rather reinforces them. New solutions will also be bound to man's creativity.

34.2.4 Building Automation

The term *building automation* defines the entirety of monitoring, control, and optimization systems in buildings. It is part of technical facility management. This includes the integration of building-specific processes, functions, and components in the fields of heating, ventilation, climate, lighting, security, or accession control. The continuous cross-linking of all components and functions in the building as well as their decentralized control are the characteristics of building automation [34.28].

Building automation aims to reduce costs of buildings via a methodological approach to planning, design, construction, and operation. For this, operational sequences are conducted in an independent way or simplified in their handling or controlling. Functions can, for example, be aligned according to changing operating conditions (season, time of day, weather, etc.) and activities can be combined into scenarios.

Due to construction automation the technical and organizational degree of complexity increases as well as the demand according to a functional integration. Here, we have to differentiate between the demands and needs of different user groups (i. e., users, operators, and service staff):

- *User*: Functions of the MMS have to be reduced to a necessary minimum. They have to be intuitively comprehensible and easily manageable. Interference in operation has to be possible at any time (with the exception of safety functions).
- *Operator*: MMS has to provide optimal support for maintenance and support as well as optimizing operation of the construction technology. Depending on the object's size and complexity, this can comprise a spectrum of simple fault indication up to teleguided control systems.
- *Service staff:* Operating functions, which are unnecessary in a common process, have to be available exclusively to service staff.

34.2.5 Traffic Control

Traffic control means active control of the flow of traffic by traffic management systems. Traffic telemetry is a main application of traffic management systems, comprising all electronic control and assisting systems that coordinate the flow of traffic automatically and support driver routing [34.29]. Traffic telemetry has the following goals [34.30]:

- Increase of efficiency of existing traffic infrastructure for a high volume of traffic
- Avoidance of traffic jams as well as of empty cars and *look-around* drives
- Combination of advantages of the individual carriers (that is to say, railway, street, water, air) and integration into one general concept
- Increase of traffic safety: decrease of accidents and traffic jams
- Decrease of environmental burden due to traffic control

Traffic control depends on the availability of appropriate traffic data, which is collected by optical or inductive methods, amongst others. The collected data is processed in a primary traffic control unit and transformed into traffic information, on the basis of which traffic scenarios can be developed and traffic streams can be processed. Manipulation of traffic streams occurs, for example, through warning notices, speed limitations, or rerouting recommendations.

Information on the infrastructure is carried out from vehicle to driver through intercommunication signs, light signals, navigation systems or radio.

Satellite-navigation systems are widely used in vehicles; they carry out supported route calculation and vehicle-specific traffic control or goal orientation. Telemetric systems are also used for mileage measurement in regard to road charging.

Traffic telemetry appliances can avoid or lessen disturbances and optimize traffic flow in a timely, geographical, and modal way [34.31]. Even though traffic telemetry systems have great potential to ameliorate the entire traffic situation, their usage is still limited. One reason is the insufficient quality of collected data regarding traffic and street status for traffic control. Another reason is that the possibility of intervention in daily traffic is limited.

In the future, oriented adaptive traffic control systems will have to be able to dynamically link individual and public vehicles as well as traffic data. In addition to stationary detectors, vehicle-generated traffic announcements are also included in the area-wide extension of databases regarding traffic situation and traffic prognosis. Mobil communication systems contribute to the exchange of information between vehicle and infrastructure.

34.2.6 Vehicle Automation

Automated systems are used in road vehicles and air transportation. They support and control the driver or pilot in his task.

Assisting systems in a car stabilize the vehicle (for example, antiblock system, stability programs, brake assistant, and emergency brake) and help the car to remain in lane, maintain the correct distance to the car in front, control lighting (for example, through an adaptive lighting system), assist in routing (for example, navigation systems and destination guides), as well as accomplish driving maneuvers and parking [34.32].

Moreover, assisting systems facilitate the usage of numerous comfort, communication, and entertainment functions in the vehicle. Figure 34.8 presents an overview of assisting systems in a car. Assisting systems, which are only barely noticed, are for example, a radio that automatically regulates the volume according to the surrounding noise, a display that optimizes its brightness according to the external light level, and automatic windscreen wipers that regulate their cleaning intervals according to the force of rain. Nowadays we combine several assisting functions into adaptive driver assisting systems [34.33].

In order to support steering, numerous development ideas have been discussed. The final goal is to create a system that supports steering in order to stay in lane and maintain the distance to the preceding cars [34.34]. In this regard, a video camera records the forward lane structure. With the help of some dynamic driving factors and evaluation of the captured images, the system can determine the current position of the vehicle relative to the lane markings. If the vehicle diverges from the required lane, the driver will feel small but continuous correcting forces through the steering wheel. Using the same technology we can also produce an alert in case of strong divergence from the road, using a synthetically generated noise or vibration feeling. These stimuli reduce the possibility of unintended divergence from the road and increase the likelihood that an error will be noticed and corrected early enough.

Another system that helps lane control and maintenance of the correct distance to preceding cars is called the *electronic drawbar*. This is a nontactile coupling be-

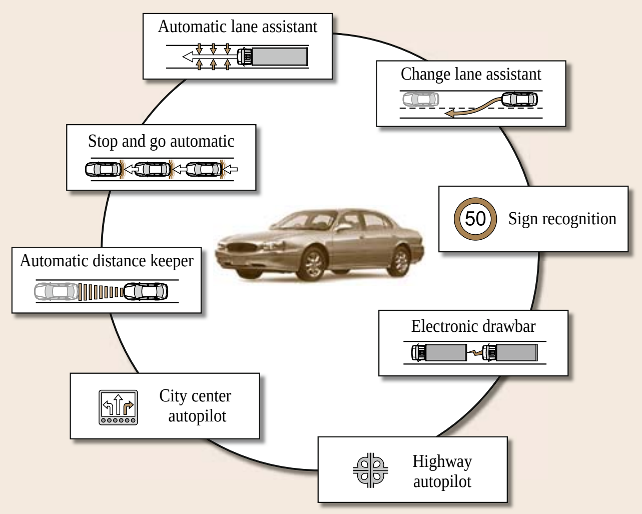

Fig. 34.8 Overview of an assistance system in a car

tween (usually commercial) vehicles based on sensors and computer technology. The following vehicles follow the leading vehicle automatically, as if they were connected to the preceding vehicle with a drawbar. The *electronic drawbar* should make it possible for just one driver to lead and control a line of cars following each other, all within a short distance. Due to the resulting low aerodynamic residence, gas consumption should be decreased.

Figure 34.9 shows a prototype adaptive, multifunctional driver-assistance system in a car.

Advising navigation systems that react to the current traffic situation are in serial production and show increasingly better results. Integrated diagnosis systems refer to disturbances and maintenance intervals. Table 34.2 presents the assisting functions according to the realized assistant type. Moreover, this

Table 34.2 Assisting systems in cars [34.8]

Modality/ assistance type	**Visual**	**Acoustic**	**Haptic**	**Without information**
Intervention			Antiblock system (ABS), servotronics, reflex control, collision assistant	Crash prevention, belt pretensioner, seat conditioning, sunroof
Command		Lane control, problem report, navigation order	Lane control, distance keeping, intersection assistant, curve assistant	
Consultation	Navigation systems, traffic jam alarm			
Information	Diagnoses systems			

Table 34.3 Assisting systems in aircrafts [34.8]

Modality/ assisting type	Visual	Acoustic	Haptic
Intervention			Maneuver delimiter, quickening
Command		Ground proximity warning system (GPWS)	Flight vector display, stick-shaker, callouts
Consultation	Flight management system (FMS), electronically centralized aircraft monitoring system (ECAM)		
Information	Navigation databank, plane state variables and maneuver borders		

table shows which dialog system addresses with sense modality.

The idea of the self-controlling vehicle has been abandoned. Although technical control systems are generally available, public opinion has determined that the driver is responsible for driving and not the lane control or tailgate protection system. Possible legal consequences in the case of failure of the technology are difficult to assess.

The application area of *aviation* is traditionally characterized by progressive technologies. As a result, many assisting systems exist in the field. Table 34.3 presents an assistant type and the used modality for some assisting functions in a plane.

On the level of plane stabilization, we find intervening systems, including maneuver delimiter and commanding systems such as light vector displays, a stick-shaker, and callouts. Steering is supported by collision-prevention commands and ground-proximity warnings.

For the planning of the flight path, the flight management system is supported by an informational system that leads the pilot from the start to the destination via previously entered travel points. The electronically centralized aircraft monitoring (ECAM) system is a consultation system that supports the pilot actively when managing system resources and correcting errors. Error messages are determined by individual phases of the flight. Furthermore, a plan possesses dialog systems through which the pilot executes the flight path, the management of subsystems, and the management of errors. More assisting systems concern information exchange with air-traffic control, communication with the operating airline (company regulations), and execution of braking maneuvers on the runway (break-to-vacate).

34.3 Design Rules for Automation

The design of automated work systems are usually geared to systematic work design. It is subject to specific requirements and methods, which will be presented below.

34.3.1 Goal System for Work Design

The decision for a specific kind of design of a work system – including the option of automation – is mainly determined by the following three goals [34.35]:

1. *Functional goals:* Optimal accomplishment of functions (for example, dependability, endurance, precision, and reproduction). The limited capabilities of man regarding sensors (for example, no adequate receptors for voltage, operations being fast, objects being small) or motor functions (for example, regarding the height and endurance of body power) often demand the use of technologies. Man's broad capabilities and flexibility, which allows him to diverge, if necessary, from fixed algorithms and to react to changed situations, demand the inclusion of a human being [34.36].
2. *Human-oriented goals:* Goals that concern human health, as well as performance prerequisites (for example, work safety, level of task demands, and qualification).
3. *Economic goals:* Given function fulfillment with preferably low costs, or best function fulfillment with fixed costs.

It is not possible to derive a priority for a single design goal in the goal system, as usually one has to choose an optimum between opposing subgoals. In individual cases anthropocentric or technocentric approaches of design result from the emphasis of different goals. Here, we favor a anthropocentric (that is to say, human-oriented) approach to design.

34.3.2 Approach to the Development and Design of Automated Systems

Consideration of Life Cycles

The development of a man–machine system occurs based on a formalized plan. The development of a system is subdivided into individual phases (Fig. 34.10):

- The process of development and design begins with a *prerun phase*, during which a system concept is processed. This phase aims to identify the current problem, and to evaluate whether it is really necessary to build the intended system and where it should be used.

- During the *definition phase*, the system is deconstructed into subfunctions and subsystems. Specifications are developed, in which all characteristics and performance features as well as demands for man and technology have to be included. Performance is related to the system's different phases of use, e.g., operation and maintenance [34.37]. With regard to the predetermined aspects, the layout and evaluation of alternative solutions are developed for each subsystem.
- During the *development phase*, a detailed design of the subsystem's hardware and software is realized. The developed solutions are integrated into a complete functional system.
- The *acquisition phase* comprises production of the system's hard- and software, testing of the technical subsystem's functionality, integration of mechanical components, and production of user and maintenance instructions. Furthermore, staff will be included in this phase.
- During the *use phase*, usage of the system is realized. Operational experiences, which include a normal, disturbed, and maintained operation, form the basis for improvement, modernization, and redesign of similar systems.

A review at the end of each phase decides upon the start of the next phase, when the development project has achieved a definite level of maturity.

Design Projects

The following design projects are exercised for each phase of a man–machine system (Fig. 34.9)

- With the help of system analysis the general goals for the complete system are determined, then the problem is firmly established and detailed.
- Within the framework of the *function analysis*, the system functions necessary to achieve the predetermined goals are established. The analyses of individual functions and their allocation to the machine or to man is the task of the technological work design.
- The tasks for the human result from the assignment of functions. Through a *task analysis* we have to evaluate whether the function and its related task can generally be conducted by the available staff. A group of users has to be selected and trained.
- *Technical, organizational, and ergonomic work design* aims for optimal development of the system components and work conditions through alignment of the conditions to the user (Sect. 34.1.1).
- An evaluation helps to verify the efficiency of the enforced design measurements for the implemented system. In order to achieve system optimization, the design methods have to be adjusted in case of goal divergence.

Emphasis on Human-Oriented Design

Within the realm of the human-oriented design of a man–machine system, the functions and components with a high degree of interaction between men and machine [34.38] are the most important. When designing partly automated systems or assisting systems, the following tasks are mainly affected:

- Tasks for function division between man and machine as well as for structuring the task given to man (i. e., technical/technological or organizational work design)
- Tasks for optimization of integration of communication at the interface of man and machine (i. e., ergonomic design)

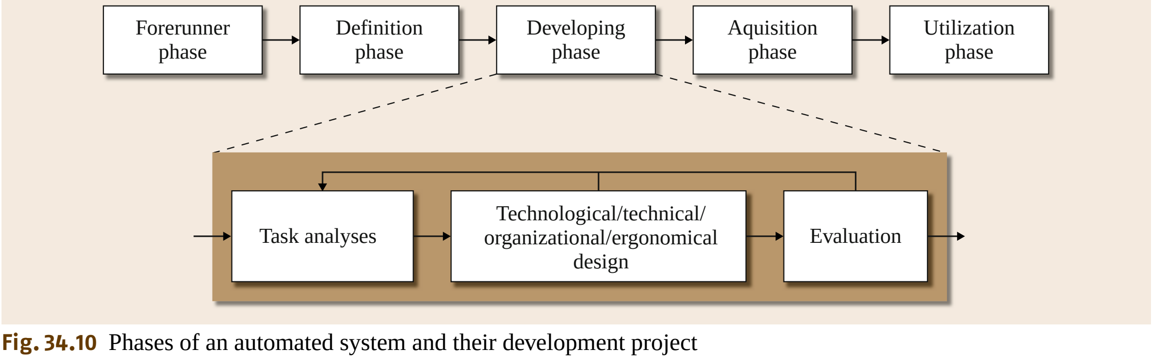

Fig. 34.10 Phases of an automated system and their development project

- Tasks to increase job or machine safety (i. e., technical design) by including hazardous factors of the work environment (e.g., noise, climate, vibrations).

Task-specific criteria and requirements of human-oriented work design as well as methodical approaches will be discussed in the following sections.

34.3.3 Function Division and Work Structuring

Subfunctions of a work system can be achieved by man and by a machine. If man is the center of interest, the design of the work system is geared towards the following levels of evaluation of human work [34.39]:

- *Feasibility:* anthropometrical, psychophysical, biomechanical thresholds for brief workload duration in order to prevent health damage
- *Tolerability:* physiological and medical thresholds for a long workload duration
- *Reasonability:* sociological, group specific, and individual thresholds for a long workload duration
- *Satisfaction:* individual sociopsychological thresholds with long and short validity.

In manual assembly, for example the joining of parts, certain thresholds result for the worker due to the required speed or accuracy of motions. Figure 34.11 presents this situation schematically.

Ergonomic optimization is desirable, if the combination of stress parameters resulting from the work task leads to tolerable work conditions (i. e., ergonomic design, see Sect. 34.1.1). If work can be done but is not tolerable, mainly the content of the working task has to be changed with the help of measurements regarding work structuring (i. e., organizational design, see Sect. 34.1.1). If the work task cannot be fulfilled, automation (i. e., a technical/technological design, see Sect. 34.1.1) of the work system is recommended, which implies extensive transfer of functions to a machine.

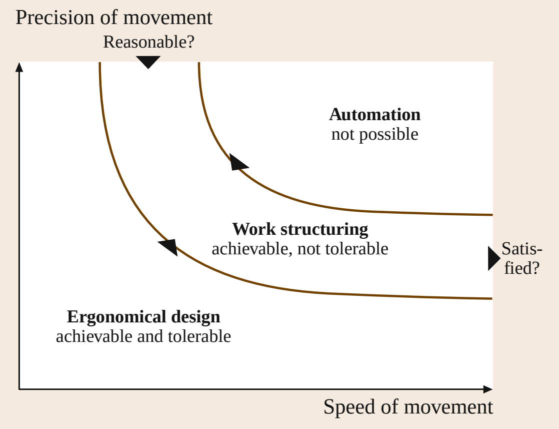

Fig. 34.11 Dimensions of work design from an ergonomic point of view [34.4]

Further influences on the design of systems result from technical and economical requirements. Due to the numerous influences on the design, it is impossible to distinguish specific design dimensions from each other. In factories we can find work systems with different degrees of automation among which are obvious combinations of manual and automated systems (hybrid systems).

When assigning functions within the man–machine system, the psychological and physiological performance requirements of the working man have to be taken into consideration (Sect. 34.1.8). In this way overextension of the worker can be avoided and health damage can be averted. Appropriate work structuring also takes into consideration not giving the man solely leftover functions, where he compensates or conducts nonautomated functions. Function division and work structuring therefore have to be developed in such a way that interesting, motivating, and diversified task arise [34.40] and optimal system effectiveness is guaranteed.

34.3.4 Designing a Man–Machine Interface

A central task when developing human-oriented automated work systems is the design of the man–machine interface. Ergonomically designed workplaces and machines – both in regard to hardware and software with the corresponding desktop – contribute to user-friendly and efficient task accomplishment.

Workplace

The workplace is the place where the task will be accomplished. At workplaces on the production level the following problems often occur:

- Inappropriate posture, forced posture due to limited free space or awkward positioning of appliances
- One-sided, repetitive movements
- Inappropriate movement of arms and legs
- Appliance of body forces.

In terms of ergonomic work design the demand arises to adjust the workplace in regard to its dimensions, visual and active area, and the forces that have to be applied to the conditions of the working man. The starting point for workplace design is the working task. Depending on the working task, specific demands arise in regard to motor functions and visual perception. The demands of the working task have to match man's performance prerequisites. Figure 34.12 shows factors that have to be taken into consideration when designing a workplace. The technologies or materials that are used can lead to further demands in regard to the configuration of the workplace, for example, lighting, ventilation, and storage.

Anthropometric Design of Workplaces. The starting point for anthropometric design of workplaces is the size of the human body. In order to prevent forced posture, e.g., intense bending forward or to the side, workplaces have to be aligned with the body size of the workers who work at that particular place.

When discussing the anthropometric design of the workplace, it has to be clarified whether work will take place sitting or standing (Fig. 34.13). A balanced position can be achieved by a change of posture. Basically it is important to set the human body size in relation to the correct distance between floor or feet height, working height, and seat height. The working height has to be adjusted to the conditions of the work task. In addition it is important to have sufficient horizontal and vertical space.

If several persons work at different times at the same workplace (for example, shift work), the workplace has to be equipped with appropriate adjustability in order to be adjusted to different body shapes and heights.

Physiological Design of Workplaces. Physical strength also has to be taken into consideration at automated workplaces, as the basis for lifting and carrying of loads and operation of the system elements. Tasks that require intensive body movements and a large amount of physical strength should be conducted in a standing position. Tasks that require a high degree of preciseness (e.g., subtle assembly) and little physical strength can be conducted while sitting. Information about the dimensions of working tasks and their required physical strength is given in ergonomic literature [34.1, 5, 41].

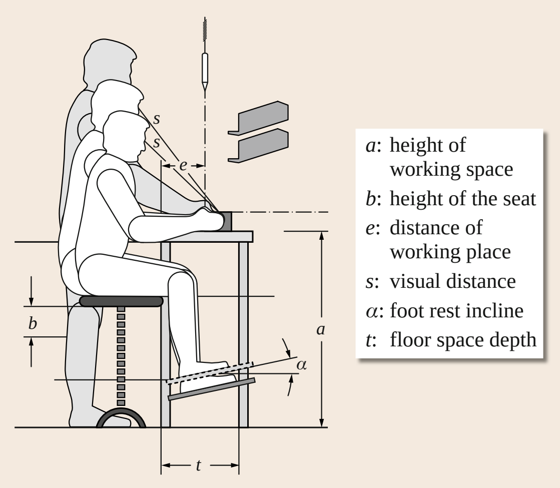

Fig. 34.13 Blueprint of a possible seat-standing workplace

Anatomically Favorable Alignment of Working Tools. Anatomically favorable alignment of appliances and working tools avoids unnecessary movement and assists balanced physical strain on the human body. Figure 34.14 presents an example of how to align appliances in a partly automated workplace. Objects that have to be grasped (bin with parts) are arranged within

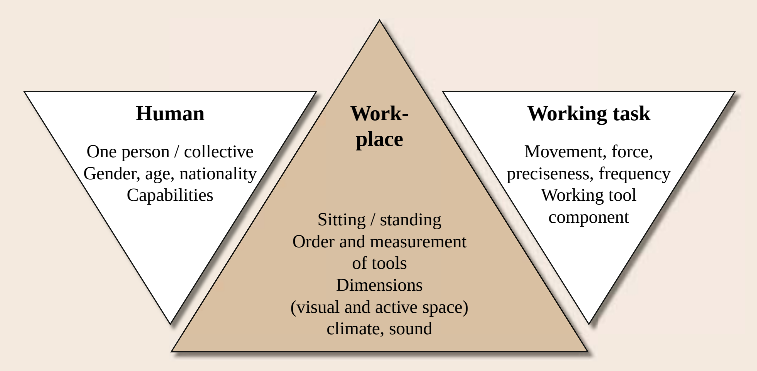

Fig. 34.12 Factors for the design of a workplace

Fig. 34.14 Partly automated manufacturing workplace

a reachable distance and the machine is positioned in the center.

Design of VDU Workplaces. Most of the time automated work in an office is performed at visual display units (VDUs). In addition to the working postures already mentioned above, the following factors have to be taken into account when working at a VDU [34.43]:

- *Strain of the supporting apparatus or musculoskeletal system:* Continuous, static sitting strains the supporting apparatus and the musculoskeletal system extremely and can lead to muscle tensions and degeneration effects. Repetitive tasks such as data entry can lead to pain in the wrist (for example, repetitive strain injury) and chronic back pain.
- *Eyestrain*: Frequent change of eye contact between screen, draft, and keyboard (that is to say, accommodation) and the resulting adjustment to the changing light level (that is to say, adaptation) provoke enormous strain on the eyes and can cause eye damage.
- *Psycho-mental strain:* Man is stressed while carrying out demanding informational tasks when being exposed to (unintentional) interruptions, time pressure, and fragmentation of the work task.

The demand to configure the daily work schedule with a change of activities or regular breaks is very important for the human-oriented design of a workplace. VDU tasks and other activities should be alternated in order to avoid burden on the eyes and encourage movement. If a change of activity cannot be realized, regularly short breaks from work at the screen should be included [34.27].

Man–Machine Communication

In the course of automation, interaction between man and machine becomes an information exchange, i. e., man–machine communication. This information exchange is realized by man's sensors (i. e., senses) and actuating elements (i. e., effectors) on the one hand, and input and display systems of the machine on the other. This exchange of information is controlled by the human or technical processing of the information. Software ergonomic work design has the function of designing input and display systems and the machine's processing of information according to ergonomic goals (Sect. 34.3.3). While so doing, the task and conditions of the working environment are taken into account. Additional tasks result from the selection and education of users who operate these systems.

Sensory, cognitive, and motor characteristics have to be taken into account when designing man–machine communication. The visual channel (the eye) can be addressed via optical displays, the auditory channel (the ear) via acoustic displays, and the tactile channel (sense of touch) via haptic displays. As the hand and foot motor functions are available for the mechanical input after processing of information by the brain (cognition), so language is available for linguistic input. Now input via body movement (gestures) also plays an important role, for example, through the use of the mouse or via the measurement of hand, head, and eye movement (movement tracking). According to Fig. 34.15, the

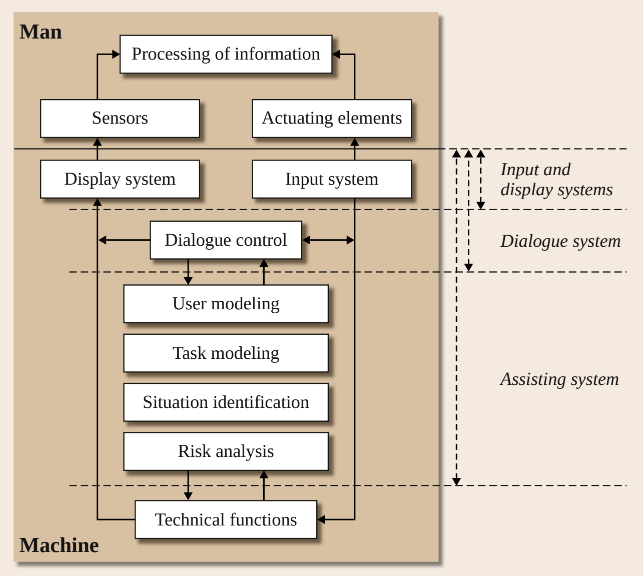

Fig. 34.15 Levels of man–machine communication [34.42]

design of man–machine communication can be represented at three levels:

- The highest level shows the interface between man and machine, the input and display systems, which are often defined as the *desktop*.
- The next level is the *dialogue system*, which creates the connection between the input and display, and which causes the machine's control of information flow.
- The third level refers to the application of assisting systems, which support the user when developing processing strategies and system control.

The design of these levels has the goal of tuning the technical system for the acceptance, processing, and display of information for man and his tasks.

Input and Display Systems. The design of an input and display system has to resolve three tasks [34.44]:

- It has to choose appropriate design parameters according to human conditions when adjusting the system to the human's motor function and sensors.
- It has to display the information codes that are necessary for exchange of information between man and machine; in this case, compatibility has to be taken into account.
- The organization of information designs the input or output of connected information.

Appropriate input systems are those that use human capabilities for the transmission of information: exercise of body force on objects, gestures, mimics, talking, and writing. Technical input systems are also useful if they can absorb and interpret the provided information. The best available technology allows the extended utilization of the previously mentioned human capabilities by using switches, levers, hand wheels, dials, keys, keyboards (for example, work at the VDU), etc. Speech recognition systems have seen immense progress, so that the use of speech signal input can be realized, for example, when entering numeric codes. Writing input is used with electronic notebooks.

When releasing information, visual, auditory, and tactile kinesthetic sense modalities are addressed. Furthermore, speech output is becoming increasingly important. Haptic displays are mainly used to facilitate blind operation of switches. Due to the amount and variability of the presented information and the optional access options, optical displays – mostly in the form of screens – play a dominant role. Multimedia forms of communication connect the different forms of coding: number, text, speech, and picture.

Compatibility of the design of (complex) input and output display systems is extremely important. Compatibility can also be defined as the decoding process, which the human has to achieve when evaluating the different forms of information. Inner compatibility is achieved when compatibility exists between man's periphery and the inner models (i. e., associations and stereotypes). A good example is the fact that one expects an increase in value when turning the adjusting knob to the right. An outer compatibility is in place when a display turns to the right according to the movement of the operating element.

Dialogue Systems. Dialogue represents the interactive exchange of information between man and machine in order to achieve a task. Depending on the user's previous knowledge, different dialogue forms are possible: question–answer dialogue, form dialogue, menu dialogue, key dialogue, command dialogue, and natural conversational dialogue. Dialogue forms as well as a direct manipulation comprise concrete actions (for example, display or sketching), pictures, and speech. These demand less abstraction from the user than text-based dialogues. There is always the possibility to adjust the dialogue system to a user-specific demand.

Continuous technical progress leads to rapid introduction of new program versions with dialogue alternatives. In order to guarantee reliable utilization, the user has to learn continuously. As printed instruction sheets are often ignored, integrated guidance of the user in the dialogue is practical. This guidance should be in line with the user's learning progress and the assisting and support systems, which the user can use in the dialogue.

Assisting Systems. Man–machine communication is generally designed as a dialogue, i. e., interaction between information input and output. Assisting systems (or dialogue assistants) support the user during goal-oriented use of a dialogue system by explaining the system's functions and user directions (Sect. 34.1.7). In order to guarantee progress of the dialogue, data is taken from the user (that is to say, user modeling), from the task to be solved (that is to say, task modeling), and from the present state of the system (that is to say, situation identification). In so doing, the field of man–machine communication comprises increasingly higher levels of technical processing of information. Whereas at the beginning only the desktop was affected in the form of display and input elements, nowadays the entire design of informational–technical systems are directed to the user.

Principles of Design for Man–Machine Communication

The design of man–machine communication mainly comprises aspects of dialogue development and control hierarchy.

Dialogue Development. Software ergonomic development of man–machine communication is geared towards the following demands for appropriate dialogue development [34.45]:

- *Usability* characterizes the degree to which a product can be used effective, efficiently, and in a satisfying way.
- *Effectiveness* determines the precision and completeness with which the user can achieve a certain task goal. Errors can have a negative impact on effectiveness. This is the case when the user is incapable of achieving the defined goal correctly or completely.
- *Efficiency* describes the cost-related effectiveness, referring to the relation between the achieved precision and completeness of the effort used by the user while attaining the goal. Deficiencies affect efficiency of utilization (*fitness for use*). The result is correct, but the effort is inappropriate, as the user, for example, can hardly avoid making mistakes.
- *Satisfaction* is an indicator of the acceptance of utilization.

Central criteria for dialogue design are *functionality* (i. e., the suitability of the task) and *usability* (i. e., suitability for learning). The ISO 9241 standard [34.3] defines established principles for the design of man–machine communication (Fig. 34.16):

- *Suitability for the task:* While working, the user should experience support instead of interference or unnecessary demands.
- *Self-descriptiveness:* The dialogue should make it clear what the user should do next.
- *Controllability:* The user should be able to control the pace and sequence of the interaction.
- *Compatibility, conformity with user expectations:* General experiences, schooling, experiences with work processes or similar software are effectively applicable. In terms of the expectation conformity, boundaries of the technical system have to be transparent (for example, safety functions).
- *Error tolerance:* The dialogue should be forgiving. In spite of defective input, the result will be achieved with only a few corrections.
- *Suitability for individualization:* The dialogue system allows adjustments to the demands of the working task, to the user's individual preferences, and to the utilization capability.
- *Suitability for learning:* The user will be supported and instructed while learning the dialogue system.

Burmester [34.46] recommends a simple and clear presentation of information, direct and unambiguous language, direct feedback, as well as user-oriented terminology for the implementation of design principles. In order to design the utilization capability of the man–

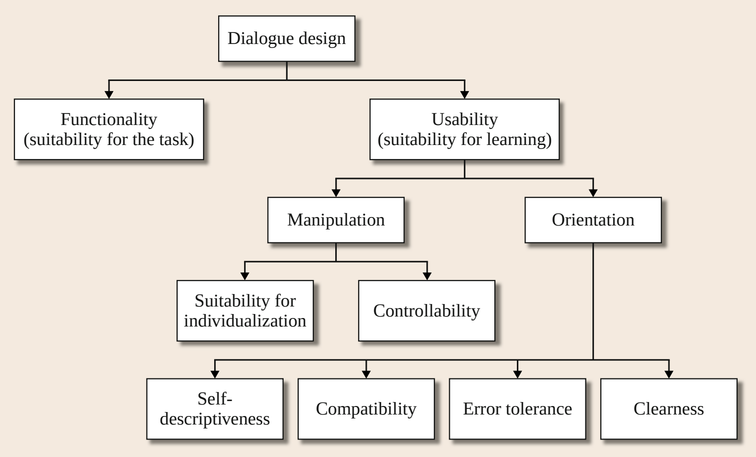

Fig. 34.16 Design principles of the ISO 9241 standard for man–machine communication

machine system more intuitively, known objects, for example, office folders, are displayed on the software's desktop.

Control Hierarchy. The embedding of the dialogue system into the control hierarchy of a man–machine system is as important as the dialogue design itself. Here we have to clarify, if and how far the technical system is allowed to limit man's freedom to take decisions and carry out actions. This question can be illustrated with the help of the example of a driving assisting system, which leads to increased safety for the driver when maintaining an inappropriate distance to the preceding vehicle and a reduction in speed.

Man's capability to make a decision is dependent on his position in the MMS. *Decker* [34.47] classifies three different performance types:

- *Restitution performances:* Here, the machine enables a disabled human being to achieve standard performances. Examples are prosthesis for amputated body limbs.
- *Expansion performances:* Here, man achieves together with the machine a higher level of performance than a standard performance. A good example is a databank system, which simplifies the data management and data organization.
- *Substitution performances:* The performance, which so far has been accomplished by man, is now achieved by a machine supervised by man. An example is the autopilot in a plane.

Experts are of the opinion that, as long as it is not possible to completely substitute man by a machine, man should have the highest level of decision making in a man–machine environment [34.48]. This implies that man will have the final decision. In this way, man can correct the MMS in case of errors.

The following problem appears however with partly automated MMS: During long working phases of uninterrupted automated production, man is permanently unchallenged and easily fatigued. If man then actually has to interfere due to a breakdown of the automated system, the once unchallenging situations transforms into a too challenging one. Consequently, we should aim for a continuous activity level, in order to guarantee manual takeover of the controlling system. Moreover, redundancy should assure that the entire system is reliable.

34.3.5 Increase of Occupational Safety

Automation of working systems needs to take into account occupational safety. Occupational safety is a necessary requirement for work processing. Safe working conditions should minimize or even prevent health damage to the working man. Generally speaking, the work result cannot be guaranteed if unsafe work conditions exist. A high level of safety is guaranteed by measures of machine safety. Occupational safety comprises safety measures and rules of conduct, which should provide the user of technical systems with the highest protection possible.

Automation measures basically reduce the hazardous risks to the worker. However, when breakdowns occur, the untrained worker has to interfere under time pressure, which can cause new danger situations.

The design of a man–machine interface with an abstract representation of information between user and system, and that also screens mechanical noises and vibrations, results in the risk that man's contact with reality is weakened. It has been observed that some drivers compensate for safety gained through assisting systems by changing to a risky driving style [34.49]. As a result we can state that the demand for increased occupational safety always has to be seen in the context of system reliability.

System Reliability

The term *system reliability* defines the probability that the system works without any errors in a defined timeframe. An error can be defined as an intolerable divergence from a defined level of quality. Human reliability describes man's capability to accomplish a task in an acceptable way under fixed conditions within a defined time frame. Here a basic difference between human and technical reliability becomes visible: man works in a goal-oriented manner, whereas the machine works in a functional way. Man is able to control his actions autonomously. Human errors do not usually lead to an immediate breakdown, but can be corrected before they negatively affect system operations. The technical design of systems should assure the reliability of the machine and its components through optimal construction and selection of appropriate materials. Human reliability can be increased by rapid identification of errors by the technical system and a supporting decision-making process. Man is able to recognize and correct for his own errors prior to their interference with the system. He can also stop processes that seem to be becoming problematic [34.50].

Design for Safety

Design Strategies. Adequate actions can contribute to an increase in the safety level of automated working systems and minimization of hazardous risks. The following kinds of risks have to be taken into account:

- Hazardous risks linked to the utilization of the working tool
- Hazardous risks that emerge at the workplace due to interaction of the working tools with each other
- Hazardous risks caused by the working materials or the working environment.

Here we have to conduct a risk analysis of the working tool at the predetermined workplace. We have to set this analysis in relation to other working mediums and take all operating conditions (i. e., normal mode, malfunction mode, and reconnection) into consideration.

The following rules have to be followed when designing for safety [34.43]:

- Elimination or minimization of hazardous risks (i. e., indirect measures, for example, integration of a safety concept when developing or constructing a machine)
- Implementing safety measures against risks that cannot be eliminated (i. e., indirect measures)
- Supply of information to users about remaining risks due to the incomplete effectiveness of the implemented safety measures; indication of eventual necessary special training and personal protection equipment (i. e., information measures).

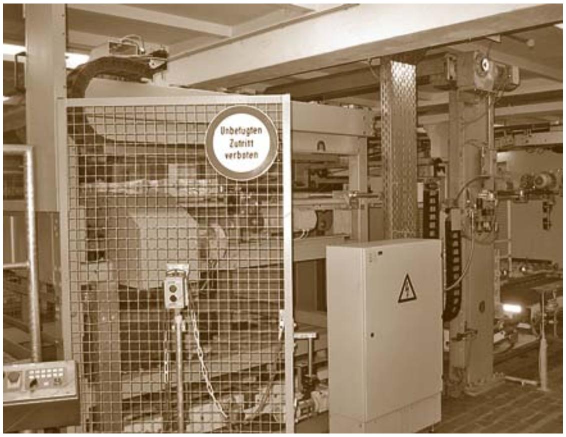

Fig. 34.17 Disjunctive safety device at a palletizing automaton

Risk Minimization of Mechanical Hazards. Mechanical hazards are, for example, objects that fall or slide out, dangerous surfaces and forms, moveable parts, instability or material failure. Appropriate protective measures have to been chosen for risk minimization of mechanical hazards. Here we have to differentiate between inherently safe construction and technical safety measures.

Inherently safe construction minimizes or eliminates risks through an adequate design. Examples of inherently safe constructions are the following:

- Avoidance of sharp edges
- Consideration of geometric and physical factors (for example, limitation of amount, speed, energy, and noise)
- Electrical supply of energy at extra-low voltage.

Technical safety measures should be used when the inherently safe constructions are not sufficient enough. Technical safety measures differ between disjunctive and nondisjunctive appliances [34.51].

A separating safety device is part of a machine which is used as a special kind of bodily shield (Fig. 34.17). Depending on its construction, a separating safety measure can be a cabinet, cover, shield, door, casing, etc. The following two devices are examples of separating safety devices [34.40]:

- *Fixed separating safety device:* These are either lasting (for example welded) or fixed to the machine with the help of elements (for example, a bolt). They block access to a dangerous area.
- *Movable separating safety device:* These are mostly mechanical in nature and connected to the machine (by hinges, for example). They can be opened even without the utilization of tools. A touch-sensitive switch prevents the execution of dangerous machine functions while the safety device is open.

The physical barrier between man and the hazardous machine function is absent in the case of a nonseparating safety device. The worker will be recognized as soon as he enters or reaches into the danger area. As soon as the worker is recognized, the existing risk is minimized or eliminated. We can differentiate between the following nonseparable safety devices:

- *Control device with automatic reset device:* Control devices that start and maintain operation of mechan-

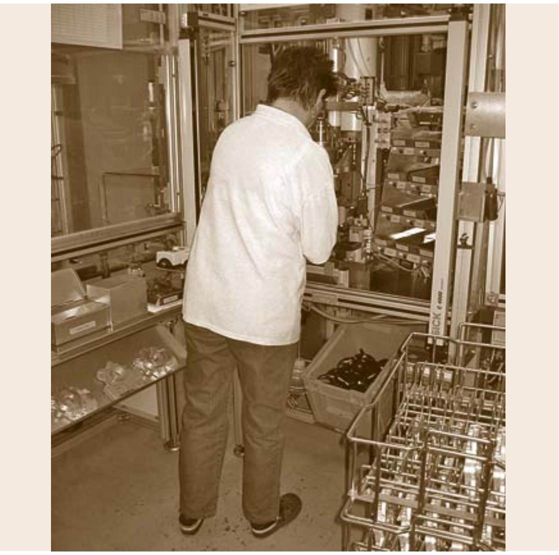

Fig. 34.18 Safety measure with approximation function (light barrier) at a partly automated assembly area

ical parts only as long as a hand control or operating element is actuated. Examples are hand drills and an edge grinder:

- *Two-hand coupling:* Control devices that demands the use of both hands at the same time in order to start or maintain the machine's functions.
- *Protective device with approximation function:* Devices that stop hazardous mechanical parts as soon as a person or a part of the human body crosses a well-defined boundary (for example, light barrier, see Fig. 34.18).

Man–Machine Interface. Switches for the operation mode and the removal of the energy supply are applied when designing a safe man–machine-interface (Sect. 34.1.3). Consequently, we find the following specific design features:

- *Switch for operation mode:* Machines have to be reliably stopped in all functions or safety levels (for example, maintenance, inspection).
- *Energy supply:* The spontaneous restart of a machine after a breakdown of energy supply has to be avoided, if this implies danger to the worker.

When designing a man–machine interface for safety, displays have to be adjusted to human perceptive senses so that relevant signals, warnings or information can be quickly and reliably noticed. In order to evaluate a situation, man allocates the role of key elements to a multiplicity of sensations. These key elements are incorporated into superior strategies. If complex information is arranged in functional groups, decision-making processes will be accomplished in a better way. Man, for example, recognizes qualitative changes of process parameters faster and is also able to assess them better if they are presented in graphical patterns. The combination of graphical elements produces a pattern in which changes can be recognized right away. In the case of a change in the pattern, man can selectively change to the next deeper level of information processing, in which detailed information about the situation and other characteristics relevant to the decision such as quantitative measures is available. A superior graphical model functions as an early warning system.

34.4 Emerging Trends and Prospects for Automation

34.4.1 Innovative Systems and Their Application

In the light of technical innovation it can be expected that automation of the value-creation processes will increase in all branches and application areas. When used adequately, automation can contribute to the improvement of product quality, the increase of productivity, and the enhancement of quality of work [34.52]. Without automation technology, some fields of human work would not be accomplishable. The operation of complex control systems in modern aircrafts may exemplify this circumstance.

With the help of efficient methods and procedures of automation technology, new systems and products can be obtained. Flexible automation, rather then the highest degree of automation, is the aim. Characteristics of these systems and products are increasing complexity and decentralization, a higher degree of cross-linking, and dynamic behavior. However, they are only controllable with the help of automated appliances. Example products can be found in the field of mechatronics. As well as in the traditional application areas in the field of process and production automation, automated solutions are also frequently used in the service industries, maintenance areas, and the field of leisure activities

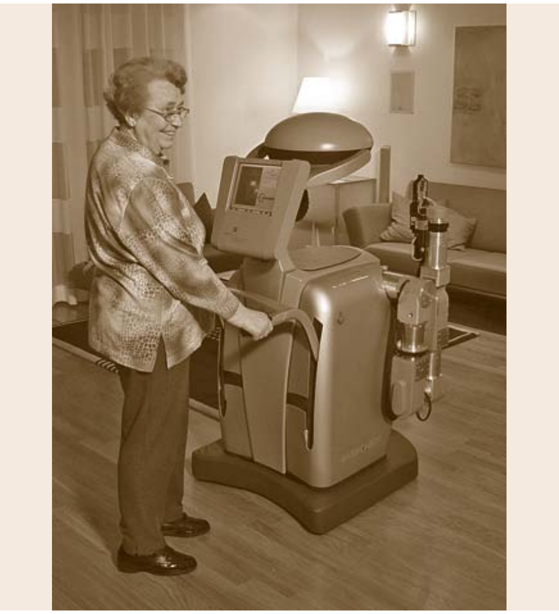

Fig. 34.19 Care-O-bot is a supporting system for the care of elderly people (photo taken with permission of Fraunhofer IPA)

(Fig. 34.19). Appliances can be found in the following fields:

- Health, e.g., intelligent prosthesis
- Service industry, e.g., fueling, cleaning, and household robot
- Building industry, e.g., energy optimizing systems
- Biotechnology, e.g., monitoring systems
- Technology of mobile systems, e.g., digital assistants.

An automated product has to fulfill strong requirements regarding precision and reliability, utilization characteristics, handling, and cost–value ratio [34.53]. Further development of all technical innovations demands the central inclusion of man. All technology should be geared to the human being, and his demands and performance prerequisites. The development of methods and procedures for ambient intelligence [34.54] is associated with human-oriented design (ambient intelligence is a technological paradigm which, first of all, is connected to the European research program on Information Society Technologies. It is related to the more hardware-oriented approach of the US-American research project on Ubiquitous Computing, as well as the industrial concept of pervasive computing). Ambient intelligence includes the vision of the information society, which stresses the factors of usability and efficiency of user support with the help of intelligent systems, in order to facilitate interaction between men or between man and computer.

One example application area is the *intelligent house*, whose entire functions and appliances (e.g., heat, kitchen appliances, and shutters) can be operated by a computer and be adjusted to the inhabitants' needs.

Natural and demand-oriented forms of interaction with an intelligent environment should lead to the situation in which utilization of the computer does not require more attention than the fulfillment of other daily activities, such as walking, eating, or reading.

The technical core of ambient intelligence is the omnipresence of information technology and consequently unlimited access to information and performance measures at any time, from any location. Man will thus be surrounded by a multitude of artifacts with intelligent and intuitive usable interfaces – from household objects used daily to facilities in public spaces. They will be able to recognize people and react actively to their informational needs in a discrete and fast way [34.55]. It is necessary that the ambient intelligence system registers the users' presence and situation and reacts to their needs, habits, gestures, and emotions in a sensitive and adaptive way.

Hence, ambient intelligence systems differ from present computer-based man–machine systems, whose technology is mostly focused on the realization of the task and forces the user to adjust to these requirements.

Ambient intelligence unifies a multiplicity of complex technologies and methods from different disciplines, such as: multisensor ad hoc networks, social user interfaces, dynamic integration of components for speech, and gesture recognition, and invisible computing. Further development of ambient intelligence systems requires intensive cooperation of these disciplines. Ambient intelligence always puts the human being with all his capabilities and needs at the center of the technologies that need to be developed.

34.4.2 Change of Human Life and Work Conditions

Continuous automation of different fields of life – first and foremost at work – leads to significant changes of human habits, task contents, and qualification requirements.

In production, workplaces that have been replaced by automation technology now demand higher and different qualifications from its workers. On the one hand, we have to assume that repetitious use, charging, disposal, and control functions, as well as administration and formalization of control tasks will continue to decrease. On the other hand, it is likely that maintenance work, demanding control functions, goal-oriented tasks, programming, and analytical tasks will increase [34.56].

As the importance of intellectually demanding tasks at work increases, so will demands on the workers, and stress will change. In the future, man will take a more social, and communicative role.

As the level of automation increases, so does its responsibility for business economics. The amount of instrumentation necessary for production will increase. From an economical point of view it is important to achieve multilayered efficiency for this productive technology. As a result, the habits of workers doing shift work and their rhythm of life have to change. The demands of the level of organization and the peculiarity of mutual responsibility will also increase correspondingly.

Different forms of automation development can create long-lasting effects that will diminish the separation between *white-collar* and *blue-collar* work that has existed to date. In so doing, they overcome the fixed and sometimes rigid separation of functions when working. The resulting changes regarding the content and execution of work comprise an individual chance for development for the working human.

35. Machining Lines Automation

Xavier Delorme, Alexandre Dolgui, Mohamed Essafi, Laurent Linxe, Damien Poyard

This chapter deals with automation of machining lines, sometimes called transfer lines, which are serial machining systems dedicated to the production of large series. They are composed of a set of workstations and an automatic handling system. Each workstation carries out one identical set of operations every cycle time. The design of transfer lines is comprised of several steps: product analysis, process planning, line configuration, transport system design, and line implementation. In this chapter, we deal with line configuration. Its design performance is crucial for companies to compete in the market. The main problem at this step is to assign the operations necessary to manufacture a product to different workstations while respecting all constraints (i. e., the line balancing problem). The aim is to minimize the cost of this line while ensuring a desired production rate. After a review of the existing types of automated machining lines, an illustration of a developed methodology for line configuration is given using an industrial case study of a flexible and reconfigurable transfer line.

Manufacturers are increasingly interested in the optimization of their production systems. The objective is to optimize some criteria such as total investment cost, floor area, number of workstations, production rate, etc.

The automatic serial line, often called a transfer line, is a widely used production system in machining environments [35.1–6]. Transfer lines also exist in the assembly industry. Their properties are defined, for example, by *Nof* et al. [35.7]. In such a line, a repeatable set of operations is executed each cycle. The line is composed of sequentially arranged workstations and a transport system which ensures a constant flow of parts along the workstations. This automatic handling system is generally composed of conveyors fixed on rails that transfer the part from one station to the next with holder robots for part loading and unloading at stations. The transfer machining lines produce large series of identical or similar items.

Automation of a machining line for a given product family (or reconfiguration of an existing line for a new product family) is a significant investment, and requires a long period for its design (often 18 months). Manufacturers have to invest heavily when installing these lines or for their reconfiguration. This investment influences to a large extent the cost of the finished products over the lifetime of the line. Therefore, profitability depends directly on the success of the line design or reconfiguration. Investment cost should be minimized and the configuration obtained should be as efficient as possible. Thus, optimization is a crucial issue at the transfer line design or reconfiguration stage.

The design of transfer lines is comprised of several steps: product analysis, process planning, line configuration, transport system design, and line implementation. In this chapter, we deal with line configuration. Its design performance is crucial for companies to compete in the market.

As a rule, the configuration of a transfer line involves two principle steps:

1. choice of line type
2. logical synthesis of the manufacturing process, which consists of grouping the operations into stations (i. e., *line balancing*).

In this chapter, we focus on the second step of this procedure, because the decisions made there define the principal characteristics of the line. An error at this time is too costly to rectify. A brief description of this problem is in order.

Automated machining lines are composed of a set of serial workstations. The stations are visited in a given order. The line investment cost depends on the number of stations and equipment of each station. Both are defined via an assignment of operations to workstations. Usually, each task is characterized by: (1) its time, (2) a set of operations which must be assigned before (precedence constraints), (3) a set of operations which must be executed on the same workstation (inclusion constraints), and (4) a set of operations which cannot be executed on the same workstation (exclusion constraints). Of course, in actual industrial problems, various additional specific constraints may have to be taken into account as well. Thus, at the line configuration stage, it is necessary to solve the line balancing problem, which consists of assigning the operations to workstations, minimizing the line investment cost while respecting the objective production rate as well as the aforementioned constraints.

This chapter is organized as follows. In Sect. 35.1, the fundamental assumptions and existing types of automated machining lines are introduced. In Sect. 35.2, some challenges and a general methodology for design and reconfiguration of these lines are explained. In Sect. 35.3, the role and importance of line balancing at the design or reconfiguration stage are presented. Section 35.4 illustrates our approach and models on an industrial case study. Moreover, in this section, a novel and promising exact resolution method is suggested for balancing of machining lines with parallel machines and setup times.

35.1 Machining Lines

A machining line is a production system composed of several sequential workstations; each workstation contains various machining equipment. A given set of operations is performed at each station to obtain the final product. The most frequent machining operations are:

- *Drilling*, to fabricate holes in parts
- *Milling* of shapes or removal of material with various milling cutters to form concave or convex grooves, etc.
- *Tapping*, which involves cutting internal screw threads in holes
- *Boring* to enlarge a hole that has already been drilled to precise dimensions.

A combination of these operations is usually needed to manufacture complex parts such as cylinder heads, cylinder blocks; see, for example, Fig. 35.1.

The machining process has numerous specific properties that directly influence the organization of the automated machining lines. Because of the complexity involved, special studies and decision-aid tools are required for competitive design and reconfiguration of these lines.

There are three principal types of automated machining lines for large series, namely, dedicated, flexible, and reconfigurable transfer lines. Each of these has its own characteristics and assumptions, which will be briefly detailed in the following.

35.1.1 Dedicated Transfer Lines

A dedicated transfer line (DTL) is the most economic form of machining systems with a large productivity and profitability if there is enough volume. DTLs are used for the production of a single type of product (or close variants) in large series: a large quantity of identical products is manufactured with the same sequences of operations on stations. The stations are arranged serially. Each station is equipped with multispindle heads. Each multispindle head executes several operations simultaneously. Depending on the architecture of the line, spindle heads can be activated at each station in parallel

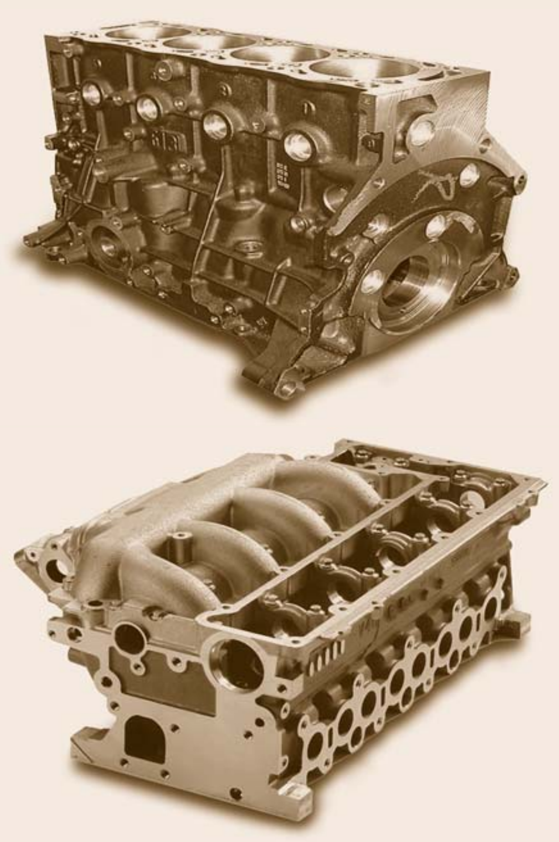

Fig. 35.1 Examples of parts produced by automated machining lines

or in sequence. An example of such a multispindle head is shown in Fig. 35.2.

When customer demand is significant and stable for a number of years, this type of machining line is the most profitable solution.

One of the design principles for the dedicated lines is the reduction of the cycle time and minimizing the amount of equipment (machines, spindle heads, tools, etc.) which, as mentioned above, has a direct influence on the reduction of the unit production cost.

Principal *advantages* of dedicated transfer lines are:

- High precision: these lines are designed to maximize the accuracy when machining of the part.
- Quality: there are no tool changes; therefore, once quality is established, it is stable.
- Mass production: the annual production can be in the millions.

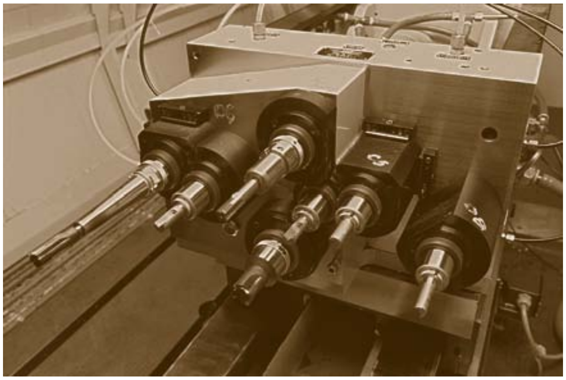

Fig. 35.2 A multispindle head for a dedicated transfer line (property of PCI/SCEMM)

- Simplifying handling operations reduces the needs for flow management and production control.

  Disadvantages of these lines are:

- The dedicated transfer lines demand large investments and must have a long lifetime to be profitable, the *ramp up* of the production is relatively long (2–4 weeks).
- Taking into account specific aspects of the product during the line design stage is possible, but once the line is defined it is very difficult to modify (line reconfiguration is costly).
- Breakdowns are a crucial problem; when a breakdown occurs in a single station, the entire line is stopped (in addition, if the corresponding operation did not end on time because of this breakdown, the product is automatically defective).

Note that for these lines the criterion to be optimized is easy to identify and calculate: minimizing the investment cost. Moreover, the interest in studying DTLs lies in the fact that their structure represents a basic form of organization for other machining systems. Indeed, all the problems that appear during the optimization of a dedicated transfer line are present in the design of other automated machining lines.

35.1.2 Flexible Transfer Lines

The flexible transfer line (FTL) is a special case of a flexible manufacturing system (FMS). The flexibility of a FMS is ensured thanks to the utilization of computer numerical control (CNC) machines (machining centers), automated transport, and warehousing systems with sophisticated control software [35.8]. An example of a flexible machining center with the devices for change of tools is shown in Fig. 35.3.

FMS can produce several types of products, belonging to a broad family. By family we mean products having comparable dimensions and similar geometric characteristics, as well as the same tolerances. These related products can be manufactured by the same equipment. Software takes care of possible changes by reprogramming the machining or rescheduling the products to be manufactured.

There are three basic types of FMS [35.7]:

- Flexible lines: these consist generally of sequentially arranged workstations with programmable CNC machines (machining centers) and are used especially for products with several product variations and a short lifetime for each variation.
- Flexible cells: such a system is composed of disconnected programmable cells, where each cell consists of one or several machining centers and carries out processes that comprise complete or almost complete tasks. The number of distinct parts in such a cell is often restricted, from eight to ten. This is due to a limited capacity of the cells.
- Flexible systems: are composed of linked flexible cells. There are two types of linkage: (1) with a rigid sequence of linking (cells are connected in a given invariable order); (2) with linkages that can be adapted to any particular production and/or assembly process.

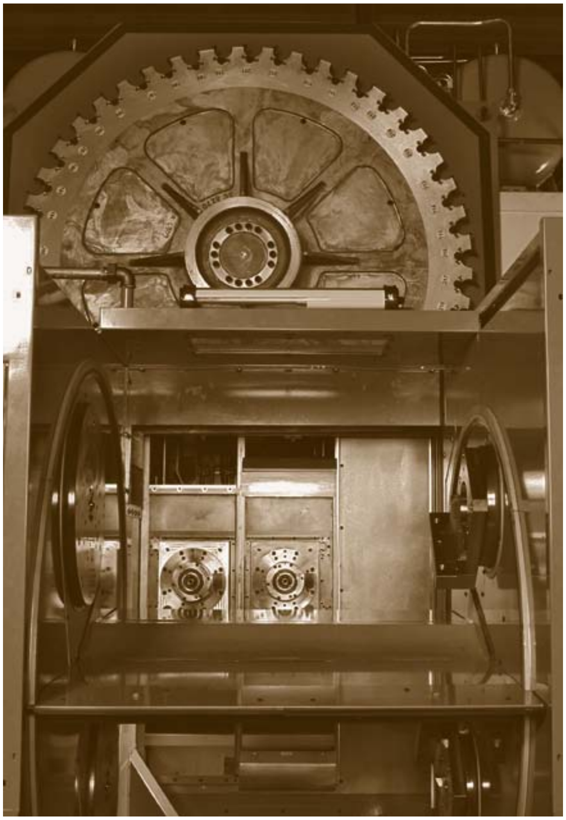

Fig. 35.3 Machining center Meteor ML (property of PCI/SCEMM)

The main objective of flexible transfer lines (FTLs) is to be able to produce several variations of the same product in large series. These lines assure a quick passage from one variation to another. FTLs are also able to change production volumes, if necessary, within a given range. The *ramp up* of production is short (1–2 days). However, they present a certain number of drawbacks:

1. These systems are very expensive mainly because they are composed of CNC machines. These machines are designed for a forecasted family of parts and produced without optimal process planning for each actual part. At the line design stage, the machining specifications are not accurately known. Therefore, the designer tends to insert more functions than necessary. Obviously, this increases the cost.
2. The development of software for the line control system is also very expensive because this flexible equipment requires sophisticated rules of management for each machine as well as for the entire line.
3. Contrary to dedicated machines, which contain multispindle heads with fixed tools, CNC machines use single spindle heads with frequent tool changes. Therefore, it is often difficult to maintain the level of precision in machining operations equal to that of dedicated lines.
4. Owing to rapid technological advances, these sophisticated and costly machines are quickly subject to obsolescence.
5. Because of their complexity, these flexible transfer lines tend to be less reliable.

35.1.3 Reconfigurable Transfer Lines

The concept of reconfigurable manufacturing systems (RMS) was introduced in *Koren* et al. [35.9]. The authors highlight the industry's new requirements for machining systems given the increasingly shorter product runs and the need for more customization. From the beginning, an RMS is designed to be able to make changes in its physical configuration to answer market fluctuations in both volume and type of product.

For RMS, and especially for reconfigurable transfer lines (RTL), the principal characteristics are:

- Modularity: in a reconfigurable manufacturing system, all the major components are modular (system, software, control, machines, and process). Selection of basic modules and the way they can be connected provide systems that can be easily integrated, diagnosed, customized, and converted.
- Integrability: to aid in designing reconfigurable systems, a set of system configurations and their integration rules must be established. Initially, such rules were developed for configurable computing [35.10]. In the machining domain, these rules should allow designers to relate clusters of part features and their corresponding machining operations to workstations and machine modules, thereby enabling product–process integration.
- Customization: this characteristic distinguishes RMS from FMS and DTL, and can reduce system and machine costs. This type of system provides customized flexibility for a particular part family, and is open ended.
- Convertibility: rapid changeover between members of the existing part family and quick system adaptability for future products.

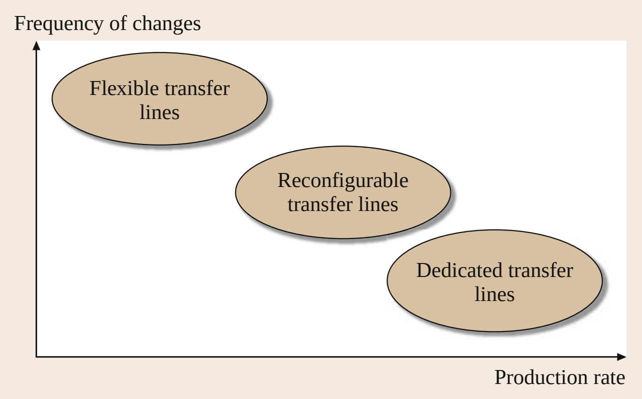

Fig. 35.4 Trade-off between production rate and frequency of market changes

- Diagnosability: detects machine failure and identifies causes of unacceptable part quality.

RTLs are usually conceived when there is little or no knowledge of future production volume or product changes. In this sense, they can be viewed as a compromise between the DTL and FTL (see Fig. 35.4). On the other hand, as they allow hardware reconfiguration in addition to software reconfiguration of FTL, some authors judge them more flexible.

35.2 Machining Line Design

We will now consider the preliminary design of transfer lines: corresponding challenges and general methodology.

35.2.1 Challenges

Usually for this type of project, the procedure is as follows: a company (client) contacts the transfer line manufacturer. The client gives the parts properties (part plans, characteristics, etc.) and the required output (production rate). Then comes the critical phase: the manufacturer should quickly offer a complete preliminary design solution for the corresponding line in terms of line architecture, number of machines, etc., and an approximate line cost. The acceptance of this solution by the client, and consequently the continuation of the negotiation and further development of the project, depends on the quality of this early solution. The temporal progress of the negotiation process and its critical phase are illustrated in Fig. 35.5.

The manufacturer's objective is to reduce the preliminary design time while minimizing the cost of the potential line. This is decisive, due to strong competition among manufacturers in this domain. Moreover, these lines are technically very complex and require huge investments.

If a preliminary solution is more expensive than those of the competitors, then the contract (several hundred million euros) may be lost. If it is cheaper, then the manufacturer increases the chances of obtaining the contract. However, if the proposal is not feasible, because some constraints were not considered due to the lack of time, then this can generate additional costs for the manufacturer in correcting the solution. Therefore, this contract may be not profitable. Thus, the manufacturer is under a deadline to produce an initial feasible

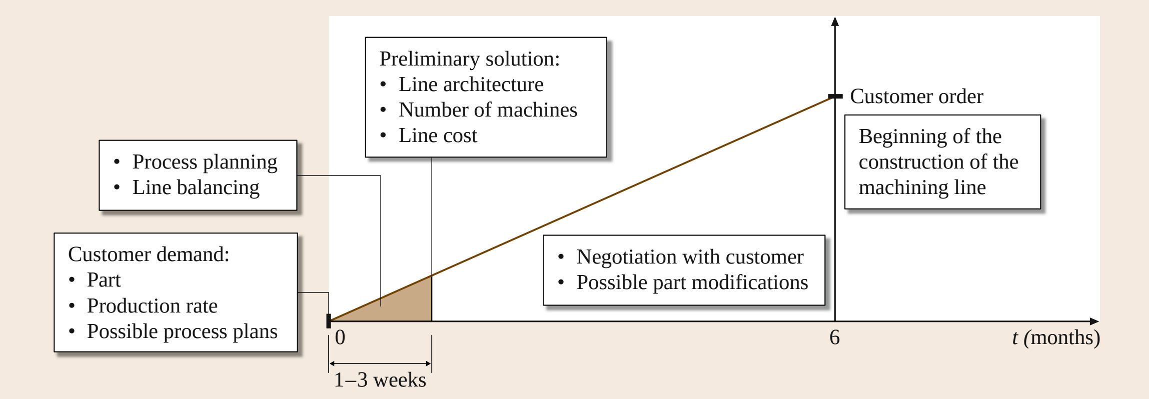

Fig. 35.5 Negotiation process: the critical phase

solution at the lowest possible cost within a very short time period.

In addition, after the preliminary design, almost always the product to be manufactured undergoes some modifications during the stage of detailed design of the line. The line manufacturer must continuously take into account these modifications. Furthermore, modifications of the design solution are difficult and time consuming. Therefore, decision-aid models are eminently useful for the preliminary design and to take into account the modifications during the detailed design. We will now present the methodology as applied to one such decision-making process.

35.2.2 General Methodology

Independent of the type of transfer line considered (dedicated, flexible or reconfigurable), its design demands an overall approach requiring the resolution of several interconnected problems [35.2]. Ideally, decisions relating to all these problems must be considered simultaneously. However, the total problem is very complex. Therefore, it is necessary to decompose this problem into several subproblems, each engendering less complex decisions [35.3].

Note that only the preliminary design stage is considered in this chapter, i. e., when all principal decisions are made concerning line architecture and its elements. Usually, this is followed by a detailed design (specifications for mechanical elements, tools, spindle heads, etc.), which is outside the scope of this chapter (see [35.4, 5] for a presentation).

The following general steps can summarize the preliminary design process. Note that the importance of each step depends on the type of transfer line considered. Some steps can be omitted.

- Product analysis: this gives a complete description of the operations that have to be executed for the future products.
- Process planning: covers the selection of processes required to transform raw parts into finished products. Here, technological constraints are defined. For instance, during process planning, partial order between operations, inclusion and exclusion constraints are established. This requires an accurate understanding of the functional specifications for the products and technological conditions for the operations.
- Configuration design and balancing problem: selection of the type of machining line and the resolution of the balancing problem, i. e., the allocation of operations to workstations in order to obtain the necessary production rate meeting demand while achieving the quality required. It is imperative to consider here all the constraints, particularly those of precedence.
- Dynamic flow analysis and transport system design: simulation is used to study the flow of products taking into account random events as well as variability in production. The objective is to analyze the dynamic flows and choose the material handling system as well as optimize the facilities layout, i. e., placement of machines. The decisions must be coherent with those defined at the previous steps.
- Detailed design and implementation of the line.

In addition, for flexible lines, a scheduling step also has to be considered [35.11]. After the implementation, if product and/or volume change, a similar analysis should be performed for the optimal reconfiguration of the transfer line (note that this is rarely considered for dedicated lines of mass production; more precisely, a reconfiguration of a dedicated line deals with specific engineering approaches). As illustrated in Fig. 35.6, these steps are executed sequentially. Of course, the designer can return to the previous steps as often as necessary (i. e., the decision-making process is iterative).

Such a methodology was already implemented in a decision-aid software tool for the preliminary design of dedicated transfer lines [35.12]. The developed software includes a database of parameterized features for product analysis. The product analysis provides a set of features which will be used at the process planning step. The process planning generates several process plans with the best one chosen for each feature. A set of operations and constraints are obtained. Then, a type of transfer line is selected by considering the process plans, part dimensions, required productiveness, cost of equipment, variability and longevity of market demand, etc. For the obtained process plans and production system type, the corresponding line balancing problem is solved. Finally, an estimation of the cost of the production system is made. If the solution or the cost is unsatisfactory, the designer can modify the data and constraints and restart the procedure.

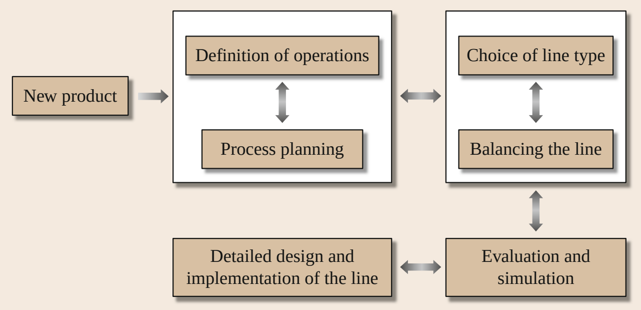

Fig. 35.6 Design of transfer lines

While this software was initially developed to design dedicated transfer lines, the general methodology is valid for all transfer lines (dedicated, flexible or reconfigurable). The difference is that for the dedicated transfer line it is applied once (at the preliminary design stage). In the case of flexible transfer lines, this tool should be used in real time, each time a new product is launched. For reconfigurable transfer lines, it is useful for each physical reconfiguration of the line.

This approach is based on a set of engineering procedures, knowledge-based constraints, and some optimization techniques for transfer line balancing. The optimization techniques are the core (and originality) of this methodology, which is why, the rest of this chapter will consider this aspect.

35.3 Line Balancing

As aforementioned, the line balancing (assignment of operation to workstations) is the key problem in the design of transfer lines.

Historically, the line balancing problem was first stated for assembly lines. As far as we know, the earliest publication on assembly line balancing (ALBP) was presented by *Salveson* [35.13]. Furthermore, exhaustive studies were made by several researchers in the last 50 years, with many interesting applications covered. One comprehensive state of the art has been presented in a special issue [35.14]. Several articles provide broad surveys of this problem; see, for example [35.15–20]. To summarize, the ALBP is NP-hard; see, for example [35.21]. Much research has been generated to solve the problem by developing approximate or exact methods [35.22–32].

The problem of machining line balancing is rather recent. This problem was mentioned in [35.33]. In *Dolgui* et al. [35.34], it was defined for dedicated transfer lines and first called transfer line balancing problem (TLBP).

Industry favors solving TLBP because the machining lines become too expensive otherwise. The TLBP consists of answering the following questions:

1. Which machining units are to be chosen to execute the required operations?
2. How many workstations are necessary?
3. How should the machining units be assigned to the stations?

These questions can be answered by an intelligent assignment of operations and machining units to workstations, minimizing the line cost while satisfying the objective production rate as well as respecting all other constraints.

Several exact and approximate (or heuristic) methods for TLBP have been proposed. Exact methods are useful to better understand the problem, however for large-scale problems they require excessive computation time. Contrarily, approximate methods can provide quicker results but do not guarantee the optimality of solutions. Additionally, a heuristic algorithm is often easier to develop than optimal procedures.

The most significant methods for an exact resolution of the TLBP are:

- Linear programming in mixed variables: the problem is modeled as a mixed integer program and solved with an optimization tool such as ILOG Cplex [35.35–37].
- Dynamic programming: a recursive method used for the resolution of problems having an additive objective function. Examples of this approach for TLBP are given in [35.33, 34, 38, 39], where the initial problems were transformed into constrained shortest-path problems and solved with appropriate algorithms.
- Branch and bound: an implicit enumerative procedure which avoids verifying all solutions. Several works use this approach for the resolution of the TLBP; see, for example, [35.40, 41].

Also, the column generation method can be used for TLBP. Indeed, it was already successfully used for assembly line balancing; see, for example, [35.42].

For large-scale problems, or when the allocated computing time is severely limited (e.g., for flexible transfer lines), several approximate methods have been designed. We classify these methods into two categories:

1. Heuristics based on priority rules derived from the methods for ALBP. There are several heuristic algorithms, which differ in the rule(s) used:
   - Ranked positioned weight (RPW) [35.22]): based on the weights of the operations calculated from their execution time and the operational times of their successors [35.43].
   - Computer method of sequencing operations for assembly lines (COMSOAL) [35.24]): solutions are generated by assigning operations randomly to the stations [35.44–47].
2. Metaheuristics, i. e., solving strategies applicable to a wide range of combinatorial optimization problems:
   - A multistart decomposition approach was suggested in [35.43, 48].

An example of machining line balancing via simulation can be found in [35.49].

Note that most of these methods were developed for dedicated transfer lines. In the next section, we will show how this approach can be applied to flexible and reconfigurable transfer lines. To illustrate, an industrial case study will be presented with a mixed integer programming model.

35.4 Industrial Case Study

35.4.1 Description of the Case Study

In Fig. 35.7, the machining line considered in this case study is presented. This line is designed to manufacture automotive cylinder heads. It is equipped with CNC machines (machining centers) for the output of 1250 parts per day. All the machines are identical (line modularity principle), with some exceptions. In contrast to dedicated transfer lines with multispindle machines, here, each machine contains one spindle and a magazine for tools. For each machine, to pass from one operation to the next it is necessary to consider an additional time due to tool changes and displacements or/and the rotation of the part (setup time). Taking into account the fact that a part is held at a machine with some fixtures in a given position (part fixing and clamping), some faces and elements of the part are not accessible for machining even after part displacement or rotation. Whatever positioning and clamping are chosen some areas on the part will be hidden or covered. Therefore, the choice of a part position for part fixing should be also considered in the optimization procedure.

In Fig. 35.7, lines (1) represent the transport system composed of conveyors. Robots are used for part loading and unloading. The boxes (2) represent the CNC machines. Machines in a group aligned vertically represent a workstation. Then a workstation can comprise more than one machine; in this case, the same operations are duplicated and executed on different machines. With the parallel machines at each station, the line is easily reconfigurable. The line cycle time can be modified, if necessary, and even be shorter than the

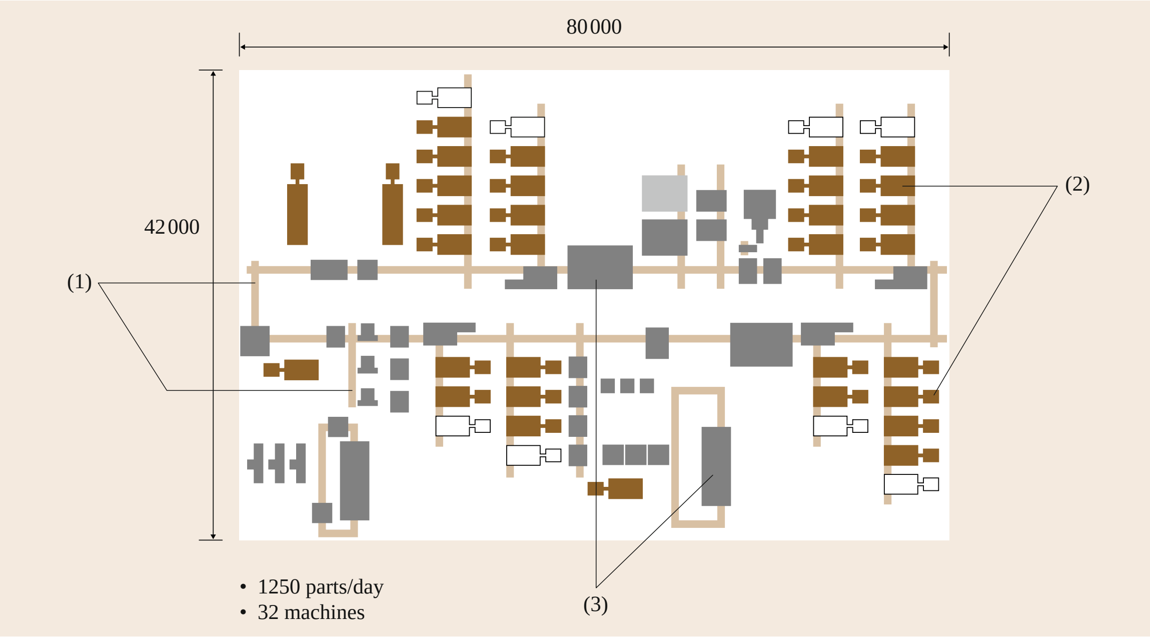

Fig. 35.7 Schema of a line for machining cylinder heads (PCI/SCEMM)

time of an operation. The boxes (3) represent dedicated stations for specific operations such as assembly or washing.

To help the designer of this line, we developed a model for line balancing. The input data used were:

- Cycle time (*takt* time) imposed by the objective production rate: one part is produced at each cycle.
- Precedence constraints: relations of order between operations. These relations define feasible sequences of operations.
- Inclusion constraints: the need to carry out fixed groups of operations on the same workstation.
- Exclusion constraints: the impossibility of carrying out certain subsets of operations at the same workstation.
- Accessibility constraints: these are related to the positioning of the part; indeed, for a position some part sides are not accessible, and thus operations on these sides cannot be carried out without repositioning. In the considered machining line, only one part fixing position is defined for each workstation (part repositioning occurs between two stations).
- Sequence-dependent setup times: the time required for the execution of two sequential operations is not equal to the sum of their times but also depends on the order in which they are done, because the time needed for the displacement/change of tool and part rotation are not negligible.
- Parallel machines: at each workstation several identical CNC machines are installed. Thus, the local cycle time of the workstation is equal to the number of parallel machines multiplied by the line cycle time (*takt* time). The machines of the same workstation execute the same operations (in parallel on different product units).

Hence, here, we have a special case of line balancing with a sequential execution of operations, setup times, parallel machines, as well as accessibility, exclusion, and inclusions constraints.

The line of the case study can be regarded as reconfigurable. Indeed, while designed for the production of a single product, if there are changes on the product characteristics, the reconfiguration of this line is possible and easy thanks to:

- The use of standard and identical CNC machining centers, which simplifies the reallocation of operations to the workstations.
- At each station, machining centers can be added or eliminated as needed thanks to this modularity.

Now, we present a mixed integer programming (MIP) model for the design of this line for a given product. Furthermore, at the end of this section, we will give an extension of this model which can be used when reconfiguring the line for another product.

35.4.2 Mixed Integer Programming (MIP)

To summarize the optimization problem, we will enumerate its main assumptions.

The set of all operations N to be executed at the line is determined by the process plans for the product for which the line is designed. A part to be machined will pass through a sequence of workstations in the order of their installation. Each workstation is provided with at least one machine which carries out operations during the line cycle time. In the case where workload time of a workstation exceeds the line cycle time, parallel and identical machines are installed. In this case, the local cycle time is equal to the number of parallel machines multiplied by the line cycle time. All machines of the same station execute the same operations.

There are four types of additional constraints on the assignment of the operations (as detailed earlier), namely:

- Precedence constraints
- Exclusion constraints
- Inclusion constraints
- Accessibility constraints.

The time required for the execution of two operations is not equal to the sum of their times but depends on the sequence in which they are executed (Fig. 35.8).

The optimization problem consists of assigning operations to workstations to minimize the total number of machines on the line while respecting the given constraints.

Mathematical Model

We will introduce the following notations.

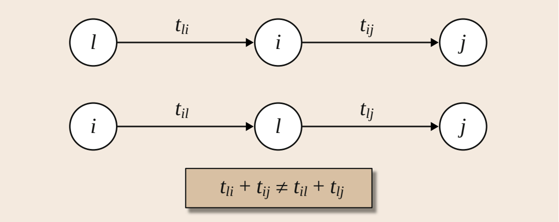

Fig. 35.8 Sequence-dependent setup times

Indexes:

- i, j for operations
- q for the place (order) of an operation in the sequence of assigned operations
- n for the number of parallel machines at a workstation
- k for the workstations
- a for the part fixing positions

Parameters:

- N, the set of operations to be assigned ($i, j = 1, \ldots, |N|$)
- A, the set of possible part positions for part fixing in a machining center; only one of these positions is chosen for each workstation; a part fixing position defines the accessibility constraints for the part ($a = 1, \ldots, |A|$)
- l_0, the maximum number of operations authorized to be assigned to a workstation: each workstation created cannot contain more than l_0 operations
- n_0, the maximum number of machines on a workstation
- m_0, the maximum number of workstations
- $q_0 = l_0 \cdot m_0$, the maximum number of possible assignments (places) for operations
- t_i, the operational time for operation i ($i = 1, \ldots, |N|$)
- t_{ij}, the setup time when operation j is processed directly after operation i at the same workstation
- T_0, the objective line cycle time (*takt* time)
- P_i, the set of direct predecessors of operation i
- P_i^*, the set of all predecessors of i (direct and indirect predecessors)
- F_i^*, the set of all successors of i (direct and indirect successors)
- ES, the collection of subsets e ($e \subset N$) of operations which must be imperatively assigned to the same workstation
- $\overline{\text{ES}}$, the set of pairs of operations (i, j) which cannot be assigned to the same workstation
- $A(i)$, the set of the possible part fixing positions for which the execution of operation i is possible
- $S(k)$, the set of possible places for operations at workstation k; this set is given by an interval of indexes; the maximum possible interval is $S(k) = \{l_0(k-1)+1, l_0(k-1)+2, \ldots, l_0k\}$; $\forall k = 1, 2, \ldots, m_0$
- $K(i)$, the set of workstations on which operation i can be processed: $K(i) \subseteq \{1, 2, \ldots, m_0\}$

- $Q(i)$, the set of possible places for operation i in the sequence of all operations: $Q(i) \subseteq \{1, 2, \ldots, l_0 m_0\}$
- $N(k)$, the set of operations which can be processed at workstation k
- $M(q)$, the set of operations which can be assigned to the place q in the sequence
- E_i, the earliest workstation to which operation i can be assigned
- L_i, the last workstation to which operation i can be assigned

Variables:

- $x_{iq} = 1$, if operation i is in qth place (q is its order in the overall assignment sequence), otherwise $x_{iq} = 0$;
- τ_q, the setup time required between operations assigned to the same workstation in place q and $q+1$ (Fig. 35.9);
- $y_{nk} = 1$, if there are n parallel machines at the workstation k, 0 otherwise;
- $z_{ka} = 1$, if for the part of the workstation k the fixing position a is used, 0 otherwise.

Note that, if an operation is assigned to place q, it is the $q - (\lceil q/l_0 \rceil - 1) \cdot l_0$th operation of the workstation $\lceil q/l_0 \rceil$.

The optimization model is as follows:

- The objective function (35.1) minimizes the total number of machines

$$\text{Minimize} \sum_{k=1}^{m_0} \sum_{n=1}^{n_0} n \cdot y_{nk} \,. \tag{35.1}$$

- Equation (35.2) verifies that there is only one value for the number of parallel machines on each workstation

$$\sum_{n=1}^{n_0} y_{nk} \leq 1, \forall k = 1, 2, \ldots, m_0 \,. \tag{35.2}$$

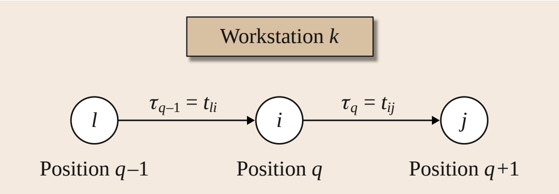

Fig. 35.9 Definition of the parameter τ_q

- Equation (35.3) assures that a workstation is open only if the preceding workstation is also open

$$\sum_{n=1}^{n_0} y_{nk} \geq \sum_{n=1}^{n_0} y_{n(k+1)} \,, \quad \forall k = 1, 2, \ldots, m_0 - 1 \,. \tag{35.3}$$

- Equation (35.4) assures that each operation i is assigned once and only once

$$\sum_{q \in Q(i)} x_{iq} = 1 \,, \quad \forall i \in N \,. \tag{35.4}$$

- The constraints (35.5) assure that a place in the sequence is occupied by only one operation

$$\sum_{i \in M(q)} x_{iq} \leq 1 \,, \quad \forall q = 1, 2, \ldots, q_0 \,. \tag{35.5}$$

- Equation (35.6) assures that an operation is assigned to a place only if another operation is assigned to the preceding place of the sequence (there is no empty place in the sequence of assigned operations)

$$\sum_{i \in M(q-1)} x_{i(q-1)} \geq \sum_{i \in M(q)} x_{iq} \,, \quad \forall q \in S(k) \backslash \min\{S(k)\} \,, \quad \forall k = 1, 2, \ldots, m_0 \,. \tag{35.6}$$

- Equation (35.7) verifies that only one part fixing position is chosen for each workstation

$$\sum_{a \in A} z_{ka} \leq 1 \,, \quad \forall k = 1, 2, \ldots, m_0 \,. \tag{35.7}$$

- Equation (35.8) assures that accessibility constraints are respected (the part fixing position chosen for a workstation authorizes the execution of every operation assigned to this station)

$$\sum_{q \in S(k)} x_{iq} \leq \sum_{a \in A(i)} z_{ka} \,, \quad \forall k = 1, 2, \ldots, m_0, \forall i \in N \,. \tag{35.8}$$

- Equation (35.9) calculates the additional time between operation i and operation j when operation j is processed directly after operation i at the same workstation

$$\begin{aligned} &\tau_q \geq t_{ij} \cdot (x_{iq} + x_{j(q+1)} - 1) \,, \\ &\forall i \in M(q) \,, \quad \forall j \in M(q+1) \,, \\ &\forall q \in S(k) \backslash \max\big\{S(k)\big\} \,, \\ &\forall k = 1,\ 2,\ \ldots,\ m_0 \,. \end{aligned} \tag{35.9}$$

- Equation (35.10) assures that the workload time of every workstation does not exceed the local cycle time, which corresponds to the number of installed parallel machines at this workstation multiplied by the objective cycle time of the line

$$\sum_{q\in S(k)\setminus \max\{S(k)\}} \tau_q + \sum_{i\in N(k)} \sum_{q\in S(k)} t_i \cdot x_{iq} \\ \leq T_0 \cdot \sum_{n=1}^{n_0} n \cdot y_{nk} , \quad \forall k = 1, 2, \dots, m_0 . \tag{35.10}$$

- Equation (35.11) defines the precedence constraints between operations

$$\sum_{q\in Q(j)} q \cdot x_{jq} \leq \sum_{q\in Q(i)} q \cdot x_{iq}, \forall i \in N , \quad \forall j \in P_i . \tag{35.11}$$

- Equation (35.12) represents the inclusion constraints

$$\sum_{q\in S(k)\cap Q(i)} x_{iq} = \sum_{q\in S(k)\cap Q(j)} x_{jq} , \\ \forall i, j \in e , \quad \forall e \in ES , \quad \forall k \in K(i) . \tag{35.12}$$

- Equation (35.13) represents the exclusion constraints

$$\sum_{q\in S(k)} (x_{iq} + x_{jq}) \leq 1 , \\ \forall (i, j) \in \overline{ES} , \quad \forall k \in K(i) \cap K(j) . \tag{35.13}$$

- Equations (35.14)–(35.17) provide additional constraints on the possible values of variables

$$\tau_q \geq 0 , \quad \forall q = 1, 2, \dots, q_0 , \tag{35.14}$$
$$x_{iq} \in \{0, 1\} , \quad \forall i \in N , \quad \forall q \in Q(i) , \tag{35.15}$$
$$y_{nk} \in \{0, 1\} , \\ \forall n = 1, 2, \dots, n_0 , \quad \forall k = 1, 2, \dots, m_0 , \tag{35.16}$$
$$z_{ka} \in \{0, 1\} , \quad \forall k = 1, 2, \dots, m_0 , \quad \forall a \in A . \tag{35.17}$$

35.4.3 Computing Ranges for Variables

The model (35.1–35.17) can be solved using a standard operational research solver, for example, ILOG Cplex. Nevertheless, the calculation time is prohibitive. The resolution time for the model (35.1–35.17) can be greatly decreased using efficient techniques to reduce the number of variables (the size of the model) and consequently to accelerate the search for an optimal solution.

We propose a technique for calculating bounds for the possible indexes for the variables of the mathematical model. This can simplify the problem and thus reduce the calculation time.

Taking into account the different constraints between operations, we can calculate the sets $K(i)$, $N(k)$, $S(k)$, $Q(i)$, and $M(q)$ more precisely. Note that these sets give intervals of possible values for the corresponding indexes.

The following additional notations can be defined:

- $E_i[r]$ is a recursive variable for the step by step calculation of the value of E_i taking into account setup times between operations, $r = 0, 1$.
- $L_i[r]$ is a recursive variable for the step by step calculation of the value of L_i taking into account setup times between operations, $r = 0, 1$.

With P_i^*, which is the set of all predecessors of operation i, and F_i^*, which is the set of all successors of operation i, we can also introduce:

- $Sp_i[r]$: the sum of the $\left(\left|P_i^*\right| - E_i[r] + 1\right)$ shortest setup times between the operations of the set $P_i^* \cup \{i\}$ composed of operation i and all its predecessors, $i \in N$
- $Sf_i[r]$: the sum of the $\left(\left|F_i^*\right| - m_0 + L_i[r]\right)$ shortest setup times between the operations of the set $F_i^* \cup \{i\}$ composed of operation i and all its successors, $i \in N$
- $d[i, j]$: a parameter (distance) which has the following property: if (i, j) or $(j, i) \in \overline{ES}$, then $d[i, j] = 1$, else $d[i, j] = 0$.

The total operational time T_{sum} without considering the setup times between operations is calculated as follows

$$T_{\text{sum}} = \sum_{i\in N} t_i .$$

A lower bound on the number of workstations can be calculated by supposing that each workstation contains n_0 machines. Therefore, the local cycle time of each workstation is equal to $(T_0 \cdot n_0)$. The line becomes a serial line composed of identical workstations with a cycle time which is equal to $(T_0 \cdot n_0)$. Then, a lower bound on the number of workstations LB_{ws} can be calculated as follows

$$LB_{\text{ws}} = \left\lceil T_{\text{sum}} / (T_0 \cdot n_0) \right\rceil ,$$

where the notation $\lceil x \rceil$ indicates the lowest integer value higher than or equal to x.

In the same way, a lower bound on the number of machines in the line (LB_m) can be determined by the following expression

$$LB_\mathrm{m} = \left\lceil T_\mathrm{sum}/T_0 \right\rceil .$$

Thus, the following procedure calculates the sets $K(i)$, $Q(i)$, $M(q)$, $N(k)$, and $S(k)$. Note that the operations are numbered in order of precedence graph ranks (in topological order). Some lines are annotated with comments. The symbol “//” is used to mark the beginning and the end of these comments.

Algorithm

```
**Step 1** // step-by-step calculation of $E_i$ and $L_i$, taking into account precedence constraints and setup times//
**for** all $i \in N$ **do**
    **begin**
    // calculate the earliest workstation $E_i[0]$ on which operation $i$ can be processed taking into account the precedence constraints; note that an operation cannot be processed before its predecessors //
    $E_i[0] \leftarrow \left\lceil (t_i + \sum_{j \in P_i^*} t_j)/(n_0 \cdot T_0) \right\rceil$;
    // calculate the latest workstation $L_i[0]$ on which operation $i$ can be processed considering the precedence constraints, note that an operation cannot be processed after its successors //
    $L_i[0] \leftarrow m_0 - \left\lceil (t_i + \sum_{j \in F_i^*} t_j)/(n_0 \cdot T_0) \right\rceil + 1$;
    // calculate $E_i[1]$, which are new values of $E_i$ obtained by taking into account in addition setup times between operations //
    $E_i[1] \leftarrow \left\lceil (t_i + Sp_i[0] + \sum_{j \in P_i^*} t_j)/(n_0 \cdot T_0) \right\rceil$;
    // calculate $L_i[1]$, which are new values of $L_i$ obtained by taking into account in addition setup times between operations //
    $L_i[1] \leftarrow m_0 - \left\lceil (t_i + Sf_i[0] + \sum_{j \in F_i^*} t_j)/(n_0 \cdot T_0) \right\rceil + 1$;
    // updating the values of $E_i$ //
    **if** $E_i[1] \neq E_i[0]$ **then** $E_i \leftarrow \max\left( E_i[0] + 1, \left\lceil (t_i + Sp_i[1] + \sum_{j \in P_i^*} (t_j))/(n_0 \cdot T_0) \right\rceil \right)$
    **else** $E_i \leftarrow E_i[1]$;
    // updating the values of $L_i$ //
    **if** $L_i[1] \neq L_i[0]$ **then** $L_i \leftarrow \min\left( L_i[0] - 1, m_0 - \left\lceil (t_i + Sf_i[1] + \sum_{j \in F_i^*} t_j)/(n_0 \cdot T_0) \right\rceil + 1 \right)$
    **else** $L_i \leftarrow L_i[1]$;
    **end**

**Step 2** // step-by-step calculation of $E_i$, taking into account exclusion and inclusion constraints//
$j_\mathrm{cur} \leftarrow 1$;
**do**
    $j_\mathrm{min} \leftarrow j_\mathrm{cur}$;
    $j_\mathrm{cur} \leftarrow |N|$;
    // new values of $E_i$ are calculated by considering exclusion constraints //
    **for** $j \leftarrow j_\mathrm{min} + 1, \ldots, |N|$ **do**
        $E_j \leftarrow \max\left( \max_{i \in P_j^*} \{E_i + d[i, j]\}, E_j \right)$;
    **for** each $e \in$ ES
        **begin**
        $E_e \leftarrow \max_{j \in e}(E_j)$;
        **for** each $j \in e$ **if** $E_j < E_e$ **then**
            **begin**
            // new value of $E_i$ is calculated, now taking into account an inclusion constraint//
            $E_j \leftarrow E_e$;
            $j_\mathrm{cur} \leftarrow \min\{j_\mathrm{cur}, j\}$;
            **end**
        **end**
**until** $j_\mathrm{cur} = |N|$.

**Step 3** // step-by-step calculation of $L_i$, taking into account inclusion and exclusion constraints //
$j_\mathrm{cur} \leftarrow |N|$;
**do**
    $j_\mathrm{max} \leftarrow j_\mathrm{cur}$;
    $j_\mathrm{cur} \leftarrow 1$;
    // new values of $L_i$ are calculated by considering exclusion constraints //
    **for** $j \leftarrow j_\mathrm{max} - 1, \ldots, 1$ **do**
        $L_j \leftarrow \min\left( \min_{i \in F_j^*} \{L_i - d[j, i]\}, L_j \right)$;
    **for** each $e \in$ ES
        **begin**
        $L_e \leftarrow \min_{j \in e}(L_j)$;
        **for** each $j \in e$ **if** $L_j > L_e$ **then**
            **begin**
            // new values of $L_i$ are again calculated, now taking into account inclusion constraints //
            $L_j \leftarrow L_e$;
            $j_\mathrm{cur} \leftarrow \max\{j_\mathrm{cur}, j\}$;
```

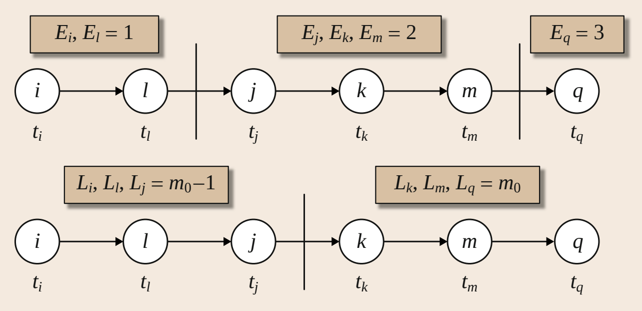

Fig. 35.10 An example of initial values for E_i and L_i

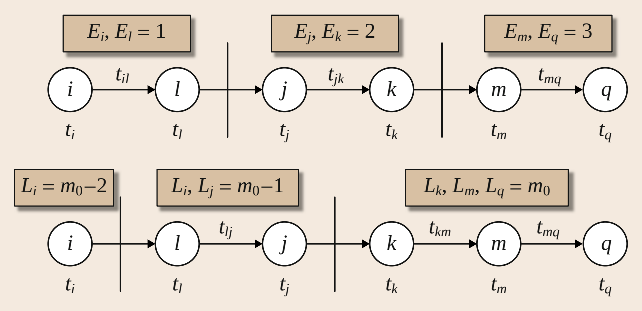

Fig. 35.11 Modified values of E_i and L_i taking into account setup times

```
            end
        end
    until $j_{\text{cur}} = 1$ .

Step 4 // calculation of the sets $K(i)$, $N(k)$, $S(k)$, $Q(i)$, and $M(q)$ //
for all $i \in N$ do
    $K(i) \leftarrow [E_i, L_i]$;
for $k \leftarrow 1, 2, \ldots, m_0$ do
    begin
    $N(k) \leftarrow \{i | i \in N, k \in K(i)\}$;
    $S(k) \leftarrow \left[1 + \sum_{k'=1}^{k-1} |S(k')|, \; \min\left(|N(k)|, l_0\right) + \sum_{k'=1}^{k-1} |S(k')|\right]$;
    end
for all $i \in N$ do
    $Q(i) \leftarrow [\min\{S(E_i)\}, \max\{S(L_i)\}]$;
for $q \leftarrow 1, 2, \ldots, \max\{S(m_0)\}$ do
    $M(q) \leftarrow \{i | q \in Q(i)\}$;
End of algorithm.
```

Some illustrations of the algorithm rules are presented in Figs. 35.10–35.13.

Numerical Example

In order to better explain the suggested algorithm, we present a numerical example with ten operations. Figure 35.14 shows the precedence graph and operational times.

The objective line cycle time is: $T_0 = 16$ units of time; the maximum number of stations $m_0 = 6$; the maximum number of machines to be installed on a station $n_0 = 3$; the maximum number of operations to be assigned to a station $l_0 = 8$.

The inclusion constraints are: $\text{ES} = \{(2,4); (8,9); (5,6)\}$.

The exclusion constraints are: $\overline{\text{ES}} = \{(2,7); (3,4)\}$.

The setup times are reported in Table 35.1. For example, the setup time $t_{4,5} = 3$ corresponds to the time that is required to perform operation 5 immediately after operation 4.

The total operational time, $T_{\text{sum}} = \sum_{i \in N} t_i = 161$ units of time.

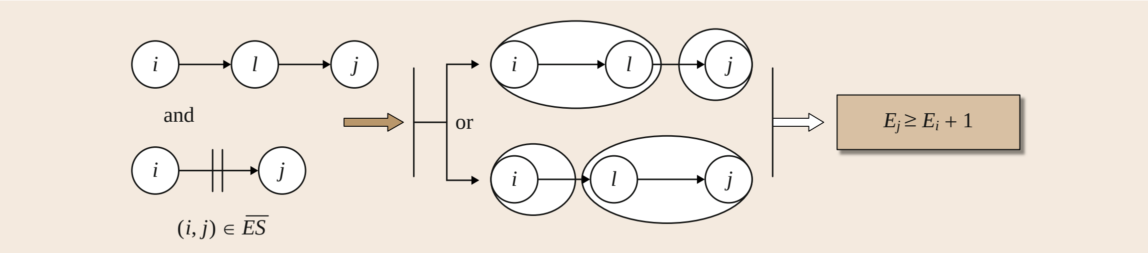

Fig. 35.12 An example of modifications of E_i by considering an exclusion constraint

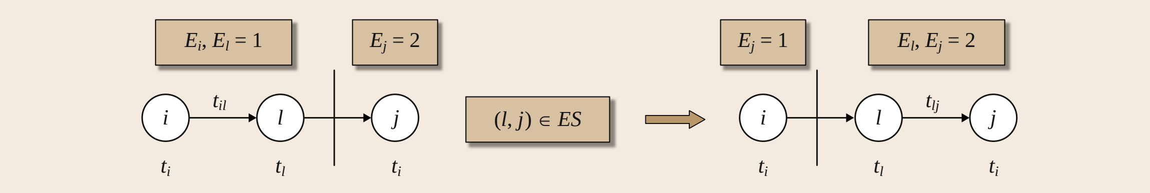

Fig. 35.13 An example of modification for E_i by taking into account an inclusion constraint

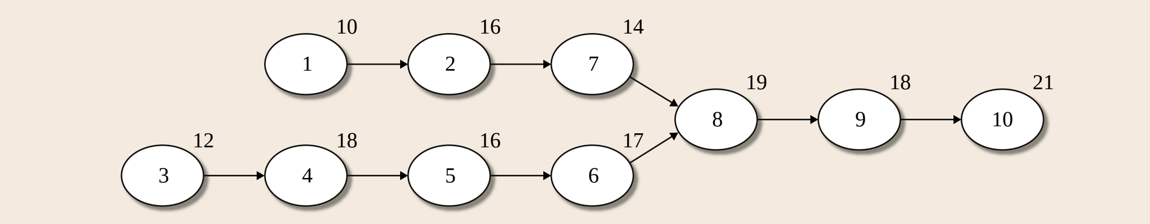

Fig. 35.14 Precedence graph

Table 35.1 Setup times

i j	1	2	3	4	5	6	7	8	9	10
1	–	4	4	3	2	1	1	2	1.5	1.5
2	5	–	1.5	1	1	2.5	3	3	3	3.5
3	1.5	3.5	–	2.5	1.2	3.4	4	4.2	3	2.2
4	4.5	4	3	–	**3**	1.5	3	2	4.5	1.8
5	4	4	5	5	–	2.5	2	2	4.5	1
6	25	1.5	3	1.2	1	–	2	2	3	4
7	4	3.8	3	1.8	4	3	–	4.7	4	1.4
8	3	2.5	4	3.4	3.2	2.4	1.6	–	2	4
9	3	4.9	4	2.3	1.6	3.6	3	1.2	–	3
10	1.5	4	1.5	4.6	3.7	2.2	2.7	1.2	4.8	–

A lower bound on the number of workstations is: $LB_{\mathrm{ws}} = \lceil T_{\mathrm{sum}}/(T_0 \cdot n_0) \rceil = \lceil 161/(16 \cdot 3) \rceil = 4$.

Thus, the optimal solution cannot have fewer than four workstations.

A lower bound on the number of machines is: $LB_{\mathrm{m}} = \lceil T_{\mathrm{sum}}/T_0 \rceil = \lceil 161/16 \rceil = 11$.

Then, the optimal solution cannot have fewer than 11 machines.

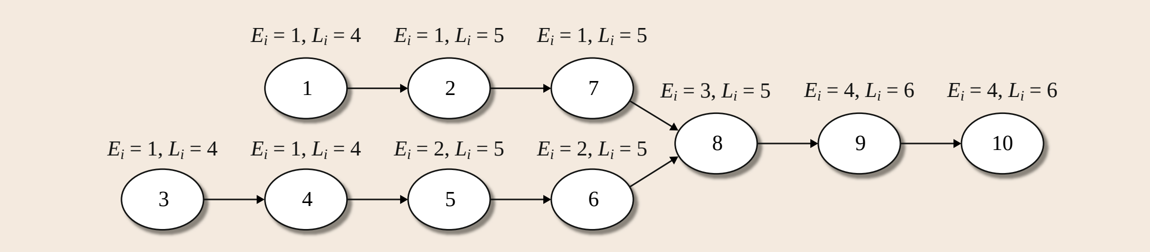

Fig. 35.15 Values of E_i and L_i obtained considering precedence constraints and setup times

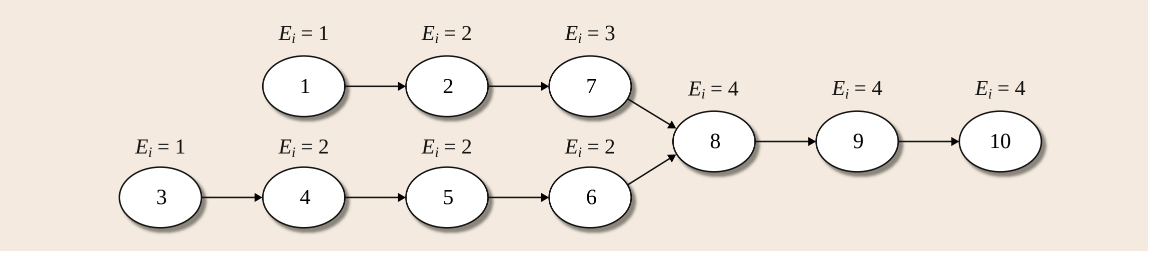

Fig. 35.16 Values of E_i considering exclusion and inclusion constraints

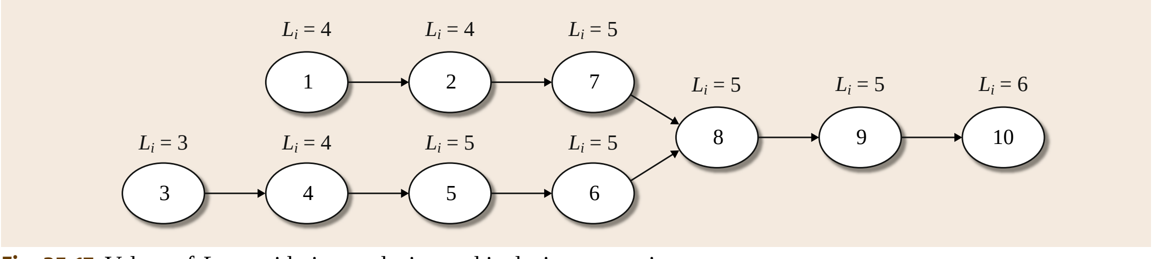

Fig. 35.17 Values of L_i considering exclusion and inclusion constraints

Now, the procedure of range calculation for indexes is applied:

- *Step 1* The initial values of E_i and L_i for each operation are calculated considering set-up times between operations and precedence constraints (Fig. 35.15).
- *Step 2* The new values of E_i are obtained by considering the exclusion and inclusion constraints (Fig. 35.16).
- *Step 3* The new values of L_i are calculated by considering the exclusion and inclusion constraints (Fig. 35.17).
- *Step 4*
  - Sets $K(i)$ for operations $i \in N$ are obtained (Table 35.2)
  - Sets of operations $N(k)$ for stations $k = 1, 2, \dots, m_0$ are defined (Table 35.3)
  - Range of places $S(k)$ for operations of station k is calculated, $k = 1, 2, \dots, m_0$ (Table 35.4)
  - Finally, the range of places $Q(i)$ for operation i is found, for all $i \in N$ (Table 35.5).

35.4.4 Reconfiguration of the Line

As indicated at the beginning of this section, the studied line is reconfigurable. After the implementation of the line, if there are changes in the product characteristics or if there is a new product to be machined, the line can be reconfigured. Such a reconfiguration problem consists of reassigning operations to the stations

Table 35.2 The ranges $K(i)$ for the operations

Operation i	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**
$K(i)$	[1,4]	[2,4]	[1,3]	[2,4]	[2,5]	[2,5]	[3,5]	[4,5]	[4,5]	[4,6]

Operation i	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**
$Q(i)$	[1,23]	[3,23]	[1,15]	[3,23]	[3,29]	[3,29]	[9,29]	[16,29]	[16,29]	[16,30]

while minimizing the number of additional machines and/or those that move from a workstation to another in order to rebalance the line. This problem is similar to the design problem considered in the previous sections. Therefore, the proposed MIP model (35.1–35.17) can be easily adapted for this new problem.

The following modifications are made in the model (35.1–35.17): a new objective function is considered (35.1') along with additional constraints (35.18) and a new set of variables (35.19) which represents the gap between the number of machines for each station in the line before reconfiguration (y_{nk}^{Old}), and their number in the line reconfigured.

$$\text{Minimize} \sum_{k=1}^{m_0} \left(\delta_k^+ + \delta_k^-\right) , \tag{35.1'}$$

$$\sum_{n=1}^{n_0} n \cdot y_{nk} - \sum_{n=1}^{n_0} n \cdot y_{nk}^{\text{Old}} = \delta_k^+ - \delta_k^- ,$$
$$\forall k = 1, 2, \dots, m_0 , \tag{35.18}$$

$$\delta_k^+, \delta_k^- \geq 0 , \quad \forall k = 1, 2, \dots, m_0 \tag{35.19}$$

35.5 Conclusion and Perspectives

Transfer lines are used in many manufacturing domains, especially in machining systems, to efficiently effectuate high-quality and economical production. In today's competitive business environment, several manufacturers have opted for transfer lines to benefit from their advantages, namely precision, quality, productivity, reduction of handling cost, etc. However, transfer lines also present some drawbacks, such as requiring a large investment. Normally, transfer lines are highly automated, but the level of automation depends on the type of customer demand. Three types of transfer lines exist: dedicated, flexible, and reconfigurable. Dedicated lines are composed of workstations with multispindle heads. Flexible transfer lines have several types of CNC machines. Reconfigurable lines offer a mix of different types of machines (special machines, CNC machines, machining units, etc.) and can have different architectures (simple line, U-line, parallel stations, etc.).

With increasing technological progress and development of ever more sophisticated and efficient machining equipment, the problem of automated machining line design is exceptionally pertinent. Indeed, the concepts for machining lines are continuously improved through the development of new types of architectures and machines. Unfortunately, there is a gap between industrial cases and research problems treated. In contrast with assembly systems, in the domain of machining lines, the gap is often due to the lack of collaboration between the industrial and academic worlds.

In this chapter, written jointly by academic (Ecole des Mines de Saint Etienne) and industrial (PCI/SCEMM) partners, a general overview of the automated machining lines is presented. The principal characteristics of these lines and a general methodology for their design are introduced. This methodology is valid independent of the type of the line: dedicated, flexible or reconfigurable. The goal is to help machining line manufacturers to design efficient lines and become more competitive.

On receipt of a customer demand for a line which includes a part description (plans, characteristics, etc.) and the required output, the machining line manufacturer must be able to propose a complete solution within a very short time interval. This preliminary solution concerns the line architecture, number of machines, and equipment, with a line cost evaluation. A major difficulty deals with line balancing, which is a hard combinatorial optimization problem. All types of transfer lines are concerned. In this chapter, a short survey of general line balancing approaches is given. The methods developed for the balancing of the automated machining lines are enumerated and commented. Then, an industrial case study is presented. It illustrates and highlights the importance of the line balancing problem. Afterwards, a mixed integer program for the considered case is proposed. The presented model and approach are useful from a practical perspective. They generate more appropriate preliminary solutions to customer needs within a very short timeframe. From an academic point of view, this is a new formulation of the line balancing problem with sequence-dependent setup times and parallel machines.

For future research work, beside the improvement of the models and resolution algorithms, numerous research perspectives have yet to be studied in this field. Among them, the combination of optimization methods and discrete-event simulation seems promising. Simulation is a powerful method to illustrate and study the flow of material on the line and to determine the effect of its architecture on line reliability and performance. Also, the development of interactive and iterative software could provide useful decision-aid systems for industry.

36. Large-Scale Complex Systems

Florin-Gheorghe Filip, Kauko Leiviskä

Large-scale complex systems (LSS) have traditionally been characterized by large numbers of variables, structure of interconnected subsystems, and other features that complicate the control models such as nonlinearities, time delays, and uncertainties. The decomposition of LSS into smaller, more manageable subsystems allowed for implementing effective decentralization and coordination mechanisms. The last decade revealed new characteristic features of LSS such as the networked structure, enhanced geographical distribution and increased cooperation of subsystems, evolutionary development, and higher risk sensitivity. This chapter aims to present a balanced review of several traditional well-established methods and new approaches together with typical applications. First the hierarchical systems approach is described and the transition from coordinated control to collaborative schemes is highlighted. Three subclasses of methods that are widely utilized in LSS – decentralized control, simulation-based, and artificial-intelligence-based schemes – are then reviewed. Several basic aspects of decision support systems (DSS) that are meant to enable effective cooperation between man and machine and among the humans in charge with LSS management and control are briefly exposed. The chapter concludes by presenting several technology trends in LSS.

There is not yet a universally accepted definition of the *large-scale complex systems* (LSS) though the *LSS movement* started more than 40 years ago. However, by convention, one may say that a particular system is a large and complex one if it possesses one or several characteristic features. For example, according to *Tomovic* [36.1], the set of LSS characteristics includes the structure of interconnected subsystems and the presence of multiple objectives, which, sometimes, are vague and even conflicting. A similar viewpoint is proposed by *Mahmoud*, who describes a LSS as [36.2]:

> *A system which is composed of a number of smaller constituents, which serve particular functions, share common resources, are governed by interrelated goals and constraints and, consequently, require more than one controllers.*

Šiljak [36.3] states that a LSS is characterized by its high dimensions (large number of variables), constraints in the information infrastructure, and the presence of uncertainties. At present there are software products on the market which can be utilized to solve optimization problems with thousands of variables. A good example is Solver.com [36.4]. Complications may still be caused by system nonlinearities, time delays, and different time constants, and, especially over recent years, risk sensitivity aspects.

36.1 Background and Scope

In real life one can encounter lots of natural, manmade, and social entities that can be viewed as LSS. From the early years of the *LSS movement*, the LSS class has included several particular subclasses such as: steelworks, petrochemical plants, power systems, transportation networks, water systems, and societal organizations [36.5–7]. Interest in designing effective control schemes for such systems was primarily motivated by the fact that even small improvements in the LSS operations could lead to large savings and important economic effects.

The structure of interconnected subsystems has apparently been the characteristic feature of LSS to be found in the vast majority of definitions. Several subclasses of interconnections can be noticed (Fig. 36.1).

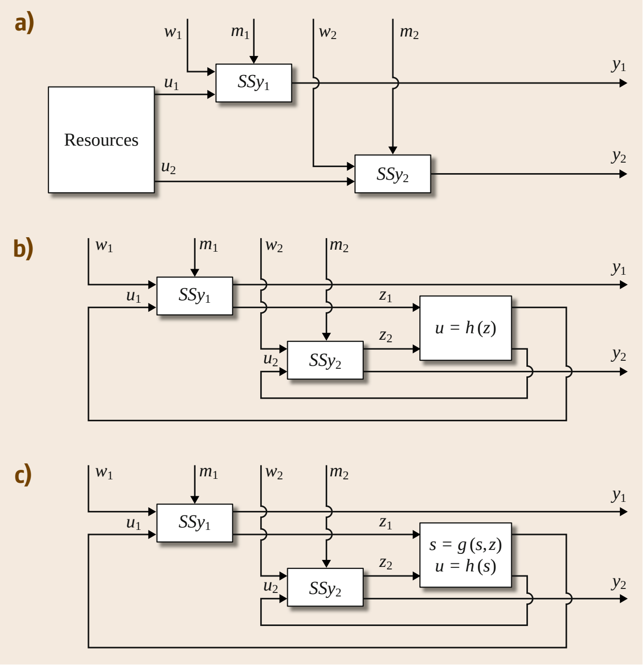

Fig. 36.1a–c Interconnection patterns: **(a)** resource sharing, **(b)** direct interconnection, **(c)** flexible interconnection; SSy = subsystem, m = control variable, y = output variable, w = disturbance, u = interconnection input, z = interconnection output, $g(\cdot)$ = stock dynamics function, $h(\cdot)$ = interconnection function

First there are the *resource sharing* interconnections described by *Findeisen* [36.8], which can be identified at the *system level* as remarked by *Takatsu* [36.9]. Also, at the *system level*, subsystems may be interconnected through their common objectives [36.8]. Subsystems may also be interconnected through buffer units (tanks), which are meant to attenuate the effects of possible differences in the operation regimes of plants which feed or drain the stock in the buffer. This type of *flexible interconnection* can frequently be met in large industrial and related systems such as refineries, steelworks, and water systems [36.10]. The dynamics of the stock value s in the buffer unit can be modeled by a differential equation. In some cases buffering units are not allowed because of technological reasons; for example, electric power cannot be stocked at all and reheated ingots in steelworks must go immediately to rolling mills to be processed. When there are no buffer units, the subsystems are coupled through *direct interconnections*, at the *process level* [36.9].

In the 1990s, integration of systems continued and new paradigms such as the *extended/networked/virtual enterprise* were articulated to reflect real-life developments. In this context, *Mårtenson* [36.11] remarked that complex systems became even more complex. She provided several arguments to support her remark: first, the ever larger number of interacting subsystems that perform various functions and utilize technologies belonging to different domains such as mechanics, electronics, and *information and communication technologies* (ICT); second, that experts from different domains can encounter hard-to-solve communication problems; and also, that people in charge of control and maintenance tasks, who have to treat both routine and emergence situations, possess uneven levels of skills and training and might even belong to different cultures.

Nowadays, *Nof* et al. show that [36.12]:

> *There is the need to create the next generation manufacturing systems with higher levels of flexibility, allowing these systems to respond as a component of enterprise networks in a timely manner to highly dynamic supply-and-demand networked markets.*

They also emphasize that *e-Manufacturing is highly dependent on the efficiency of collaborative human–human and human–machine e-Work*. See Chap. 88 on *Collaborative e-Work, e-Business, and e-Service*. In general, there is a growing trend to understand the design, management, and control aspects of complex *supersystems* or *systems of systems* (SoS). Systems of systems can be met in space exploration, military and civil applications such as computer networks, integrated education systems, and air transportation systems. There are several definitions of SoS, most of them being articulated in the context of particular applications; for example, *Sage* and *Cuppan* [36.13] state that a SoS is not a monolithic entity and possesses the majority of the following characteristics: geographic distribution, operational and management independence of its subsystems, emergent behavior, and evolutionary development. All these developments obviously imply ever more complex control and decision problems. A particular case which has received a lot of attention over recent years is large-scale *critical infrastructures* (communication networks, the Internet, highways, water systems, and power systems) that serve not only the business sector but society in general [36.14, 15]. All of these recent developments are likely to provide fresh strong stimuli for new research in the LSS domain.

36.1.1 Approaches

The progresses made in information and communication technologies have enabled the designer to overcome several difficulties he might have encountered when approaching a LSS, in particular those caused by a large number of variables and the low performance (with respect to throughput and reliability) of communication links. However, as *Cassandras* points out [36.58]:

> *The complexity of systems designed nowadays is mainly defined by the fact that computational power alone does not suffice to overcome all difficulties encountered in analyzing, planning and decision-making in the presence of uncertainties.*

A plethora of methods have been proposed over the last four decades for managing and controlling large-scale complex systems such as: decomposition, hierarchical control and optimization, decentralized control, model reduction, robust control, perturbation-based techniques, usage of artificial-intelligence-based techniques, integrated problems of system optimization and parameter estimation [36.59], and so on. Two common ideas can be found in the vast majority of approaches proposed so far:

a) Replacing the original problem with a set of simpler ones which can be solved with the available tools and accepting the satisfactory, near optimal solutions
b) Exploiting the particular structure of each system to the extent possible.

Table 36.1 presents a summary of the main methods to be described in this chapter.

36.1.2 History

Though several ideas and methods for controlling LSSs were proposed in the 1960s and even earlier, it is accepted by many authors that the book of *Mesarovic* et al. published in 1970 [36.7] triggered the *LSS movement*. The concepts revealed in that book, even though they were strongly criticized in 1972 by *Varaiya* [36.60] (an authority among the pioneers of the *LSS movement*), have inspired many academics and practitioners. A series of books including those of *Wismer* [36.61], *Titli* [36.17], *Ho* and *Mitter* [36.62], *Sage* [36.63], *Šiljak* [36.3, 64], *Singh* [36.65], *Findeisen* et al. [36.16], *Jamshidi* [36.6], *Lunze* [36.66], and *Brdys* and *Tatjewski* [36.18] followed on and contributed to the consolidation of the LSS domain of research and paved the way for practical applications.

In 1976, the first International Federation of Automatic Control (IFAC) conference on *Large-Scale Systems: Theory and Applications* was held in Udine, Italy. This was followed by a series of symposia which were organized by the specialized Technical Committee of IFAC and took place in various cities in Europe and Asia (Toulouse, Warsaw, Zurich, Berlin, Beijing, London, Patras, Bucharest, Osaka, and Gdansk). The scientific journal *Large Scale Systems* published by North Holland played an important role in the development of LSS domain, especially in the 1980s.

36.2 Methods and Applications

36.2.1 Hierarchical Systems Approach

The central idea of the *hierarchical multilevel systems* (HMS) approach to LSS consists of replacing the original system (and the associated control problem) with a multilevel structure of *smaller* subsystems (and associated less complicated problems). The subproblems at the bottom of the hierarchy are defined by the *interventions* made by the higher-level subproblems, which in turn utilize the *feedback information* they receive from the solutions of the lower-level subproblems.

There are three main subclasses of hierarchies which can be obtained in accordance with the complexity of *description*, *control task*, and *organization* [36.7].

Levels of Description

The first step in analyzing an LSS and designing the corresponding control scheme consists of model building. As *Steward* [36.67] points out, practical experience witnessed there is a *paradoxical law of systems*. If the description of the plant is too complicated, then the designer is tempted to consider only a part of the system or a limited sets of aspects which characterize its behavior. In this case it is very likely that the very ignored parts and aspects have a crucial importance. Consequently it emerges that more aspects should be considered, but this may lead to a problem which is too complex to be solved in due time. To solve the conflict between the necessary *simplicity* (to allow for the usage of existing methods and tools with a reasonable consumption of time and other computer resources) and the acceptable *precision* (to avoid obtaining wrong or unreliable results), the LSS can be represented by a family of models. These models reflect the behavior of the LSS as viewed from various perspectives, called [36.7] *levels of description* or *strata*, or *levels of influence* [36.63, 68]. The description levels are governed by independent laws and principles and use different sets of descriptive variables. The lower the level is, the more detailed the description of a certain entity is. A unit placed on the n-th level may be viewed as a subsystem at level $n-1$. For example, the same manufacturing system can be described from the top stratum in terms of economic and financial models, and, at the same time, by control variables (states, controls, and disturbances) as viewed from the middle stratum, or by physical and chemical variables as viewed from the bottom description level (Fig. 36.2).

Levels of Control

In order to act in due time even in emergency situations, when the available data are uncertain and the decision consequences are not fully explored and evaluated, a hierarchy of specialized control functions can be an effective solution as shown by *Eckman* and *Lefkowitz* [36.70]. Several examples of sets of levels of control are:

a) Regulation, optimization, and organization [36.71]
b) Direct control, supervisory control, optimization, and coordination [36.72]
c) Stabilization, dynamic coordination, static optimization, and dynamic optimization [36.8]
d) Measurement and regulation, production planning and scheduling, and business planning [36.73].

The levels of control, also called *layers* by *Mesarovic* et al. [36.7], can be the result of a time-scale decomposition. They can be defined on the basis of time horizons taken into consideration, or the frequency of disturbances which may show up in process variables, operation conditions, parameters, and structure of the plant as stated by *Schoeffler* [36.68], as shown in Fig. 36.2.

Levels of Organization

The hierarchies based on the complexity of organization were proposed in mid 1960s by *Brosilow* et al. [36.74] and *Lasdon* and *Schoeffler* [36.75] and were formalized in detail by *Mesarovic* et al. [36.7]. The hierarchy with several levels of organization, also called *echelons* by *Mesarovic* et al. [36.7], has been, for many years, a natural solution for management of large-scale military, industrial, and social systems, which are made up of several interconnected subsystems when a centralized scheme cannot be either technically possible or economically acceptable.

The central idea of the multiechelon hierarchy is to place the control/decision units, which might have different objectives and information bases, on several levels of a management and control pyramid. While the multilayer systems implement the vertical division of the control effort, the multiechelon systems include also a horizontal division of work. Thus, on the n-th organization level the i-th control unit, CU_i^n, has limited autonomy. It sends *coordination* signals downwards to a well-defined subset of control units which are placed at the level $n-1$ and it receives coordination signals from the corresponding unit placed

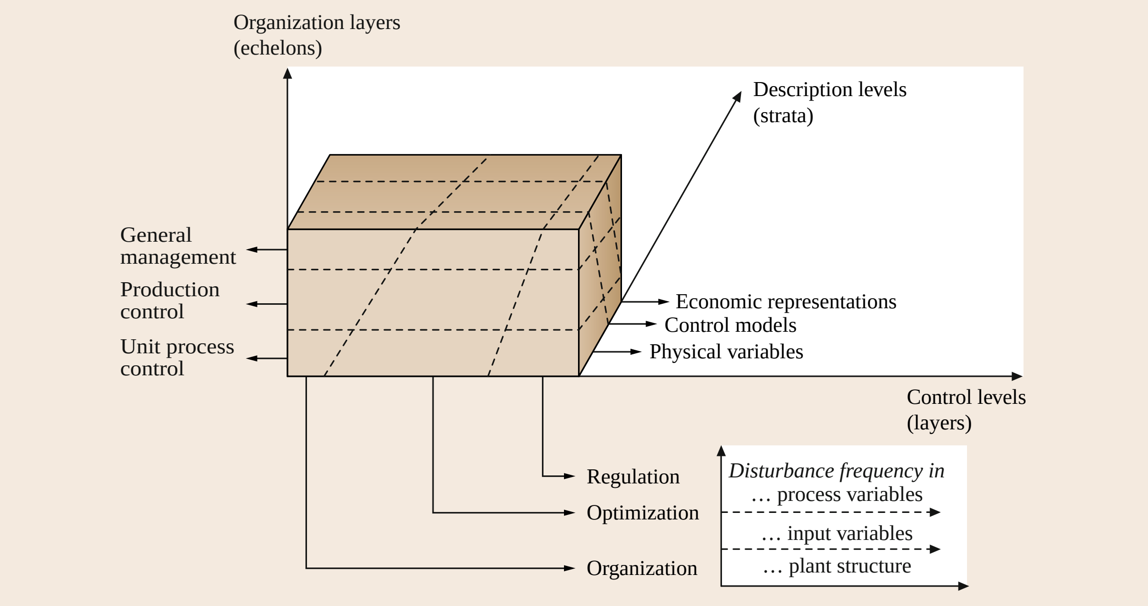

Fig. 36.2 A hierarchical system approach applied to an industrial plant (after [36.69])

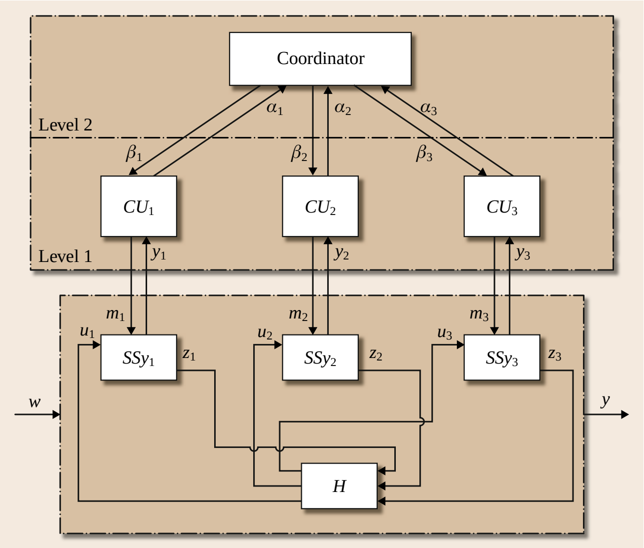

Fig. 36.3 A simple two-level multilevel control system ($CU =$ control unit, $SSy =$ controlled subsystem, $H =$ interconnection function, $m =$ control variable, $u =$ input interconnection variable, $z =$ output interconnection variable, $y =$ output variable, $w =$ disturbance)

on level $n+1$. The unit on the top of the pyramid is called the *supremal coordinator* and the units to be found at the bottom level are called *infimal units*.

Manipulation of Complex Mathematical Problems

To take advantage of possible benefits of hierarchical multilevel systems a systematic decomposition of the original large-scale system and associated control problem is necessary. There are many situations when the control problem may be formulated as (or reduced to) an *optimization problem* **(P1)**, which is, defined in general terms as

$$(\mathbf{P1}):\quad \operatorname*{extr}_{v} J(v)\,;\qquad v \in V\,, \tag{36.1}$$

where v is the decision variable (a scalar, or a vector), V is the admissible variation domain (which can be defined by differential or difference equations and/or algebraic inequations), and J is the performance measure (which can be a function or a functional).

The decomposition methods are based on various combinations of several *elementary manipulations* [36.76]. There are two main subsets of *elementary manipulations*:

a) Transformations, which are meant to substitute the original large-scale complex problem by a more manipulable one
b) *Decompositions*, which are meant to replace a large-scale problem by a number of smaller subproblems.

In the sequel several elementary manipulations will be reviewed following the lines exposed by *Wilson* [36.76].

The *variable transformation* replaces the original problem **(P1)** by an equivalent one **(P2)** through the utilization of a new variable $y = f(x)$ and a new performance measure $Q(y)$ and admissible domain Y, so that there is the inverse function $v = f^{-1}(v)$. The new problem is defined as

$$\begin{aligned}(\mathbf{P2}):\quad &\operatorname*{extr}_{y} Q(y)\,;\\ &(y \in Y)\,,\ (\forall y) = f(v)[Q(y) = J(v)]\,.\end{aligned} \tag{36.2}$$

The *Lagrange transformation* can simplify the admissible domain; for example, let the domain V be defined by complicated equalities and inequalities

$$V = \left\{v : (v \in V_1)\,,\ (g_0(v)\,,\ g_-(v) \le 0)\right\}\,, \tag{36.3}$$

where V_1 is a certain set, g_0 and g_- represent equality and inequality constraints, respectively.

A Lagrangian can be defined

$$L(v,\pi,\gamma) = J(v) + \langle \pi, g_0(v)\rangle - \langle \gamma, g_-(v)\rangle\,, \tag{36.4}$$

where π are the Lagrange multipliers, γ are the Kuhn–Tucker multipliers, and $\langle\cdot,\cdot\rangle$ is the scalar product.

If L possesses a saddle point, the solution of **(P1)** is also the solution of the transformed problem **(P2)** defined as

$$(\mathbf{P2}):\quad \max_{\pi\gamma}\min_{v}[L(v,\pi,\gamma)]\,;\ v \in V_1\,. \tag{36.5}$$

The manipulation called *evolving the problem* is utilized when not all parameters are known or the priorities and the constraints are subject to alteration in time. In such situations, the problem is solved even under uncertainties and then is reformulated to take into account the accumulation of new information. The *repetitive control* proposed by *Findeisen* et al. [36.16] is based on such a transformation.

Having transformed the original problem into a convenient form, a subset of *smaller* subproblems can be obtained through *decomposition* as shown in the sequel.

The partitioning of the large-scale problem can be applied if several subsets of independent variables can be identified; for example, let (**P1**) be defined as

$$(\mathbf{P1}): \quad \operatorname{extr}[J^1(v^1) + J^2(v^2)]\ ;\ v^1 \in V^1\ ;\ v^2 \in V^2\ , \tag{36.6}$$

then, two independent subproblems ($\mathbf{P2}^1$) and ($\mathbf{P2}^2$) can be obtained

$$(\mathbf{P2}^1): \quad \operatorname{extr}[J^1(v^1)]\ ; \quad v^1 \in V^1\ , \tag{36.7}$$

$$(\mathbf{P2}^2): \quad \operatorname{extr}[J^2(v^2)]\ ; \quad v^2 \in V^2\ . \tag{36.8}$$

This decomposition is utilized in assigning separate subproblems to the controllers which are situated at the same level of a hierarchical pyramid or in decentralized control schemes where the controllers act independently.

The parametric decomposition divides the large-scale problem into a pair of subproblems by setting temporary values to a set of *coupling parameters*. While in one problem of the pair the coupling parameters are fixed and all other variables are free, in the second subproblem they are free and the remaining variables are fixed as solutions of the first subproblem. The two subproblems are solved through an iterative scheme which starts with a set of guessed values of the coupling parameters; for example, let the large-scale problem be defined as follows

$$(\mathbf{P1}): \quad \underset{v}{\operatorname{extr}}[J(v)]\ ;\ v = (\alpha, \beta)\ ;\ (\alpha \in A)\ ,\ (\beta \in B)\ ;$$
$$\alpha R \beta\ ,$$

where α and β are the components of v, A and B are two admissible sets, β is the coupling parameter, and R is a relation between α and β. The problem (**P1**) can be divided into the pair of subproblems (**P2**) and (**P3**)

$$(\mathbf{P2}): \quad \underset{\alpha}{\operatorname{extr}}\left[J\left(\alpha, \overset{*}{\beta}\right)\right]\ ;\ (\alpha \in A)\ ,\ (\alpha R \beta)\ ,$$
$$(\mathbf{P3}): \quad \underset{\beta}{\operatorname{extr}}\left[J\left(\overset{*}{\alpha}(\beta), \beta\right)\right]\ ;\ (\beta \in B)\ ,$$
$$\left\{\exists \overset{*}{\alpha}\left[\left(\overset{*}{\alpha} \in A\right)\ ,\ \left(\overset{*}{\alpha} R \beta\right)\right]\right\}\ ,$$

where $\overset{*}{\alpha}(\beta)$ is the solution of (**P2**) for the given value $\beta = \overset{*}{\beta}$ and $\overset{*}{\beta}$ is the solution of (**P3**) for the given value $\alpha = \overset{*}{\alpha}$.

The parametric decomposition is utilized to divide the effort between a coordinating unit and the subset of coordinated units situated at lower organization level (echelon).

The *structural decomposition* divides the large-scale problem into a pair of subproblems through modifying the performance measure and/or constraints. While one subproblem consists in setting the best/satisfactory formulation of the performance measure and/or admissible domain, the second one is to find the solution of the modified problem. This manipulation is utilized to divide the control effort between two levels of control (layers).

From Coordination to Cooperation

The traditional multilevel systems proposed in the 1970s to be used for the management and control of large-scale systems can be viewed as *pure hierarchies* [36.77]. They are characterized by the circulation of *feedback* and *intervention* signals only along the vertical axis, up and down, respectively, in accordance with traditional concepts of the command and control systems. They constituted a theoretical basis for various industrial distributed control systems which possess at highest level a powerful minicomputer. Also the *multilayer* and *multiechelon* hierarchies served in the 1980s as a conceptual reference model for the efforts to design *computer-integrated manufacturing* (CIM) systems [36.78, 79].

Several new schemes have been proposed over the last 25 years to overcome the drawbacks and limits of the practical management and control systems designed in accordance with the concepts of pure hierarchies such as: inflexibility, difficult maintenance, and limited robustness to major disturbances. The more recent solutions exhibit ever more increased communication and cooperation capabilities of the management and control units. This trend has been supported by the advances in communication technology and artificial intelligence; for example, even in 1977, *Binder* [36.80] introduced the concept of *decentralized coordinated control with cooperation*, which allowed limited communication among the control unit placed at the same level. Several years later, *Hatvany* [36.81] proposed the *heterarchical* organization, which allows for exchange of information among the units placed at various levels of the hierarchy.

The term *holon* was first proposed by *Koestler* in 1967 [36.82] with a view to describing a general organization scheme able to explain the evolution and life of biological and social systems. A holon cooperates with other holons to build up a larger structure (or to solve a complex problem) and, at the same time, it works toward attaining its own objectives and treats the various situations it faces without waiting for any instructions from the entities placed at higher levels. A *holarchy* is a hierarchy made up of holons. It is characterized by several features as follows [36.83]:

- It has a tendency to continuously grow up by attracting new holons.
- The structure of the holarchy may permanently change.
- There are various patterns of interactions among holons such as: communication messages, negotiations, and even aggressions.
- A holon may belong to more than one holarchy if it observes their operation rules.
- Some holarchies may work as pure hierarchies and others may behave as heterarchical organizations.

Figure 36.4 shows an object-oriented representation of a holarchy. The rectangles represent various classes of objects such as pure hierarchies, heterarchical systems, channels, and holons. This shows that the class of holarchies may have particular subclasses such as *pure hierarchies* and *heterarchical systems*. Also a holarchy is composed of several constituents (subclasses) such as: holons (at least one *coordinator* unit and two *infimal/coordinated units* in the care of pure hierarchies) and *channels for coordination* (in the case of pure hierarchies) or *channels for cooperation* (in the case of pure heterarchies). Coordination channels link the supremal unit to, at least, two infimal units. While there are, at least, two such coordination links in the case of pure hierarchies, a heterarchical system may have no such link. While, at least, one cooperation channel is present in a heterarchical system, no such a link is allowed in a pure hierarchy.

Fig. 36.4 Holarchies: an object-oriented description

Management and control structures based on holarchy concepts were proposed by *Van Brussel* et al. [36.84], *Valckenaers* et al. [36.85] for implementation in complex discrete-part manufacturing systems.

To increase the autonomy of the decision and control units and their cooperation the multiagent technology is recommended by *Parunak* [36.57] and *Hadeli* et al. [36.53]. An *intelligent software agent* encapsulates its code and data, is able to act in a proactive way, and cooperates with other agents to achieve a common goal [36.86]. The control structures which utilize the agent technology have the advantage of simplifying industrial transfer by incorporating existing legacy systems, which can be encapsulated in specific agents. *Mařík* and *Lažanský* [36.55] make a survey of industrial applications of agent technologies which also considers pros and cons of agent-based systems. They also present two applications:

a) A shipboard automation system which provides flexible and distributed control of a ship's equipment
b) A production planning and scheduling system which is designed for a factory with the possibility of influencing the developed schedules by customers and suppliers.

36.2.2 Other Methods and Applications

Decentralized Control

Feedback control of large-scale systems poses the standard control problem: *to find a controller for a given system with control input and control output ensuring closed-loop systems stability and reach a suitable input–output behavior*. The fundamental difference between small and large systems is usually described by a pragmatic view: a system is large if it is conceptually or computationally attractive to decompose it into interconnected subsystems. Such subsystems are typically of small size and can be solved easier than the original system. The subsystem solutions can be combined in some manner to obtain a satisfactory solution for the overall system [36.87].

Decentralized control has consistently been a control of choice for large-scale systems. The prominent reason for adopting this approach is its capability to solve effectively the particular problems of dimensionality, uncertainty, information structure constraints, and time delays. It also attenuates the problems that communication lines may cause. While in the hierarchical control schemes, as shown above, the control units are coordinated through intervention signals and may be allowed to exchange cooperation messages, in decentralized control, the units are completely independent or at least almost independent. This means that the information flow network among the control units can be divided into completely independent partitions. The units that belong to different subnetworks are completely separate from each other. Only restricted communication at certain time moments or intervals or limited to small part of information among the units is allowed. Decentralized structures are often used but their performance is worse compared with the centralized case. The basic decentralized control schemes are as follows:

- *Multichannel system*. The global system is considered as one whole. The control inputs and the control outputs operate only locally. This means that each channel has available only local information about the system and influences only a local part of the system.
- *Interconnected systems*. The overall system is decomposed according to a selected criterion. Then local controllers are designed for each subsystems. Finally, the local closed-loop subsystems and interconnections are tested to satisfy the desired overall system requirements.

At present a serious problem is the lack of relevant theoretic and methodological tools to support the scalable solution of new networked complex large-scale problems including asynchronous issues. The recent accomplishments are aimed at broadening the scope of decentralized control design methods using *linear matrix inequalities* (LMIs) [36.31], dynamic interaction coordinator design to ensure the desired level of interconnections [36.32], advanced decentralized control strategies for complex switching systems [36.26], hybrid large-scale systems [36.27], Petri nets [36.25], large-scale supply chain decentralized coordination [36.28, 29], and distributed control systems with network communication [36.30].

Simulation-Based Scheduling and Control in LSS

In continuous, large-scale industrial plants such as in chemical, power, and paper industries and waste-water treatment plants, simulation-based scheduling starts from creating scenarios for production and comparing these scenarios for optimality and availability. Problems can vary from order allocation between multiple production lines to optimal storage usage and detection and compensating for bottlenecks. Heuristic rules are usually connected to simulation, making it possible to adjust the production to varying customer needs, minimize the use of raw materials and energy, decrease the environmental load, stabilize or improve the quality, etc. Early applications in the paper industry are given by *Leiviskä* et al. [36.38, 39]. The main problem is to balance the production and several intermediate storages in (multiple) production lines, and give room for maintenance shutdowns and coordinate production rate changes. The model is based on the state model with storage capacities as the state variables and production rates as the control variables. Heuristics and bottleneck considerations are connected to these systems. A newer, agent-based solution has also been proposed [36.52]. There are also several classical optimization-based solutions for this problem [36.19, 21–24].

Modern chemical batch processes are large scale, complex, serial/parallel, multipurpose processes. They are especially common in the food and fine chemicals industries. They resemble flexible manufacturing systems common in electronics production. From the scheduling and control point of view complexity brings along also difficult interactions and uncertainty that are difficult to tackle with conventional tools. Simulation-based scheduling can include as much complexity as needed, and it is a largely used tool in the evaluation of the performance of different optimizing systems. Connecting heuristics or rule-based systems to simulation makes it also a flexible tool for batch process scheduling. Modeling approaches differ, e.g., real-time simulation using Petri nets [36.36] and the combination of discrete event simulation with genetic algorithms for the steel annealing shop have been proposed [36.40].

Flexible manufacturing systems, e.g., for components assembly, offer several difficulties for production scheduling and control. Dynamic, random nature is one main concern in operation control. Also quickly changing products and production environments, especially in electronics production, lead to a great variability in requirements for production control. In real cases, it is also typical that several scenarios must be created and evaluated. The handling of uncertain and vague information itself causes also problems in real-world applications. Uncertain data has to be extracted from data sources avoiding noise, or at least avoiding increasing it.

Discrete event simulation models the system as it propagates over time, describing the changes as separate discrete events. This approach also found a lot of applications in manufacturing industries, queuing systems, and so on. An early application to jobshop scheduling is presented by *Filip* et al. [36.20], who utilize various combinations of several dispatching rules to create the list of future events. *Taylor* [36.17] reported on an application of discrete event simulation, combined with heuristics, to the scheduling of the printed circuit board (PCB) assembly line. The situation is complicated by the fact that the production control must operate on three levels: at the system level concerning production mix problems, at the cell level for routing problems, and at the machine level to solve sequencing problems. Discrete event simulation is also the key element in the shop floor scheduling system proposed by *Gupta* et al. [36.35]. The procedure starts by creating feasible schedules for the telephone terminals plant, helps in taking other requirements into account and in tackling uncertainties, and makes rescheduling possible. A system integrating simulation and neural networks has been used in photolithography toolset scheduling in wafer production [36.33]. The system uses the weighted-score approach, and the role of the neural network is to update the weights set to different selection criteria. Fuzzy logic provides the arsenal of methods for dealing with uncertainties. Several examples for PCB production are given by *Leiviskä* [36.45].

Two-stage approaches have been used in bottleneck-based approaches [36.34]. The first-pass simulation recognizes the bottlenecks, and their operation are optimized during the second-pass simulation. Better control of work in bottlenecks improves the performance of the whole system. The main dispatching rule is to group together the lots that need the same setups. The system also reveals the non-bottleneck machines and makes it possible to apply different dispatching rules according to the process state. The example is from semiconductor production.

In practice, scheduling is a part of the decision hierarchy starting from the enterprise-level strategic decisions and going down to machine-level order or tools scheduling. Simulation is used at different levels of this hierarchy to provide interactive means for guaranteeing the overall optimality or at least the feasibility of the decisions made at different levels. Such integrated and interactive approaches exist also in supply-chain management systems. In large-scale manufacturing systems, supply-chain control must take four interacting factors into account: suppliers, manufacturing, distribution, network, and customers. To control all these interactions successfully, various operating factors and constraints – processing times, production capacities, availability of raw materials, inventory levels, and transportation times – must be considered.

Discrete event simulation is also one possibility to create an object-oriented, scalable, simulation-based control architecture for supply-chain control [36.41]. Requirements for modularity and maintainability also lead to distributed simulation models, especially when a simulation-based control architecture is controlling supply chain interactions. This means a modeling technique including a federation of simulation models that are solved in a coordinated manner. The system architecture is presented in [36.42]. Each supply-chain entity has two simulation models associated with it – one running in real time and the other as a lookahead simulation. The lookahead model is capable of predicting the impact of a disturbance observed by the real-time model. A *federation object coordinator* (FOC) coordinates the real-time simulation models. In this case, a *master event calendar* allocates interprocess events to all simulation models and resynchronizes all simulations at the end of every activity [36.37].

In simulation-based control the controller makes decisions based both on the current state of the system and future scenarios, usually produced by simulation. Here, the techniques for calculation of these scenarios play the main role. *Ramakrishnan* and *Thakur* [36.42] proposed the extension *sequential dynamic systems* (SDS) that they call *input–output SDS* to model and analyze distributed control systems and to compensate for the weaknesses of automata-based models. They use the discrete-part production plant as an example.

Artificial Intelligence-Based Control in LSS

Artificial intelligence (AI)-based control in large-scale systems uses, in practice, all the usual methods of intelligent control: fuzzy logic, neural networks, and genetic algorithms together with different kinds of hybrid solutions [36.88]. The complex nature of applications makes the use of intelligent systems advantageous. Dealing with this complexity is also the biggest challenge for the methodological development: the large-scale process structures, complicated interconnections, nonlinearity, and multiple time scales make the systems difficult to model and control. *Fuzzy logic control* (FLC) has found most of its applications in cases which are difficult to model, suffer from uncertainty or imprecision, and where a skilful operator is superior to conventional automation systems. *Artificial neural networks* (ANN) contribute to modeling and forecasting tasks and combined with fuzzy logic in neuro-fuzzy systems combine the benefits of both approaches. *Genetic algorithms* (GA), which are basically optimization systems, are used in tuning models and controllers. See Chap. 14 on *Artificial Intelligence and Automation* for additional content.

As shown above, the control of large-scale industrial plants have usually been based on distributed hardware and hierarchical design of control functions [36.89, 90]. The supervisory and local control levels lay under enterprise and mill-wide control levels. Supervisory control provides the local controls with the set points that fulfil the quality and schedule requirements coming from the mill-wide level and help in optimizing the operation of the whole plant. This *optimization* leaves room for versatile application of intelligent methods. Local units on the other hand, control the actual process variables according to the set points given by the supervisory control level. Even though the proportional–integral–differential (PID) controller is by far the most important tool, intelligent control plays an increasing role also at the local control level. Intelligent methods have been useful in tuning local PID controllers. In practice, fuzzy controllers must have adaptive capabilities. Gain scheduling is a typical approach for large-scale systems, but applications of model reference adaptive control and self-tuning adaptive control exist. Self-tuning has been used in controlling a pilot-scale rotary drum where the disturbances are due to long and varying time delays and changes in the raw materials [36.46].

Model-based control techniques, e.g., *model predictive control* (MPC), have been applied for the control of processes with a long delay or dead time. In MPC, the controller based on a plant model determines a manipulated variable profile that optimizes some performance objectives over the time in question. ANN are used in replacing the mathematical models in optimization as shown in a survey made by *Hussain* [36.48]. Also Takagi–Sugeno fuzzy models are used in connection with *model-based predictive control* [36.44]. Hybrid systems include both continuous- and/or discrete-time dynamics together with discrete events. So their state consists of real-valued, discrete-valued, and/or logical variables. *Support vector machines* have been used as a part of MPC strategy for hybrid systems [36.91].

Power systems have been an important application field for intelligent control since 1990s [36.92]. Design of centralized controllers is difficult for many obvious reasons: power systems are large scale and decentralized by nature. They are also nonlinear and have multiple dynamics and considerable time delays. Decentralized local control can apply linear models and purely local measurements. *Available transfer capability* (ATC) is a real-time index used in monitoring and controlling the power transactions and avoiding overloading of the transmission lines [36.47]. There are difficulties in calculating it accurately online for large-scale systems. Decreasing the number of input variables to only three and using fuzzy modeling helps in this. Simulations show that neural-networks-based local excitation controls can take care of interactions between generators and dampen oscillations effectively. Neural networks are used in approximating unknown dynamics and interconnections [36.40]. The designing of the controller for two-area hydrothermal power systems based on genetic algorithm improves the rise time and settling time, and simulations show that the proposed technique is superior to the traditional methods [36.51]. A local Kalman filter and genetic algorithms estimate all local states and interactions between subsystems in a large-scale power system. The controller uses these estimates, optimizes a given performance index, and then regulates the system states [36.50].

Agent-based technologies have been used in complex, distributed systems. Good examples come from intelligent control of highly distributed systems in the chemical industry and in the area of utility distribution (power, gas, and waste-water treatment). As shown above, holonic agents take care of machine or cell-level (local) controls, sometimes even integrated with machines. Intelligent agents can be associated with each manufacturing unit and they communicate, coordinate their activities, and cooperate with each other.

Fault detection and diagnosis (FDD) may be tackled by decomposing the large-scale problem into smaller subtasks and performing control and FDD locally [36.93]. Large-scale complex power systems need systematic tools for protection and control. The supervisory control technique and a design procedure of a supervisor that coordinates the behavior of relay agents to isolate fault areas are presented in [36.56]. Multiagent systems have also been used in identification and control of a 600 MW boiler–turbine–generator unit [36.54]. In this case, online identifiers are used for control and offline identifiers for fault diagnosis. Event-based approaches are used for building large-scale distributed systems and applications, especially in a networked environment. A hybrid approach of event-based communications for real-time manufacturing supervisory control is applied for large-scale warehouse management [36.94]. See Chap. 30 on *Automating Error and Conflict Prognostics and Prevention* for additional content.

Computer-Supported Decision Making in Large-Scale Complex Systems

As shown above, a possible solution to many LSS control problems is the use of artificial-intelligence methods. However, in the field, due to strange combinations of external influences and circumstances, rare or new situations may show up that were not taken into consideration at design time. Already in 1990, *Martin* et al. remarked that [36.95]:

> *although AI and expert systems were successful in solving problems that resisted to classical numerical methods, their role remains confined to support functions, whereas the belief that evaluation by man of the computerized solutions may become superfluous is a very dangerous error.*

Based on this observation, *Martin* et al. [36.95] recommended *appropriate automation*, which integrates technical, human, organizational, economical, and cultural factors.

The *decision support system concept* (DSS) appeared in the early 1970s. As with any new term, the significance of DSS was in the beginning rather vague and controversial. While some people viewed it as a new redundant term used to describe a subset of management information systems (MIS), some other argued it was a new label abusively used by some vendors to take advantage of a new fashion. Since then many research and development activities and applications have witnessed that the DSS concept definitely meets a real need and there is a market for it even in the context of real-time applications in the industrial milieu [36.96, 97].

The Nobel Prize winner *H. Simon* [36.98] identified three steps of the *decision-making* (DM) process, namely:

a) *Intelligence*, consisting of activities such as data collection and analysis in order to recognize a decision problem
b) *Design*, including activities such as model statement and identification/production and evaluation of various potential solutions to the problem
c) *Choice*, or selection of a feasible alternative for implementation.

Later, he added a fourth step – implementation and result evaluation – which may correspond to supervisory control in industrial milieu. If a decision problem cannot be entirely clarified and all possible decision alternatives cannot be fully explored and evaluated before a choice is made, then the problem is said to be *unstructured* or *semistructured*. If the problem were completely structured, an automatic device could have solved the problem without any human intervention. On the other hand, if the problem has no structure at all, nothing but hazard can help. If the problem is semistructured a computer-aided decision can be envisaged.

Most of the developments in the DSS domain have initially addressed business applications not involving any real-time control. However, even in the early 1980s DSS were reported to be used in manufacturing control [36.20, 99]. In 1987, *Bosman* [36.100] stated that control problems could be looked upon as a *natural extension* and as a *distinct element* of planning *decision-making processes* (DMP). Almost 20 years later, *Nof* et al. state [36.12]:

> ... *the development and application of intelligent* decision support systems *can help enterprises cope with problems of uncertainty and complexity, to increase efficiency, join competitively in production networks, and improve the scope and quality of their* customer relations management *(CRM).*

Real-time decision-making processes (RT DMPs) for control applications are characterized by several particular aspects such as:

a) They involve continuous monitoring of a dynamic environment.
b) They are short time horizon oriented and are carried out on a repetitive basis.
c) They normally occur under time pressure.
d) Long-term effects are difficult to predict [36.101].

It is quite unlikely that an *econological* (*economically logic*) approach, involving optimization, be technically possible for genuine RT DMPs. *Satisficing* approaches, which reduce the search space at the expense of the decision quality, or fully automated DM systems, if taken separately, cannot be accepted either, but for some exceptions. At the same time, one can notice that genuine RT DMP can show up in *crisis* situations only; for example, if a process unit must be shut down due to an unexpected event, the production schedule of the entire plant might become obsolete. The right decision will be to take the most appropriate compensation measures to *manage the crisis* over the time period needed to recomputed a new schedule or update the current one. In this case, a *satisficing decision* may be appropriate. If the crisis situation has been met previously and successfully surpassed, an almost automated solution based on past decisions stored in the

information system can be accepted and validated by the human operator. On the other hand, the minimization of the probability of occurrences of crisis situations should be considered as one of the inputs (expressed as a set of constraints or/and objectives) in the scheduling problem [36.96, 102].

In many problems, decisions are made by a group of persons instead of an individual. Because the *group decision* is either a combination of individual decisions or a result of the selection of one individual decision, this may not be *rational* in Simon's acceptance. The group decision is not necessarily the best choice or a combination of individual decisions, even though those might be optimal, because various individuals might have various perspectives, goals, information bases, and criteria of choice. Therefore, group decisions show a high *social* nature, including possible conflicts of interest, different visions, influences, and relations [36.103]. Consequently, a *group* (or *multiparticipant*) DSS needs an important communication facility.

The generic framework of a DSS, proposed by *Bonczek* et al. in 1980 [36.104] and refined later by *Holsapple* and *Whinston* [36.105] is quite general and can accommodate the most recent technologies and architectural solutions. It is based on three essential components. The first one is the *language* (and *communications*) *subsystem* (LS). This is used for:

a) Directing data retrieval, allowing the user to invoke one out of a number of report generators
b) Directing numerical or symbolic computation, enabling the user either to invoke the models by names or construct model and perform some computation at his/her free will
c) Maintaining knowledge and information in the system
d) Allowing communication among people in case of a group DM
e) Personalizing the user interface.

The *knowledge subsystem* (KS) normally contains:

a) *Empirical knowledge* about the state of the application environment in which the DSS operates

b) *Modeling knowledge*, including basic modeling blocks and computerized simulation and optimization algorithms to use for deriving new knowledge from the existing knowledge
c) *Derived knowledge* containing the constructed models and the results of various computations
d) *Meta-knowledge* (knowledge about knowledge) supporting model building and experimentation and result evaluation
e) *Linguistic knowledge* allowing the adaptation of system vocabulary to a specific application
f) *Presentation knowledge* to allow for the most appropriate information presentation to the user.

The third essential component of a DSS is the *problem processing subsystem* (PPS), which enables combinations of abilities and functions such as information acquisition, model formulation, analysis, evaluation, etc.

It has been noticed that some DSS are *oriented* towards the left hemisphere of the human brain and some others are oriented towards the right hemisphere. While in the first case quantitative and computational aspects are important, in the second pattern recognition and reasoning based on analogy prevail. In this context, there is a significant trend towards combining numerical models and models that emulate the human reasoning to build advanced DSS [36.106]. A great number of optimization algorithms have been developed and carefully tested so far. However, their effectiveness in decision making has been limited. Over the last three decades traditional numerical methods have, along with databases, been essential ingredients of DSS. From an information technology perspective, their main advantages [36.107] are: compactness, computational efficiency (if the model is correctly formulated), and the market availability of software products. On the other hand, they present several disadvantages. Because they are the result of intellectual processes of abstraction and idealization, they can be applied to problems which possess a certain structure, which is hardly the case in many real-life problems. In addition, the use of numerical models requires that the user possesses certain skills to formulate and experiment the model. As was shown in the previous section, AI-based methods supporting decision making are already promising alternatives and possible complements to numerical models. New terms such as *tandem systems*, or *expert DSS (XDSS)* have been proposed for systems that combine numerical models with AI-based techniques. An ideal task assignment is given in Table 36.2 [36.97].

36.3 Case Studies

The following case studies illustrate how combinations of methods may be utilized to solve large-scale complex problems.

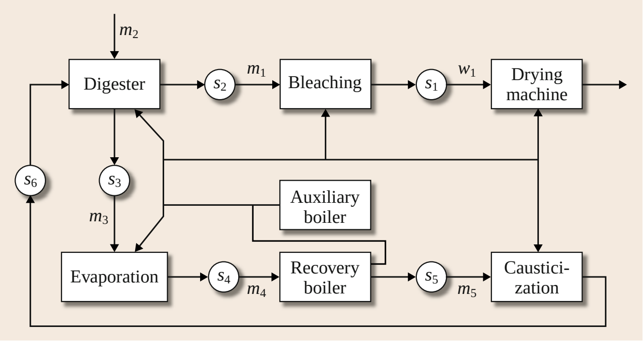

Fig. 36.5 Pulp mill model

36.3.1 Case Study 1: Pulp Mill Production Scheduling

Figure 36.5 shows the pulp mill modeled as a common state-space system. The state of the system $s(t)$ is described by the amount of material in each storage tank. The production rates of the processes are chosen as control variables forming the control vector $\boldsymbol{m}(t)$. The required pulp production is usually taken as a deterministic known disturbance vector $\boldsymbol{w}(t)$.

The operation of the plant presented in Fig. 36.5 is described by the vector–matrix differential equation

$$\frac{\mathrm{d}\boldsymbol{s}(t)}{\mathrm{d}t} = \mathbf{B}\boldsymbol{m}(t) + \mathbf{C}\boldsymbol{w}(t) ,$$

where **B** and **C** are coefficient matrices describing the relationships between the model flows (transfer ratios).

Since the most storage tanks have only one input flow and one output flow, most elements in **B** and **C** matrices equal zero.

If the steam balance (dashed line in Fig. 36.5) is included in scheduling, an additional variable describing the steam development in the auxiliary boiler is required. It is a scalar variable denoted by S. Accordingly, the steam balance is

$$S(t) = D\boldsymbol{m}(t) + E\boldsymbol{w}(t) .$$

Note that the right-hand side of the balance includes both consumption and generation terms. The variables in the model are constrained by the capacity limits of tanks and processes in the following way

$$\begin{aligned} s^{\min} &\le \boldsymbol{s}(t) \le s^{\max} , \\ \boldsymbol{m}^{\min} &\le \boldsymbol{m}(t) \le \boldsymbol{m}^{\max} , \\ S^{\min} &\le S(t) \le S^{\max} . \end{aligned}$$

Due to the fact that scheduling is concerned with relatively long time intervals, no complete and complicated process models are necessary. If all the small storage tanks are included in the model, the system dimensions increase and it becomes difficult to deal with. These tanks also have no meaning from the control point of view. Simpler model follows by combining small storage tanks.

There are several ways to solve the scheduling problem as shown before. Optimization can benefit from decomposition and solving of smaller problems as described in Sect. 36.2.1. A review of methods is presented in [36.39]. It seems, however, that no approach alone can deal with this problem successfully. Hybrid systems, consisting of algorithmic, rule-based, and intelligent parts integrated with each other, and also agent-based systems, could be the best possible answer [36.97, 110].

36.3.2 Case Study 2: Decision Support in Complex Disassembly Lines

In [36.108], the control of a complex industrial disassembly process of out-of-use manufactured products is studied. The disassembly processes are subject to uncertainties. The most difficult problem in such systems is that a disassembly operation can fail at any moment because of the product or component degradation. In this case one has to choose between applying an alternative disassembly destructive operation (dismantling), and aborting the disassembly procedure. This decision must be taken in real time because in a used product the components states are not known from the beginning of the process. The solution is to integrate a decision support system (DSS) in the architecture of a multilayer system. As shown in Fig. 36.6, the control and decision tasks are distributed among three levels: planning, decision support, and direct control. The disassembly planner gives the sequence of the components that must be separated to achieve the target component. The planner fuses the information from the artificial vision system with that contained in the database for each component or subassembly. A model of the product is generated. The DSS integrates the model and performs the simulation to rec-

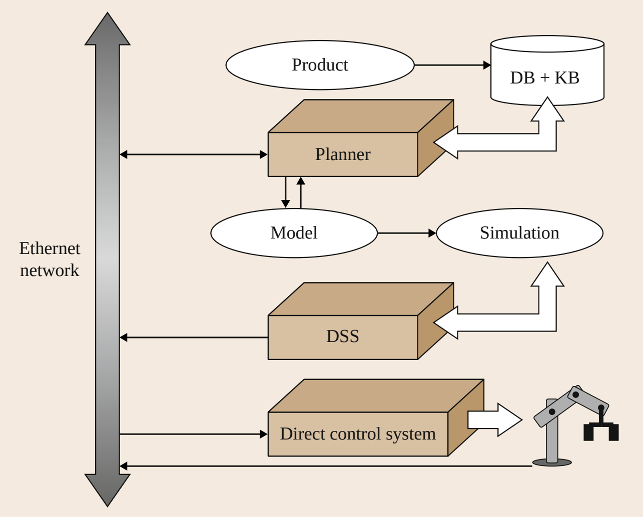

Fig. 36.6 DSS integration in the multilayer control system (after [36.108])

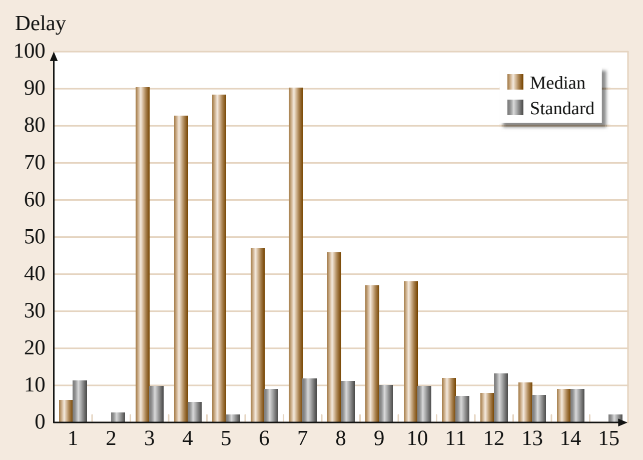

Fig. 36.7 The results of time delay estimation for one group (after [36.109])

ommend a *good* disassembly sequence with respect to the economical criteria.

36.3.3 Case Study 3: Time Delay Estimation in Large-Scale Complex Systems

In data-based modeling of large-scale complex systems, the exact determination of time delays is extremely difficult. The methods for delay estimation are widely studied in control engineering, but these studies are mainly limited to the two-variable cases, i. e., estimating the delay between the manipulated and the controlled variable in the feedback control loop. The situation is totally different when dealing with a large number of variables grouped in several groups for modeling or monitoring purposes.

Mäyrä et al. [36.109] discuss a delay estimation scheme combining genetic algorithms and principal component analysis (PCA). Delays are optimized with genetic algorithms with objective functions based on PCA. Typically, a genetic algorithm maximizes the variance explained by the first or two first principal components. The paper gives an example using simulation data of the paper machine, which includes over 50 variables. The variables were first grouped based on the cross-correlation and graphical analysis into five groups, and delays were estimated both for the variables inside the groups and between the groups. The results for one group of 15 variables are given in Fig. 36.7. The estimation was repeated 60 times and the figure shows the median and standard variance of these simulations.

36.4 Emerging Trends

Large-scale complex systems have become a research and development domain of automation with a series of rather established method and technologies and industrial application. Table 36.3 contains a summary of references to basic concepts.

At present academics and industrial practitioners are working to adapt the methods and practical solutions in the LSS field to modern information and communication technologies and new enterprise paradigms. Several significant trends which can be noticed or forecast are:

Table 36.3 Key to references on basic concepts

- A promising modern form to coordinate the actions of the intelligent agents is *stigmergy*. This is inspired by the behavior of social insects which use a form of indirect communication mediated by an active environment to coordinate their actions [36.53].
- Advanced decentralized control strategies for large-scale complex systems have recently been extended into new applied areas, such as flexible structures [36.113, 114], Internet congestion control [36.115], aerial vehicles [36.116], or traffic control [36.117], to mention a few of them.
- Recent theoretic achievements in decentralized control can be progressively extended into the areas of integrated/embedded control, distributed control (over communication networks), hybrid/discrete-event systems and networks, and autonomous systems to serve as a very efficient tool to solve various large-scale control problems.
- Incorporation and combination of newly developed numeric optimization and simulation models and symbolic/and connectionist or agent-based will continue in an effort to reach the *unification* of humans, numerical models, and AI-based tools.
- Mobile communications and web technology will be ever more considered in LSS management and control applications. In multiparticipant DSS, people will make co-decisions in *virtual teams*, no matter where they are temporarily located.

37. Computer-Aided Design, Computer-Aided Engineering, and Visualization

Gary R. Bertoline, Nathan Hartman, Nicoletta Adamo-Villani

This chapter is an overview of computer-aided design (CAD) and computer-aided engineering and includes elements of computer graphics, animation, and visualization. Commercial brands of three-dimensional (3-D) modeling tools are dimension driven, parametric, feature based, and constraint based all at the same time. The term *constraint-based* is intended to include all of these many facets. This means that, when geometry is created, the user specifies numerical values and requisite geometric conditions for the elemental dimensional and geometric constraints that define the object. Many of today's modern CAD tools also operate on similar interfaces with similar geometry-creation command sequences [37.1] that operate interdependently to control the modeling process. Core modules include the sketcher, the solid modeling system itself, the dimensional constraint engine, the feature manager, and the assembly manager [37.2]. In most cases, there is also a drawing tool, and other modules that interface with analysis, manufacturing process planning, and machining. The 3-D animation production process can be divided into three main phases:

- Concept development and preproduction
- Production
- Postproduction and delivery.

These processes can begin with the 3-D geometry generated by CAD systems in the design process or 3-D models can be created as a separate process. The second half of the chapter explains the process commonly used to create animations and visualizations.

37.1 Modern CAD Tools

Today's commercial brands of 3-D modeling tools essentially contain many of the same types of functions across the various vendor offerings. They are dimension driven, parametric, feature based, and constraint based all at the same time, and these terms have come to be synonymous when describing modern CAD systems [37.3]. For the purposes of this chapter, the term *constraint-based* will be intended to include all of these many facets. Generally this means that, when geometry is created, the user specifies numerical values and requisite geometric conditions for the elemental dimensional and geometric constraints that define the object; for example, a rectangular prism would be defined by parameter dimensions that control its height, width, and depth. In addition, many of today's modern CAD tools also operate on similar interfaces with similar geometry-creation command sequences [37.1]. Generally, most constraint-based CAD tools consist of software modules that operate interdependently to control the 3-D modeling process. They include core modules such as the sketcher, the solid modeling system itself, the dimensional constraint engine, the feature manager, and the assembly manager [37.2]. In most cases, there is also a drawing tool, and other modules that interface with analysis, manufacturing process planning, and machining. The core modules are used in conjunction with each other (or separately as necessary) to develop a 3-D model of the desired product. In so doing, most modern CAD systems will produce the same kinds of geometry, irrespective of the software interface they possess. Many of the modern 3-D CAD tools combine constructive solid geometry (CSG) and boundary representation (B-rep) modeling functionality to form hybrid 3-D modeling packages [37.2, 3]. Traditionally, CSG used mathematical primitives to create 3-D models. They were efficient for the storage of the database, but they had difficulty with sculpted surfaces and editing the finished model. B-rep modelers use surfaces directly to represent the object three-dimensionally, so they tend to be very accurate. However, they also tend to have large database structures, hence the development of hybrids to capture the best characteristics of both B-rep and CSG.

Constraint-based CAD tools create a solid model as a series of features that correspond to operations that would be used to create the physical object. Features can be created dependently or independently of each other with respect to the effects of modifications made to the geometry. If features are dependent, then an update to the parent feature will affect the child feature. This is known as a *parent–child reference*, and these references are typically at the heart of most modeling processes performed by the user [37.2]. The geometry of each feature is controlled by the use of modifiable constraints that allow for the dynamic update of model geometry as the design criteria change. When a parent feature is modified, it typically creates a ripple effect that yields changes in the child features. This is one example of *associativity* – the fact that design changes propagate through the geometric database and associated derivatives of the model due to the interrelationships between model features. This dynamic editing capability is also reflected in assembly models that are used to document the manner in which components of a product interact with each other. Modifications to features contained in a part will be displayed in the parent part as well as in the assembly that contains the part. Any working drawings of the part or assembly will also update to reflect the changes. This is another example of *associativity*.

A critical issue in the use of constraint-based CAD tools is the planning that happens prior to the creation of the model [37.3]. This is known as design intent. Much of the power and utility of constraint-based CAD tools is derived from the fact that users can edit and redefine part geometry as opposed to deleting and recreating it. This requires a certain amount of thought with respect to the relationships that will be established between and within features of a part and between components in an assembly. The ways in which the model will be used in the future and how it could potentially be manipulated during design changes are both factors to consider when building the model. The manner in which the user expects the CAD model to behave under a given set of circumstances, and the effects of that behavior on other portions of the same model or on other models within the assembly, is known as design intent [37.2, 3]. The eventual use and reuse of the model will have a profound effect on the relationships that are established within the model as well as the types of features that are used to create it, and vice versa.

37.2 Geometry Creation Process

Geometry is created in modern constraint-based CAD systems using the modules and functionality described above, especially the sketcher, the dimensional constraint engine, the solid modeling system, and the feature manager. Modern CAD systems create many different kinds of geometry, which generally fall into one of three categories: wireframe, surface or solid. Most users work towards creating solid geometry. In doing so, the user often employs the larger functionality of the CAD system described in the previous section. To create solid geometry, the user considers their design intent and proceeds to make the first feature of the model. The most common way to create feature geometry within a part file is to sketch the feature's cross-section on a datum plane (or flat planar surface already existing in the part file), dimension and constrain the sketched profile, and then apply a feature form to the cross-section. Due to the inherent inaccuracies of sketching geometric entities on a computer screen with a mouse, CAD systems typically employ a constraint solver. This portion of the software is responsible for resolving the geometric relationships and general proportions between the sketched entities and the dimensions that the user applies to them, which is another example of automation in the geometric modeling process. The final stage of geometry creation is typically the application of a feature form, which is what gives a sketch its depth element. This model creation process is illustrated in Fig. 37.1. This automated process of capturing dimensional and parametric information as part of the geometry creation process is what gives modern CAD systems their advantage over traditional engineering drawing techniques in terms of return on investment and efficiency of work. Without this level of automation, CAD systems would be nothing more than an electronic drawing board, with the user being required to recreate a design from scratch each time.

As the user continues to use the feature creation functions in the CAD system, the feature list continues to grow. It lists all of the features used to create a model in chronological order. The creation of features in a particular order also captures design intent from the user, since the order in which geometry is created will have a final bearing on the look (and possibly the function) of the object. In most cases, the feature tree is also the location where the user would go to consider modifying the order in which the model's features were created (and rebuilt whenever a change is made to the topology of the model).

As users become more proficient at using a constraint-based CAD system to create geometry, they adopt their own mental model for interfacing with the software [37.4]. This mental model typically evolves to match the software interface metaphor of the CAD system. In so doing, they are able to leverage their expertise regarding the operation of the software to devise highly sophisticated methods for using the CAD systems. This level of sophistication and automation by the user is due in some part to the nature of the constraint-based CAD tools. It is also what enables the user to dissect geometric models created by others (or themselves at a prior time) and reuse them to develop new or modified designs. Effective use of the tools requires that the user's own knowledge base comprised of the conceptual relationships regarding the capture of design intent in the geometric model and the specific software skills necessary to create geometry be used. This requires the use of an object–action interface model and metaphor on the part of the user in order to be effective [37.1]. This interface model correlates the objects and actions used in the software with those used in the physical construction of the object being modeled. If a person is to use the CAD tool effectively, these two sets of models should be similar. In relation to the object–action interface model is the idea of a user's mental model of the software tool [37.1]. This mental model is comprised of semantic knowledge of how the CAD system operates, the relationships between the different modules and commands, and syntactic knowledge that is comprised of specific knowledge about commands and the interface (Fig. 37.2).

The process of creating 3-D geometry in this fashion allows the user to automate the capture of their design intent. Semantic and syntactic knowledge are combined once in the initial creation of the model to develop the intended shape of the object being modeled. This encoding of design knowledge allows the

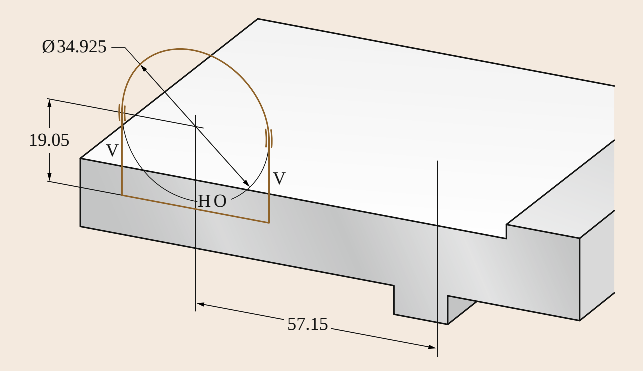

Fig. 37.1 Sketch geometry created on a plane and extruded for depth

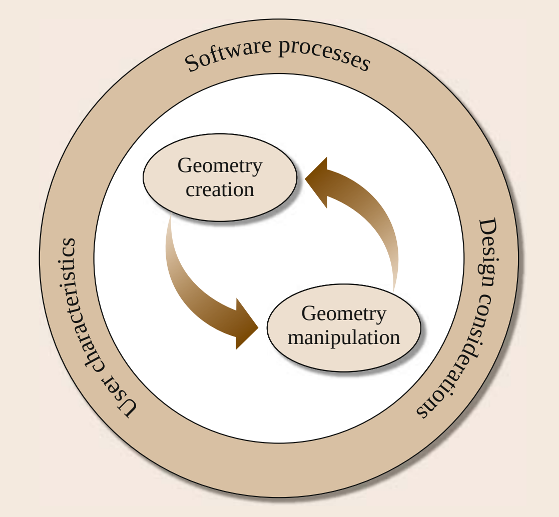

Fig. 37.2 Expert mental model of modern CAD system operation

labor of creating geometry to be stored and used again when the model is used in the future. This *labor storage* is manifested within the CAD system inside the geometric features themselves, and the *script* for playing back that knowledge-embedding process is captured within the feature manager as described in Sect. 37.2. It is generally common knowledge within the modern 3-D modeling environment that a user will likely work with models created by other people and vice versa. As such, having a predictable means to include design intent in the geometric model is critical for the reuse of existing CAD models within an organization.

37.3 Characteristics of the Modern CAD Environment

Computer-aided design systems are used in many places within a product design environment, but each scenario tends to have a common element: the need to accurately define the geometry which represents an object. This could be in the design engineering phase to depict a product, or during the manufacturing planning stage for the design if a fixture to hold a workpiece. Recently, these CAD systems have been coupled with *product data management* (PDM) *systems* to track the ongoing changes through the lifecycle of a product. By so doing, the inherent use of the CAD system can be tracked, knowledge about the design can be stored, and permissions can be granted to appropriate users of the system. While the concept of concurrent engineering is not new, contemporary depictions of that model typically show a CAD system (and often a PDM system) at the center of the conceptual model, disseminating embedded information for use by the entire product development team throughout the product lifecycle [37.3].

To use a modern CAD system effectively, one must understand the common inputs and outputs of the system, typically in light of a concurrent and distributed design and manufacturing environment. Input usually takes the form of numerical information regarding size, shape, and orientation of geometry during the product model creation process. This information generally comes directly from the user responsible for developing the product; however, it is not uncommon to get CAD input data from laser scanning devices used for quality control and inspection, automated scripts for generating seed geometry, or translated files from other systems. As with other types of systems, the quality of the information put into the system greatly affects the quality of the data coming out of the system. In today's geographically dispersed product development environment, CAD geometry is often exported from the CAD system is a neutral file format (e.g., IGES or STEP) to be shared with other users up

and down the supply chain. Detailed two-dimensional drawings are often derived from the 3-D model in a semi-automated fashion to document the product and to communicate with suppliers. In addition, 3-D CAD data is generally shared in an automated way (due to integration between digital systems) with structural and manufacturing analysts for testing and process planning.

Geometry creation within CAD systems is also automated for certain tasks, especially those of a repetitive nature. The use of geometry duplication functions often involves copying, manipulating, or moving selected entities from one area to another on a model. This reduces the amount of time that it takes a user to create their finished model. However, it is critical that the user be mindful of parent–child references as described previously. While these references are elemental to the very nature of modern CAD systems, they can make the modification and reuse of design geometry tenuous at a later date, thereby negating any positive effects of a user having copied geometry in an effort to save time. Geometry automation also exists in the form of using scripting and programming functionality in modern CAD systems to generate geometry based on common templates. This scenario is particularly helpful when it is necessary to produce variations of objects with high degrees of accuracy and around which exists a fair amount of tribal knowledge and corporate practice. A set of parameters are created that represents corporate knowledge to be embedded into the geometry to control its shape and behavior and then the CAD system generates the desired geometry based on user inputs (Figs. 37.3 and 37.4). In the example of the airfoil, aerodynamic data has been captured by an engineering analyst and input into a CAD system using a knowledge-capture module of the software. These types of modules allow a user to configure the behavior of the CAD system when it is supplied with a certain type of data in the requisite format. This data represents the work of the analyst, which is then used to automate the creation of the 3-D geometry to represent the airfoil. Such techniques are beginning to replace the manual geometric modeling tasks performed by users on designs that require a direct tie to engineering analysis data, or on those designs where a common geometry is shared among various design options.

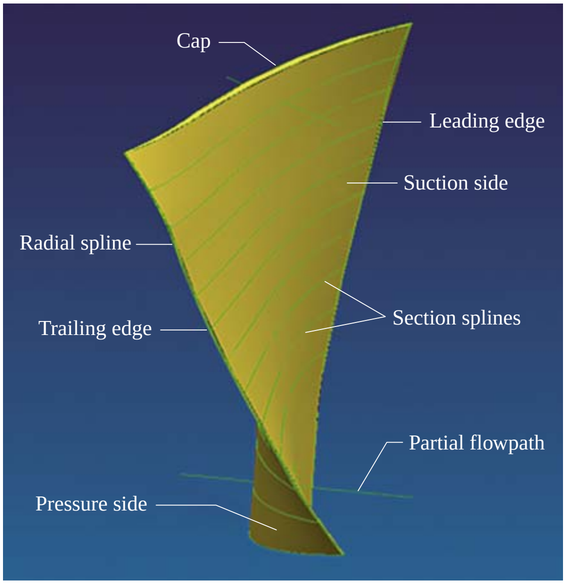

Fig. 37.4 Airfoil geometry generated from script (labels not generated as part of script)

37.4 User Characteristics Related to CAD Systems

Contemporary CAD systems require a technological knowledge base independent of (yet complementary to) normal engineering fundamentals. An understanding of design intent related to product function and how that is manifested in the creation of geometry to represent the product is critical [37.4, 5]. Users require the knowledge of how the various modules of a CAD systems work and the impact of their command choices on the usability of geometry downstream in the design and manufacturing process. In order to enable users to accomplish their tasks when using CAD tools, training in how to use the system is critical. Not just at a basic level for understanding the commands themselves, but the development of a community of practice to support the ongoing integration of user knowledge into organizational culture and best practices is critical.

Complementary to user training, and one of the reasons for why relevant training is important in the use of CAD tools, is for users to develop *strategic knowledge* in the use of the design systems. Strategic knowledge is the application of procedural and factual knowledge in the use of CAD systems directed towards a goal within a specific context [37.6–8]. It is through the development of strategic knowledge that users are able to effectively utilize the myriad functionality within modern CAD systems. Nearly all commercial CAD systems have similar user interfaces, similar geometry creation techniques, and similar required inputs and optional outputs. Productivity in the use of CAD systems requires that users employ their knowledge of engineering fundamentals and the tacit knowledge gathered from their environment, in conjunction with technological and strategic knowledge of the CAD system's capabilities, to generate a solution to the design problem at hand.

37.5 Visualization

Visualization information can be presented in visual formats such as text, graphics, charts, etc. This visualization makes applications simpler to understand by human users. Visualization is useful in automation not only for supervision, control, and decision support, but also for training. A variety of visualization methods and software are available, including geographic information systems and virtual reality (see examples in Chaps. 15, 16, 26, 27, 34, 38, and 73).

A geographic information system (GIS) is a computer-based system for capturing, manipulating, and displaying information using digitized maps. Its key characteristic is that every digital record has an identified geographical location. This process, called geocoding, enables automation applications for planning and decision making by mapping visualized information.

Virtual reality is interactive, computer-generated, three-dimensional imagery displayed to human users through a head-mounted display. In virtual reality, the visualization is artificially created. Virtual reality can be a powerful medium for communication and collaboration, as well as entertainment and learning. Table 37.1 lists examples of visualization applications (see also Chap. 15 on *Virtual Reality and Automation*).

Table 37.1 Examples of visualization applications

Application domain	Examples of visualization applications
Manufacturing	Virtual prototyping and engineering analysis

37.6 3-D Animation Production Process

Computer animations and simulations are commonly used in the engineering design process to visualize movement of parts, determine possible interferences of parts, and to simulate design analysis attributes such as fluid and thermal dynamics. The 3-D model files of most CAD systems can be converted into a format that can be used as input into popular animation software programs, such as Maya and 3ds Max. Once the files have been input into the animation software program, the animation process can begin. The animation process can be quite complex, depending on the level of realism necessary for the design visualization. This section will describe the steps necessary to create design animations from CAD models.

The 3-D animation production process can be divided into three main phases:

- Concept development and preproduction (Sect. 37.6.1)
- Production (Sect. 37.6.2)
- Postproduction and delivery (Sect. 37.6.3).

37.6.1 Concept Development and Preproduction

Several key activities take place during this phase, including story development and visual design, production planning, storyboarding, soundtrack recording, animation timing, and production of the animatic.

Every animation tells a *story*, "…you need not to have characters to have a story …" [37.9]; for example an architectural walkthrough or a medical visualization has a story in the sense that the events progress in a logical and effectively developed way. Story development begins with a *premise* – an idea in written form [37.10]. When the premise is approved, it is expanded into an *outline* or *treatment* – a scene-by-scene description of the animation – and the treatment is fleshed out into a full *script*. Visual design is carried out concurrently to story development. It is during this conceptual stage that the visual style of the animation is defined, character/object/environment design is finalized and approved for production, and the story idea is translated into a visual representation – the *storyboard*.

A *storyboard* is a sequence of images – *panels* – and textual descriptions describing the story, design, action, pacing, sound track, effects, camera angles/moves, and editing of the animation. Figure 37.5 shows an example of a preliminary storyboard. *Animation timing* is the process of pacing the action on the storyboard panels in order to tell the story in a clear and effective manner. The most common method of timing is the creation of a *story reel* or *animatic*. The creation of the animatic [37.11]: "… is essentially the process of combining the sound track with the storyboard to pace out the sequence". In addition to scanned-in storyboard panels with digitized soundtrack, the animatic can include simulated camera moves and rough motion of characters and objects. The main purpose of the animatic is to show the flow of the story by blocking the timing of the individual shots and defining the transitions between them. It provides an opportunity to

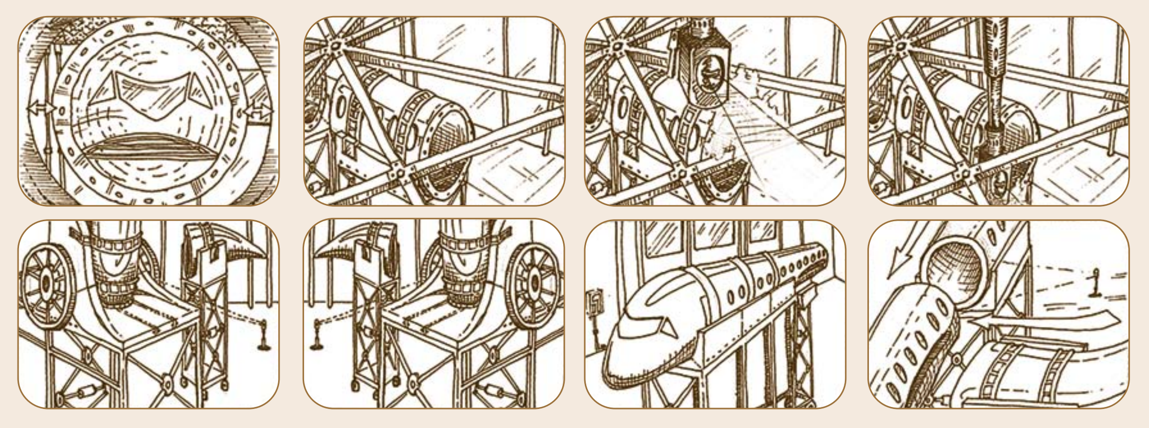

Fig. 37.5 An example of preliminary storyboard illustrating the futuristic assembly process of a Boeing 787 (courtesy of Purdue University, with permission from *N. Adamo-Villani, C. Miller*)

experiment with different cinematic solutions and to visualize whether the final animation makes sense as a filmic narrative.

37.6.2 Production

The production phase includes the following activities: 3-D modeling, texturing, rigging, animation, camera setup, lighting, and rendering.

Modeling

"Modeling is the spatial description and placement of objects, characters, environments and scenes with a computer system" [37.12]. In general, 3-D models for animation are produced using one of four approaches: *surface modeling*, *particle-system modeling*, *procedural modeling* or *digitizing techniques*.

In *surface modeling* surfaces are created using *spline*, *polygon* or *subdivision surfaces* modeling methods. A *spline* model consists of one or several *patches*, i. e., surfaces generated from two spline curves. Different splines generate different types of patches; the majority of spline models used in 3-D animation consist of nonuniform rational B-splines (NURBS) patches, which are generated from NURBS curves. A *polygonal model* consists of flat polygons, i. e., multisided objects composed of *edges*, *vertices*, and *faces*; a *subdivision surface* results from repeatedly refining a polygonal mesh to create a progressively finer mesh. Each subdivision step refines a submesh into a supermesh by inserting more vertices. In this way several levels of detail are created, allowing highly detailed modeling in isolated areas.

Common techniques used to create surface models include: *lathe*, *extrude*, *loft*, and *Boolean operations*; for instance, a polygonal mesh or a NURBS surface can be created by drawing a curve in space and rotating it around an axis (*lathe* or *revolve*); or by drawing a curve and pushing it straight back in space (*extrude*); or by connecting a series of contour curves *(loft)*. *Boolean operators* allow for combination of surfaces in various ways to produce a single piece of geometry. Three Boolean operations are commonly used in 3-D modeling for animation: *addition* or *union*, *subtraction*, and *intersection*. The *addition* operation combines two surfaces into a single, unified surface; the *subtraction* operation takes away from one object the space occupied by another object, and the *intersection* operation produces an object consisting of only those parts shared by two objects, for instance, overlapping parts.

Particle-system modeling is an approach used to represent phenomena as fire, snow, clouds, smoke, etc. which do not have a stable and well-defined shape. Such phenomena would be very difficult to model with surface or solid modeling techniques because they are composed of large amounts of molecule-sized *particles* rather than discernible surfaces. In particle-system modeling, the animator creates a system of particles, i. e., graphical primitives such as points or lines, and defines the particles' physical attributes. These attributes control how the particles move, how they interact with the environment, and how they are rendered. Dynamics fields can also be used to control the particles' motion.

Procedural modeling includes a number of techniques to create 3-D models from sets of rules. *L-systems*, *fractals*, and *generative modeling* are examples of procedural modeling techniques since they apply algorithms for producing scenes; for instance, a terrain model can be produced by plotting an equation of fractal mathematics that recursively subdivides and displaces a patch.

When a physical model of an object already exists, it is possible to create a corresponding 3-D model using various *digitizing methods*. Examples of digitizing tools include *3-D digitizing pens* and *laser contour scanners*. Each time the tip of a 3-D pen touches the surface of the object to be digitized, the location of a point is recorded. In this way it is possible to compile a list of 3-D coordinates that represent key points on the surface. The 3-D modeling software uses these points to build the corresponding digital mesh, which is often a polygonal surface. In *laser contour scanning* the physical object is placed on a turntable, a laser beam is projected onto its surface, and the distance the beam travels to the object is recorded. After each 360° rotation a contour curve is produced and the beam is lowered a bit. When all contour curves have been generated, the 3-D software builds a lofted surface.

Surface models can be saved to a variety of formats. Some file formats are exclusive to specific software packages (*proprietary formats*), while others are *portable*, which means they can be exchanged among different programs. The two most common portable formats are ".obj" (short for object) introduced by Alias for high-end computer animation and visual effects productions, and the drawing interchange format (DXF) developed by Autodesk and widely used to exchange models between CAD and 3-D animation programs.

Texturing

Texturing is the process of defining certain characteristics of a 3-D surface such as color, shininess, reflectivity, transparency, incandescence, translucence, and smoothness. Frequently, these characteristics or *parameters* are treated as a *single set* called a *shader* or a *computer graphics (CG) material*. A *shader parameter* can be assigned a single value (for, example the color parameter can be assigned an RGB value of 255,0,0; in this case the entire surface is red), or the value can vary across the surface. *Two-dimensional (2-D) texture mapping* is a method of varying the texture parameter values across the surface using 2-D images. For example a 2-D picture can be applied to a 3-D surface to produce a certain color or transparency pattern. The 2-D picture can be a digital photo, a scanned image, an image produced with a 2-D paint program, or it can be generated procedurally. In general, the application of the 2-D image to the 3-D surface can be implemented in two ways: by projecting the image onto the surface (*projection mapping*) or by stretching it across the surface (*parameterized mapping*). In certain situations 2-D texture mapping does not produce realistic texture effects; for instance, a virtual block of marble rendered using 2-D texture techniques will appear to be wrapped in marble-patterned paper, rather than made of marble. To solve this problem it is possible to use another technique called *solid texture mapping*. The idea behind this technique is that *you create a virtual volume of texture and you immerse your object in that volume* [37.9]. Many 3-D software packages allow for creation of procedural 3-D textures. Figure 37.6 shows a rendering produced using a variety of texturing techniques.

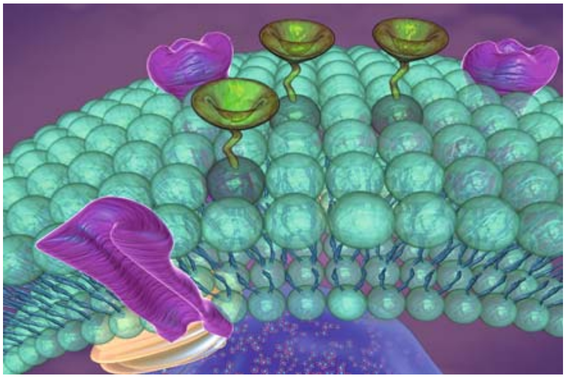

Fig. 37.6 A 3-D image produced using a variety of texture maps: color, transparency, bump, reflection, and translucence (courtesy of Purdue University, with permission from *N. Adamo-Villani*)

Rigging

Rigging is the process of setting up a 3-D object or character for animation. Common rigging techniques include: *forward kinematics* (FK) and *inverse kinematics* (IK), *hierarchical models*, *skeletal systems*, *limits*, and *constraints*. When the 3-D object/character to be animated is made of multiple segments, the segments (or *nodes*) can be organized in an FK *hierarchical model*. In an FK hierarchy a node just below another node is called a *child*, while the node just above is called a *parent*, and the flow of transformations goes from parent to child. In order to animate an FK hierarchical model, each node needs to be selected and transformed individually to attain a certain pose. This process can become complicated and tedious when the model is very elaborate; for example, imagine a situation in which the animator needs to place the hand of a 3-D human-like character on a particular object. With an FK model, the animator has to first rotate the shoulder, then the lower arm, then the wrist, hand and fingers, working from the top of the hierarchy down. He cannot select the hand and place it on the object because the other parts of the arm will not follow, as they are parents of the hand. This problem can be solved by creating an *inverse kinematics* model in which the transformations travel upward through the hierarchy, for instance, from the hand to the shoulder. In this case the animator can place the hand on the object and have the other segments (lower arm and upper arm) follow the motion. An IK model is also called an *IK chain* and each node is referred to as a *link*. The first link of the chain is called the *root* of the chain and the end point of the last link is called the *effector* (as it *affects* the positions of all the other links, i. e., it effects the *IK solution*). In principle, each link in a chain can rotate any number of degrees around any axis. While these unrestricted rotations may be appropriate in certain situations, they are not likely to produce realistic results when the IK system is applied, for instance, to a human or animal model. This is due to the fact that human and animal joints have rotational limits; for example, the knee joint cannot bend beyond $\approx 180°$. To solve this problem it is common to set up *limits* and *constraints*. Limits can be defined for any of a model's three basic transformations (translation, rotation and scale); in addition, the transformations can be constrained (i. e., associated) to the transformations of other objects. *Position* or *point*, *rotation* or *orient*, and *direction* or *aim* are common types of constraints used in 3-D animation.

Many 3-D animation packages allow for creation of both FK and IK models. In general, to rig complex characters or objects the animator creates a *skeletal system*, i. e., a hierarchical model composed of joints connected by bones. The segments that make up the 3-D character/object are parented to the joints of the skeleton and the skeleton can function as an FK or IK model, with the possibility to switch between the two modes of operation during the animation process. If the 3-D object/character is supposed to deform during motion, the 3-D geometry can be attached (or *skinned*) to the skeletal joints; in this case the skeleton functions as a *deformation system*.

Animation

Common 3-D animation techniques include: *keyframe*, *motion path*, *physically-based*, and *motion capture animation*. In *keyframe animation*, the animator sets *key* values to various objects' parameters and saves these values at particular points in the timeframe; this process is called *setting keyframes*. After the animator has defined the keyframes, the 3-D software interpolates the values of the object's parameters between the keyframes. To gain more control of the interpolation, a parameter curve editor is available in the majority of 3-D animation packages. The parameter curve editor shows a graphical representation of the variation of a parameter's value over time (the *animation curve*. The animation curves are Bézier curves whose control points are the actual keyframes. Two tangent handles (vectors) are available at each control point (or keyframe) and allow the animator to manipulate the shape of the curve and thus the interpolation.

Motion path animation is used when the object to be animated needs to follow a well-defined path (for instance, a train moving along the tracks). In this case the animator draws the path, attaches the object to the path, and defines the number of frames required to reach the end of the path. In addition, the animator has the ability to control the rate of motion along the path, and the orientation of the object. The main advantage of motion path over keyframe animation is that, if the path is modified, the animation of the object that follows it updates to the path's changes.

Physically based animation is based on dynamics methods and is used to generate physically accurate simulations. Several steps are required to set up a dynamic simulation including definition of the objects' physical attributes (i. e., mass, initial velocity, elasticity, etc.); modeling of dynamic forces acting upon the objects; and definition of collisions. A dynamic simulation can be *baked* before the animation is rendered; *baking* is the process of generating an animation curve for each parameter of an object whose change over time is caused by the dynamic simulation.

Motion capture animation, also referred to as *performance animation* or *digital puppetry* [37.13]:

> ... *involves measuring an actor's (or object) position and orientation in physical space and recording that information in a computer-usable form.*

In general the position or orientation of the actor is measured by a collection of input devices (*optical markers* or *sensors*) attached to the actor's body. Each input device has three degrees of freedom (DOF) and produces 3-D rotational or translational data which are channeled to the joints of a virtual character. As the actor moves, the input devices send data to the computer model. These data are used to control the movements of the character in real time, and to generate the animation curves. Motion capture animation is often used when the animation of the 3-D character needs to match the performance of the actor very precisely.

Camera Setup

The point of view from which a scene is observed is defined by the CG camera. The point of view is determined by two components or nodes: the *location of the camera* and the camera *center of interest*. The location is a point in space, while the center of interest can be specified as a location in space (i. e., a triplet of XYZ coordinate values) or as camera direction (i. e., a triplet of XYZ rotational values). In addition to location and center of interest, important attributes of a CG camera include the *zoom* parameter [whose value determines the width of the field of view (FOV) angle], *depth of field*, and *near and far clipping planes*, used to *clip* the viewable (and therefore renderable) 3-D space in the Z direction.

Lighting

The process of lighting a CG scene involves selecting the types of light to be used, defining their attributes, and placing them in the virtual environment. Common types of light used in CG lighting include *ambient lights*, *spotlights*, *point lights*, and *directional lights*. An *ambient light* simulates the widely distributed, indirect light that has bounced off objects in the 3-D scene and provides a uniform level of illumination; a *point light* emanates light in all directions from a specific location in space (simulating a light bulb); a *spotlight* is defined by location and direction and emits light in a cone-shaped beam of variable width; and a *directional light (or infinite light*) is assumed to be located infinitely far away and simulates the light coming from the sun. Common parameters of CG lights are: *intensity*, *color*, *falloff* (i. e., decrease of intensity with distance from the light source), and *shadow characteristics* such as shadow color, resolution, and density. In general, CG shadows are calculated using two popular techniques: *ray-tracing* and *shadow depth-maps*. *Ray-tracing* traces the path of a ray of light from the light source and determines whether objects in the scenes would block the ray to create a shadow; *depth-mapped shadows* use a pre-calculated *depth map* to determine the location of the shadows in the scene. Each pixel in the depth map represents the distance from the light source to the nearest shadow-casting surface in a specific direction. During rendering the light is cut off at the distances specified by the depth map with the result of making the light appear to be blocked by the objects. The shadows in Fig. 37.7 were generated using this technique.

Rendering

Rendering is the process of producing images from 3-D data. Most rendering algorithms included in 3-D animation software packages use an approach called *scan-line rendering*. A *scan line* is a row of pixels in a digital image; in scan-line rendering the program calculates the color of each pixel one after the other, scan line by scan line. The calculation of the pixels' colors can be done using different algorithms such as *ray-casting*, *ray-tracing*, and *radiosity*. The idea behind *ray-casting* is to cast rays from the camera location, one per pixel, and find the closest object blocking the path of that ray. Using the material properties and the effect of the lights on the object, the ray-casting algorithm can determine the shading of this object. Ray-casting algorithms do not render reflections and refractions because they render the shading of each surface in the scene as if it existed in isolation, in other words other objects in the scene do not have any effect on the object being rendered. *Ray-tracing* addresses this limitation by considering all surfaces in the scene simultaneously. As each ray per pixel is cast from the camera location, it is tested for intersection with objects within the scene. In the event of a collision, the pixel's color is updated, and the ray is either recast or terminated based on material properties (such as reflectivity and refraction) and maximum recursion allowed. Although the ray-tracing algorithm can represent optical effects in a fairly realistic way, it does not render the diffuse reflection of light from one surface to another. This effect happens, for instance, when a blue object is close to a white wall. Even if the wall has very low specularity and reflectivity it will take a bluish hue because light bounces in a very diffuse way from the surface of the object to the surface of the wall. It is possible to render this phenomenon using a *radiosity* algorithm, which divides the surfaces in the scene into smaller subsurfaces or patches. A *form factor* is computed for each pair of subsurfaces; form factors are a coefficient describing how well the patches can see each other. Patches that are far away from each other, or oriented at oblique angles relative to one an-

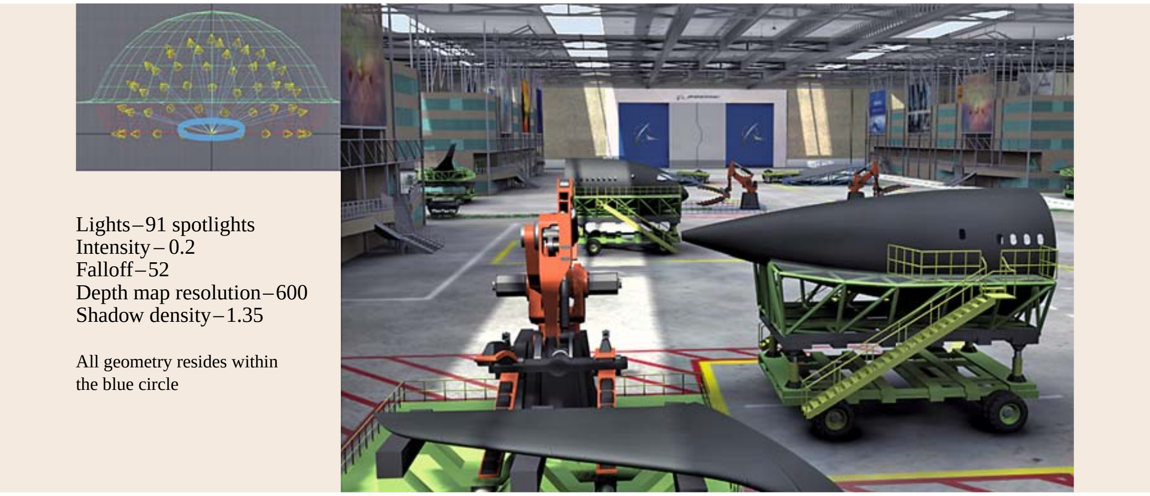

Fig. 37.7 A 3-D image rendered using a lighting setup composed of a dome of spotlights with depth-mapped shadows (courtesy of Purdue University, with permission from *N. Adamo-Villani*, *C. Miller*)

other, will have small form factors while patches that are close to each other and facing each other 100% will have a form factor close to 1. The form factors are used as coefficients in a linearized form of the rendering equation, which yields a linear system of equations. Solving this system yields the radiosity, or brightness, of each patch, taking into account diffuse interreflections and soft shadows [37.14].

Key activities of the preproduction and production phases are illustrated in Fig. 37.8.

37.6.3 Postproduction

The postproduction phase includes two main activities: digital compositing and digital output.

Digital Compositing

In general an animated sequence includes images from multiple sources that are integrated into a single, seamless whole. *Digital compositing* is the process of digitally manipulating and combining at least two source images to produce an integrated result [37.15]; for example, Fig. 37.9 is a composite created from three different original images: the buildings, roads, and grass areas are a CG rendering produced from a three-dimensional model; the trees are also computer generated 3-D imagery rendered in a different pass as paint effects strokes; and the sky is a digital photograph projected onto a 3-D dome and used as a backdrop. In addition many of the elements in the image had some additional processing performed on them as they were added to the scene (for example, color and size adjustments).

Digital Output

Computer animation sequences can be output in the form of digital files, video or film. Some of the most popular digital file formats for saving animation sequences include: QuickTime, Motion Pictures Expert Group (MPEG), audio video interleaved (AVI), and Windows Media. The QuickTime format stores both video and audio data. It is a cross-platform format that supports different spatial and temporal resolutions and provides a variety of compression options. MPEG

(developed by the Motion Pictures Expert Group) is a popular format for compressing animations; the data compression is based on the removal of data that are identical or similar not just within the frame, but also between frames [37.12]. The AVI format (introduced by Microsoft in 1992) is a generic Windows-only format for moving images; a more recent version of this format is *Windows Media*, which offers more efficient compression for streaming high-resolution images.

Output on video can be done on a variety of video formats (both analog and digital). Commonly used digital formats include *high-definition* formats such as D6, HD-D5, HDCAM, DVCPRO and *standard-definition* formats such as D1, Digital Betacam, IMX, DV(NTSC), D-VHS, and DVD.

Conclusions and Emerging Trends

This chapter provided an overview of computer-aided design and computer-aided engineering and included elements of computer graphics, animation, and visualization. Today's commercial brands of 3-D modeling tools essentially contain many of the same functions, irrespective of which software vendor is chosen. CAD software programs are dimension driven, parametric, feature based, and constraint based all at the same time, and these terms have come to be synonymous when describing modern CAD systems. Computer animations and simulations are commonly used in the engineering design process to visualize movement of parts, determine possible interferences of parts, and to simulate design analysis attributes such as fluid and thermal dynamics. Today most CAD systems 3-D model files can be converted into a format that can be used as input into popular animation software programs, such as Maya and 3ds Max. However, in the future it is anticipated that there will be a tighter integration between CAD and animation programs. CAD vendors will be under greater pressure to partner large enterprise software companies and become more product life cycle management (PLM) centric. This will result in CAD and animation becoming a part of a larger suite of software products used in industry. The rapid development of information technology and computer graphics technology will impact the hardware platforms and software development related to CAD and animation. This will result in even more feature-rich CAD software programs and capabilities. Faster screen refresh rates of large CAD models, the ability to collaborate at great distances in real time, shorter animation rendering times, and higher-resolution images are a few improvements that will result from the rapid development of information technology and computer graphics technology. Overall, there is an exciting future for CAD and animation in the future that will result in many positive impacts and changes for industries and businesses that depend on CAD and animation as a part of their day-to-day business.

38. Design Automation for Microelectronics

Deming Chen

Design automation or computer-aided design (CAD) for microelectronic circuits has emerged since the creation of integrated circuits (IC). It has played a crucial role to enable the rapid development of hardware and software systems in the past several decades. CAD techniques are the key driving forces behind the reduction of circuit design time and the optimization of circuit quality. Meanwhile, the exponential growth of circuit capacity driven by Moore's law prompts new and critical challenges for CAD techniques. Moore's law describes an important trend in the history of the semiconductor industry: that the number of transistors per unit chip area would be doubled approximately every 2 years. This observation was first made by Intel co-founder Gordon E. Moore in a paper in 1965. Moore's law has held true for the past four decades, and many people believe that it will continue to apply for at least another decade before reaching the fundamental physical limits of device fabrication.

In this chapter we will introduce the fundamentals of design automation as an engineering field. We begin with several important processor technologies and several existing IC technologies. We then present a typical CAD flow covering all the major steps in the design cycle. We also cover some important topics such as verification and technology computer-aided design (TCAD). Finally, we introduce some new trends in design automation.

38.1 Overview

Microelectronic circuits are ubiquitous nowadays. We can find them not only in desktop computers, laptops, and workstations, but also in consumer electronics, home and office appliances, automobiles, military applications, telecommunication applications, etc. Due to different requirements of these applications, circuits are designed differently to pursue unique features suitable for the specific application. In general, these devices are built with two fundamental and orthogonal technologies: *processor technology* and *IC technology*.

38.1.1 Background on Microelectronic Circuits

Processor technology refers to the architecture of the computation engine used to implement the desired functionality of an electronic circuit. It is categorized into three main branches: *general-purpose processors*, *application-specific instruction set processors*, and *single-purpose processors* [38.1]. A general-purpose processor, or microprocessor, is a device that executes software through instruction codes. Therefore, they are software-programmable. This processor has a program memory that holds the instructions and a general datapath that executes the instructions. The general datapath consists of one or several general-purpose arithmetic logic units (ALUs). An application-specific instruction set processor (ASIP) is a software-programmable processor optimized for a particular class or domain of applications, such as signal processing, telecommunication, or gaming applications. To fit the application, the datapath and instructions of such a processor are customized; for example, one type of ASIP, the digital signal processor (DSP), may have special-purpose datapath components such as a multiply–accumulate unit, which can perform multiply-and-add operations using only one instruction. Finally, a single-purpose processor is a digital circuit designed to serve a single purpose – executing exactly one program. It represents an exact fit of the desired functionality and is not software-programmable. Its datapath contains only the essential components for this program and there is no program memory. A general-purpose processor offers maximum flexibility in terms of the variety of applications it can support but with the least efficiency in terms of performance and power consumption. On the contrary, single-purpose processors offer the maximum performance and power efficiency but with the least flexibility in terms of the applications they can support. The ASIP offers a compromise between these two extremes.

IC technology refers to the specific implementation method or the design style of the processing engine on an IC. It is categorized into three main branches: *full custom*, *semicustom*, and *programmable logic device* (PLD) [38.2]. Full custom refers to the design style where the functional and physical designs are hand-crafted. This would provide the best design quality but also requires the extensive effort of a design team to optimize each detailed feature of the circuit. Since the design effort and cost are high, this design style is usually used in high-volume (thus cost can be amortized) or high-performance applications. Semicustom design is also called application-specific integrated circuit (ASIC). It tries to reduce the design complexity by restricting the circuit primitives to a limited number. Such a restriction allows the designer to use well-designed circuit primitives (gates or functional blocks) and focus on their efficient interconnection. Such a restriction also makes it easier to develop computer-aided design tools for circuit design and optimization and reduce the design time and cost. Today the number of semicustom designs outnumbers custom designs significantly, and some high-performance microprocessors have been designed partially using semicustom style, especially for the control logic (e.g., IBM's POWER-series processors and SUN Microsystems' UltraSPARC T1 processors).

Semicustom designs can be further partitioned into several major classes. Figure 38.1a shows such a partition. *Cell-based design* generally refers to *standard cell design*, where the fundamental cells are stored in a library. Cells often are simple gates and latches, but can be complex gates, memories, and logic blocks as well. These cells are pretested and precharacterized. The maintenance of the library is not a trivial task since each cell needs to be characterized in terms of area, delay, and power over ranges of temperatures and supply voltages [38.2]. Companies offer standard cell libraries for use with their fabrication and design technologies, and amortize the effort of designing the

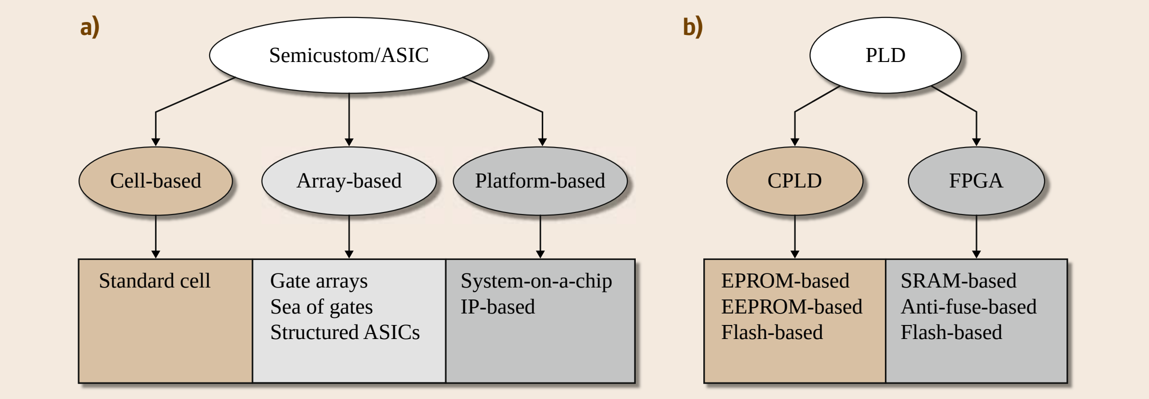

Fig. 38.1a,b Classification of **(a)** semicustom design and **(b)** PLD design (SRAM: static random access memory; EPROM: erasable programmable read-only memory; EEPROM: electrically erasable programmable read-only memory)

Table 38.1 Comparison of IC technologies

Metrics	Full custom	Semicustom	PLD
Nonrecurring engineering (NRE) cost	Very high	Medium-high	Low
Unit cost (low volume)	Very high	Medium-high	Low
Unit cost (high volume)	Low	Low	High
Design time	Very long	Medium-long	Short
Logic density	Very high	High	Low-medium
Circuit performance	Very high	High	Low-medium
Circuit power consumption	Low	Medium	High
Flexibility	Low	Medium	High

cell library over all the designs that use it. *Array-based design* in general refers to the design style of constructing a common base array of transistors and personalizing the chip by altering the metallization (the wiring between the transistors) that is placed on top of the transistors. It mainly consists of *gate arrays*, *sea of gates*, and *structured ASICs* (refer to Chap. 8 in [38.3] for details). *Platform-based design* [38.4–6] refers to the design style that heavily reuses hardware and software intellectual property (IP), which provide preprogrammed and verified design elements. Rather than looking at IP reuse in a block-by-block manner, platform-based design aggregates groups of components into a reusable platform architecture. There is a slight difference between *system-on-a-chip* and *IP-based* design. A system-on-a-chip approach usually incorporates at least one software-programmable processor, on-chip memory, and accelerating function units. IP-based design is more general and may not contain any software-programmable processors. Nonetheless, both styles heavily reuse IPs.

The third major IC technology is programmable logic device (PLD) technology (Fig. 38.1b). In PLD, both transistor and metallization are already fabricated but they are hardware-programmable. Such programming is achieved by creating and destroying wires that connect logic blocks either by making an *antifuse*, which is an open circuit device that becomes a short device when traversed by an appropriate current pulse, or setting a bit in a programmable switch that is controlled by a memory cell. There are two major PLD types: complex programmable logic devices (CPLDs) and field-programmable gate arrays (FPGA). The main difference between these two types of PLDs is that the basic programmable logic element in a CPLD is the PLA (programmable logic array) (two-level AND/OR array), and the basic element in an FPGA is the look-up table (LUT). The PLAs are programmed through a mapping of logic functions in a two-level representation onto the AND/OR logic array, and the LUTs are programmed by setting bits in the LUT memory cells that store the truth table of logic functions. In general, CPLDs' routing structures are simpler than those of FPGAs. Therefore, the interconnect delay of CPLD is more predictable compared with that of FPGAs. FPGAs usually offer much larger logic capacity than CPLDs, mainly because LUTs offer finer logic granularity than PLAs so they are suitable to be replicated massively to help achieve complex logic designs. Nowadays, a high-end commercial FPGA, such as Altera Stratix III and Xilinx Virtex-5, can contain more than 300 K LUTs. Hardware programmability has significant advantages of short design time, low design cost, and fast time to market, which become more important when the design is complex. However, PLDs offer less logic density compared with semicustom designs, mainly because they occupy a significant amount of circuit area to add in the programming bits [38.7]. Nonetheless, the number of new design starts using PLDs significantly outnumbers the new semicustom design starts. According to research firm Gartner/Dataquest, in the year 2007, there were nearly 89 000 FPGA design starts, and this number will swell to 112 000 in 2010 – some 25 times that of semicustom/ASIC designs [38.8]. Figure 38.1b provides further characterization for the implementation styles of CPLDs and FPGAs.

An important fact is that different IC technologies have different advantages and disadvantages in terms of circuit characteristics. Table 38.1 lists the comparison of these technologies using some key metrics: nonrecurring engineering (NRE) cost (a one time charge for design and implementation of a specific product), unit cost, design time, logic density, circuit performance, power consumption, and flexibility (referring

Table 38.2 Combinations between processor technologies and IC technologies

	Processor types		
IC technology types	**General purpose**	**Single purpose**	**ASIP**
Full custom	Intel Core 2 Quad AMD Opteron	Intel 3965ABG (802.11 a/b/g wireless chip) Analog ADV202 (JPEG 2000 Video CODEC)	TI TMS320C6000 (DSP)
Semicustom	ARM9 PowerPC	ATMEL AT83SND1C (MP3 Decoder)	Infineon C166 (Microcontroller)
PLD	Altera NIOS II Xilinx MicroBlaze	Altera Viterbi Decoder (Error detection)	AllianceCORE C32025 (DSP)

to the ease of changing the hardware implementation corresponding to design changes). Another important fact is that processor technologies and IC technologies are orthogonal to each other, which means that each of the three processor technologies can be implemented in any of the three IC technologies. Table 38.2 lists some representative combinations between these two technologies; for instance, general-purpose processors can be implemented using full-custom (Intel Core 2), semicustom (ARM9), or PLD (NIOS II). Each of the nine combinations has the combined features of the two corresponding technologies; for instance, Intel Core 2 represents the top but costly implementation of a general-purpose processor(s), and the Altera Viterbi Decoder represents the fast-time-to-market version of a single-purpose processor.

38.1.2 History of Electronic Design Automation

Electronic design automation (EDA) creates software tools for computer-aided design (CAD) of electronic systems ranging from printed circuit boards (PCBs) to integrated circuits. We describe a brief history of EDA next. General CAD information was provided in Chap. 37 of this Handbook. Integrated circuits were designed by hand and manually laid out before EDA. This design method obviously could not handle large and complex chips. By the mid 1970s, designers started to automate the design process using placement and routing tools. In 1986 and 1987 respectively, Verilog and VHDL (very high speed integrated circuit hardware description language) were introduced as hardware description languages. Circuit simulators quickly followed these inventions, allowing direct simulation of IC designs. Later, logic synthesis was developed, which would produce circuit netlists for downstream placement and routing tools. The earliest EDA tools were produced academically, and were in the public domain. One of the most famous was the *Berkeley VLSI Tools Tarball*, a set of UNIX utilities used to design early VLSI (very large scale integration) systems. Meanwhile, the larger electronic companies had pursued EDA internally, where the seminal work was done at IBM and Bell Labs. In the early 1980s, managers and developers spun out of these big companies to start up EDA as a separate industry. Within a few years there were many companies specializing in EDA, each with a slightly different emphasis. Many of these EDA companies merged with one another through the years. Currently, the major EDA companies include Cadence, Magma, Mentor Graphics, and Synopsys. The total annual revenue of EDA is close to six billion US dollars.

According to the International Technology Roadmap for Semiconductors, the IC technology scaling driven by the Moore's law will continue to evolve and dominate the semiconductor industry for at least another 10 years. This will lead to over 14 billion transistors integrated on a single chip in the 18 nm technology by the year 2018 [38.9]. Such a scaling, however, has already created a large design productivity gap due to inherent design complexities and deep-submicron issues. The study by the research consortium SEMATECH shows that, although the level of on-chip integration, expressed in terms of the number of transistors per chip, increases at an approximate 58% annual compound growth rate, the design productivity, measured in terms of the number of transistors per staff-month, grows only at a 21% annual compound rate. Such a widening gap between IC capacity and design productivity presents critical challenges and also opportunities for the CAD community. Better and new design methodologies are needed to bridge this gap.

38.2 Techniques of Electronic Design Automation

EDA can work on digital circuits and analog circuits. In this article, we will focus on EDA tools for digital integrated circuits because they are more prominent in the current EDA industry and occupy the major portion of the EDA market. For analog and mixed-signal circuit design automation, readers are referred to [38.10] and [38.11] for more details. Note that we can only briefly introduce the key techniques in EDA. Interested readers can refer to [38.12–14] for more details.

38.2.1 System-Level Design

Modern system-on-a-chip or FPGA designs contain embedded processors (hard or soft), busses, memory, and hardware accelerators on a single device. These embedded processors are software-programmable IP cores. Hard processors are built with full-custom or semicustom technologies, and soft processors are built with PLD implementations (Table 38.2). On the one hand, these types of circuits provide opportunities and flexibilities for system designers to develop high-performance systems targeting various applications. On the other hand, they also immediately increase the design complexity considerably, as mentioned in Sect. 38.1. To realize the promise of large system integration, a complete tool chain from concept to implementation is required. System- and behavior-level synthesis techniques are the building blocks for this automated system design flow. System-level synthesis compiles a complex application in a system-level description (such as in C or SystemC) into a set of tasks to be executed on various software-programmable processors (referred to as *software*), or a set of functions to be implemented in single-purpose processors (referred to as *customized hardware* or simply *hardware*), together with the communication protocols and the interface logic connecting different components. Such capabilities are part of the *electronic system-level* (ESL) design automation that has emerged recently to deal with the design complexity and improve design productivity. The design challenges in ESL are mainly on effective hardware/software partitioning and co-design, system integration, and related issues such as standardization of IP integration, system modeling, performance/power estimation, and system verification, etc.

Figure 38.2 illustrates a global view of the ESL design flow. The essential task is the hardware/software co-design, which requires hardware/software partitioning and incorporates three key synthesis tasks: *processor synthesis*, *interface synthesis*, and *behavioral synthesis*. Hardware/software partitioning defines the parts of the application that would be executed in software or hardware. Processor synthesis for software-programmable processors usually involves instantiation of processor IP cores or generation of processors with customized features (customized cache size, datapath, bitwidth, or pipeline stages, etc.). Behavioral synthesis is also called high-level synthesis. It is a process that takes a given behavioral description of a hardware circuit and produces an RTL (register transfer level) design automatically. We will introduce more details about behavioral synthesis in the next section. Every time the designer explores a different system architecture with hardware/software partitioning, the system interfaces must be redesigned. Interface synthesis is the process of automatic derivation of both the hardware and software interfaces to bind hardware/software elements together and permit them to communicate correctly and efficiently. Interface synthesis results need to meet bandwidth and performance requirements. The end product of ESL is an integrated system-level IC (e.g., system on a chip,

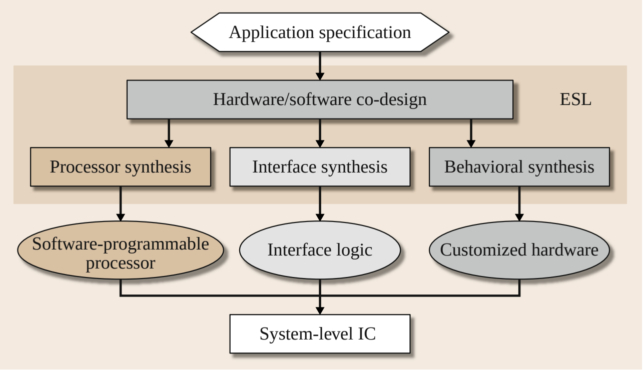

Fig. 38.2 Electronic system-level (ESL) design flow

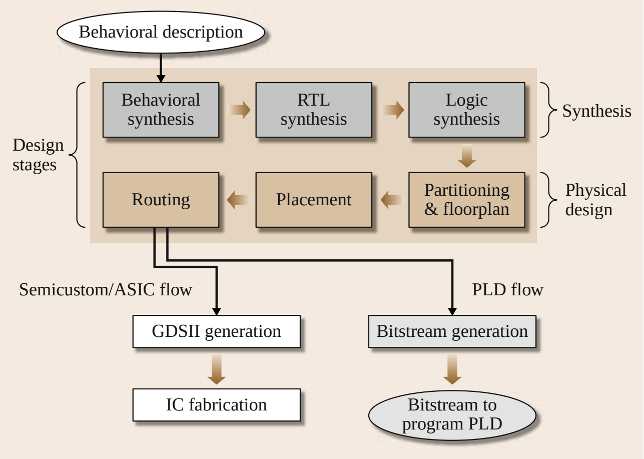

Fig. 38.3 A typical design flow

system in an FPGA, etc.) that aggregates software-programmable processors, customized hardware, and interface logic to satisfy the overall area, delay, and power constraints of the design. Interested readers can refer to [38.1, 12, 13] and [38.15–23] for further study.

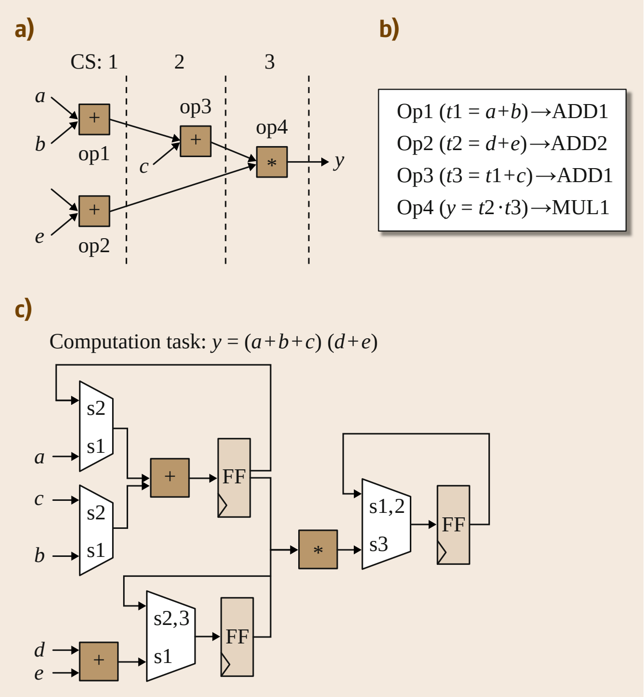

Fig. 38.4a–c A behavioral synthesis example: **(a)** scheduling solution, **(b)** binding solution, and **(c)** final datapath (after [38.24])

38.2.2 Typical Design Flow

The majority of the development effort for CAD techniques is devoted to the design of single-purpose processors using semicustom or PLD IC technologies. We will introduce a typical design flow step by step as shown in Fig. 38.3.

Behavior Synthesis

The basic problem of behavioral synthesis or high-level synthesis is the mapping of a behavioral description of a circuit into a cycle-accurate RTL design consisting of a *datapath* and a *control unit*. Designers can skip behavioral synthesis and directly write RTL codes for circuit design. This design style is facing increasing challenges due to the growing complexity of circuit design. A datapath is composed of three types of components: *functional units* (e.g., ALUs, multipliers, and shifters), *storage units* (e.g., registers and memory), and *interconnection units* (e.g., buses and multiplexers). The control unit is specified as a finite-state machine which controls the set of operations for the datapath to perform during every control step (clock cycle). The behavioral synthesis process mainly consists of three tasks: *scheduling*, *allocation*, and *binding*. Scheduling determines when a computational operation will be executed; allocation determines how many instances of resources (functional units, registers, or interconnection units) are needed; binding binds operations, variables, or data transfers to these resources. In general, it has been shown that the code density and simulation time can be improved by tenfold and hundredfold, respectively, when moving to behavior-level synthesis from RTL synthesis [38.23]. Such an improvement in efficiency is much needed for design in the deep-submicron era. Figure 38.4 shows the scheduling and the binding solution for a computation $y = (a + b + c) \times (d + e)$. Figure 38.4a shows the scheduling result, where CS means control step or clock cycle number. Figure 38.4b shows the binding solution for operations, which is a mapping between operations and functional units ($t1$, $t2$, $t3$ are temporary values). Figure 38.4c shows the final datapath. Note that the marks s1, s2, and s3 in the multiplexers indicate how the operands are selected for control steps 1, 2, and 3, respectively. A controller will be generated accordingly (not shown in the figure) to control the data movement in the datapath.

Behavior synthesis is a well-studied problem [38.2, 24–27]. Most of the behavioral synthesis problems are NP-hard problems due to various constraints, including latency and resource constraints. The subtasks of behavioral synthesis are highly interrelated with one another; for example, the scheduling of operations is directly constrained by resource allocation. Behavioral synthesis also faces challenges on how to connect better to the physical reality. Without physical layout information, the interconnect delay cannot be accurately estimated. In addition, there is a need of powerful data-dependence analysis tools to analyze the operational parallelism available in the design before one can allocate proper amount of resources to carry out the computation in parallel. In addition, how to carry out memory partitioning, bitwidth optimization, and memory access pattern optimization, together with behavioral synthesis for different application domains are important problems. Given all these challenges, much research is still needed in this area. Some recent representative works are presented in [38.28–35].

RTL Synthesis

The next step after behavioral synthesis is RTL synthesis. RTL synthesis performs optimizations on the register-transfer-level design. Input to an RTL synthesis tool is a Verilog or VHDL design that includes the number of datapath components, the binding of operations/variables/transfers to datapath components, and a controller that contains the detailed schedule of computational, input/output (I/O), and memory operations. In general, an RTL synthesis tool would use a front-end parser to parse the design and generate an intermediate representation of the design. Then, the tool can traverse the intermediate representation and create a netlist that consists of typical circuit substructures, including memory blocks, *if* and *case* blocks, arithmetic operations, registers, etc. Next, synthesis and optimization can be performed on this netlist, which can include examining adders and multipliers for constants, operation sharing, expression optimization, collapsing multiplexers, re-encoding finite-state machines for controllers, etc. Finally, an inferencing stage can be invoked to search for structures in the design that could be mapped to specific arithmetic units, memory blocks, registers, and other types of logic blocks from an RTL library. The output of the RTL synthesis provides such a mapped netlist. For the controller and glue logic, generic Boolean networks can be generated. RTL synthesis may need to consider the target IC technologies; for example, if the target IC technology is PLD, the regularity of PLD logic fabric offers opportunities for directly mapping datapath components to PLD logic blocks, producing regular layout, and reducing chip delay and synthesis runtime [38.37]. There are interesting research topics for further study in RTL synthesis, such as retiming for glitch power reduction, resource sharing for multiplexer optimization, and layout-driven RTL synthesis, to name just a few.

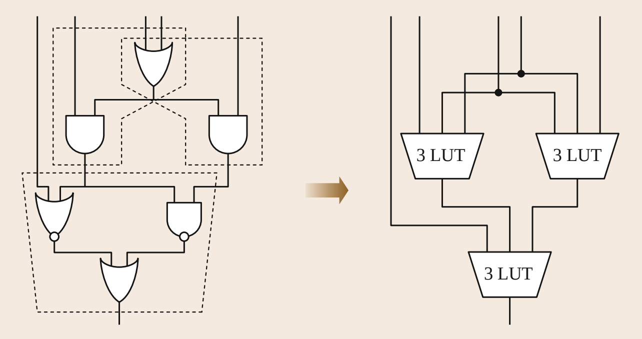

Fig. 38.5 An example of technology mapping for FPGAs (after [38.36])

Logic Synthesis

Logic synthesis is the task of generating a structural view of the logic-level implementation of the design. It can take the generic Boolean network generated from the RTL synthesis and perform logic optimization on top of it. Such optimizations include both sequential logic optimization and combinational logic optimization. Typical sequential optimization includes finite-state machine encoding/minimization and retiming for the controller, and typical combinational optimization includes constant propagation, redundancy removal, logic network restructuring, and optimization, and don't-care-based optimizations. Such optimizations can also be carried out either in a general sense or targeting a specific IC technology. General optimization is also called *technology-independent optimization* with objectives such as minimizing the total amount of gates or reducing the logic depth of the Boolean network. Famous examples include the two-level logic minimizer ESPRESSO [38.38], the sequential circuit optimization system SIS [38.39], binary decision diagram (BDD)-based optimizations [38.40], and satisfiability (SAT)-based optimizations [38.41]. Logic optimization targeting a specific IC technology is also called *technology-dependent optimization*. The main task in this type of optimization is *technology mapping*, which transforms a Boolean network into an interconnection of logic cells provided from a cell library. Figure 38.5 demonstrates an example of mapping a Boolean network into an FPGA. In Fig. 38.5, each subcircuit in the dotted box is mapped into a three-input LUT.

Representative works in technology mapping include DAGON [38.42], FlowMap [38.36], ABC [38.43], and others (e.g. [38.44–46]). Logic synthesis is a critical step in the design flow. Although this area in general is fairly mature, new challenges need to be addressed such as fault-aware logic synthesis and logic synthesis considering circuit parameter variations. Synthesis for specific design constraints is also challenging. One example is synthesis with multiple clock domains and false paths [38.47]. False paths will not be activated during normal circuit operation, and therefore can be ignored. Multicycle paths refer to signal paths that carry a valid signal every few clock cycles, and therefore have a relaxed timing requirement.

Partitioning and Floorplan

We now get into the domain of physical design (Fig. 38.3). The input of physical design is a circuit netlist, and the output is the layout of the circuit. Physical design includes several stages such as *partitioning*, *floorplan*, *placement*, and *routing*. Partitioning is usually required for multimillion-gate designs. For such a large design, it is not feasible to layout the entire chip in one step due to the limitation of memory and computation resources. Instead, the circuit will be first partitioned into subcircuits (blocks), and then these blocks can go through a process called floorplan to set up the foundation of a good layout. A disadvantage of the partitioning process, however, is that it may degrade the performance of the final design if the components on a critical path are distributed into different blocks in the design [38.48]. Therefore, setting timing constraints is important for partitioning. Meanwhile, partitioning should also work to minimize the total number of connections between the blocks to reduce global wire usage and interconnect delay. Representative partitioning works include *Fiduccia–Mattheyses* (FM) partitioning [38.49] and hMETIS [38.50]. Other works (e.g. [38.51, 52]) are also well known.

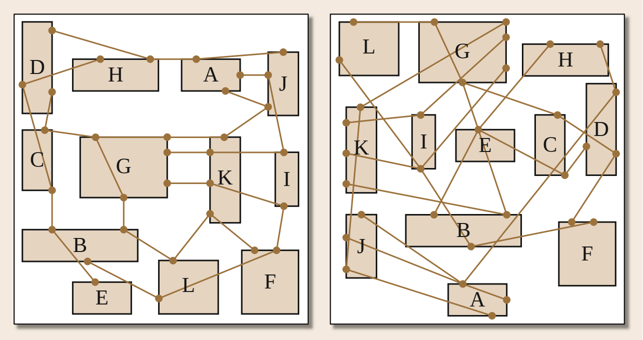

Fig. 38.6 Two different placements of the same problem (after [38.48])

Floorplan will select a good layout alternative for each block and for the entire chip as well. Floorplan will consider the area and the aspect ratio of the blocks, which can be estimated after partitioning. The number of terminals (pins) required by each block and the nets used to connect the blocks are also known after partitioning. The net is an important concept in physical design. It represents one wire (or a group of connected wires) that connect a set of terminals (pins) so these terminals will be made electrically equivalent.

In order to complete the layout, we need to determine the shape and orientation of each block and place them on the surface of the layout. These blocks should be placed in such a way as to reduce the total area of the circuit. Meanwhile, the pin-to-pin wire delay needs to be optimized. Floorplan also needs to consider whether there is sufficient routing area between the blocks so that the routing algorithms can complete the routing task without experiencing routing congestions. Partitioning and floorplan are optional design stages. They are required only when the circuit is highly complex. Usually, physical design for PLDs can skip these two stages. The PLD design flow, especially for hierarchical-structured FPGAs, would require a clustering design stage after the technology mapping stage. The clustering stage would gather groups of LUTs into logic blocks (e.g., each logic block contains ten LUTs). The netlist of logic blocks is then fed to a placement engine to determine the locations of the logic blocks on the chip. Some floorplanning works are [38.53–56].

Placement

Placement is a key step in the physical design flow. It deals with the similar problem as floorplan – determining the positions of physical objects (logic blocks and/or logic cells) on the layout surface. The difference is that, in placement, we can deal with a large number of objects (up to millions of objects) and the shape of each object is predetermined and fixed. Therefore, placement is a scaled and restricted version of the floorplan problem and is usually applied within regions created during floorplanning. Placement has a significant impact on the performance and routability of a circuit in nanometer design because a placement solution, to a large extent, defines the amount of interconnects, which have become the bottleneck of circuit performance. Figure 38.6 shows a simple example of a placement problem [38.48]. It shows two different placements for the same problem. The wire congestion in Fig. 38.6a is much less than that in Fig. 38.6b. Thus, the solution in Fig. 38.6a can be considered more easily routable than that in Fig. 38.6b. In placement, several optimization objectives may contradict each other; for example, minimizing layout area may lead to increased critical path delay and vice versa. Placement, like most of other physical design tasks, is an NP-hard problem and hence the algorithms used are generally heuristic in nature. Because of the importance of placement, an extensive amount of research has been carried out in the CAD community. Placement algorithms can be mainly categorized into simulated-annealing-based (e.g., [38.57, 58]), partitioning-based (e.g., CAPO [38.59]), analytical placement (e.g., BonnPlace [38.60]), and multilevel placement (e.g., mPL [38.61]). Some other well known placers include FastPlace [38.62], grid warping [38.63], Dragon [38.64], NTUplace [38.65], and APlace [38.66]. In general, for small placement instances (<50 K movable objects), simulated annealing is successful. For routability-driven placement of mid-size instances (up to 100–200 K movable objects), partitioning-based placement does well. However, for large instances (above 200 K and into the millions), especially with many fixed pins/IP blocks, analytical and multilevel placement methods are the most successful.

It is worth mentioning that there is research on placement/floorplan-driven synthesis (also called *physical synthesis*). Once placement is available, interconnects are defined and may become a performance bottleneck. These interconnect delay values however can be fed back to the synthesis stages so that further optimization can be carried out in the presence of interconnect delays, including operations rebinding, logic restructuring, and remapping, etc. After such operations, an incremental placement step is needed to finalize the placement again given the new synthesis results. Placement-driven optimization is optional, but may improve design performance considerably.

Routing

After placement, the routing stage determines the geometric layouts of the nets to connect all the logic blocks and/or logic cells together. Routing is the last step in the design flow before either creating the GDSII (graphic data system II) file for fabrication in the semi-custom/ASIC design style or generating the bitstream to program the PLD (Fig. 38.3). GDSII is a database file format used as the industry standard for IC layout data exchange. The objective of routing can be reducing the total wire length, minimizing the critical path delay, minimizing power consumption, or improving manufacturability, etc. A deep-submicron VLSI chip may contain tens of millions of gates. As a result, millions of nets have to be routed while each net may have hundreds of possible routes. This makes the routing problem computationally expensive and hard. To deal with such complexity, the current solution is to divide routing into two phases: *global routing* and *detailed routing*. Global routing will generate a coarse route for each net, which basically assigns routing regions to each net without specifying the actual geometric layout of the net. Detailed routing then finds the actual geometric layout of each net within the assigned regions.

The global routing problem is typically studied as a graph problem with different graph models, including the grid model, checkerboard model, and channel intersection model. Also, there are two kinds of ap-

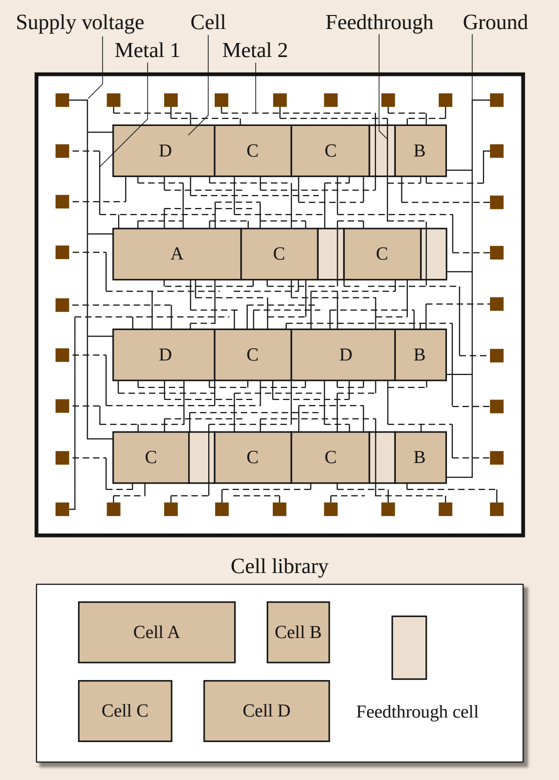

Fig. 38.7 The final layout of a simple standard cell-based design (metal 1: the first metal layer; metal 2: the second metal layer; feedthrough cell, dummy cells making space for routing wires to go through) (after [38.48])

proaches to solve the global routing problem: *sequential* and *concurrent*. The sequential approach routes the nets one by one, following an order determined by some criteria such as the nets' criticality or number of terminals. Some important algorithms include maze routing [38.67], line-probe [38.68], shortest-path-based, negotiation-based [38.69], and Steiner tree-based [38.70] algorithms. The concurrent approach avoids the ordering problem by considering routing of all the nets simultaneously. It usually follows a hierarchical partitioning of the problem instance into smaller subinstances, which can be solved by integer programming. Detailed routing is usually solved incrementally by routing a net one region at a time in a predefined order considering number of terminals, net width and type, pin locations, via restrictions, number of metal layers, etc. There has been an extensive amount of research published for routing algorithms [38.12, 48, 71]. Figure 38.7 illustrates the final layout of a simple standard cell design.

38.2.3 Verification and Testing

The major design steps in Sect. 38.2.2 focus on design implementation. Implementation is a transformation process that converts a design from a more abstract level into a lower, more detailed level. Verification, on the other hand, is the task of verifying that such a transformation is done correctly. Also, due to manufacturing imperfections, each fabricated chip needs to go through a testing procedure to make sure it is functioning as desired. Verification and testing are essential for timely delivery of correct ICs. These steps can occupy more than half of the total design time. We briefly introduce these topics here. Interested readers can refer to [38.3, 12, 13] for further details.

Verification

Ideally, verification should be carried out after each implementation step to catch any design errors. Otherwise, errors can propagate to the lower design levels and may eventually lead to faulty manufacturing masks, which then requires a design respin and generates a large cost overhead. Verification can be carried out in several different ways, namely *simulation*, *formal verification*, *emulation*, and *post-silicon validation*.

Simulation. Simulation uses mathematical models to simulate the behavior of an actual electronic device or circuit. In general, people obtain typical input vectors (stimuli), track the propagation of these input values through the circuit, and check whether the simulated outputs are identical to the intended outputs of the circuit. Once mismatches are identified, the errors need to be localized and fixed. Simulations can be carried out at different levels (e.g., system level, RT (register transfer) level, or gate level). Usually, one cannot afford exhaustive simulation using all the input vectors because it would be very slow (the number of input vectors is an exponential function of the number of total inputs). Thus, in practice, only a subset of all the input vectors is used. As a result, how to select such a subset becomes extremely important; only the most relevant vectors should be selected for the maximum simulation coverage, which then leads to high fault coverage. Fault coverage is defined as a percentage that reports the ratio of output ports actually toggling between 1 and 0 during simulation, compared with the total number of output ports present in the circuit. However, the downside of this compromise is that some corner case design errors may remain undetected if testing vectors are not properly selected.

Simulation is also widely used to analyze the timing of the circuit, especially for analog and mixed-signal circuits. Simulation-based timing analysis is able to consider the correlation among the circuits' inputs and avoid timing analysis hurdles due to false paths. However, the main concern of this approach is its runtime complexity, especially for large and complex digital circuits. A popular replacement is static timing analysis (STA), which is carried out in an input-independent manner and tries to find the worst-case delay of the circuit over all possible input combinations. The computational complexity is liner in the number of edges in the circuit netlist. However, due to the *static* feature of STA, it is vulnerable to false paths, which the STA may treat as critical, but in reality they may never be sensitized. A series of works have been dedicated to dealing with this problem [38.72–74].

Formal Verification. Instead of simulation, formal verification strives to prove the correctness of a circuit implementation using formal methods of mathematics. Used correctly, this method can decrease the verification time as well as guarantee the correctness. However, due to the intrinsic difficulty of the problem, this proof-based method cannot scale to very large designs. There are two main techniques for formal verification, namely *model checking* and *equivalence checking*. model checking verifies that a design satisfies certain properties. It generally requires that the designer knows what desired properties the design should have. Equivalence checking compares two implementations (one of which is known to be correct) and proves that they are functionally equivalent; for example, two Boolean functions can be compared using their reduced-ordered binary decision diagram (ROBDD) representations, and two finite-state machines can be compared using their state diagrams.

Emulation and Post-silicon Validation. Emulation is the implementation of a prototype of the design using a PLD (Sect. 38.1.1). Once the prototype is completed, the verification process applies input vectors to the PLD and compares its outputs with the intended outputs. This is similar to simulation in principle, but is much faster due to the significant hardware acceleration effect provided by the hardware resources in the PLD. Thus, designers can afford to operate on more input vectors for better verification results. A drawback of this approach is that, for each design, designers need to spend time and effort to come up with its prototype upfront, before emulation starts (system- and behavior-level design automation can speed up this process). Post-silicon validation uses actual fabricated chips and tests them at full speed. This method is obviously the fastest but is also the most expensive among all the verification methods.

Testing

Verification works on the functional or timing aspect of the design before manufacturing. Even if the chip is without design errors, hardware defects may occur during the manufacturing process. A number of factors such as optical proximity effects, airborne impurities, and processing material flaws during fabrication can result in defective transistors and interconnect. There are also hard errors caused by sophisticated mechanisms, such as those caused by antenna, thermal, and inductive effects. Thus, testing after manufacturing is essential. Since each individual chip must be tested, testing can be very time consuming and expensive. Testing can be also challenging because the behavior of a million-gate VLSI chip has to be tested using only a small number of pads (e.g., < 100).

People have identified fault models for testing purposes. The best known is the model of *stuck-at* faults, where a fault causes the signal of a wire to be fixed at the value 0 or at the value 1. With this model, one tries to observe the faults' effect on the circuit behavior instead of directly detecting a physical defect. The main issues and techniques involved with testing include the following:

1. Automatic test pattern generation (ATPG): This technique automatically selects high-quality test vectors to minimize the testing time of each chip on the tester.
2. Controllability and observability of signals: *Controllability* means ease of forcing an internal logic gate to 0 or 1 by driving input pins of the chip, whereas *observability* is the ease of observing an internal logic gate by watching external output pins of the chip. Testing ideally would check every gate in the circuit to prove it is not stuck. Therefore, it is desirable to design the chip to increase gate observability and controllability.
3. Scan chain: Convert each flip–flop to a scan register, which has normal mode and scan mode. In the scan mode, specific values can be scanned in for testing purposes.
4. Built-in self-test (BIST): Circuits test themselves. The circuit contains extra testing circuitry, which in the testing mode generates input vectors to test the circuit by itself.

38.2.4 Technology CAD

Technology computer-aided design (TCAD) is an important branch in CAD which carries out numeric simulations of semiconductor processes and devices. Process TCAD takes a process flow, including essential steps such as ion implantation, diffusion, etching, deposition, lithography, oxidation, and silicidation, and simulates the active dopant distribution, the stress distribution, and the device geometry. Mask layout is also an input for process simulation. The layout can be selected as a linear cut in a full layout for a two-dimensional simulation or a rectangular cut from the layout for a three-dimensional simulation. Process TCAD produces a final cross-sectional structure. Such a structure is then provided to device TCAD for modeling the device electrical characteristics. The device characteristics can be used to either generate the coefficients of compact device models or develop the compact models themselves. These models are then used in circuit simulators, such as the SPICE (simulation program with integrated circuit emphasis) simulator, to model the circuit behavior. Because of the detailed physical modeling involved, TCAD is mostly used to aid the design of single devices.

Fig. 38.8 Power-saving opportunities at different design levels (after [38.76]) (ISA: instruction set architecture)

TCAD has become a critical tool in the development of next-generation IC processes and devices. The reference [38.75] summarizes applications of TCAD in four areas:

1. Technology selection: TCAD tools can be used to eliminate or narrow technology development options prior to starting experiments.
2. Process optimization: Tune process variables and design rules to optimize performance, reliability, cost, and manufacturability.
3. Process control: Aid the transfer of a process from one facility to another (including from development to manufacturing) and serve as reference models for diagnosing yield issues and aiding process control in manufacturing.
4. Design optimization: Optimize the circuits for cost, power, performance, and reliability.

The challenge for TCAD is that the physics and chemistry of fabrication processes are still not well understood. Therefore, TCAD cannot replace experiments except in very limited applications so far. It is worth mentioning that electromagnetic field solvers are considered part of TCAD as well. These solvers solve Maxwell's equations, which govern the electromagnetic behavior, for the benefits of IC and PCB design; for example, one objective is to help account accurately for parasitic effects of complicated interconnect structures.

38.2.5 Design for Low Power

With the exponential growth of the performance and capacity of integrated circuits, power consumption has become one of the most constraining factors in the IC design flow. There are three power sources in a circuit: *switching power*, *short-circuit power*, and *static* or *leakage power*. The first two types of power can only occur when a signal transition takes place at the gate output; together they are called *dynamic power*. There are two types of signal transitions: one is the signal transition necessary to perform the required logic functions; the other is the unnecessary signal transition due to the unbalanced path delays to the inputs of a gate (called *spurious transition* or *glitch*). Static power is the power consumption when there is no signal transition for a gate. As technology advances to feature sizes of 90 nm and below, static power starts to become a dominating factor in the total chip power dissipation. Design for low power is a vast research topic involving low-power device/circuit/system architecture design, device/circuit/system power estimation, and various CAD techniques for power minimization [38.77–80]. Power minimization can be performed in any of the design stages. Figure 38.8 shows the power-saving techniques and power saving potentials during each design level [38.76]. Note that some techniques are not unique to only one design level; for example, glitch elimination and retiming can be applied to logic-level design as well.

38.3 New Trends and Conclusion

Due to technology scaling, nanoscale process technologies are fraught with nonidealities such as process variations, noise, soft errors, leakage, and others. Designers are also facing unprecedented design complexity due to these issues. CAD techniques need new innovations to continue to deliver high-quality IC designs in a short period of time. Under this vision, we introduce some new trends in CAD below.

Design for Manufacturing (DFM)

Nanometer IC designs are deeply challenged by manufacturing variations. The industry is currently using 193 nm photolithography for fabrication of ICs in 130 nm and down (to 32 nm or even 22 nm). Therefore, it is challenging for the photolithography process to precisely control the manufacturing quality of the circuit features. There are other manufacturing/process challenges, such as topography variations, random defects due to missing/extra material, via void/failure, etc. DFM will take the manufacturing issues into the design process to improve circuit manufacturability and yield. The essential task in DFM is the development of resolution enhancement techniques (RETs), such as tools for optical proximity correction (OPC) and phase-shift mask (PSM) [38.81–85]. As an example, Fig. 38.9 shows the OPC optimization for a layout, which manipulates mask geometry to compensate for image distortions. Another area is to develop efficient engineering change order (ECO) tools, so that when some changes need to be made, as few layers as possible need to be modified [38.86, 87]. Meanwhile, post-silicon debug and repair techniques are gaining importance as well [38.88, 89].

Statistical Static Timing Analysis (SSTA)

Large variation in process parameters makes worst-case design too expensive in terms of power and delay. Meanwhile, nominal case design will result in a loss in yield as performance specifications may not be met for a large percentage of chips. SSTA is an effort to specifically improve performance yield to combat manufacturing variations. SSTA treats the delay of each gate as a random variable and propagates gates' probability density functions (PDFs) through the circuit to create a PDF of the output delay random variable. Spatial correlations among the circuit components need to be considered. A vast amount of research has been reported (e.g., [38.90–98]) in the past 5 years. SSTA is critical to guide statistical design methodologies. An important application is SSTA-driven placement and routing to improve performance yield.

Design for Nanotechnology

Sustained exponential growth of complex electronic systems will require new breakthroughs in fabrication and assembly with controlled engineering of nanoscale components. *Bottom-up* approaches, in which integrated functional device structures are assembled from chemically synthesized nanoscale building blocks (so-called nanomaterials), such as *carbon nanotubes*, *nanowires*, and other molecular electronic devices, have the potential to revolutionize the fabrication of electronic systems. Nanoelectronic circuits always have a certain percentage of defects as well as nanomaterial-specific variations over and above process variations introduced by lithography. Using simplified nanode-

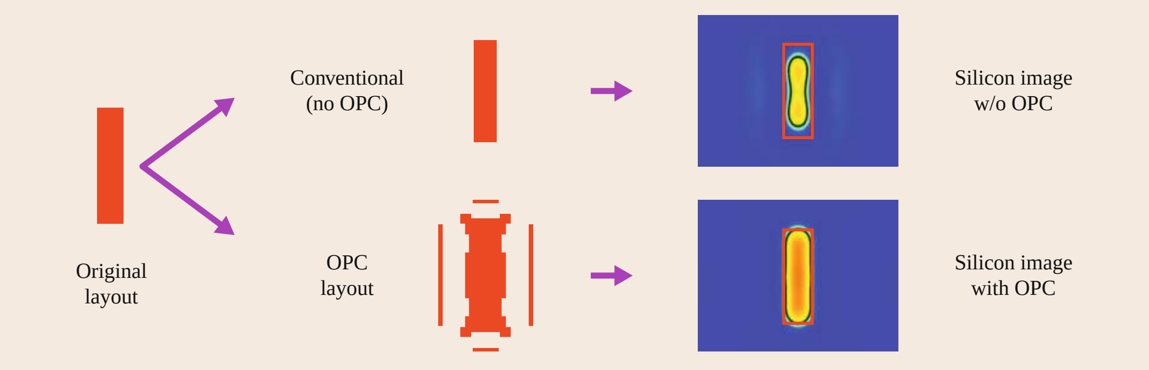

Fig. 38.9 An illustration of optical proximity correction (after [38.81])

vice assumptions and traditional scaled design flows will lead to suboptimal and impractical nanocircuit designs and inaccurate system evaluation results. For nanotechnology to fulfill its promise, there is a need to understand and incorporate nano-specific design techniques, such as nanosystems modeling, statistical approaches, and fault-tolerant design, systematically from devices all the way up to systems. Initial effort has been made in this important area [38.99–107], but much more research has to be done to enable the large integration capability of nanosystems. Chapter 53 provides more information on micro and nano manipulation related to design of nanotechnology.

Design for 3-D ICs

One promising way to improve circuit performance, logic density or power efficiency is to develop three-dimensional integration, which increases the number of active die layers and optimizes the interconnect network vertically [38.108–115]. Potentially, three-dimensional (3-D) IC provides improved bit bandwidth with reduced wire length, delay, and power. There are different bonding technologies for 3-D ICs, including die-to-die, die-to-wafer, and wafer-to-wafer, and the two parties can be bonded face-to-face or face-to-back. One disadvantage of the 3-D IC is its thermal penalty. The 3-D stacks will increase heat density, leading to degraded chip performance and reliability if not handled properly.

Design for Reliability

Besides fabrication defects, soft errors and aging errors have emerged as the new sources of circuit unreliability for nanometer circuit designs. A soft error occurs when a cosmic particle, such as a neutron, strikes a portion of the circuit, upsetting the state of a bit. Aging errors are due to the wearing effect of an operating circuit. As device dimensions scale down faster than the supply voltage [38.9], the resulting high electric fields combined with temperature stresses lead to device aging and hence failure. Especially, transistor aging due to negative-bias temperature instability (NBTI) has become the determining factor in circuit lifetime. Reliability analysis and error mitigation techniques under soft errors, aging effects, and process variations have been proposed [38.116–126]. Ultimately, chip reliability would need to become a critical design metric incorporated into mainstream CAD methodologies.

Design with Parallel Computing

An important way to deal with design complexity is to take advantage of the latest advances of parallel computing with multicore computer systems so that computation can be carried out in parallel for acceleration. Although there are some studies on parallel CAD algorithms (e.g., [38.127, 128]), much more work is needed to come up with parallel CAD algorithms to improve design productivity.

Design for Network on Chip (NoC)

The increasing complexity and heterogeneity of future SoCs (system-on-a-chip) prompt significant system scalability challenge using conventional on-chip communication schemes, such as the point-to-point (P2P) and bus-based communication architectures. NoC emerged recently as a promising solution for the future [38.129–133]. In a NoC system, modules such as processor cores, memories, and other IP blocks exchange data using a network on a single chip. NoC communication is constructed from a network of data links interconnected by switches (or routers) such that messages can be relayed from any source module to any destination module. Because all links in the NoC can operate simultaneously on different data packets, a high level of parallelism can be achieved with a great scaling capability. However, many challenging research problems remain to be solved for NoC, from the design of the physical link through the network-level structure, all the way up to the system architecture and application software.

Electronic design automation or computer-aided design as an engineering field has been evolving through the past several decades since its birth shortly after the invention of integrated circuits. On the one hand, it has become a mature engineering area to provide design tools for the electronic semiconductor industry. On the other hand, many challenges and unsolved problems still remain in this exciting field as on-chip device density continues to scale. As long as electronic circuits are impacting our daily lives, design automation will continue to diversify and evolve to further facilitate the growth of the semiconductor industry and revolutionize our future.

39. Safety Warnings for Automation

Mark R. Lehto, Mary F. Lesch, William J. Horrey

Automated systems can provide tremendous benefits to users; however, there are also potential hazards that users must be aware of to safely operate and interact with them. To address this need, safety warnings are often provided to operators and others who might be placed at risk by the system. This chapter discusses some of the roles safety warnings can play in automated systems, from both the traditional perspective of warnings as a form of hazard control and the perspective of warnings as a form of automation. During this discussion, the chapter addresses some of the types of warnings that might be used, along with issues and challenges related to warning effectiveness. Design recommendations and guidelines are also presented.

Automated systems have become increasingly prevalent in our society, in both our work and personal lives. Automation involves the execution by a computer (or machine) of a task that was formerly executed by human operators [39.1]; for example, automation may be applied to a particular function in order to complete tasks that humans cannot perform or do not want to perform, to complete tasks that humans perform poorly or that incur high workload demands, or to augment the capabilities and performance of the human operator [39.2]. The potential benefits of automation include increased productivity and quality, greater system safety and reliability, and fewer human errors, injuries or occupational illnesses. These benefits follow because some demanding or dangerous tasks previously performed by the operator can be completely eliminated through automation, and many others can be made easier. On the other hand, automation can create new hazards and increase the potential for catastrophic human errors [39.3]; for example, in advanced manufacturing settings, the use of robots and other forms of automation has reduced the need to expose workers to potentially hazardous materials in welding, painting, and other operations, but in turn has created a more complex set of maintenance, repair, and setup tasks, for which human errors can have serious consequences, such as damaging expensive equipment, long periods of system downtime, production of multiple runs of defective parts, and even injury or death.

As implied by the above example, a key issue is that automation increases the complexity of systems [39.4]. A second issue is that the introduction of automation into a system or task does not necessarily remove the human operator from the task or system. Instead, the role and responsibilities of the operator change. One common result of automation is that operators may go from active participants in a task to passive monitors of the system function [39.5, 6]. This shift in roles from active participation to passive monitoring can reduce the operator's situation awareness and ability to respond appropriately to automation failures [39.7]. Part of the problem is that the operator may have few opportunities to practise their skills because automation failures tend to be rare events. Further complicating the issue, system monitoring might be done from a remote location using one or more displays that show the status of many different subsystems. This also can reduce situation awareness, for many different reasons. Another common problem is that workload may be too low during routine operation of the automated system, causing the operator to become complacent and easily distracted. Furthermore, designers may assign additional unrelated tasks to operators to make up for the reduced workload due to automation. This again can impair situation awareness, as performing these unrelated tasks can draw the operator's attention away from the automated system. The need to perform these additional tasks can also contribute to a potentially disastrous increase in workload in nonroutine situations in which the operator has to take over control from the automated system.

Many other aspects of automated systems can make it difficult for operators and others to be adequately aware of the hazards they face and how to respond to them [39.4, 8]. To address this issue, safety warnings are often employed in such systems. This chapter discusses some of the roles safety warnings can play in automated systems, from both the traditional perspective of warnings as a form of hazard control and the perspective of warnings as a form of automation. During this discussion, the chapter addresses some of the types of warnings that might be used. We also discuss issues related to the effectiveness of warnings and provide design recommendations and guidelines.

39.1 Warning Roles

The role of warnings in automated systems can be viewed from two overlapping perspectives: (1) warnings as a method of hazard control, and (2) warnings as a form of automation.

39.1.1 Warning as a Method of Hazard Control

Warnings are sometimes viewed as a method of last resort to be relied upon when more fundamental solutions to safety problems are infeasible. This view corresponds to the so-called hierarchy of hazard control, which can be thought of as a simple model that prioritizes control methods from most to least effective. One version of this model proposes the following sequence: (1) eliminate the hazard, (2) contain or reduce the hazard, (3) contain or control people, (4) train or educate people, and (5) warn people [39.9]. The basic idea is that designers should first consider design solutions that completely eliminate the hazard. If such solutions are technically or economically infeasible, solutions that reduce but do not eliminate the hazard should then be considered. Warnings and other means of changing human behavior, such as training, education, and supervision, fall in this latter category for obvious reasons. Simply put, these behavior-oriented approaches will never completely eliminate human errors and violations. On the other hand, this is also true for most design solutions. Consequently, warnings are often a necessary supplement to other methods of hazard control [39.10].

There are many ways warnings can be used as a supplement to other methods of hazard control; for example, warnings can be included in safety training materials, hazard communication programs, and within various forms of safety propaganda, including safety posters and campaigns, to educate workers about risks and persuade them to behave safely. Particularly critical procedures include start-up and shut-down procedures, setup procedures, lock-out and tag-out procedures during maintenance, testing procedures, diagnosis procedures, programming and teaching procedures, and numerous procedures specific to particular applications. The focus here is to reduce errors and intentional violations of safety rules by improving worker knowledge of what the hazards are and their severity, how to identify and avoid them, and what to do after exposure. Inexperienced workers are often the target audience at this stage. Warnings can also be included in manuals or job performance aids (JPAs), such as written procedures, checklists, and instructions. Such warnings usually consist of brief statements that either instruct less-skilled workers or remind skilled workers to take necessary precautions when performing infrequent maintenance or repair tasks. This approach can prevent workers from omitting precautions or other critical steps in a task. To increase their effectiveness, such warnings are often embedded at the appropriate stage within step-by-step instructions describing how to perform a task. Warning signs, barriers, or markings at appropriate locations, can play a similar role; for example, a warning sign placed on a safety barrier or fence surrounding a robot installation might state that no one except properly authorized personnel is allowed to enter the area. Placing a label on a guard to warn that removing the guard creates a hazard also illustrates this approach.

Warning signals can also serve as a supplement to other safety devices such as interlocks or emergency braking systems; for example, presence sensing and interlock devices are sometimes used in installations of robots to sense and react to potentially dangerous workplace conditions. Sensors used in such systems include (1) pressure-sensitive floor mats, (2) light curtains, (3) end-effector sensors, (4) ultrasound, capacitive, infrared, and microwave sensing systems, and (5) computer vision. Floor mats and light curtains are used to determine whether someone has crossed the safety boundary surrounding the perimeter of the robot. Perimeter penetration will trigger a warning signal and in some cases will cause the robot to stop. End-effector sensors detect the beginning of a collision and trigger emergency stops. Ultrasound, capacitive, infrared, and microwave sensing systems are used to detect intrusions. Computer vision theoretically can play a similar role in detecting safety problems.

auto-body assembly line, might be installed for point of operation, area, perimeter, or entry/exit safeguarding. Figure 39.2 illustrates a safety laser scanner. By reducing or eliminating the need for physical barriers, such systems make it easier to access the robot system during setup and maintenance. By providing early warnings prior to entry of the operator into the safety zone, such systems can also reduce the prevalence of nuisance machine shut-downs (Fig. 39.3). Furthermore, such systems can prevent the number of accidents by providing warning signals and noises to alert personnel on the floor (Fig. 39.4).

39.1.2 Warning as a Form of Automation

Automated warning systems have been implemented in many domains, including aviation, medicine, process control and manufacturing, automobiles and other surface transportation, military applications, and weather forecasting, among others. Some specific examples of automated systems include collision warning systems and ground proximity warning systems in automobiles and aircraft, respectively. These systems will alert drivers or pilots when a collision with another vehicle or the ground is likely, so that they can take evasive action. In medicine, anesthesiologists and medical care workers must monitor patients' vitals, sometimes remotely. Similarly, in process control, such as nuclear power plants, workers must continuously monitor multiple subsystems to ensure that they are at safe and tolerable levels. In these situations, automated alerts can be used to inform operators of any significant departures from normal and acceptable levels, whether in the patients' condition or in plant operation and safety. Automation may be particularly important for complex systems, which may involve too much information (sometimes referred to as *raw data*), creating difficulties for operators in finding relevant information at the appropriate times. In addition to simply informing or alerting the human operator, automation can play many different roles, from guiding human information gathering to taking full control of the system.

As implied by the above examples, automated warning systems come in many forms, across a wide variety of domain applications. *Parasuraman* et al. [39.11] propose a taxonomy of human–automation interaction that provides a useful way of categorizing the function of these systems according to the psychological process they are intended to replace or supplement. As shown in Fig. 39.5, automation can be applied at any of four stages: (1) information acquisition, (2) information analysis (3) decision selection, and (4) action implementation. These four stages are based on a simple model of human information processing (sensory processing, cognition/working memory, decision making, response execution). The model proposed by *Parasuraman* et al. [39.11] also maps onto *Endsley*'s [39.12] model of situation awareness (SA), with early stages of automation contributing to the establishment and maintenance of SA (as also shown in Fig. 39.5). Good situation awareness is an important precursor to accurate decision making and action selection.

For any given automated system, the level of automation at each stage of the model can vary from low to high and this level will dictate how much control the human is afforded in the operation of the system. As expanded upon in the following discussion, the functions performed by automated warning systems tend to fall into the second and third stages of automation (information analysis and decision selection, respectively), depending on whether they simply provide human operators with alerts or whether they indicate also the appropriate course of action.

Stage 1: Information Acquisition

At the first stage, automation involves the acquisition and registration of multiple sources of input data. Au-

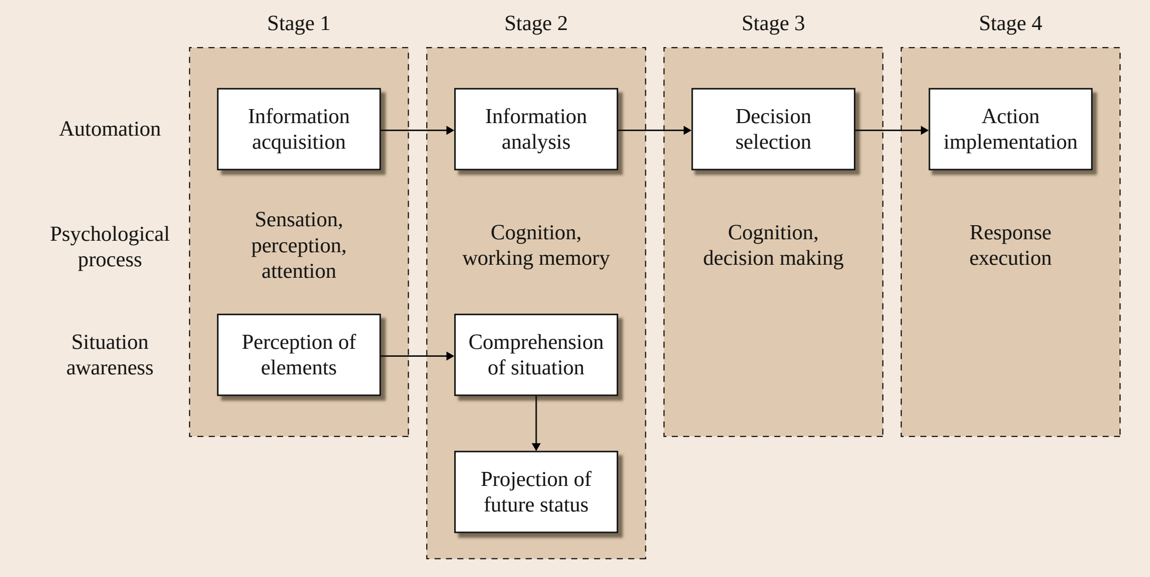

Fig. 39.5 Stages of automation [39.13] and the corresponding psychological processes and level of situation awareness [39.12] (after *Horrey* et al. [39.14])

tomation in this stage acts to support human sensory and attentional processes (e.g., detection of input data). A high level of automation at this stage may filter out all information deemed to be irrelevant or less critical to the current task, presenting only the most critical information to the operator. Thus, only relevant cues and reports (at least those deemed relevant by the system) would pass through the filters, allowing operators the capacity to make more effective decisions, especially when under time duress. Systems using a lower level of automation, on the other hand, may present all of the available input data but guide attention to what the automation infers to be the most relevant features (e.g., target cueing; information highlighting).

There has been extensive research into the effects of stage 1 automation (attention guidance) in target detection tasks. Basic research has reliably demonstrated the capacity for visual cues to reduce search times in target search tasks [39.15]. Applied research has also demonstrated these benefits in military situations [39.16, 17], helicopter hazard detection [39.18], aviation and air-traffic control [39.6, 19], and a number of other domains. These generally positive results support the potential value of stage 1 automation in applications where operators can receive an excessive number of warnings. Example applications might filter the warnings in terms of urgency or limit the warnings to relevant subsystems.

Stage 2: Information Analysis

Information analysis involves higher cognitive functions such as working memory, information integration, and cognitive inference. Automation at stage 2 may help operators by integrating the raw data, drawing inferences, and/or generating predictions. In this stage, lower levels of automation may extrapolate current information and predict future status (e.g., cockpit predictor displays [39.20]). Higher levels of automation at this stage may reduce information from a number of sources into a single hypothesis regarding the state of the world; for example, collision warning systems in automobiles will use information regarding the speed of the vehicle ahead, the intervehicle separation, and the driver's own velocity (among other potential information) to indicate to the driver when a forward collision is likely [39.21–24]. In general, operators are quicker to respond to the relevant event when provided with these alerts. Studies of automated alerts have been performed in many different domains, including aviation [39.25], process control [39.26], unmanned aerial vehicle operation [39.27], medicine [39.28], air-traffic control [39.6], and battlefield operations [39.14].

Stage 3: Decision Selection

The third stage involves the selection, from among many alternatives, of the appropriate decision or action. This will typically follow from some form of information integration performed at stage 2. Lower levels of stage 3 automation may provide users with a complete set (or subset) of alternatives from which the operator will select which one to execute (whether correct or no). Higher levels may only present the *optimal* decision or action or may automatically select the appropriate course of action. At this stage the automation will utilize implicit or explicit assumptions about the costs and benefits of different decision outcomes; for example, the ground proximity warning system in aviation – a system designed to help avoid aircraft–ground collisions – will recommend a single maneuver to pilots when a given threshold is exceeded (*pull up*).

Stage 4: Action Implementation

Finally, automation in the fourth stage aids the user in the execution of the selected action. A low level of automation may simply provide assistance in the execution of the action (e.g., power steering). High levels of automation at this stage may take control from the operator; for example, adaptive cruise control (ACC) systems in automobiles will automatically adjust the vehicle's headway by speeding up or slowing down in order to maintain the desired separation.

In general, one of the ironies of automation is that those systems that incorporate higher stages of automation tend to yield the greatest performance in normal situations; however, these also tend to come with the greatest costs in off-normal situations, where the automated response to the situation is inappropriate or erroneous [39.29]. We will discuss the issue of automation failure in a later section.

39.2 Types of Warnings

Warning systems serve many functions. Typically, they provide the user/operator with information on the status of the system. This information source aids the user in maintaining situational awareness, and does not necessarily require that specific action be taken (stage 2 automation). Alternatively, other warning systems signal the user that a specific response needs to be made at a specific time in order to reduce associated risks (stage 3 automation). Below, we will review the different methods and modes of presenting warning information that can be used to accomplish these goals.

39.2.1 Static Versus Dynamic Warnings

Perhaps the most familiar types of warnings are the visually based signs and labels that we encounter everyday whether on the road (e.g., *slippery when wet*), in the workplace (industrial warnings such as *entanglement hazard – keep clear of moving gears*), or on consumer products (e.g., *do not take this medication if you might be pregnant*). These signs and labels indicate the presence of a hazard and may also indicate required or prohibited actions to reduce the associated risk, as well as the potential consequences of failing to comply with the warning. This type of warning is *static* in the sense that its status does not change over time [39.30]. However, as noted by *Lehto* [39.31], even these static displays have a dynamic component in that they are noticed at particular points in time. In order to increase the likelihood that a static warning, such as a sign or label, is *received* (i. e., noticed, perceived, and understood) by the user at the appropriate moment, it should be physically as well as temporally placed such that using the product requires interaction with the label prior to the introduction of the hazard to the situation; for example, *Duffy* et al. [39.32] examined the effectiveness of a label on an extension cord which stated: "Warning. Electric shock and fire. Do not plug more than two items into this cord." Interactive labels in which the label was affixed to the outlet cover on the female receptacle were found to produce greater compliance than a no-label control condition, and a tag condition in which the warning label was attached to the extension cord 5 cm above the female receptacle. Other studies [39.33, 34] have found that a warning that interrupts a user's script for interacting with a product increases compliance. A *script* consists of a series of temporally ordered actions or events which are typical of a user's interactions with a class of objects [39.35].

Additionally, varying the warning's physical characteristics can also increase its conspicuity or noticeability [39.36]; for example, larger objects are more likely to capture attention than smaller objects. Brightness and contrast are also important in determining whether an object is discernible from a background. As a specific form of contrast, highlighting can be used to emphasize different portions of a warning label or sign [39.37]. Ad-

Table 39.1 Contrast between the fundamental properties of visual, auditory, and haptic modalities of information processing (after *Sanderson* [39.38])

Visual	Auditory	Haptic
Persistent – signal typically persistent in time so that information about past has same sensory status as information about present	*Transitory* – signal happens in time and recedes into past: creating persistent information or information about past are design challenges	*Transitory* – signal happens in time and recedes into past: creating persistent information or information about past are design challenges
Localized – can be sensed only from specific locations such as monitors or other projections (eyeballs needed)	*Ubiquitous* – can be sensed from any location unless technology is used to create localized qualities	*Personal* – can be sensed only by the person whom the display is directed (unless network or shared)
Optional – there are proximal physical means for completely eliminating signal (eyeballs, eyelids, turn)	*Obligatory* – there are no proximal physical means for completely eliminating signal (unless earplugs block signal)	*Obligatory* – there are no proximal physical means for completely eliminating signal (unless remove device)
Moderately socially inclusive – others aware of signal but need not look at screen	*Socially inclusive* – others always receive signal unless signal is sent only to an earpiece	*Not socially inclusive* – others probably unaware of signal
Sampling-based monitoring – temporal sampling process needed for coverage of all needed variables	*Peripheral monitoring* – temporal properties of process locked into temporal properties of display	*Interrupt-based monitoring* – monitoring based on interrupts
High information density – many variables and relationships can be simultaneously presented	*Moderate information density* – several variables and relationships can be simultaneously presented	*Low information density* – few variables and relationships can be simultaneously presented

ditionally, lighting conditions influence detectability of signs and labels (i. e., reduced contrast).

In contrast to static warnings, dynamic warning systems produce different messages or *alerts* based on input received from a sensing system – therefore, they indicate the presence of a hazard that is not normally present [39.30, 39]. Environmental variables are monitored by a sensor, and an alert is produced if the monitored variables exceed some threshold. The threshold can be changed based on the criticality of potential consequences – the more trivial the consequences, the higher the threshold and, for more serious consequences, the threshold would be set lower so as reduce the likelihood of *missing* the critical event. However, the greater the system's sensitivity, the greater the likelihood that an alert will be generated when there is no hazard present. Ideally, an alert should always be produced when there is a hazard present, but never be produced in the absence of a hazard. Implications of system departures from this ideal will be discussed later in this chapter.

The remainder of this chapter will focus on the implementation and functioning of dynamic warning systems. These warnings serve to alert users to the presence of a hazard and its associated risks. Accordingly, they must readily capture attention and be easily/quickly understood. The ability of the warning to capture attention is especially important in the case of complex systems, in which an abundance of available information may overload the operator's limited attentional resources. When designing a warning system, it is critical to take into account the context in which the warning will appear; for example, in a noisy construction environment, in which workers may be wearing hearing protection, an auditory warning is not likely to be effective. Whatever the context, the warning should be designed to *stand out* against any background information (i. e., visual clutter, ambient noise). *Sanderson* [39.38] has provided a taxonomy/terminology for thinking about sensory modality in terms of whether information is persistent in time; whether information delivery is localized, ubiquitous, or personal; whether sensing the information is optional or obligatory; whether the information is socially inclusive; whether monitoring occurs through sampling, peripheral awareness, or is interrupt based; and information density (Table 39.1). Next, advantages and disadvantages of different modes of warning presentation will be discussed in related terms.

39.2.2 Warning Sensory Modality

Visual Warnings

The primary challenge in using visual warnings is that the user/operator needs to be looking at a specific location in order to be alerted, or the warning needs to be sufficiently salient to cause the operator to reorient their focus towards the warning. As discussed earlier in the section on static warnings, the conspicuity of visually based signals can be maximized by increasing size, brightness, and contrast [39.36]. Additionally, flashing lights attract attention better than continuous indicator-type lights (e.g., traffic signals incorporating a flashing light into the red phase) [39.36]. Since flash rates should not be greater than the critical flicker fusion frequency (≈ 24 Hz; resulting in the perception of a continuous light), or so slow that the *on* time might be missed, *Sanders* and *McCormick* [39.40] recommend flash rates of around 10 Hz.

Auditory Warnings

Auditory stimuli have a naturally alerting quality and, unlike visual warnings, the user/operator does not have to be oriented towards an auditory warning in order to be alerted, that is, auditory warnings are omnidirectional (or *ubiquitous* in Sanderson's terminology) [39.41, 42]. Additionally, localization is possible based on cues provided by the difference in time and intensity of the sound waves arriving at the two ears. To maximize the likelihood that the auditory warning is effective, the signal should be within the range of about 800–5000 Hz (the human auditory system is most sensitive to frequencies within this range – frequencies contained in speech; e.g., *Coren* and *Ward* [39.43]) – and should have a tonal quality that is distinct from that of expected environmental sounds – to help reduce the possibility that it will be masked by those sounds (see *Edworthy* and *Hellier* [39.44] for an in-depth discussion of auditory warning signals).

Verbal Versus Nonverbal

Any auditory stimulus, from a simple tone to speech, can serve as an alert as long as it easily attracts attention. However, the human auditory system is most sensitive to sound frequencies contained within human speech. Speech warnings have the further advantage of being composed of signals (i. e., words) which have already been well learned by the user/operator. There is a redundancy in the speech signal such that, if part of the signal is lost, it can be *filled in* based on the context provided by the remaining sounds [39.45, 46]. However, since speech is a temporally based code that unfolds over time, it is only physically available for a very limited duration. Therefore, earlier portions of a warning message must be held in working memory while the remainder of the message continues to be processed. As a result, working memory may become overloaded and portions of the warning message may be lost. With visually based verbal warnings, on the other hand, there is the option of returning to, and rereading, earlier portions of the warning; that is, they persist over time. However, since the eyes must be directed towards the warning source, the placement of visually based warnings is critical so as to minimize the loss of other potentially critical information (i. e., such that other *signals* can be processed in peripheral vision).

While verbal signals have the obvious advantage that their meaning is already established, speech warnings require the use of recorded, digitized, or synthesized speech which will be produced within a noisy background – therefore, intelligibility is a major issue [39.44]. Additionally, as indicated earlier, the speech signal unfolds over time and may take longer to produce/receive than a simpler nonverbal warning signal. However, nonverbal signals must somehow encode the urgency of the situation – that is, how quickly a response is required by the user/operator. Extensive research in the auditory domain indicates that higher-frequency sounds have a higher perceived urgency than lower-frequency sounds, that increasing the modulation of the amplitude or frequency of a pulse decreases urgency, that increases in number of harmonics increases perceived urgency, and that spectral shape also impacts perceived urgency [39.44, 47, 48]. *Edworthy* et al. [39.48] found that faster, more repetitive bursts are judged to be more urgent; regular rhythms are perceived as more urgent than syncopated rhythms; bursts that are speeded up are perceived as more urgent than those that stay the same or slow down; and the larger the difference between the highest and lowest pitched pulse in a burst, the higher the perceived urgency.

Haptic/Tactile Warnings

While the visual and auditory channels are most often used to present warnings, haptic or tactile warnings are also sometimes employed; for example, the improper maneuvering of a jet will cause tactile vibrations to be delivered through the pilot's control stick – this *alert* serves to signal the need to reorient the control. In the domain of vehicle collision warnings, *Lee* et al. [39.49] examined driver preferences for auditory or haptic warning systems as supplements to a visual warning system. Visual warnings were presented on a head-down display in conjunction with either an auditory warning or a haptic warning, in the form of a vibrating seat. Preference data indicated that drivers found auditory warnings to be more annoying and that they would be more likely to purchase a haptic warning system.

In the domain of patient monitoring, *Ng* et al. [39.50] reported that a vibrotactile wristband results in a higher identification rate for heart rate alarms than does an auditory display. In *Sanderson*'s [39.38] terminology, a haptic alert is discrete, transitory, has low precision, has obligatory properties, and allows the visual and auditory modalities to continue to monitor other information sources. Therefore, patient monitoring represents a good use of haptic alarms.

Another example of a tactile or haptic warning, though not technologically based, is the use of rumble strips on the side of the highway. When a vehicle crosses these strips, vibration and noise is created within the vehicle. Some studies have reported that the installation of these strips reduced drift-off road accidents by about 70% [39.51]. A similar application is the tactile ground surface indicators that have become more common as a result of the Americans with Disabilities Act (ADA). These surfaces are composed of truncated cones which provide a distinctive pattern which can be felt underfoot or through use of a cane. It is intended to alert individuals with visual impairments of hazards associated with blending pedestrian and vehicular traffic (i. e., on curb ramps on the approach to the street surface).

Multimodal Warnings

For the most part, we have focused our discussion on the use of individual sensory channels for the presentation of automated warnings. However, research suggests that multimodal presentation results in significantly improved warning processing. *Selcon* et al. [39.52] examined multimodal cockpit warnings. These warnings must convey the nature of the problem to the pilot as quickly as possible so that immediate action can be taken. The warnings studied were visual (presented using pictorials), auditory (presented by voice), or both (incorporating visual and auditory components) and described real aircraft *warning* (high priority/threat) and *caution* (low priority/threat) situations. Participants were asked to classify each situation as either *warning* or *caution* and then to rate the threat associated with it. Response times were measured. Depth of understanding was assessed using a measure of situational awareness [39.53, 54]. Performance was faster in the condition incorporating both visual and auditory components (1.55 s) than in the visual (1.74 s) and auditory (3.77 s) conditions and there was some indication that this condition was less demanding and resulted in improved depth of understanding as well.

Sklar and *Sarter* [39.55] examined the effectiveness of visual, tactile, and redundant visual and tactile cues for indicating unexpected changes in the status of an automated cockpit system. The tactile conditions produced higher detection rates and faster response times. Furthermore, provision of tactile feedback and performance of concurrent visual tasks did not result in any interference suggesting that tactile feedback may better support human–machine communication in information-rich domains (see also *Ng* et al.'s [39.50] findings reviewed earlier).

Research also indicates that multimodal presentation provides comprehension and memory benefits for verbal warnings. Using a laboratory task in which participants measured and mixed *chemicals*, *Wogalter* and *Young* [39.42] (see also *Wogalter* et al. [39.41]) observed higher compliance rates in conditions in which warnings to wear a mask and gloves were presented using both text and voice (74% of participants complied) than in conditions in which the warnings were presented via voice (59%) or text alone (41%). A similar pattern was observed in a field experiment in which text and voice warnings warned of a wet floor in a shopping center. Voice warnings are more likely to capture attention. However, most of the participants in the text warning condition also reported awareness of the warning. Therefore, awareness alone cannot account for the higher compliance rates. Additionally, the combined text and voice condition resulted in higher compliance than the voice-alone condition. The combination of voice and print appears more persuasive than print or voice alone.

In another study, *Conzola* and *Wogalter* [39.56] used voice and print warnings to supplement product manual instructions during the unpacking of a computer disk drive. The supplemental voice warnings were presented via digitized voice while the text was presented via printed placard. Compliance was higher in conditions with the supplemental messages than in the manual-only condition, but there was no significant difference in compliance between the voice and print conditions. As regards to memory, the voice message resulted in greater recall than the print or manual-only conditions. This finding is consistent with what is known as the *modality effect* in working memory research – since verbal information is stored in memory in an auditory/acoustic format, memory for verbal information is better when the information is presented auditorily (i. e., by voice) than when that same information is presented visually (i. e., as text) (see *Penney* [39.57] for a review). Performance suffers when verbal information is presented visually as translation into an auditory code is required for storage in memory. Translation is unnecessary with voice presentation.

To summarize, by providing redundant delivery channels, a multimodal approach helps to ensure that the warning attracts attention, is received (i. e., understood) by the user/operator, and is remembered. Future research should focus on further developing relatively underused channels for warning delivery (i. e., haptic) and using multiple modalities in parallel in order to increase the attentional and performance capacity of the user/operator [39.38].

39.3 Models of Warning Effectiveness

Over the past 20 years, much research has been conducted on warnings and their effectiveness. The following discussion will first introduce some commonly used measures of effectiveness. Attention will then shift to modeling perspectives and related research findings which provide guidance as to when, where, and why warnings will be effective.

39.3.1 Warning Effectiveness Measures

The performance of a warning can be measured in many different ways [39.39]. The ultimate measure of effectiveness is whether a warning reduces the frequency and severity of human errors and accidents in the real world. However, such data is generally unavailable, forcing effectiveness to be evaluated using other measures, sometimes obtained in controlled settings that simulate the conditions under which people receive the warning; for example, the effectiveness of a collision avoidance warning might be assessed by comparing how quickly subjects using a driving simulator notice and respond to obstacles with and without the warning system. For the most part, such measures can be derived from models of human information processing that describe what must happen after exposure to the warning, for the warning to be effective [39.31, 39]. That is, the human operator must notice the warning, correctly comprehend its meaning, decide on the appropriate action, and perform it correctly. Analysis of these intervening events can provide substantial guidance into factors influencing the overall effectiveness of a particular warning.

A complicating issue is that the design of warnings is a polycentric problem [39.58], that is, the designer will have to balance several conflicting objectives when designing a warning. The most noticeable warning will not necessarily be the easiest to understand, and so on. As argued by *Lehto* [39.31], this dilemma can be partially resolved by focusing on decision quality as the primary criterion for evaluating applications of warnings; that is, warnings should be evaluated in terms of their effect on the overall quality of the judgments and decisions made by the targeted population in their naturalistic environment. This perspective assumes that decision quality can be measured by comparing people's choices and judgments to those prescribed by some objective *gold standard*. In some cases, the gold standard might be prescribed by a normative mathematical model, as expanded upon below.

39.3.2 The Warning Compliance Hypothesis

The warning compliance hypothesis [39.59] states that people's choices should approximate those obtained by applying the following optimality criterion:

> *If the expected cost of complying with the warning is greater than the expected cost of not complying, then it is optimal to ignore the warning; otherwise, the warning should be followed.*

The warning compliance hypothesis is based on statistical decision theory which holds that a rational decision-maker should make choices that maximize expected value or utility [39.60, 61]. The expected value of choosing an action A_i is calculated by weighting its consequences C_{ik} over all events k, by the probability P_{ik} that the event will occur. More generally, the decision-maker's preference for a given consequence C_{ik} might be defined by a value or utility function $V(C_{ik})$, which transforms consequences into preference values. The preference values are then weighted using the same equation. The expected value of a given action A_i becomes

$$EV[A_i] = \sum_k P_{ik} V(C_{ik}) \, . \tag{39.1}$$

From this perspective, people who decide to ignore the warning feel that avoiding the typically small cost of compliance outweighs the large, but relatively unlikely cost of an accident or other potential consequence of not complying with the warning. The warning compliance hypothesis clearly implies that the effectiveness of warnings might be improved by

1. Reducing the expected cost of compliance, or
2. Increasing the expected cost of ignoring the warning.

Many strategies might be followed to attain these objectives; for example, the expected cost of compliance might be reduced by modifying the task or equipment so the required precautionary behavior is easier to perform. The benefit of following this strategy is supported by numerous studies showing that even a small cost of compliance (i. e., a short delay or inconvenience) can encourage people to ignore warnings (for reviews see *Lehto* and *Papastavrou* [39.62], *Wogalter* et al. [39.63], and *Miller* and *Lehto* [39.64]). Some strategies for reducing the cost of compliance include providing the warning at the time it is most relevant or more convenient to respond to.

Increasing the expected cost of ignoring the warning is another strategy for increasing warning effectiveness suggested by the warning compliance hypothesis. The potential value of this approach is supported by studies indicating that people will be more likely to take precautions when they believe the danger is present and perceive a significant benefit to taking the precaution. This might be done through supervision and enforcement or other methods of increasing the cost of ignoring the warning. Also, assuming the warning is sometimes given when it does not need to be followed (i. e., a false alarm), the expected cost of ignoring the warning will increase if the warning is modified in a way that reduces the number of false alarms. This point leads us to the topic of information quality.

39.3.3 Information Quality

In a perfect world, people would be given warnings if, and only if, a hazard is present that they are not already aware of. When warning systems are perfect, the receiver can optimize performance by simply following the warning when it is provided [39.65]. Imperfect warning systems, on the other hand, force the receiver to decide whether to consult and comply with the provided warning.

The problem with imperfect warning systems is that they sometimes provide false alarms or fail to detect the hazard. From a short-term perspective, false alarms are often merely a nuisance to the operator. However, there are also some important long-run costs, because repeated false alarms shape people's attitudes and influence their actions. One problem is the *cry-wolf* effect which encourages people to ignore (or mistrust) warnings [39.66, 67]. Even worse, people may decide to completely eliminate the nuisance by disconnecting the warning system [39.68]. Misses are also an important issue, because people may be exposed to hazards if they are relying on the warning system to detect the hazard. Another concern is that misses might reduce operator trust in the system [39.18].

Due to the potentially severe consequences of a miss, misses are often viewed as automation failures. The designers of warning systems consequently tend to focus heavily on designing systems that reliably provide a warning when a hazard is present. One concern, based on studies of operator overreliance upon imperfect automation [39.1, 19, 69], is that this tendency may encourage overreliance on warning systems. Another issue is that this focus on avoiding misses causes warning systems to provide many false alarms for each correct identification of the hazard. This tendency has been found for warning systems across a wide range of application areas [39.65, 67].

39.3.4 Information Integration

As discussed by *Edworthy* [39.70] and many others, in real-life situations people are occasionally faced with choices where they must combine what they already know about a hazard with information they obtain from hazard cues and a warning of some kind. In some cases, this might be a warning sign or label. In others, it might be a warning signal or alarm that indicates a hazard is present that normally is not there. A starting point for analyzing how people might integrate the information from the warning with what they already know or have determined from other sources of information is given by Bayes' rule, which describes how to infer the probability of a given event from one or more pieces of evidence [39.61]. Bayes' rule states that the posterior probability of hypothesis H_i given that evidence E_j is present, or $P(H_i|E_j)$, is given by

$$P(H_i|E_j) = \frac{P(E_j|H_i)}{P(E_j)} P(H_i)\,, \qquad (39.2)$$

where $P(H_i)$ is the probability of the hypothesis being true prior to obtaining the evidence E_j, and $P(E_j|H_i)$ is the probability of obtaining the evidence E_j given that the hypothesis H_i is true. When a receiver is given an imperfect warning, we can replace $P(E_j|H_i)$ in the above equation with $P(W|H)$ to calculate the probability that the hazard is present after receiving a warning. That is,

$$P(H|W) = \frac{P(W|H)}{P(W)} P(H)\,, \qquad (39.3)$$

where $P(H)$ is the prior probability of the hazard, $P(W)$ is the probability of sending a warning, $P(W|H)$ is the probability of sending a warning given the hazard is present, and $P(H|W)$ is the probability that the hazard is present after receiving the warning.

A number of other models have been developed in psychology that describe mathematically how people combine sources of information. Some examples include social judgment theory, policy capturing, multiple cue probability learning models, information integration theory, and conjoint measurement approaches [39.31]. From the perspective of warnings design, these approaches can be used to check which cues are actually used by people when they make safety-related decisions and how this information is integrated. A potential problem is that research on judgment and decision making clearly shows that people integrate information inconsistently with the prescriptions of Bayes' rule in some settings [39.71]; for example, several studies show that people are more likely to attend to highly salient stimuli. This effect can explain the tendency for people to overestimate the likelihood of highly salient events.

One overall conclusion is that significant deviations from Bayes' rule become more likely when people must combine evidence in artificial settings where they are not able to fully exploit their knowledge and cues found in their naturalistic environment [39.72–74]. This does not mean that people are unable to make accurate inferences, as emphasized by both Simon and researchers embracing the ecological [39.75, 76] and naturalistic [39.77] models of decision making. In fact, the use of simple heuristics in rich environments can lead to inferences that are in many cases more accurate than those made using naive Bayes, or linear, regression [39.75]. Unfortunately, many applications of automation place the operator in a situation which removes them from the rich set of naturalistic cues available in less automated settings, and forces the operator to make inferences from information provided on displays. In such situations, it may become difficult for operators to make accurate inferences since they no longer can rely on simple heuristics or decision rules that are adapted to particular environments.

39.3.5 The Value of Warning Information

As mentioned earlier, the designers of warning systems tend to focus heavily on designing systems that reliably provide a warning when a hazard is present, which results in many false alarms. From a theoretical perspective it might be better to design the warning system so that it is less conservative. That is, a system that occasionally fails to detect the hazard but provides fewer false alarms might improve operator performance. From the perspective of warning design, the critical question is to determine how selective the warning should be to minimize the expected cost to the user as a function of the number of false alarms and correct identifications made by the warning [39.68, 78, 79].

Given that costs can be assigned to false alarms and misses, an optimal warning threshold can be calculated that maximizes the expected value of the provided information. If it is assumed that people will simply follow the recommendation of a warning system (i. e., the warning system is the sole decision-maker) the optimal warning threshold can be calculated using classical signal detection theory (SDT) [39.80, 81]. That is, a warning should be given when the likelihood ratio $P(E|S)/P(E|N)$ exceeds the optimal warning threshold β, calculated as shown below.

$$\beta = \frac{1 - P_S}{P_S} \times \frac{c_r - c_a}{c_i - c_m} , \qquad (39.4)$$

where

P_S the a priori probability of a signal (hazard) being present,
$P(E|S)$ the conditional probability of the evidence given a signal (hazard) is present,
$P(E|N)$ the conditional probability of the evidence given a signal (hazard) is not present,
c_r cost of a correct rejection,
c_a cost of a false alarm,
c_i cost of a correct identification,
c_m cost of a missed signal.

In reality, the problem is more complicated because, as mentioned earlier, people might consider other sources in addition to a warning when making decisions. The latter situation corresponds to a team decision made by a person and warning system working together, as expanded upon later.

39.3.6 Team Decision Making

The distributed signal detection theoretic (DSDT) model focuses on how to determine the *optimal* decision thresholds of both the warning system and the human operator when they work together to make the best possible decision [39.65]. The proposed approach is based on the distributed signal detection model [39.82–86]. The key insight is that a warning system and human operator are *both* decision-makers who *jointly* try to make an optimal team decision.

The DSDT model has many interesting implications and applications. One is that the warning system and human decision-maker should adjust their decision thresholds in a way that depends upon what the other is doing. If the warning system uses a low threshold and provides a warning even when there is not much evidence of the hazard, the DSDT model shows that the human decision-maker should adjust their own threshold in the opposite direction. That is, the rational human decision-maker will require more evidence from the environment or other source before complying with the warning. At some point, as the threshold for providing the warning gets lower, the rational decision-maker will ignore the warning completely.

The DSDT model also implies that the warning system should use different thresholds depending upon how the receiver is performing. If the receiver is disabled or unable to take their observation from the environment, the warning should take the role of primary decision-maker, and set its threshold accordingly to that prescribed in traditional signal detection theory. Along the same lines, if the decision-maker is not responding in an optimal manner when the warning is or not given, the DSDT model prescribes ways of modifying the warning systems threshold; for example, if the decision-maker is too willing to take the precaution when the warning is provided, the warning system should use a stricter warning threshold. That is, the warning system should require more evidence before sending a warning.

Research has been performed that addresses predictions of the DSDT model [39.65, 87, 88]. One study showed that the performance of subjects on a simple inference task changed dramatically, depending on the warning threshold value [39.65]. The optimal warning threshold varied between subjects, and subjects changed their own decision thresholds, consistently with the DSDT model's predictions, when the warning threshold was modified. A second study, using a similar inference task, also showed that the optimal threshold varied between subjects [39.87]. Performance was significantly improved by adjusting the warning threshold to the optimal DSDT value calculated for each particular subject based on their earlier performance. A third study, in a more realistic environment, compared the driving performance of licensed drivers on a driving simulator [39.88]. Overall, use of the DSDT threshold improved passing decisions significantly over the SDT warning threshold. Drivers also changed their own decision thresholds, in the way the DSDT model predicted they should, when the warning threshold changed. Another interesting result was that use of the DSDT threshold resulted in either *risk-neutral* or *risk-averse* behavior, while, on the other hand, use of the SDT threshold resulted in some *risk-seeking* behavior; that is, people were more likely to ignore the warning and visual cues indicating that a car might be coming. Overall, these results suggest that, for familiar decisions such as choosing when to pass, people can behave nearly optimally.

One of the more interesting aspects of the DSDT model is that it suggests ways of adjusting the warning threshold in response to how the operator is performing.

39.3.7 Time Pressure and Stress

Time pressure and stress is another important issue in many applications of warnings. Reviews of the literature suggest that time pressure often results in poorer task performance and that it can cause shifts between the cognitive strategies used in judgment and decision-making situations [39.89,90]. One change is that people show a tendency to shift to noncompensatory decision rules. This finding is consistent with contingency theories of strategy selection. In other words, this shift may be justified when little time is available, because a noncompensatory rule can be applied more quickly. *Maule* and *Hockey* [39.89] also note that people tend to filter out low-priority types of information, omit processing information, and accelerate mental activity when they are under time pressure.

The general findings above indicate that warnings may be useful when people are under time pressure and stress. People in such situations are especially likely to make mistakes. Consequently, warnings that alert people after they make mistakes may be useful. A second issue is that people under time pressure will not have a lot of extra time available, so it will become especially important to avoid false alarms. A limited amount of research addresses the impact of time stress on warnings compliance. In particular, a study by *Wogalter* et al. [39.63] showed that time pressure reduced compliance with warnings. Interestingly, subjects performed better in both low- and high-stress conditions when the warnings were placed in the task instructions than on a sign posted nearby. The latter result supports the conclusion that warnings which efficiently and quickly transmit their information may be better when people are under time stress or pressure. In some situations, this may force the designer to carefully consider the tradeoff between the amount of information provided and the need for brevity. Providing more detailed information might improve understanding of the message but actually reduce effectiveness if processing the message requires too much time and attentional effort on the part of the receiver.

39.4 Design Guidelines and Requirements

Safety warnings can vary greatly in behavioral objectives, intended audiences, content, level of detail, format, and mode of presentation. Accordingly, the design of adequate warnings will often require extensive investigations and development activities involving significant resources and time [39.91], well beyond the scope of this chapter. The following discussion will briefly address methods of identifying hazards for applications of automation, along with some legal requirements and design specifications found in warning standards.

39.4.1 Hazard Identification

The first step in the development of warnings is to identify the hazards to be warned against. This process is guided by past experience, codes and regulations, checklists, and other sources, and is often organized by separately considering systems and subsystems, and potential malfunctions at each stage in their life cycles. Numerous complementary hazard analysis methods, which also guide the process of hazard identification, are available [39.92, 93]. Commonly used methods include work safety analysis, human error analysis, failure modes and effects analysis, and fault tree analysis.

Work safety analysis (WSA) [39.94] and human error analysis (HEA) [39.95] are related approaches that organize the analysis around tasks rather than system components. This process involves the initial division of tasks into subtasks. For each subtask, potential effects of product malfunctions and human errors are then documented, along with the implemented and the potential countermeasures. In automation applications, the tasks that would be analyzed fall into the categories of normal operation, programming, and maintenance.

Failure modes and effects analysis (FMEA) is a systematic procedure for documenting the effects of system malfunctions on reliability and safety [39.93]. Variants of this approach include preliminary hazard analysis (PHA), and failure modes effects and criticality analysis (FMECA). In all of these approaches, worksheets are prepared which list the components of a system, their potential failure modes, the likelihood and effects of each failure, and both the implemented and the potential countermeasures that might be taken to prevent the failure or its effects. Each failure may have multiple effects. More than one countermeasure may also be relevant for each failure. Identification of failure modes and potential countermeasures is guided by past experience, standards, checklists, and other sources. This process can be further organized by separately considering each step in the operation of a system; for example, the effects of a power supply failure for a welding robot might be separately considered for each step performed in the welding process.

Fault tree analysis (FTA) is a closely related approach used to develop fault trees. The approach is top-down in that the analysis begins with a malfunction or accident and works downwards to basic events at the bottom of the tree [39.93]. Computer tools which calculate minimal cut-sets and failure probabilities and also perform sensitivity analysis [39.96] make such analysis more convenient. Certain programs help analysts draw fault trees [39.97,98]. Human reliability analysis (HRA) event trees are a classic example of this approach.

FTA and FMEA are complementary tools for documenting sources of reliability and safety problems, and also help organize efforts to control these problems. The primary shortcoming of both approaches is that the large number of components in many automated systems imposes a significant practical limitation on the analysis, that is, the number of event combinations that might occur is an exponential function of the large number of components. Applications for complex forms of automation consequently are normally confined to the analysis of single-event failures [39.100].

FTA and FMEA both provide a way of estimating the system reliability from the reliability of its components. *Dhillon* [39.101] provides a comprehensive overview of documents, data banks, and organizations for obtaining failure data to use in robot reliability analysis. Component reliabilities used in such analysis can be obtained from sources such as handbooks [39.102], data provided by manufacturers (Table 39.2), or past experience. Limited data is also available that documents error rates of personnel performing reliability-related tasks, such as maintenance (Table 39.3). Methods for estimating human error rates have been developed [39.103], such as technique for human error rate prediction (THERP) [39.104] and success likelihood index method-multiattribute utility decomposition (SLIM-MAUD) [39.105]. THERP follows an approach analogous to fault tree analysis, to estimate human error probabilities (HEPs). In SLIM-MAUD expert ratings are used to estimate HEPs as a function of performance shaping factors (PSFs).

Given that system component failure rates or probabilities are known, the next step in quantitative analysis is to develop a model of the system showing how system reliability is functionally determined by each component. The two most commonly used models are: (1) the systems block diagram, and (2) the system fault tree. Fault trees and system block diagrams are both useful for describing the effect of component configurations on system reliability. The most commonly considered configurations in such analysis are: (1) serial systems, (2) parallel systems, and (3) mixed serial and parallel systems.

39.4.2 Legal Requirements

In most industrialized countries, governmental regulations require that certain warnings be provided to

Table 39.2 Estimates of fire protection systems operational reliability (probability of success) [39.99]

Protection system	Warrington Delphi UK (Delphi Group)		Fire eng guidelines Australia (expert surveys)		Japanese studies (incident data)	
	Smoldering	Flaming	Smoldering	Flaming	Tokyo FD	Watanabe
Heat detector	0	89	0	90/95	94	89

MO – man overboard, GR – gas release, F&R – fire and explosion, TSR – temporary safe refuge, OIM – offshore installation manager, PA – public announcement

No.	Action	HEP			Phase	Loss of defences
		MO	GR	F&E		
1	Detect alarm	0.00499	0.0308	0.396	Awareness	Do not hear alarm. Do not properly identify alarm. Do not maintain composure (panic)
2	Identify alarm	0.00398	0.0293	0.386		
3	Act accordingly	0.00547	0.0535	0.448		
4	Ascertain if danger is imminent	0.00741	0.0765	0.465	Evaluation	Misinterpret muster initiator seriousness and fail to muster in a timely fashion. Do not return process to safe state. Leave workplace in a condition that escalates initiator or impedes others' egress
5	Muster if in imminent danger	0.00589	0.0706	0.416		
6	Return process equipment to safe state	0.00866	0.0782	0.474		
7	Make workplace as safe as possible in limited time	0.00903	0.0835	0.489		
8	Listen and follow PA announcements	0.00507	0.0605	0.42	Egress	Misinterpret or do not hear PA announcements. Misinterpret tenability of egress path. Fail to follow a path which leads to TSR; decide to follow a different egress path with lower tenability. Fail to assist others. Provide incorrect assistance which delays or prevents egress
9	Evaluate potential egress paths and choose route	0.00718	0.0805	0.476		
10	Move along egress route	0.00453	0.0726	0.405		
11	Assess quality of egress route while moving to TSR	0.00677	0.0788	0.439		
12	Choose alternate route if egress path is not tenable	0.00869	0.1	0.5		
13	Assist others if needed or as directed	0.0101	0.0649	0.358		
14	Register at TSR	0.00126	0.01	0.2	Recovery	Fail to register while in the TSR. Fail to provide pertinent feedback. Provide incorrect feedback. Do not don personal survival suit in an adequate time for evacuation. Misinterpret OIM's instructions or do not follow OIM's instructions
15	Provide pertinent feedback attained while en route to TSR	0.00781	0.0413	0.289		
16	Don personal survival suit or TSR survival suit if instructed to abandon	0.00517	0.026	0.199		
17	Follow OIM's instructions	0.0057	0.0208	0.21		
18	Follow OIM's instructions	0.0057	0.0208	0.21		

workers and others who might be exposed to hazards. For example, in the USA, the Environmental Protection Agency (EPA) has developed several labeling requirements for toxic chemicals. The Department of Transportation (DOT) makes specific provisions regarding the labeling of transported hazardous materials. The most well-known governmental standards in the USA applicable to applications of automation are the general industry standards specified by the Occupation Safety and Health Administration (OSHA). The OSHA has also promulgated a hazard communication standard that applies to workplaces where toxic or hazardous materials are in use. Training, container labeling and other forms of warnings, and material data safety sheets are all required elements of the OSHA hazard communication standard. Other relevant OSHA publications addressing automation are the *Guidelines for Robotics Safety* [39.106] and the *Occupational Safety and Health Technical Manual* [39.107].

In the USA, the failure to warn also can be grounds for litigation holding manufacturers and others liable for injuries incurred by workers. In establishing liability, the *theory of negligence* considers whether the failure to adequately warn is unreasonable conduct based on (1) the foreseeability of the danger to the manufacturer, (2) the reasonableness of the assumption that a user would realize the danger and, (3) the degree of care that the manufacturer took to inform the user of the danger. The *theory of strict liability* only requires that the failure to warn caused the injury or loss.

39.4.3 Voluntary Standards

A large set of existing standards provide voluntary recommendations regarding the use and design of safety information. These standards have been developed by both: (1) international groups, such as the United Nations, the European Economic Community (EURONORM), the International Organization for Standardization (ISO), and the International Electrotechnical Commission (IEC), and (2) national groups, such as the American National Standards Institute (ANSI), the British Standards Institute, the Canadian Standards Association, the German Institute for Normalization (DIN), and the Japanese Industrial Standards Committee.

Among consensus standards, those developed by ANSI in the USA are of special significance. Over the last decade or so, five new ANSI standards focusing on safety signs and labels have been developed and one significant standard has been revised. The new standards are: (1) ANSI Z535.1 *Safety Color Code*, (2) ANSI Z535.2 *Environmental and Facility Safety Signs*, (3) ANSI Z535.3 *Criteria for Safety Symbols*, (4) ANSI Z535.4 *Product Safety Signs and Labels*, and (5) ANSI Z535.5 *Accident Prevention Tags*. The recently revised standard is ANSI Z129.1-1988, *Hazardous Industrial Chemicals – Precautionary Labeling*. Furthermore, ANSI has published a *Guide for Developing Product Information*.

Warning requirements for automated equipment can also be found in many other standards. The most well-known standard in the USA that addresses automation safety is ANSI/RIA R15.06. This standard was first published in 1986 by the Robotics Industries Association (RIA) and the American National Standards Institute (ANSI) as ANSI/RIA R15.06, the *American National Standard for Industrial Robots and Robot Systems – Safety Requirements* [39.109]. A revised version of the standard was published in 1992 and the standard is currently undergoing revisions once again. Several other standards developed by the ANSI are potentially important in automation applications. The latter standards address a wide variety of topics such as machine tool safety, machine guarding, lock-out/tagout procedures, mechanical power transmission, chemical labeling, material safety data sheets, personal protective equipment, safety markings, workplace signs, and product labels. Other potentially relevant standards developed by nongovernmental groups include the National Electric Code, the Life Safety Code, and the proposed UL1740 safety standard for industrial robots and robotics equipment. Literally thousands of consensus standards contain safety provisions. Also, many companies that use or manufacture automated systems will develop their own guidelines [39.110]. Companies often will start with the ANSI/RIA R15.06 robot safety standard, and then add detailed information that is relevant to their particular situation.

39.4.4 Design Specifications

Design specifications can be found in consensus and governmental safety standards specifying how to design (1) material safety data sheets (MSDS), (2) instructional labels and manuals, (3) safety symbols, and (4) warning signs, labels, and tags.

Material Safety Data Sheets

The OSHA hazard communication standard specifies that employers must have a MSDS in the workplace for each hazardous chemical used. The standard requires that each sheet be written in English, list its date of preparation, and provide the chemical and common name of hazardous chemicals contained. It also requires the MSDS to describe (1) physical and chemical characteristics of the hazardous chemical, (2) physical hazards, including potential for fire, explosion, and reactivity, (3) health hazards, including signs and symptoms of exposure, and health conditions potentially aggravated by the chemical, (4) the primary route of entry, (5) the OSHA permissible exposure limit, the American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value, or other recommended limits, (6) carcinogenic properties, (7) generally applicable precautions, (8) generally applicable control measures, (9) emergency and first-aid procedures, and (10) the name, address, and telephone number of a party able to provide, if necessary, additional information on the hazardous chemical and emergency procedures.

Instructional Labels and Manuals

Few consensus standards currently specify how to design instructional labels and manuals. This situation is, however, quickly changing. The ANSI *Guide for Developing User Product Information*, was recently published in 1990, and several other consensus or-

Table 39.4 Summary of recommendations in selected warning systems (after *Lehto* and *Miller* [39.39], and *Lehto* and *Clark* [39.9])

System	Signal words	Color coding	Typography	Symbols	Arrangement
ANSI Z129.1 Precautionary labeling of hazardous chemicals	Danger Warning Caution Poison optional words for *delayed* hazards	Not specified	Not specified	Skull-and-crossbones as supplement to words. Acceptable symbols for three other hazard types	Label arrangement not specified; examples given
ANSI Z535.2 Environmental and facility safety signs	Danger Warning Caution Notice [General safety] [Arrows]	Red Orange Yellow Blue Green as above; B&W otherwise per ANSI Z535.1	Sans serif, Upper case, Acceptable typefaces, Letter heights	Symbols and pictographs per ANSI Z535.3	Defines signal word, word message, symbol panels in 1–3 panel designs. Four shapes for special use. Can use ANSI Z535.4 for uniformity
ANSI Z535.4 Product safety signs and labels	Danger Warning Caution	Red Orange Yellow per ANSI Z535.1	Sans serif, Upper case, Suggested typefaces, Letter heights	Symbols and pictographs per ANSI Z535.3; also Society of Automotive Engineers (SAE) J284 Safety Alert Symbol	Defines signal word, message, pictorial panels in order of general to specific. Can use ANSI Z535.2 for uniformity. Use ANSI Z129.1 for chemical hazards
National Electrical Manufacturers Association (NEMA) guidelines: NEMA 260	Danger Warning	Red Red	Not specified	Electric shock symbol	Defines signal word, hazard, consequences, instructions, symbol. Does not specify order
SAE J115 Safety signs	Danger Warning Caution	Red Yellow Yellow	Sans serif, Typeface, Upper case	Layout to accommodate symbols; specific symbols/pictographs not prescribed	Defines 3 areas: signal word panel, pictorial panel, message panel. Arrange in order of general to specific
ISO standard: ISO R557, 3864	None. Three kinds of labels: Stop/prohibition Mandatory action Warning	Red Blue Yellow	Message panel is added below if necessary	Symbols and pictographs	Pictograph or symbol is placed inside appropriate shape with message panel below if necessary

ganizations are working on draft documents. Without an overly scientific foundation, the ANSI Consumer Interest Council, which is responsible for the above guidelines, has provided a reasonable outline to manufacturers regarding what to consider in producing instruction/operator manuals. They have included sec-

Table 39.4 (cont.)

System	Signal Words	Color Coding	Typography	Symbols	Arrangement
OSHA 1910.145 Specification for accident prevention signs and tags	Danger Warning (tags only) Caution Biological Hazard, BIOHAZARD, or symbol [Safety instruction] [Slow-moving vehicle]	Red Yellow Yellow Fluorescent Orange/ Orange-Red Green Fluorescent Yellow-Orange & Dark Red per ANSI Z535.1	Readable at 5 ft or as required by task	Biological hazard symbol. Major message can be supplied by pictograph (tags only). Slow-moving vehicle (SAE J943)	Signal word and major message (tags only)
OSHA 1910.1200 [Chemical] Hazard communication	Per applicable requirements of Environmental Protection Agency (EPA), Food and Drug Administration (FDA), and Consumer Product Safety Commission (CPSC)		In English		Only as material safety data sheet
Westinghouse handbook; FMC guidelines	Danger Warning Caution Notice	Red Orange Yellow Blue	Helvetica bold and regular weights, Upper/lower case	Symbols and pictographs	Recommends 5 components: signal word, symbol/pictograph, hazard, result of ignoring warning, avoiding hazard

tions covering *organizational elements*, *illustrations*, *instructions*, *warnings*, *standards*, *how to use language*, and *an instructions development checklist*. While the guideline is brief, the document represents a useful initial effort in this area.

Safety Symbols

Numerous standards throughout the world contain provisions regarding safety symbols. Among such standards, the ANSI Z535.3 standard, *Criteria for Safety Symbols*, is particularly relevant for industrial practitioners. The standard presents a significant set of selected symbols shown in previous studies to be well understood by workers in the USA. Perhaps more importantly, the standard also specifies methods for designing and evaluating safety symbols. Important provisions include: (1) new symbols must be correctly identified during testing by at least 85% of 50 or more representative subjects, (2) symbols which do not meet the understandability criteria should only be used when equivalent word messages are also provided, and (3) employers and product manufacturers should train users regarding the intended meaning of the symbols. The standard also makes new symbols developed under these guidelines eligible to be considered for inclusion in future revisions of the standard.

Warning Signs, Labels, and Tags

ANSI and other standards organizations provide very specific recommendations about how to design warning signs, labels, and tags. These include, among other factors, particular signal words and text, color coding schemes, typography, symbols, arrangement, and hazard identification (Table 39.4).

Among the most popular signal words recommended are: *danger*, to indicate the highest level of hazard; *warning*, to represent an intermediate hazard; and *caution*, to indicate the lowest level of hazard. Color coding methods, also referred to as a *color system*, consistently associate colors with particular levels of hazard; for example, red is used in all of the standards to represent the highest level of danger. Explicit recommendations regarding typography are given in nearly all the systems. The most general commonality between the systems is the recommended use of sans-serif typefaces. Varied recommendations are given regarding the use of symbols and pictographs.

The FMC and the Westinghouse systems advocate the use of symbols to define the hazard and to convey the level of hazard. Other standards recommend symbols only as a supplement to words. Another area of substantial variation shown in Table 39.4 pertains to the recommended label arrangements. The proposed arrangements generally include elements from the above discussion and specify the image's graphic content and color, the background's shape and color, the enclosure's shape and color, and the surround's shape and color. Many of the systems also precisely describe the arrangement of the written text and provide guidance regarding methods of hazard identification.

Certain standards also specify the content and wording of warning signs or labels in some detail; for example, ANSI Z129.1 specifies that chemical warning labels include (1) identification of the chemical product or its hazardous component(s), (2) signal word, (3) statement of hazard(s), (4) precautionary measures, (5) instructions in case of contact or exposure, (6) antidotes, (7) notes to physicians, (8) instructions in case of fire and spill or leak, and (9) instructions for container handling and storage. This standard also specifies a general format for chemical labels that incorporate these items and recommended wordings for particular messages.

There are also standards which specifically address the design of automated systems and alerts; for example, the Department of Transportation, Federal Aviation Administration's (FAA) *Human Factors Design Standard* (HFDS) (2003) indicates that alarm systems should alert the user to the existence of a problem, inform of the priority and nature of the problem, guide the user's initial response, and confirm whether the user's response corrected the problem. Furthermore, it should be possible to identify the first event in a series of alarm events (information valuable in determining the cause of a problem). Consistent with our earlier discussion, the standard suggests that information should be provided in multiple formats (e.g., visual and auditory) to improve communication and reduce mental workload, that auditory signals be used to draw attention to the location of a visual display, and that false alarms should not occur so frequently so as to undermine user trust in the system. Additionally, users should be informed of the inevitability of false alarms (especially in the case of low base rates). A more in-depth discussion of the FAA's recommendations is beyond the scope of this chapter – for additional information, see the *Human Factors Design Standard* [39.111]. Recommendations also exist for numerous other applications including automated cruise control/collision warning systems for commercial trucks greater than 10 000 pounds [39.112] as well as for horns, backup alarms, and automatic warning devices for mobile equipment [39.113].

39.5 Challenges and Emerging Trends

The preceding sections of this chapter reveal that warnings can certainly play an important role in automated systems. One of the more encouraging results is that people often tend to behave consistently with the predictions of normative models of decision making. From a general perspective, this is true both if people comply with warnings because they believe the hazard is more serious, and if people ignore warnings with little diagnostic value or when the cost of compliance is believed to be high. This result supports the conclusion that normative models can play an important role in suggesting and evaluating design solutions that address issues such as operator mistrust of warnings, complacency, and overreliance on warnings. Perhaps the most fundamental design challenge is that of increasing the value of the information provided by automated warning systems. Doing so would directly address the issue of operator mistrust.

The most fundamental method of addressing this issue is to develop improved sensor systems that more accurately measure important variables that are strongly related to hazards or other warned against events. Successful implementations of this approach could increase the diagnostic value of the warnings provided by automated warning systems by reducing either false alarms or misses, and hopefully both. Given the significant improvements and reduced costs of sensor technology that have been observed in recent years, this strategy seems quite promising. Another promising strategy for increasing the diagnostic value of the warnings is to develop better algorithms for both integrating information from multiple sensors and deciding upon when to provide a warning. Such algorithms might include methods of adaptive automation that monitor the operator's behavior, and respond accordingly; for example, if the system detects evidence that the user is ignoring the provided warnings, a secondary, more urgent warning that requires a confirmatory response might be given to determine if the user is disabled (i. e., unable to respond because they are distracted or even sleeping). Other algorithms might track the performance of particular operators over a longer period and use this data to estimate the skill of the operator or determine the types of information the operator uses to make decisions. Such tracking might reveal the degree to which the operator relies on the warning system. It also might reveal the extent to which the other sources of information used by operator are redundant or independent of the warning.

Another challenge that has been barely, if it all, addressed in most current applications of warning systems is related to the tacit assumption that the perceived costs and benefits of correct detections, misses, false alarms, and correct rejections are constant across operators and situations. This assumption is clearly false, because operators will differ in their attitudes toward risk. Furthermore, the costs and benefits are also likely to change greatly between situations; for example, the expected severity of an automobile accident changes, depending on the speed of the vehicle. This issue might be addressed by algorithms based on normative models which treat the costs and benefits of correct detections, misses, false alarms, and correct rejections as random variables which are a function of particular operators and situations.

Many other challenges and areas of opportunity exist for improving automated warnings; for example, more focus might be placed on developing warning systems that are easier for operators to understand. Such systems might include capabilities of explaining why the warning is being provided and how strong the evidence is. Other systems might give the user more control over how the warning operates.

Part E

Automati

Part E Automation Management

Automation Management. Part E The main aspects of automation management are covered by the chapters in this part: Cost effectiveness and economic reasons for the design, feasibility analysis, implementation, rationalization, use, and maintenance of particular automation; performance and functionality measures and criteria, such as quality of service, energy cost, reliability, safety, usability, and other criteria; issues involved with managing automation over its life cycles, and the use of embedded automation for this management; how to best prepare the next generation of automation engineers, practitioners, inventors, developers, scientists, operators, and general users, and how to best prepare and qualify automation professionals. Related also to the above topics are the issues of how to manage automatically and control the increasingly complex and rapidly evolving software assets, their maintenance, replacement, and upgrading; how to simplify the specification of increasingly more integrated, inter-dependent and complex automation; and what are some of the ethical concerns with automation and solutions being developed to prevent abuse of automation and with automation.

This part concludes the first portion of the Handbook, which is devoted to the science, theory, design, and management aspects and challenges of automation. The next portion is devoted to the main functional areas of automation, demonstrating the role of the previously discussed theories, techniques, models, tools and guidelines, as they are applied and implemented specifically and successfully and the obstacles they face in those functional areas.

40. Economic Rationalization of Automation Projects

José A. Ceroni

The future of any investment project is undeniably linked to its economic rationalization. The chance that a project is realized depends on our ability to demonstrate the benefits that it can convey to a company. However, traditional investment evaluation must be enhanced and used carefully in the context of rationalization to reflect adequately the characteristics of modern automation systems. Nowadays automation systems often take the form of complex, strongly related autonomous systems that are able to operate in a coordinated fashion in distributed environments. Reconfigurability is a key factor affecting automation systems' economic evaluation due to the reusability of equipment and software for the manufacturing of several products. A new method based on an analytical hierarchy process for project selection is reviewed. A brief discussion on risk and salvage consideration is included, as are aspects needing further development in future rationalization techniques.

Worldwide adoption of automation advanced technologies such as robotics, flexible manufacturing, and computer-integrated manufacturing systems has been key to continued improvement of competitiveness in present global markets [40.1]. Adequate definition and selection of automation technology offers substantial potential for cost savings, increased flexibility, better product consistency, and higher throughput. However, justifying automation technology based only on traditional economic criteria is at least biased and often wrong. Lack of consideration of automation strategic and long-term benefits has often led to failure in adopting it [40.2–5]. Ignoring automation's long-term benefits and impact on company strategy leads to poor decision-making on technologies to implement. Usually nowadays, the long-range cost of not automating can turn out to be considerably greater than the short-term cost of acquiring automation technology [40.6].

A primary objective of any automation project must be to develop a new integrated system able to provide financial, operational, and strategic benefits. Thus the automation project should avoid replicating current operational methods and support systems. In this way, the automation project should make clear the four differences from any other capital equipment project:

- Automation provides flexibility in production capability, enabling companies to respond effectively to market changes, an aspect with clear economic value.
- Automation solutions force users to rethink and systematically define and integrate the functions of

their operations. This reengineering process creates major economic benefits.
- Modern automation solutions are reprogrammable and reusable, with components often having lifecycles longer than the planned production facility.
- Using automation significantly reduces requirements for services and related facilities.

These differences lead to operational benefits that include:

- Increased flexibility
- Increased productivity
- Reduced operating costs
- Increased product quality
- Elimination of health and safety hazards
- Higher precision
- Ability to run longer shifts
- Reduced floor space.

Time-based competition and mass customization of global markets are key competitive strategies of present-day manufacturing companies [40.7]. Average product lifecycle in marketplaces has changed from years to months for products based on rapidly evolving technologies. This demands agile automated systems, created through the concept of common manufacturing processes organized modularly to allow rapid deployment in alternative configurations. These reconfigurable automated systems represent the cornerstone in dealing with time-based competition and mass customization.

Justification of reconfigurable automation systems must necessarily include strategic aspects when comparing them with traditional manufacturing systems developed under the product-centric paradigm. Product-specific systems generally lack the economical reconfiguration ability that would allow them to meet the needs of additional products. Consequently traditional systems are typically decommissioned well before their capital cost can be recovered, and are then held in storage until fully depreciated for tax purposes before being sold at salvage value. However, it must be kept in mind that reconfigurability claims for additional investment in design, implementation, and operation of the system. Quick-change tooling are an example of reconfigurability equipment which allows rapid product changeover. It is estimated that generic system capabilities can increase the cost of reconfigurable system hardware by as much as 25% over that of a comparable dedicated system. On the other hand, software required to configure and run reconfigurable automation systems is often much more expensive to develop than simple part-specific programs. Traditional economic evaluation methods fail to consider benefits from capital reutilization over multiple projects and also disregard strategic benefits of technology. Upgrade of traditional economic evaluation methods is required to account for the short-term economic and long-term strategic value of investing in reconfigurable automation technologies to support the evolving production requirements of a family of products. In this chapter the traditional economic justification approach to automation system justification is first addressed. A related discussion on economic aspects of automation not discussed in this chapter can be found in Chap. 7. New approaches to automated system justification based on strategic considerations are presented next. Finally, a discussion on justification approaches currently being researched for reconfigurable systems is presented.

40.1 General Economic Rationalization Procedure

In general terms, an economic rationalization enables us to compare the financial benefits expected from a given investment project with alternative use of investment capital. Economic evaluation measures capital cost plus operating expenses against cash-flow benefits estimated for the project. This section describes a general approach to economic rationalization and justification of automation system projects.

40.1.1 General Procedure for Automation Systems Project Rationalization

The general procedure for rationalization and analysis of automation projects presented here consists of a pre-cost-analysis phase, followed by a cost-analysis phase. Figure 40.1 presents the procedure steps and their sequence. The sequence of steps in Fig. 40.1 is reviewed in detail in the rest of this section and an example cost-analysis phase is described.

40.1.2 Pre-Cost-Analysis Phase

The pre-cost-analysis phase evaluates the feasibility of the automation project. Feasibility is evaluated in terms of the technical capability to achieve production capacity and utilization as estimated in production schedules. The first six steps of the procedure include determining the most suitable manufacturing method, selecting the tasks to automate, and the feasibility of these options (Fig. 40.1). Noneconomic considerations must be studied and all data pertinent to product volumes and operation times gathered.

Alternative Automated Manufacturing Methods

Production unit cost at varying production volumes for three main alternative manufacturing methods (manual labor, flexible automation, and hard automation) are compared in Fig. 40.2 [40.8]. Manual labor is usually the most cost-effective method for low production volumes; however, reconfigurable assembly is changing this situation drastically. Flexible, programmable automation is most effective for medium production volumes, ranging from a few tens or hundreds of products per year per part type to hundreds of thousands of products per year. Finally, annual production volumes of 500 000 or above seem to justify the utilization of hard automation systems.

Boothroyd et al. [40.9] have derived specific formulas for assembly cost (Table 40.1). By using these formulas they compare alternative assembly systems such as the one-operator assembly line, assembly center with two arms, universal assembly center, free-transfer machine with programmable workheads, and dedicated machine. The last three systems are robotics-based automated systems. The general expression derived by [40.9] is

$$C_{\mathrm{pr}} = t_{\mathrm{pr}}\left(W_{\mathrm{t}} + \frac{WM'}{SQ}\right),$$

where C_{pr} = unitary assembly cost, t_{pr} = average assembly time per part, W_{t} = labor cost per time, W = operator's rate in dollars per second, M' = assembly equipment cost per time, S = number of shifts, and Q = operator cost in terms of capital equivalent.

Parameters and variables in this expression present alternative relationships, depending on the type of assembly system.

Figures 40.3 and 40.4 show the unitary cost for the assembly systems at varying annual production volumes. It can be seen that production of multiple products increases costs, by approximately 100%, for the assembly center with two arms and free-transfer ma-

Evaluation of Technical Feasibility for Alternative Methods

Feasibility of the automation system plan must be reviewed carefully. It is perfectly possible for an automation project to have a positive economic evaluation but have problems with its feasibility. Although this situation may seem strange it must be considered that an automation project is rather complex and demands specific operational conditions, far more complex than those in conventional production systems. A thorough feasibility review must consider aspects such as the answers to the following questions in case of automated assembly:

- Is the product designed for automated assembly?
- Is it possible to do the job with the planned procedure and within the given cycle time?
- Can reliability be ensured as a component of the total system?
- Is the system sufficiently staffed and operated by assigned engineers and operators?
- Is it possible to maintain safety and the designed quality level?
- Can inventory and material handling be reduced in the plant?
- Are the material-handling systems adequate?
- Can the product be routed in a smooth batch-lot flow operation?

Following the feasibility analysis, alternatives are considered further in the evaluation. If the plan fails due to lack of feasibility, a search for other type of solutions is in order. Alternative solutions may involve the development of new equipment, improvement of proposed equipment or development of other alternatives.

Selection of Tasks to Automate

Selection of tasks for automation is a difficult process. The following five job grouping strategies may assist the determination of tasks to automate:

Table 40.1 Comparison of assembly systems cost

Assembly system	t_{pr}	W_{t}	M'
Operator assembly line no feeders	$Kt_0(1+x)$	nW/k	$(n/k)(2C_{\text{B}}+N_{\text{p}}C_{\text{C}})$
Operator assembly line with feeders	$Kt'_0(1+x)$	nW/k	$(n/k)(2C_{\text{B}}+N_{\text{p}}C_{\text{C}})+N_{\text{p}}(ny+N_{\text{d}}C_{\text{F}})$
Dedicated hybrid machine	$t+xT$	$3W$	$[nyC_{\text{T}}+(T/t)(ny)C_{\text{B}}]+N_{\text{p}}\{(ny+N_{\text{d}})(C_{\text{F}}+C_{\text{w}})$ $+[ny+(T/2t)(ny)]C_{\text{C}}\}$
Free-transfer machine with programmable workheads	$k(t+xT)$	$3W$	$(n/k)[C_{\text{dA}}+(T/t+1)C_{\text{B}}+N_{\text{p}}[(ny+N_{\text{d}})C_{\text{M}}+nC_{\text{g}}$ $+(n/k)(T/2t+0.5)C_{\text{C}}]$
Assembly center with two arms	$n(t/2+xT)$	$3W$	$2C_{\text{dA}}+N_{\text{p}}[C_{\text{C}}+nC_{\text{g}}+(ny+N_{\text{d}})C_{\text{M}}]$
Universal assembly center	$n(t/2+xT)$	$3W$	$(2C_{\text{dA}}+nyC_{\text{PF}}+2C_{\text{ug}})+N_{\text{p}}C_{\text{C}}$

where: C_{pr} = product unit assembly cost, S = number of shifts, Q = equivalent cost of operator in terms of capital equivalent, W = operator's rate in dollars per second, d = degrees of freedom, k = number of parts assembled by each operator or programmable workhead, n = total number of parts, N_{p} = number of products, N_{d} = number of design changes, C_{dA} = cost of a programmable robot or workhead, C_{B} = cost of a transfer device per workstation, C_{C} = cost of a work carrier, C_{F} = cost of an automatic feeding device, C_{g} = cost of a gripper per part, C_{M} = cost of a manually loaded magazine, C_{PF} = cost of a programmable feeder, C_{S} = cost of a workstation for a single station assembly, C_{t} = cost of a transfer device per workstation, C_{ug} = cost of a universal gripper, C_{W} = cost of a dedicated workhead, T = machine downtime for defective parts, t_0, t'_0 = machine downtime due to defective parts, t = mean time of assembly for one part, x = ratio of faulty parts to acceptable parts, and y = product styles

- Components of products of the same family
- Products presently being manufactured in proximity
- Products consisting of similar components that could share part-feeding devices
- Products of similar size, dimensions, weight, and number of components
- Products with simple design possible to manufacture within a short cycle time.

Noneconomic and Intangible Considerations

Issues related to specific company characteristics, company policy, social responsibility, and management policy need to be addressed both quantitatively and qualitative in the automation project. Adequate justification of automation systems needs to consider aspects such as:

- Compliance with the general direction of the company's automation
- Satisfaction of equipment and facilities standardization policies
- Adequate accommodation of future product model changes or production plans
- Improvement of working life quality and workers morale
- Positive impact on company reputation
- Promotion of technical progress at the company.

Special differences among automated solutions (e.g., robots) and other case-specific capitalization equipment also provide numerous intangible benefits, as the following list illustrates:

- Robots are reusable.
- Robots are multipurpose and can be reprogrammed for many different tasks.
- Because of reprogrammability, robotic systems service life can often be three or more times longer than that of fixed (hard) automation devices.
- Tooling costs for robotic systems also tend to be lower owing to the programming capability around certain physical constraints.
- Production startup occurs sooner because of less construction and tooling constraints.
- Plant modernization can be implemented by eliminating discontinued automation systems.

Determination of Costs and Benefits

Although costs and benefits expected from automation projects vary according to each particular case being analyzed, a general classification of costs can include operators wages, capital, maintenance, design, and power costs. However, it must be noted that, while usually wages decrease at higher levels of automation, the rest of the cost tend to increase. Figure 40.5 shows the behavior of assembly costs at different automation levels [40.10]. Consequently, it would be possible to determine the optimal degree of automation based on the minimum total operational cost of the system.

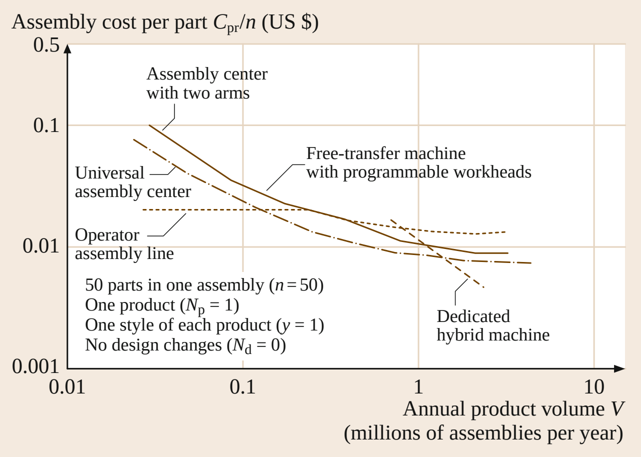

Fig. 40.3 Comparison of alternative assembly systems (one product)

Questions regarding benefits of automation systems often arise concerning long-range, unmeasurable effects on economic issues. A few such issues include the impact of the automation system on:

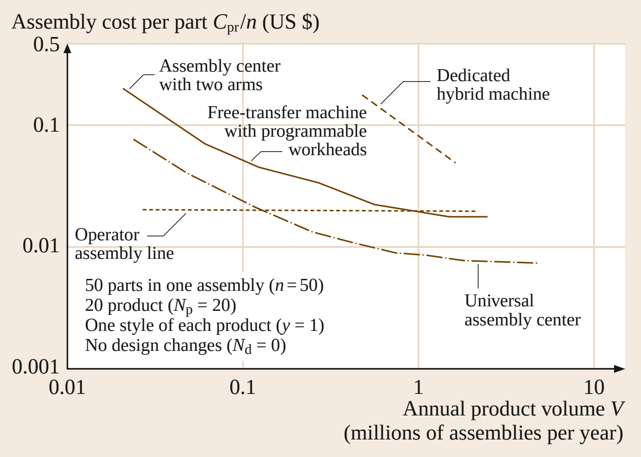

Fig. 40.4 Comparison of alternative assembly systems (20 products)

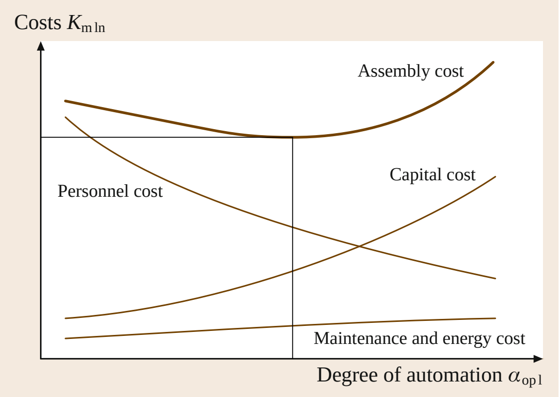

Fig. 40.5 Assembly costs as functions of the degree of automation in the assembly case

- Product value and price
- Increase of sales volume
- Decrease of production cost
- Decrease of initial investment requirements
- Reduction of products lead time
- Decrease of manufacturing costs
- Decrease of inventory costs
- Decrease of direct and indirect labor costs
- Decrease of overhead rate
- Full utilization of automated equipment
- Decrease of setup time and cost
- Decrease of material-handling cost
- Decrease of damage and scrap costs.

Table 40.2 lists additional difficult-to-quantify benefits usually associated with automation projects.

Utilization Analysis

Underutilized automated systems usually cannot be cost-justified, mainly due to the high initial startup expenses and low labor savings they result in. Consideration of additional applications or planned future growth are required to drive the potential cost-effectiveness up; however, there are also additional costs to consider, for example, tooling and feeder costs associated with new applications.

40.1.3 Cost-Analysis Phase

This phase of the methodology focuses on detailed cost analysis for investment justification and includes five

Table 40.2 Difficult-to-quantify benefits of automation. Analyzing the amount of change in each of these categories in response to automation and assigning quantitative values to these intangible factors is necessary if they are to be included in the financial analysis. Otherwise they can only be used as weighting factors when determining the best alternative

Automation can improve	Automation can reduce or eliminate
Flexibility	Hazardous, tedious jobs
Plant modernization	Safety violations and accidents
Labor skills of employees	Personnel costs for training
Job satisfaction	Clerical costs
Methods and operations	Cafeteria costs
Manufacturing productivity capacity	Need for restrooms, need for parking spaces
Reaction to market fluctuations	Burden, direct, and other overhead costs
Product quality	Manual material handling
Business opportunities	Inventory levels
Share of market	Scrap and errors
Profitability	New product launch time
Competitive position	
Growth opportunities	
Handling of short product lifecycles	
Handling of potential labor shortages	
Space utility of plant	
Level of management

steps (Fig. 40.1). To evaluate economically the automation project installation, the following data are required:

- Capital investment of the project
- Estimated changes in gross incomes (revenue, sales, savings) and costs expected from the project.

To illustrate the remaining steps of the methodology, an example will be developed. Installation cost, operation costs, and salvage for the example are as given in Table 40.3.

Period Evaluation, Depreciation, and Tax Data Requirements

Before proceeding with the economic evaluation, the evaluation period, tax rates, and tax depreciation method must be specified. We will consider in the example an evaluation period of 6 years. We will use the US Internal Revenue Service's Modified Accelerated Cost Recovery System (MACRS) for 5 years (Table 40.4). Tax rate considered is 40%. These values are not fixed and can be changed if deemed appropriate.

Project Cost Analysis

The project cost is as given in Table 40.3 (US$ 168 000). To continue it is necessary to determine (estimate) the yearly changes in operational cost and cost savings (benefits). For the example these are as shown in Table 40.5.

Economic Rationalization

Techniques used for the economic analysis of automation applications are similar to those for any manufacturing equipment purchase. They are usually based on net present value, rate of return or payback (payout) methods. All of these methods require the determination of the yearly net cash flows, which are defined as

$$X_j = (G-C)_j - (G-C-D)_j(T) - K + L_j \ ,$$

where X_j = net cash flow in year j, G_j = gross income (savings, revenues) for year j, C_j = total costs for year j, D_j = tax depreciation for year j, T = tax rate (as-

Diameter	1.80	0.77	2.40	2.49	1.00	2.40
Stroke	1.69	0.42	0.61	2.17	0.42	1.00

sumed constant), $K =$ project cost (capital expenditure), and $L_j =$ salvage value in year j.

The net cash flows are given in Table 40.6.

Net Present Value (NPV). Once the cash flows have been determined, the net present value (NPV) is determined using the equation

$$\text{NPV} = \sum_{j=0}^{n} \frac{X_j}{(1+k)^j} = \sum_{j=0}^{n} X_j(P/F, k, j) ,$$

where $X_j =$ net cash flow for year j, $n =$ number of years of cash flow, $k =$ minimum acceptable rate of return (MARR), and $1/(1+k)^j =$ discount factor, usually designated as $(P/F, k, j)$.

With the cash flows of Table 40.6 and $k = 25\%$, the NPV is

$$\begin{aligned}\text{NPV} &= -168\,000 + 53\,640(P/F, 25, 1)\\ &\quad + 61\,704(P/F, 25, 2) + \cdots\\ &\quad + 78\,271(P/F, 25, 6) = \$\,18\,431 .\end{aligned}$$

The project is economically acceptable if its NPV is positive. Also, a positive NPV indicates that the rate of return is greater than k.

Return on Invested Capital (ROIC). The ROIC or rate of return is the interest rate that makes the $\text{NPV} = 0$. It is sometimes also referred to as the internal rate of return (IRR). Mathematically, the ROIC is defined as

$$0 = \sum_{j=0}^{n} \frac{X_j}{(1+i)^j} = \sum_{j=0}^{n} X_j(P/F, i, j) ,$$

where $i =$ ROIC.

For this example the ROIC is determined from the following expression

$$\begin{aligned}0 &= -168\,000 + 53\,640(P/F, i, 1)\\ &\quad + 61\,704(P/F, i, 2) + \cdots + 78\,271(P/F, i, 6) .\end{aligned}$$

To solve the previous expression for i, a trial-and-error approach is needed. Assuming 25%, the right-hand side gives \$ 18 431 (NPV calculation) and with 35% it is \$ −11 719. Therefore the ROIC using linear interpolation is approximately 31%. This ROIC is now compared with the minimum acceptable rate of return (MARR). In this example the MARR is that used for calculating the NPV. If ROIC $\geq$ MARR the project is acceptable; otherwise it is unacceptable. Consequently the NPV and the rate-of-return methods will give the same decision regarding the economic desirability of a project (investment). It is pointed out that the definitions of cash flow and MARR are not independent. Also, the omission of debt interest in the cash-flow equation does not necessarily imply that the initial project cost (capital expenditure) is not being financed by some combination of debt and equity capital. When total cash flows are used, the debt interest is included (approximately) in the definition of MARR as

$$\text{MARR} = k_e(1-c) + k_d(1-T)c ,$$

where $k_e =$ required return for equity capital, $k_d =$ required return for debt capital, $T =$ tax rate, and $c =$ debt ratio of the pool of capital used for current capital investments.

It is not uncommon in practice to adjust (increase) k_e and k_d to account for project risk and uncertainties in economic conditions.

The effects of automation on ROIC (Fig. 40.6) are documented elsewhere in the literature [40.11]. The main effects of automation can be classified into reduction of capital or increased profits or, more desirably, both simultaneously. Automation may generate investment capital savings in project engineering, procurement costs, purchase price, installation, configuration, calibration or project execution. Working capital requirements may be lowered by reducing raw material (quantity or price), product inventories, spares parts for equipment, reduced energy and utilities utilization or

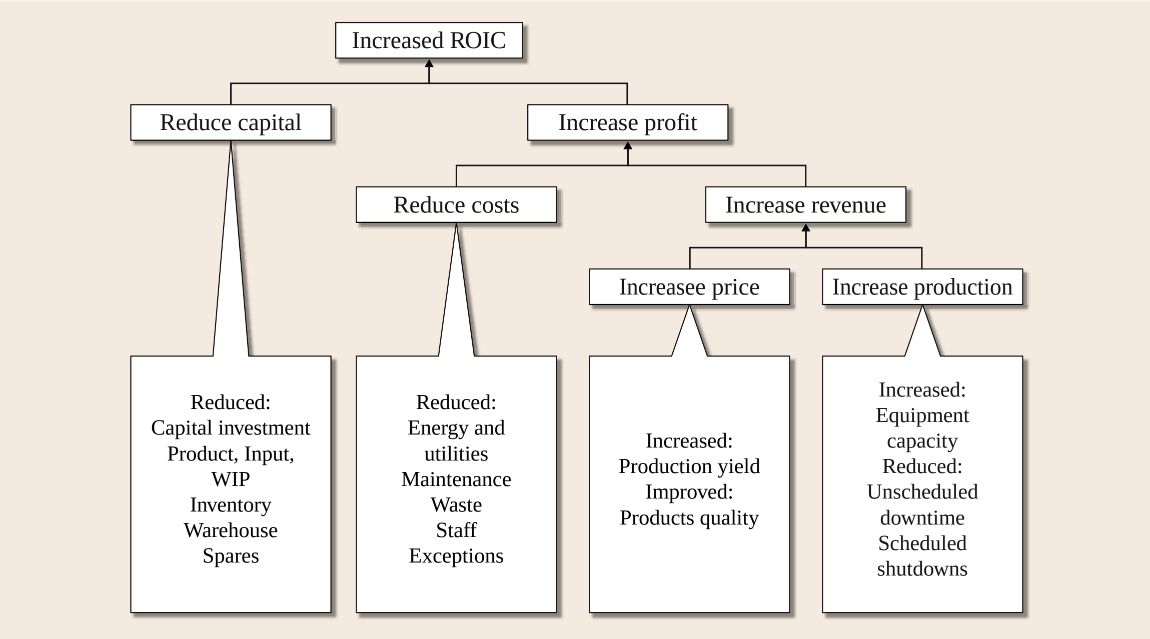

Fig. 40.6 Effects of automation on ROIC

increased product yields. Maintenance cost are diminished in automation solutions by reducing unscheduled maintenance, number of routine checks, time required for maintenance tasks, materials purchase, and number and cost of scheduled shutdown tasks. Automation also contributes to reduce impacts (often hard to quantify) due to health, safety, and environmental issues in production systems.

Profits could increase due to automation by increasing the yield of more valuable products. Reduced work-in-process inventory and waste result in higher revenue per unitary input to the system. Although higher production yield will be meaningful only if the additional products can be sold, today's global markets will surely respond positively to added production capacity.

Payback (Payout) Period. An alternative method used for economic evaluation of a project is the payback period (or payout period). The payback period is the number of years required for incoming cash flows to balance the cash outflows. The payback period (p) is obtained from the expression

$$0=\sum_{j=0}^{p} X_j\,.$$

This is one definition of the payback period, although an alternative definition that employs a discounting procedure is most often used in practice. Using the cash flow given in Table 40.6, the payback equations for 2 years gives

$$-168\,000+53\,640+61\,704=\$-52\,656$$

and for 3 years it is

$$-168\,000+53\,640+61\,704+71\,102=\$18\,446\,.$$

Therefore, using linear interpolation, the payback period is

$$p=2+\frac{52\,656}{71\,102}=2.74\ \text{years}\,.$$

40.1.4 Additional Considerations

The following aspects must be kept in mind when applying the general procedure and related techniques described in this section. Careful review of these issues will ensure that the evaluation is proven correct:

- Cash-flow equation component values are incremental. They represent increases or decreases resulting directly from the project (investment) under consideration.

- The higher the NPV and rate of return, the better (shorter) the payback period.
- Utilization of the payback period as a primary criterion is questionable since it does not consider the cash flows generated after the payback period is achieved.
- When evaluating mutually exclusive alternatives, select the highest NPV alternative. Using the highest rate of return is incorrect. This point is made clear by *Stevens* [40.12], *Blank* [40.13], *Thuesen* and *Fabrycky* [40.14].
- When selecting a subset of projects from a larger group of independent projects due to some constraint (restriction), the objective should be to maximize the NPV of the subset of projects subject to the constraint(s).

40.2 Alternative Approach to the Rationalization of Automation Projects

40.2.1 Issues in Strategic Justification of Advanced Technologies

The analysis typically performed for justifying advanced technology as outlined in Sect. 40.1 is financial and short term in nature. This has caused difficulty in adopting systems, and technology having both strategic implications and intangible benefits usually not captured by traditional justification approaches. Elsewhere in the literature a number of other issues that make justification and adoption of strategic technologies difficult can be found, including high capital costs and risks, difficulty in quantifying indirect and intangible benefits, inappropriate capital budgeting procedures, and technological uncertainties [40.15]. Another complicating factor in the justification of integrated technologies is the cultural and organizational issues involved. The impact of implementing a flexible manufacturing system crosses many organizational boundaries. The success or failure of this implementation depends on the buy-in of all organizations and individuals involved. Traditional methods of justification often do not consider these organizational impacts and are not designed for group consensus building.

The literature discusses many of the intangible and nonquantifiable benefits of implementing automated systems; the most often mentioned is flexibility. *Zald* [40.16] discusses four kinds of flexibility provided by automated systems:

- Mix flexibility: the ability to have multiple products in the same product process at the same time
- Volume flexibility: the ability to change the process so that additional or less throughput is achieved
- Multifunction flexibility: the ability to have the same device do different tasks by changing tools on the device
- New product flexibility: the ability to change and reprogram the process as the manufactured product changes.

Other frequently mentioned benefits include improved product quality, better customer service, improved response time, improved product consistency, reduction in inventories, improved safety, better employee morale, improved management and operation of processes, shorter cycle times and setups, and support for continuous improvement and just-in-time (JIT) efforts [40.3–6].

40.2.2 Analytical Hierarchy Process (AHP)

Rarely do automation systems comprise out-of-the-box solutions. In fact, most automated systems nowadays comprise a collection of equipment properly integrated into an effective solution. This integration process makes evaluation of alternative solutions more complex, due to the many combinations possible for the configuration of all available components. To assist the equipment selection process AHP has been implemented in the form of decision support systems (DSSs) [40.17]. AHP was developed by *Saaty* [40.18] as a way to convey the relative importance of a set of activities in a quantitative and qualitative multicriteria decision problem. The AHP method is based on three principles: the structure of the model [40.19], comparative judgment of alternatives and criteria [40.20], and synthesis of priorities. Despite the wide utilization of AHP, selection of casting process [40.21], improvement of human performance in decision-making [40.19], and improvement of quality-based investments [40.22], the method has shortcomings related to its inability to handle decision-maker's uncertainty and imprecision in determining values for the pairwise comparison process involved. Another difficulty with AHP lies in the fact

Machine 5	0.0478	0.0163	0.0315

that not every decision-making problem may be cast into a hierarchical structure.

Next, a proposed method implementing AHP is reviewed using a numerical application for computer numerical control (CNC) machine selection.

The AHP-PROMETHEE Method

The preference ranking organization method for enrichment evaluation (PROMETHEE) is a multicriteria decision-making method developed by *Brans* et al. [40.23, 24]. Implementation of PROMETHEE requires two types of information: (1) relative importance (weights of the criteria considered), and (2) decision-maker's preference function (for comparing the contribution of alternatives in terms of each separate criterion). Weights coefficients are calculated in this case using AHP. Figure 40.7 presents the various steps of the AHP-PROMETHEE integration method.

The AHP-PROMETHEE method is applied to a manufacturing company wanting to purchase a number of milling machines in order to reduce work-in-process inventory and replace old equipment [40.17]. A decision-making team was devised and its first task was to determine the five milling machines candidates for the purchasing and six evaluation criteria: price, weight, power, spindle, diameter, and stroke. The decision structure is depicted in Fig. 40.8. The next step is for decision team experts to assign weights on a pairwise basis to decision criteria, as presented in Table 40.7. Results from AHP calculations are shown in Table 40.8 and show that the top three criteria for the case are spindle, weight, and diameter. The consistency ratio of the pairwise comparison matrix is $0.032 < 0.1$, which indicates weights consistency and validity.

Following the application of AHP, PROMETHEE steps are carried out. The first step comprises the evaluation of five alternative milling machines according to the evaluation criteria previously defined. The resulting evaluation matrix is shown in Table 40.9.

Next, a preference function (PF) and related thresholds are defined by the decision-making team for each criterion. PF and thresholds consider features of the milling machines and the company's purchasing pol-

Table 40.9 Evaluation matrix for the milling machine case

Criteria	Price	Weight	Power	Spindle	Diameter	Stroke
Unit	US $	kg	W	rpm	mm	mm
Max/min	Min	Min	Max	Max	Max	Max
Weight	0.090	0.244	0.113	0.266	0.186	0.101
Machine 1	936	4.8	1300	24 000	12.7	58
Machine 2	1265	6.0	2000	21 000	12.7	65
Machine 3	680	3.5	900	24 000	8.0	50
Machine 4	650	5.2	1600	22 000	12.0	62
Machine 5	580	3.5	1050	25 000	12.0	62

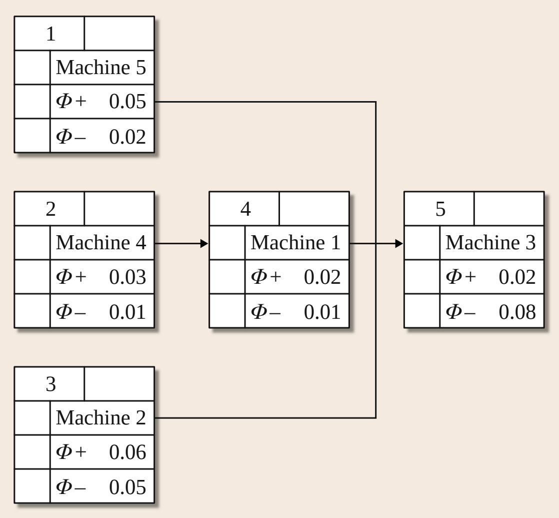

Fig. 40.9 PROMETHEE I partial ranking

icy. Table 40.10 shows preference functions and their thresholds.

The partial ranking of alternatives is determined according to PROMETHEE I, based on the positive and negative flows shown in Table 40.11. The resulting partial ranking is shown in Fig. 40.9 and reveals that machine 5, machine 2, machine 4, and machine 1 are preferred over machine 3, and machine 4 is preferred over machine 1. The partial ranking also shows that machine 5, machine 4, and machine 2 are not comparable, as well as machine 5 and machine 1, and machine 2 and machine 1.

PROMETHEE II uses the net flow in Table 40.11 to compute a complete ranking and identify the best alternative. According to the complete ranking, machine 5 is selected as the best alternative, while the other machines are ranked accordingly as machine 4, machine 2, machine 1, then machine 3 (Fig. 40.10).

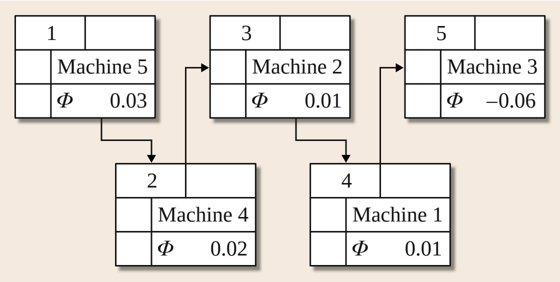

Fig. 40.10 PROMETHEE II complete ranking

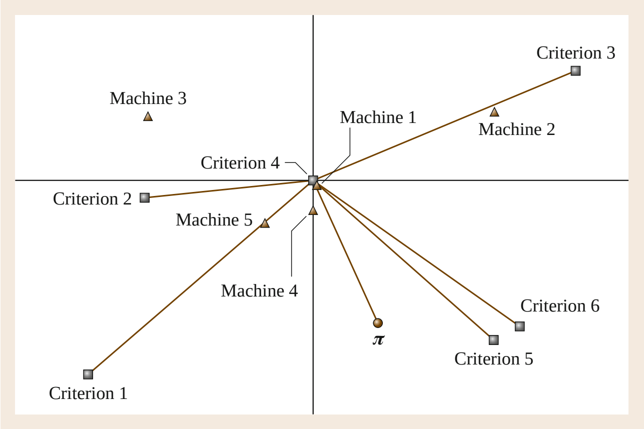

Fig. 40.11 GAIA decision plane

The geometrical analytic for interactive aid (GAIA) plane [40.25] representing the decision (Fig. 40.11) shows that: price has great differentiation power, criteria 1 (price) and 3 (power) are conflicting, machine 2 is very good in terms of criterion 3 (power), and machine 3 is very good in terms of criteria 2 and 4. The vector $\boldsymbol{\pi}$ (decision axis) represents the compromise solution (selection must be in this direction).

40.3 Future Challenges and Emerging Trends in Automation Rationalization

40.3.1 Adjustment of Minimum Acceptable Rate of Return in Proportion to Perceived Risk

Since capital investments involve particular levels of risk, it is common practice for management to increase the MARR for automation projects involving higher risk. Assigning a higher MARR forces the proposed projects to generate greater return on their capital investment. A similar strategy is proposed to recognize the fact that capital equipment that can be reused for additional projects is less likely to experience a decline in its value due to unforeseen reductions in a given product's demand and market life.

Traditionally, more stringent MARR requirements are applied to the entire capital investment. It is proposed that only the portion of the capital investment that is at risk due to sudden changes in market demand or operating conditions should be forced to meet these more demanding rate of return. This approach to assigning risk will explicitly recognize and promote the development and reuse of reconfigurable automation by compensating for its higher initial development and implementation costs through lower rate-of-return requirements.

40.3.2 Depreciation and Salvage Value Profiles

Mechanisms for capital depreciation and estimated project salvage values also have a significant effect on the financial justification of automation. Two mechanisms of depreciation must be considered: tax and book depreciation. Tax depreciation methods provide a systematic mechanism to acknowledge the reduction of capital asset value over time. Since depreciation is tax-deductible, it is generally in the best interests of the company to depreciate the asset as quickly as possible. Allowable depreciation schedules are determined by the country tax code. Tax depreciation can become a factor when comparing product-specific automation for reconfigurable systems when the projected product life is less than the legislated tax depreciation life. Under these circumstances the product-specific systems can be sold on the open market and the remaining tax depreciation would be forfeited. A second alternative is that the system would be decommissioned and stored by the company until it is fully depreciated and then sold for salvage. Instead, it is unlikely that the life of a reconfigurable system would be shorter than the established tax depreciation period due to its redeployment for a new application project. Tax depreciation terms are determined by tax and accounting conventions rather than the expected service life of the asset. Book depreciation schedules are therefore developed to predict the realizable salvage value at the end of an asset's useful life. Two approaches for determining realizable salvage value can be utilized: the internal asset value in the organization (when it is used in an additional project) and the asset value when sold for salvage. Automation equipment profitably redeployed within the same company is clearly more valuable to that organization than to an equipment reseller.

Product-specific automation, when sold off for scrap, has value for potential buyers only due to their interest in key system components. Product- and process-specific tooling will represent very little value for equipment resellers and, most likely, all the custom engineering and software development required to field the system will be lost. On the other hand, if the system has been developed based on modular components, well understood by the user and other manufacturing organizations, it may represent more value than a completely new set of system components. A redeployed system may result in lower time and cost to provide useful automation resources. Investments made in the development of process technology may be of value in subsequent projects [40.26]. Application software, if developed in a modular fashion, also has the potential for reutilization.

40.4 Conclusions

Although computation of economic performance indicators for automation projects is often straightforward, rationalization of automation technology is fraught with difficulty and many opportunities for long-term improvements are lost because purely economic evaluation apparently showed no direct economic benefit. Modern methods, taking into account risks involved in technology implementation or comparison of complex projects, are emerging to avoid such high-impact mistakes. In this chapter, in addition to providing the traditional economic rationalization methodology, strategic considerations are included plus a discussion on current trends of automation systems towards agility and reconfigurability.

41. Quality of Service (QoS) of Automation

Heinz-Hermann Erbe (△)

Quality of service (QoS) of automation involves issues of cost, affordability, energy, maintenance, and dependability. This chapter focuses on cost, affordability, and energy. (The next chapter addresses the other aspects.) Cost-effective or cost-oriented automation is part of a strategy called *low-cost automation*. It considers the life cycle of an automation system with respect to their owners: design, production, operating, and maintenance, refitting or recycling. *Affordable automation* is another part of the strategy. It considers automation or automatic control in small enterprises to enhance their competitiveness in manufacturing and service. Despite relative expensive components the automation system can be cheap with respect to operation and maintenance. As examples are discussed: numerical controls of machine tools; shop floor control with distributed information processing; programmable logic controllers (PLCs) shifting to general-purpose (PC); smart devices, i. e. information processing integrated in sensors and actuators; and distributed manufacturing, and maintenance.

Energy saving can be supported by automatic control of consumption in households, office buildings, plants, and transport. *Energy intensity* is decreasing in most developing countries, caused by changing habits of people and by new control strategies. Centralized generation of electrical energy has advantages in terms of economies of scale, but also wastes energy. Decentralized generation of electricity and heat in regional or local units are of advantage. A combination of wind energy, solar energy, hydropower, energy from biomass, and fossil fuel in small units could provide electrical energy and heat in regions isolated from grids. These hybrid energy concepts are demanding advanced, but low-cost, controls.

The term *low-cost automation* was born in 1986 at a symposium in Valencia sponsored by the International Federation of Automatic Control [41.1]. However, the use of this term led to a misunderstanding of low-cost automation as a technology with poor performance, although the intention was to promote affordable automation devices and to reduce the life cycle cost or cost of ownership of automation systems. The intention was also to bridge the gap between control theory and control engineering practice by applications using low-cost techniques. *Ortega* [41.2] pointed out that the transfer of knowledge between the academic community and the industrial user is far from satisfactory, and it still is, particular regarding small- and medium-sized industry. However, developments in control theory are based on principles that can appeal to concepts with which the practical engineer is familiar. Despite the successfully demonstration of advances of modern control methods over classical ones, actual implementations of automatic control in manufacturing plants show a preference for classical proportional–integral–derivative (PID) control. Two key factors are considered [41.3]:

1. Return on investment (better, cheaper, and faster)
2. Ease of application.

To be utilized broadly, a new technology must demonstrate tangible benefits, be easier to implement and maintain, and/or substantially improve performance and efficiency. Sometimes a new control method is not pursued due to poor usability during operation and troubleshooting in an industrial environment. The PID, due to its simplicity, whether implemented analog or digital, provides advantages in its application. However, manufacturing systems are becoming more complex. Control needs include single-input/single-output SISO and multiple-input/multiple-output MIMO controllers. Therefore control techniques beyond PID control become necessary. State-space methods are well developed and provide many advantages if well understood [41.3].

Low-cost automation is now established as a strategy to achieve the same performance as sophisticated automation but with lower costs. The designers of automation systems have a cost frame within which they have to find solutions. This is a challenge to theory and technology of automatic control, as the main parts of automation. Low-cost automation is not an oxymoron, like *military intelligence* or *jumbo shrimps*. It opposes the rising cost of sophisticated automation and propagates the use of innovative and intelligent solutions at affordable cost. The concept can be regarded as a collection of methodologies aiming at the exploitation of tolerance to imprecision or uncertainties to achieve tractability, robustness, and finally low-cost solutions. Mathematically elegant designs of automation systems are often not feasible because of their neglect of real-world problems, and in addition are often very expensive for their owners.

Cost aspects are mostly considered when designing automation systems. However, in the end, industry is looking for intelligent solutions and engineering strategies for saving cost but that nevertheless have secure, high performance. Field robots in several domains such as manufacturing plants, buildings, offices, agriculture, and mining are candidates for reducing operation cost. Enterprise integration and support for networked enterprises are considered as cost-saving strategies. Human–machine collaboration is a new technological challenge, and promises more than cooperation. Last but not least, condition monitoring of machines to reduce maintenance cost and avoid downtime of machines and equipment, if possible, is also a new challenge, and promotes e-Maintenance [41.4] and e-Service [41.5].

The reliability of low-cost automation is independent of the grade of automation, i. e., it covers all possible circumstances in its field of application. Often it is more suitable to reduce the grade of automation and involve human experience and capabilities to bridge the gap between theoretical findings and practical requirements [41.6]. On the other hand, theoretical findings in control theory and practice foster intelligent solutions with respect to saving costs. Anyway, reliability is a must for all automation systems, although this requirement has no one-to-one relation to cost.

As an example one may consider computer-integrated manufacturing (CIM). The original concept of CIM connected automatically the design of parts to machines at the workshop via shop floor planning and scheduling software, and therefore used a lot of costly components and instruments. After a while this kind of automation turned out not to be cost effective, because the centralized control system had to fight against uncertainties and unexpected events. Decentralization of control and the involvement of human experience and knowledge along the added-value chain of the production process required less sophisticated hardware and software and reduced manufacturing cost, which allowed CIM to break through even in small and medium-sized enterprises [41.7].

Low-cost automation also concerns the implementation of automation systems. This should be as easy as possible and also facilitate maintenance. Maintenance is very often the crucial point and an important cost factor to be considered. Standardization of components of automation systems could also be very helpful to reduce cost, because it fosters usability, distribution, and innovation in new applications, for example fieldbus technology in manufacturing and building automation.

The components of an automation/control system, such as sensors, actuators and the controller itself, can incorporate advances in information technology. Local information processing allows for integration at the level of components, reducing total cost and providing new features in control lines. They may be wireless connected because of low data stream rates. Smart sensors and actuators are new developments for industrial automation [41.8]. The cost of wireless links will fall while the cost of wired connections will remain about constant, making wireless increasingly a logical choice for communication links. However, wireless links will not be applicable in all situations, notably those cases where high reliability and low latencies are required. The implication for factory automation systems is that processing and storage will become cheap: every sensor, actuator, and network node can be economically provided with unlimited processing power. If processing and storage systems become inexpensive relative to wiring costs, then the trend will be to locate processing power near where it is needed in order to reduce wiring costs. The trend will be to apply more processing and storage systems when and where they will reduce the cost of interconnections. The cost of radio and networking technology has fallen to the point where a wireless connection is already less expensive than many wired connections. New technology promises to further reduce the cost of wireless connections [41.9].

Distributed collaborative engineering, i. e., the control of common work over remote sites, is now an emerging topic in cost-oriented automation. Integrated product and process development as a cost-saving strategy has been partly introduced in industry. However, as *Nnaji* et al. [41.10] mention, lack of information from suppliers and working partners, incompleteness and inconsistency of product information/knowledge within the collaborating group, and incapability of processing information/data from other parties due to the problem of interoperability hamper effective use. Hence, collaborative design tools are needed to improve collaboration among distributed design groups, enhance knowledge sharing, and assist in better decision making. (See also Chaps. 26, 88.)

Mixed-reality concepts could be useful for collaborative distributed work because they address two major issues: seamlessness and enhancing reality. In mixed-reality distributed environments information flow can cross the border between reality and virtuality in an arbitrary bidirectional way. Reality may be the continuation of virtuality, or vice versa [41.11], which provides a seamless connection between the two worlds. This bridging or mixing of reality and virtuality opens up some new perspectives not only for work environments but also for learning or training environments [41.12, 13]. (See also Chaps. 15, 86.)

The changing global context is having an impact on local and regional economies, particularly on small and medium-sized enterprises. Global integration and international competitive pressures are intensifying at a time when some of the traditional competitive advantages – such as relatively low labor costs – enjoyed by certain countries are vanishing.

One can see growing emphasis on strategies for encouraging supply-chain (vertical) and horizontal networking. These could be means for facilitating agile manufacturing. Agile manufacturing is built around the synthesis of a number of independent enterprises forming a network to join their core skills, competencies, and capacities to be able to operate profitably in a competitive environment characterized by unpredictable and continually changing customer demands. Agile manufacturing is underpinned by collaborative design and manufacturing in networks of legally separate and spatially distributed companies. Such networks are useful in optimizing current processes and mastering sporadic change in demand, material, and technology [41.14]. Distributed collaborative automation in manufacturing networks is therefore an emerging area for automatic control.

Energy-saving strategies and also individual solutions for reducing energy consumption are challenging politicians, the public, and researchers. The cost aspect is very important. Components of controllers such as sensors and actuators may be expensive, but one has to calculate savings in energy costs over a certain period or life cycle of a building or plant.

Energy provision and consumption based on finite resources can cause conflicts between customers, and between customers and suppliers. Energy savings are necessary due to these finite resources. Effective use of available energy can be supported by automatic control of consumption in households, office buildings, plants, and transportation. Energy intensity is decreasing in most developing countries. This is caused by changing habits of people but also by new control strategies. The use of energy in a country, in the residential sector, the commercial building sector, the transportation sector, and the industrial sector, influences the competitiveness of the economy, the environment, and the comfort of the inhabitants.

Building automation is generally a highly cost-oriented business. The goal is to provide acceptable comfort conditions at the lowest possible cost in terms of implementation, operation, and maintenance. Energy saving is one of the most important goals in building automation [41.15]. (See also Chap. 62.)

In Sect. 41.1 the strategy of cost-oriented automation will be explained with the examples of cost of ownership and robotics. Section 41.2 continues, covering affordable automation with subsections on smart devices, i. e., information processing embedded in sensors, and actuators, programmable logic controllers as important components of an affordable automation, and examples of low-cost production technology. Section 41.3 covers energy saving with automatic control using the aforementioned strategies. (See also Chap. 40.)

41.1 Cost-Oriented Automation

Cost-oriented automation as part of the strategy of low-cost automation considers the *cost of ownership* with respect to the life cycle of the system:

- Designing
- Implementing
- Operating
- Reconfiguring
- Maintenance
- Recycling.

Components and instruments could be expensive if life cycle costs are to decrease. An example is enterprise integration or networked enterprises as production systems that are vertically (supply chain) or horizontally and vertically (network) organized.

Cost-effective product and process realization has to consider several aspects regarding automatic control [41.13]:

- Virtual manufacturing supporting integrated product and process development
- Tele- or web-based maintenance (cost reduction with e-Maintenance systems in manufacturing)
- Small and medium-sized (SME)-oriented agile manufacturing.

Agile manufacturing here is understood as the synthesis of a number of independent enterprises forming a network to join their core skills.

As mentioned above, life cycle management of automation systems is important regarding cost of ownership. The complete production process has to be considered with respect to its performance, where maintenance is the most important driver of cost. *Nof* et al. [41.16] consider the performance of the complete automation system, which interests the owner in terms of cost, rather than only the performance of the control system; i. e., a compromise between cost of maintenance and cost of downtime of the automation system has to be found.

41.1.1 Cost of Ownership

A large amount of the cost of a manufacturing plant over its lifetime is spent on implementation, ramp up, maintenance, and reconfiguration. Cost-of-ownership analysis makes *life cycle costs* transparent regarding purchase of equipment, implementation, operation costs, energy consumption, maintenance, and reconfiguration. It can be used to support acquisition and planning decisions for a wide range of assets that have significant maintenance or operating costs throughout their usable life. Cost of ownership is used to support decisions involving computing systems, vehicles, laboratory and test equipment, manufacturing equipment, etc.

It brings out the *hidden* or nonobvious ownership costs that might otherwise be overlooked in making purchase decisions or planning budgets. The analysis is not a complete cost–benefit analysis. It pays no attention to benefits other than cost savings when different scenarios are compared. When this approach is used in decision support, it is assumed that the benefits from all alternatives are more or less equal, and that choices differ only on the cost side.

In highly industrialized countries the type and amount of automation mostly depends on the cost of labor. However, automation in general is not always effective [41.17]. A recent study carried out by the Fraunhofer Institute of Innovation and System Technology regarding the grade of automation within the German industry [41.6] found that companies are refraining from implementing highly automated systems. The costs of maintenance and reconfiguration are considered too high; it would be more cost effective to involve well-qualified operators. The same considerations were discussed by *Blasi* and *Puig* [41.18]:

> *Automation is not useful by itself: there are a lot of additional requirements to accomplish its func-*

> *tion as needed, not only putting automation into the factories, putting automation just where it is needed and economically justified.*

Blasi and *Puig* [41.18] consider the challenges of manufacturing processes of consumer goods. They stress that automation helps in providing homogeneous operation, but for many operations humans can sometimes carry out the task better than automation systems. However, humans are failure prone, emotionally driven, and do not constantly operate at the same level, which also has to be considered.

Morel et al. [41.19], as mentioned in the Introduction, stress the consideration of the whole performance of a plant, rather than the control performance only, which is what interests the owner regarding cost; i. e., a compromise between cost of maintenance and cost of downtime of the automation systems in a plant regarding commitments to customers or market must be considered. Scheduled maintenance can be shifted, but it is of course better to implement condition-based maintenance, in which degradation of parts can be observed and the decision to run a machine or piece of equipment for a certain extra time to fulfill a relevant customer order can be made reasonably based on collected data.

Blasi and *Puig* [41.18] consider the conditions for successful automation in industrial applications. Based on their experiences, a manufacturing engineer dealing with plant automation should bear in mind that proper automation is much more than a matter of machines and equipment. The *organization of work* in the whole plant involving the human experience at all stages and always considering possible improvements with automation or not is the challenge for engineers and management to save costs. Automation helps in providing homogeneous manufacturing processes. In many operations, humans can sometimes carry out the task better without automation. Humans may perform better than any automatic machine, for the time being, but it is impossible for them to assure constant quality. Where reasonable cost is critical, inspecting the image quality of a screen, for example, is a task reserved, for the moment, to humans, because computer vision is too expensive.

To summarize this section Fig. 41.1 shows the main cost contributions which are of interest to the owner of the machine and manufacturing equipment.

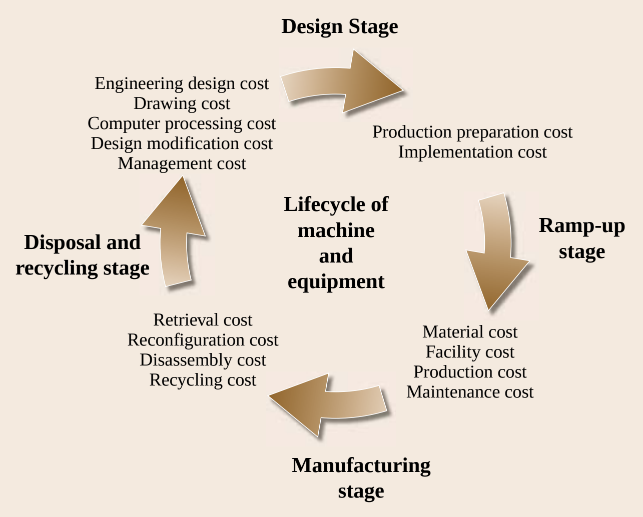

Fig. 41.1 Cost contributions of the life cycle of machine and equipment

41.1.2 Robotics

Robots were created in order to automate, optimize, and ameliorate work processes that had up to then been carried out by humans alone. For reasons of safety, humans may not enter the working space of the robot. Recently it has been shown, however, that robots cannot come close to matching the abilities or intelligence of humans. Therefore, new systems which enable collaboration between humans and robots are becoming increasingly important. The advantages of using innovative robots can especially be seen in medical or other service-oriented areas as well as in the emerging area of humanoid robots.

Although robot technology is mostly regarded as costly, one can see today applications not only in customized mass production (automobile industry) but also in small and medium-sized enterprises (SMEs), manufacturing small lots of complex parts. Increasing product variety and customer pressure for short delivery times put robots in the focus. Robots can be used for loading and unloading of machine tools or other equipment such as casting machines, injection molding machines, etc. Here mostly the robots are stationary, and their control is coordinated with the control of the machine or equipment they serve.

Even *field robots* are applicable with affordable cost. *Ollero* et al. [41.20] describe as an example (among other applications) an autonomous truck, which could also be an unmanned vehicle in a manufacturing site. Low cost should be referred to the components to be used as well as to system design and maintenance. Sometimes a trade-off between general-purpose components and components tailored to the application has

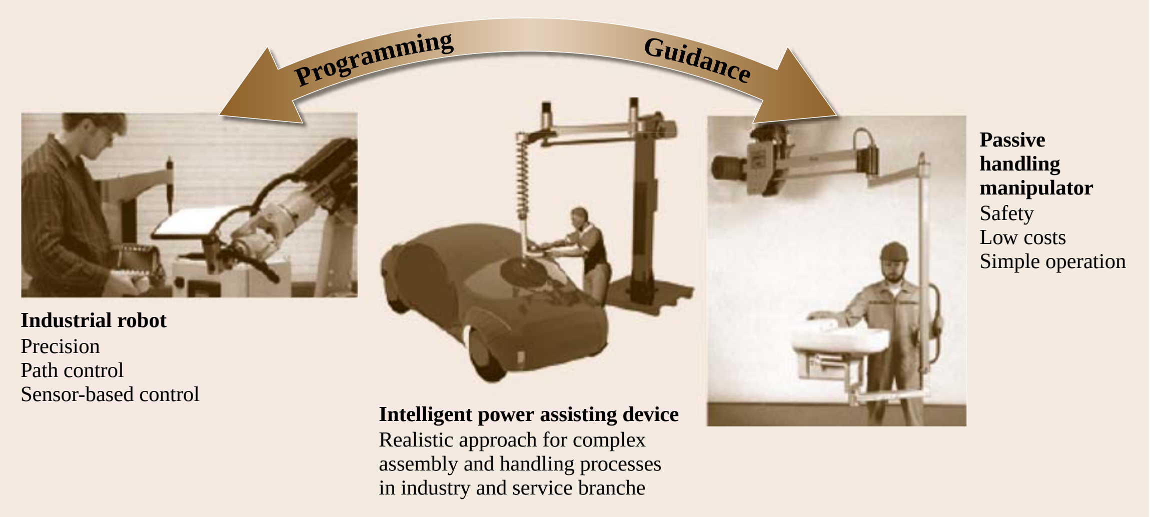

Fig. 41.2 Cobots, a new class of handling devices, which combine the characteristics of robots and hand-guided manipulators [41.24]

to be considered. Given the high cost of components, the design of the field robot should consider modularity, and simple assembly, reliability maintenance, and fault-detection properties are important for reducing cost in terms of the life cycle. *Sasiadek* and *Wang* [41.21] report on low-cost positioning of autonomous robots fusing, data sensed by global positioning system (GPS) and inertial navigation system (INS). Automation in deep mining with autonomous guided vehicles (AGV) saves cost in terms of healthcare of workers, provision of energy (using fuel cells), and compressed air required to maintain working conditions. For navigation, GPS is not available for this application, therefore radio beacons together with INS can be used. The vehicles and their control are discussed by *Dragt* et al. [41.22] and *Sasiadek* and *Lu* [41.23].

Wang et al. [41.25] developed a low-cost robot platform for control education.

Applications of robots in automated assembly and disassembly fail mostly because the environment cannot be sufficiently structured. This was the reason for the development of *collaborative robots* (cobots) or *intelligent (power) assisting devices* (I(P)AD) (Fig. 41.2). It was also motivated by ergonomic problems in assembly of parts, where parts weight endangered the human body. Cobots offer a cost-effective solution for material handling. Complete automation of assembly processes is complicated, if not impossible. Reconfiguration of robots performing assembly tasks could be very costly. Humans, on the other hand, have capabilities that are difficult to automate, such as parts-picking from unstructured environments, identifying defective parts, fitting parts together despite minor shape variations, etc. Cobots are passive systems which are set in motion and guided by humans. The cobot concept supposes that shared control, rather than amplification of human power, is the key enabler [41.26]. The main task of the cobot is to convert a virtual environment, defined in software, into physical effect on the motion of a real payload, and thus also on the motion of the worker. Overhead gantry-style rail systems used in many shops can be considered cobots but without the virtual surface. Virtual surfaces separate the region where the worker can freely move the payload from the region that cannot be penetrated. These surfaces or walls have an effect on the payload like a ruler guiding a pencil. Technically cobots are based on *continuously variable transmissions* (CVT). *Peshkin* et al. [41.26] developed spherical CVTs, and *Surdilovic* et al. [41.24] developed CVTs based on a differential transmission.

41.2 Affordable Automation

This strategy of low-cost automation focuses on making systems affordable for their owners with respect to the problem to be solved. An example is a manufacturing system in a small or medium-sized enterprise, where automation increases productivity and therefore competitiveness. Although small enterprises agree that at least routine work can be done better when automated, there is still a fear that automation will be sophisticated, failure prone, need experts for maintenance and reconfiguration, and therefore would be costly.

Soloman [41.27] points to shortening product life cycles that need more intelligent, faster, and more adaptable assembly and manufacturing processes with reduced setup, reconfiguration, and maintenance time. Machine vision, despite costly components, can reduce manufacturing cost when properly applied [41.28]. In order to survive in a competitive market it is essential that manufactures have the capability to deploy rapidly affordable automation to adapt to a changing manufacturing environment with increased productivity but reduced production costs.

41.2.1 Smart Devices

Smart devices (sensors, actuators) with local information processing in connection with data fusion are in steady development, achieving cost reduction of components in several application fields such as automotive, robotics, mechatronics, and manufacturing [41.29, 30]. One of the first discussions on smart devices regarding cost aspects was given by *Boettcher* and *Traenkler* [41.31].

The developments allow for computer-based automation system to evolve from centralized architectures to distributed ones. The first level of distribution in order to reduce the wiring cost consisted of exchanging inputs and outputs through a fieldbus as a communication support. The second level integrates data processing in a modular setting as close as possible to sensors and actuators. These smart sensors and actuators can communicate, self diagnose or make decisions [41.32]. One step to realize smart sensors is to add electronics *intelligence* for postprocessing of outputs of conventional sensors prior to use by the control system. The same can be applied to actuators. Advantages are tighter tolerance, improved performance, automatic actuator calibration, etc.

Smart devices used in continuous systems benefit from the addition of microelectronics and software that runs inside the device to perform control and diagnostic functions. Very small components such as inputs/outputs blocks and overload relays are too small to integrate data processing for technical/economic reason. However, it is possible to develop embedded intelligence and control for the smallest factory floor devices. It is not always possible to implement data storage or processing on each sensor or actuator. The alternative solution is to implement data-processing units connected to some sensors or actuators, connected together by communication links in order to obtain remote inputs/outputs. Current trends are for the development of smart equipment associated to the fieldbus, which leads to a distributed architecture. Automation systems have evolved from a centralized to a distributed architecture, yielding an automation system with an intelligent distributed architecture. Robots are following this evolution, and increasingly becoming decomposed into divided subsystems, each of which realizes an elementary function. Distributed automation systems yield several advantages, such as greater flexibility, simplicity of operation, and better commissioning and maintenance. Today's smart field devices consist of two essential parts: sensor or actuator modules, and elec-

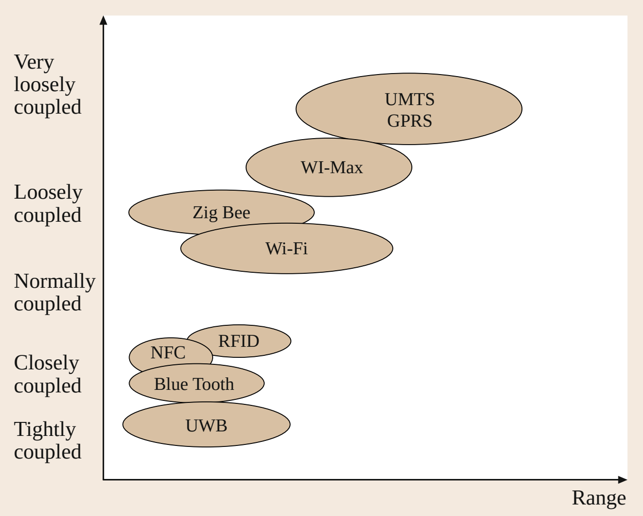

Fig. 41.3 Range and coupling modes of wireless technologies [41.9] (UMTS – universal mobile telecommunications system, GPRS – general packet radio service, WI-Max – worldwide interoperability for microwave access, Wi-Fi – wireless interoperability fidelity, RFID – radio frequency identification, NFC – near field communication, UWB – ultra wire band)

tronic modules. Microcomputers, initially responsible for PID control, communication, etc., now have diagnosis functions included. Advanced diagnosis addresses fault detection, fault isolation, and root analysis. The early detection of anomalies, either process or device related, is a key to improving plant availability and reducing production costs.

When smart devices come together with wireless communication a great cost saving can be achieved. This infrastructure will be flexible for reconfiguration. The reconfiguration of existing software for the new configuration is sometimes very costly and has to be considered. However, wireless communication eases the problem of physically inflexible communication infrastructures.

In mobile devices *wireless connections* are mandatory. Distributed sensors in a wide area do not need wireless communication, unless wiring is cost prohibitive. Without cables, cost-intensive wiring plans are not necessary. The freedom to place wireless sensors and actuators anywhere in a plant or a building becomes limited if the devices need a main power source, in which case power cables become necessary. It depends on the sensors if they can use internal batteries or can harvest energy from the environment. Several technologies for wireless communication are available at the market, with different standards and ranges (Fig. 41.3). *Cardeira* et al. [41.9] discuss the pros and cons of the available technologies. They conclude that, in spite of some initial skepticism, wireless communication is imposing itself as a complement to wired communication. Location awareness is a new feature of wireless devices. This feature may have a strong impact on service, where the physical location of a device is important for tracking, safety, security, and maintenance.

41.2.2 Programmable Logic Controllers as Components for Affordable Automation

Programmable logic controllers (PLCs) can be regarded as the classic components of affordable automation. An affordable application was already reported by *Jörgl* and *Höld* [41.33]. PLCs are meanwhile available with full capabilities for less than US$ 100. A PLC can be defined as a microprocessor-based control device, with the original purpose of supplementing relay logic. Early PLCs were only able to perform logical operations. PLCs can now perform more complex sequential control algorithms with the increase in microprocessor performance. They can admit analog inputs and outputs. The main difference from other computers is the special input/output arrangements, which connect the PLC to smart devices as sensors and actuators. PLCs read, for example, limit switches, dual-level devices, temperature indicators, and the positions of complex positioning systems. On the actuator side, PLCs can drive any kind of electric motor, pneumatic or hydraulic cylinders or diaphragms, magnetic relays or solenoids. The input/output arrangements may be built into a simple PLC, or the PLC may have external I/O modules attached to a proprietary computer network that plugs into the PLC.

PLCs were invented as less expensive replacements for older automated systems that used hundreds or thousands of relays. Programmable controllers were initially adopted by the automotive manufacturing industry, where software revision replaced rewiring of hard-wired control panels. The functionality of the PLC has evolved over the years to include typical relay control, sophisticated motion control, process control, distributed control systems, and complex networking.

There are other ways for automating machines, such as a custom microcontroller-based design, but there are differences between the two approaches: PLCs contain everything needed to handle high-power loads, while a microcontroller would need an electronics engineer to design power supplies, power modules, etc. Also a microcontroller-based design would not have the flexibility of in-field programmability of a PLC, which is why PLCs are used in production lines. Typically they are highly customized systems, so the cost of a PLC is low compared with the cost of contacting a designer for a specific one-time-only design.

The earliest PLCs expressed all decision-making logic in simple ladder diagrams (LDs) inspired by electrical connection diagrams. Electricians were quite able to trace out circuit problems with schematic diagrams using ladder logic. This was chosen mainly to address the apprehension of technicians. Today, the line between a personal computer and a PLC is thinning. PLCs have connections to personal computers (PCs) and Windows-based software-programming packages allow for easy programming and simulation. With the IEC 61131-3 standard, it is now possible to program using structured programming languages and logic elementary operations. A graphical programming notation called *sequential function charts* is available on certain programmable controllers. IEC 61131-3 currently defines five programming languages for programmable control systems: function block diagram (FBD), ladder diagram (LD), structured text (ST; similar to the Pascal programming language), instruction list (IL; similar to assembly language), and sequential function chart (SFC). These techniques emphasize logical organization of operations. *Susta* [41.34] presents a method to convert a PLC program in either of the languages mentioned above into programming statements, which can be used either for low-cost emulation of the program or as an auxiliary tool when a debugged PLC program is moved to another cheaper hardware, for instance, to a PC.

Continuous processes cannot be accomplished fast enough by PLC on–off control. The control system most often used in continuous processes is PID control. PID control can be accomplished by mechanical, pneumatic, hydraulic, or electronic control systems, as well as by PLCs. PLCs, including low-cost ones, have PID control functions included, which are able to accomplish process control effectively. To program control functions IL, ST or derived function block diagrams (DFBD) are used.

41.2.3 Production Technology

Within the last years so-called *shop-floor-oriented technologies* have been developed [41.17], and have achieved success at least but not only in small and medium-sized enterprises (SMEs). These technologies are focused on agile manufacturing, which involves using intelligent automation combined with human skill and experience on the shop floor. With shop-floor-oriented production support, human skill and automation create synergetic effects to master the manufacturing process.

Automation provides the necessary support to execute tasks and rationalize decisions. This represents a strand of low-cost automation. Running the manufacturing process effectively is not only a question of technology, though this is essential. Together with adequate work organization in which human skills can be developed, it establishes the framework for cost-effective, competitive manufacturing in SMEs.

Recent achievements for manufacturing are:

- Shop floor planning and control based on operators experience
- Low-cost numerical controls for machine tools and manufacturing systems (job-shop controls).

Shop floor control is the link between the administrative and planning section of an enterprise and the manufacturing process at the shop floor. It is the information backbone of the entire production process. What at least small and medium-sized enterprises need is shop floor control support to use the skills and experience of the workforce effectively. However, it should be stressed that this is support, not determination of what to do based on centralized automatic decision making.

In small-batch or single production (molds, tools, spare parts), devices for dynamic planning are desired. Checking all solutions to the problems arising on the shop floor while taking into account all relevant restrictions with short-term scheduling outside the shop floor either by manual or automatic means is not very effec-

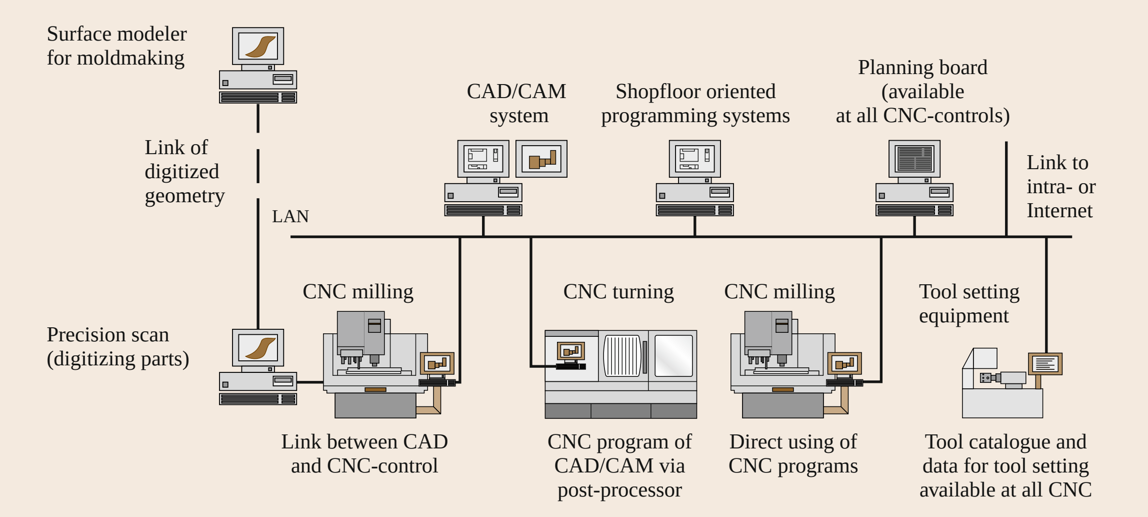

Fig. 41.4 Modules of a shop floor network

tive. It is senseless to schedule manufacturing processes exactly for weeks ahead. However, devices that are capable of calculating time corridors are of advantage. The shop floor can do the fine planning with respect to actual circumstances much better then central planning.

Human experience regarding solutions, changing parameters, and interdependencies is the very basis of shop floor decisions and needs to be supported rather than replaced.

Figure 41.4 shows a network system linking all relevant modules to be used by skilled workers. Apart from necessary devices such as tool-setting, an electronic planning board is integrated. The screen of the board is available at all computer numerical control (CNC) controls to be used at least to obtain information on tasks to be done at certain workplaces to a certain schedule. As all skilled workers in a group are responsible for the manufacturing process they have, beyond access to information, the task of fine planning of orders they received with frame data from the management. They use electronic planning boards at the CNC controls or alternatively at PCs besides the machines.

Planning and scheduling support with soft constraints was developed by [41.35], called Job-Dispo (Fig. 41.5). It consists mainly of an *intelligent planning board* with drag-and-drop functionality, a graphic editor, and a structured query language (SQL) database running on PCs under Windows. In SMEs, manufacturing groups are empowered to regulate their tasks themselves based on frame data from the management. The operators receive only rough data for orders from central management, concerning delivery time, material, required quality, supply parts, etc. Using this support the workers decide on the sequences of tasks to be done at the different parts of the manufacturing system. The electronic planning board simulates the effects of their decisions. Normally more than one task needs the same resource at the same time. The operators are enabled to change the resource limits of workplaces and machines (working time, adding or changing shift work, etc.) until the simulation results in acceptable work practice and fulfills customers' demands. If this cannot be achieved, central management has to be involved in the decision. Job-Dispo is partly automatic but allows for soft constraints to make use of the experience of human operators.

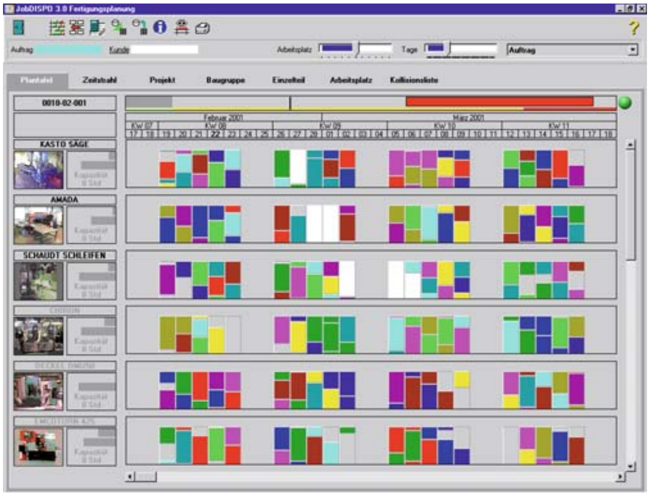

Fig. 41.5 Electronic, PC-based planning board for shop floor use [41.35]

Machine tools have a key position in manufacturing. Their functionality, attractiveness, and acceptance are determined by the efficiency of their control systems. Typical control tasks can be divided into the numerical controller, programmable logic control, controls for drives, and auxiliary equipment. Manufacturers of computer numerical control (CNC) systems are increasing effort on developing new concepts permitting flexible control functions with a broad scope of freedom to adapt the functions to the specific requirements of the planned application in order to increase the use of standardized components. This simplifies the integration of CNC of different manufactures into the same workshop environment. Even today, CNC systems are mainly offered as closed manufacturer-specific solutions and some machine tool builders develop their own, sometimes sophisticated, controls. This keeps the shop floor inflexible, but flexibility is only needed in small and medium-sized enterprises. Recently there has been a growing tendency to use industrial or personal computers as low-cost controllers in CNC technology, with a numerical control (NC) core on a card module, but connected to standard operating systems such as Windows. Because PC hardware is easily available and under constant development, CNC based on it benefits from technological advances in this field.

One of the low-cost applications of this kind of CNC is called *job-shop control*, which are now available on the market (e.g., Siemens, Heidenhain). Machine tools with job-shop control can be operated manually and if needed or appropriate also with additional software support. This is intelligent support, enabling the switch in process from manual to numerical support. These controls are suitable for job shops with small lots and are easy to handle manually (conventional turning

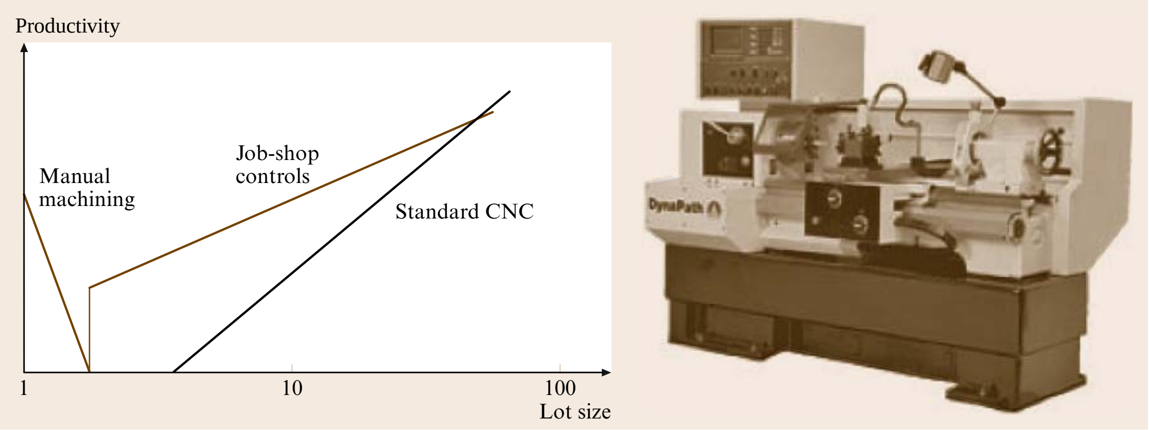

Fig. 41.6 Advantage of job-shop controls. Lathe with job-shop control

or milling) or programmable with interactive graphic support. Therefore the knowledge and experience of skilled workers can be challenged and division of work between programming and operating is unnecessary, saving costs while avoiding organizational effort and increasing flexibility. Job shop controls with PC operation systems can be integrated into an enterprise network, allowing for flexible manufacturing. It provides not only easy programming at the machines but also archiving of programs and loading of programs from other locations. Moreover connection to tool data management systems allows for quick search and ordering of the right tool at the workplace. Figure 41.6 demonstrates the range of job-shop controls with respect to lot size and productivity.

As an example of affordable automation in small enterprises, consider how to enhance the productivity and flexibility of a manufacturing process to acceptable costs. The main points in this respect are work organization and the technology used. Both of these aspects have to be considered together because they affect one another. Investing in a new, or at least better, technology is connected to decisions for machines with enhanced productivity and also to producing better quality that customers will be willing to pay for. Considering machine tools or manufacturing cells or systems it is not always necessary to replace them completely. In many enterprises one can find conventional machines in a very good state but meanwhile not suitable to produce parts of high quality in an adequate time. Conventional machine tools such as lathes or conventional milling machines usually have a machine bed with good quality and stiffness; they should not be thrown onto the scrapheap. These machines could be equipped at least with electronic measurement devices as linear rules to improve the manufactured quality with respect to required tolerances. The next improvement could be refitting with numerical control. This certainly requires servo drives for each controllable axis while the drive of the spindle will be controlled using a frequency converter. Numerically controlled machines of the first generation sometimes only need a new control to bring them up to today’s standards, a process called *upgrading*. Sometimes it is desired to retain conventional handling of machines despite the retrofit, i. e., moving tables and saddles mechanically with hand wheels in addition to numerically controlled servo drives. This facilitates the manufacturing of simple parts while using the advantages of CNC control to manufacture geometrically complex work pieces.

41.3 Energy-Saving Automation

41.3.1 Energy Generation

With energy *waste* levels in the process of electricity generation running at 66%, this sector has great potential for improvement. Using standard technology, only 25–60% of the fuel used is converted into electrical power. Combined-cycle gas turbines (CCGT) are among the most efficient plants now available, as compared with old thermal solid-fuel plants, some of which were commissioned in the 1950s.

Table 41.1 Energy savings and consumption (TW h/year) [41.36]

	Electricity savings achieved in the period 1992–2008	Consumption in 2003	Consumption in 2010 (with current policies)	Consumption in 2010, available potential (with additional policies)
Washing machines	10–11	26	23	14
Refrigerators, freezers	12–13	103	96	80
Electrical ovens	–	17	17	15.5
Standby	1–2	44	66	46
Lighting	1–5	85	94	79
Dryers	–	13.8	15	12
Domestic electrical storage water heaters	–	67	66	64
Air-conditioners	–	5.8	8.4	6.9
Dishwashers	0.5	16.2	16.5	15.7
Total	**24.5–31.5**	**377.8**	**401.9**	**333.1**

The biggest waste in the electricity supply chain (generation–transmission–distribution–supply) is the unused heat which escapes in the form of steam, mostly by heating the water needed for cooling in the generation process. The supply chain is still largely characterized by *central generation of electricity* in large power plants, followed by costly transport of the electricity to final consumers via cables. This transport generates further losses, mainly in distribution. Thus, centralized generation has advantages in terms of economies of scale, but also wastes energy. *Decentralized generation of electricity* and heat in regional or local units (including single buildings) could be of advantage. Such units are under development based on gas, or fuel cells in buildings. A combination of wind energy, solar energy, hydropower, energy from biomass, and fossil fuels in small units could provide electrical energy and heat in regions isolated from grids. These hybrid energy concepts are demanding advanced, but affordable, controls.

41.3.2 Residential Sector

Households accounted for 17% of the estimated gross energy consumption of 1725 Mtoe in 2005 in the European Union (EU), according to Eurostat energy balances. This amount could be reduced if people would change their habits to:

- Switch off appliances that are not in use, as standby consumes energy
- Select energy-efficient domestic appliances
- Use low-energy light bulbs
- Increase levels of recycling
- Monitor energy consumption
- Ensure systems are operating correctly
- Adjust the central heating set-point, and ensure correct distribution of sensors
- Double glazing of windows against heat and cold
- Insulation of walls
- etc.

However, people are lazy; automatic control can give support by managing the consumption of household appliances. The so-called *intelligent home* could provide solutions, but anyway people have to be aware of unnecessary energy consumption. Table 41.1 below shows possible savings of electrical energy in households of the EU.

41.3.3 Commercial Building Sector

Energy and therefore costs can be saved with suitable and intelligent automation. *Energy management control systems* (EMCS) are centralized computer control systems intended to operate a facility's equipment efficiently. These systems are still evolving rapidly, and they are controversial. Some applications are appropriate for computer control systems, and many are not. A range of simpler alternatives are available.

Advantage of *building automation systems* (BAS) includes monitoring, report generation, and remote control of equipment. Pitfalls are system cost, skilled staffing requirements, software limitations, vendor support, maintenance, rapid obsolescence, and lack of standardization.

BAS are also known by a variety of other names, including *energy management systems* (EMS) and *smart*

Table 41.2 Three levels of observing and improving energy consumption [41.37]

Improving performance

Policy	Structure	Resources
Formal energy policy and implementation plan. Commitment and active involvement of top management	Energy management fully integrated into management structure and systems from board level down	Full time staff and budget resources related to energy spend at recommended levels
Energy policy set and reviewed by middle management	A management structure exists but there is no direct reporting to top management	Staff and budget resources not linked to energy spend
Technical staff have developed their own guidelines	Informal and unplanned	Informal allocation of staff time and no specific energy budget

Increase commitment

building controls. A system typically has a central computer, distributed microprocessor controllers (called *local panels*, *slave panels*, *terminal equipment controllers*, and other names), and a digital communication system. The communication system may carry signals directly between the computer and the controlled equipment, or there may be tiers of communications.

Building automation can be a very effective way to reduce building operational costs and improve overall comfort and efficiency of a building. There are many definitions and examples of building automation. Simply put, building automation uses software to connect and control electrical functions in a building. Those functions usually include but are not limited to the heating, ventilation, air-conditioning (HVAC) and lighting systems. For further reading see [41.15] and Chap. 62.

41.3.4 Transportation Sector

Transport accounts of 20% of the estimated gross energy consumption of 1725 Mtoe in the European Union in 2005, according to Eurostat energy balances. Reducing this consumption is not only a technical problem, but mainly a political one. Road transport of goods receives direct or indirect subventions. The mostly state-owned railway organizations in Europe are not able to install a common system to reduce inefficient road transport. Low-cost air travel is increasing air pollution. Public transport does not always offer an acceptable alternative to individual car use.

To get people or goods from A to B there are various means of transport, via air, road, rail, or water. Today no interoperable information system is available. however, this would be an assumption for an efficient transport management system. These problems of information control could be solved.

Of course, achievements of automatic control in motor management and electrical drives reducing energy consumption can be seen. Hybrid drives in cars with automatic control of power management are favored. However, more effort is necessary to find acceptable and cost-effective solutions.

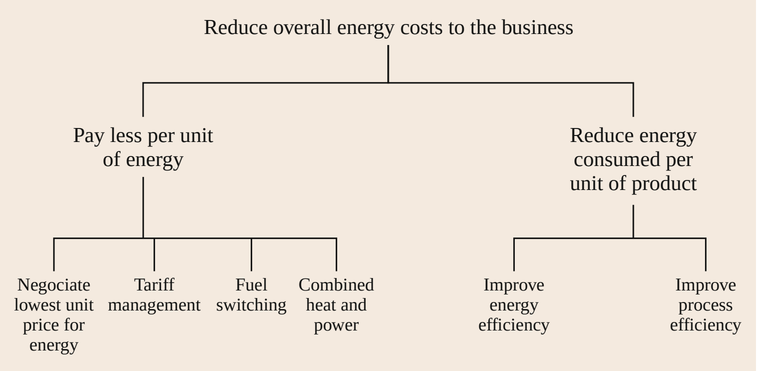
41.3.5 Industrial Sector

An enterprise should always observe and improve its energy consumption at all levels: the energy improvement cycle. A precondition for entering the cycle is commitment at all levels of the enterprise. Table 41.2 illustrated an uncommitted enterprise on the bottom row and an enterprise that is highly committed to energy improvement on the top row. It is important that the enterprise demonstrates commitment to sustained energy improvement before the process of delivering that improvement can begin.

The *energy improvement strategy* (Fig. 41.7) need not be long or complex but it is vitally important, as it will set the direction of all efforts to manage and improve energy consumption. Essentially there are two ways to cut energy bills (Fig. 41.7):

- Pay less for energy
- Consume less energy.

To reduce energy consumption it is necessary to analyze all possible sources of wasted energy: buildings, machines and equipment, production processes of goods, recycling of wasted energy (heat, etc.), and transport of



Reduce overall energy costs to the business
Pay less per unit of energy
Reduce energy consumed per unit of product
Negociate lowest unit price for energy
Tariff management
Fuel switching
Combined heat and power
Improve energy efficiency
Improve process efficiency

Fig. 41.7 Energy improvement strategy in an enterprise [41.37]

raw material, premanufactured parts, and manufactured products.

Developed automatic control concepts can help (less energy-consuming drives), but control concepts for an enterprise as a whole may be of advantage in terms of energy consumption reduction.

The use of energy in a country, in the residential sector, the commercial building sector, the transportation sector, and the industrial sector, influences the competitiveness of the economy, the environment, and the comfort of the inhabitants.

While energy efficiency measures energy inputs for a given level of service, *energy intensity* measures the efficient use of energy. It is defined as the ratio of energy consumption to a measure of the demand for services (e.g., number of buildings, total floor space, number of employees), or more generally the energy required to generate US$ 1000 of gross domestic product (GDP) (Fig. 41.8).

High energy intensity indicates a high price or cost of converting energy into GDP, while low energy intensity indicates a lower price or cost of converting energy into GDP.

Many factors influence an economy's overall energy intensity. It may reflect requirements for general standards of living and weather conditions in an economy. It is not untypical for particularly cold or hot climates to require greater energy consumption in homes and workplaces for heating or cooling. A country with an advanced standard of living is more likely to have a wider prevalence of consumer goods and thereby be impacted in its energy intensity compared with a country with a lower standard of living.

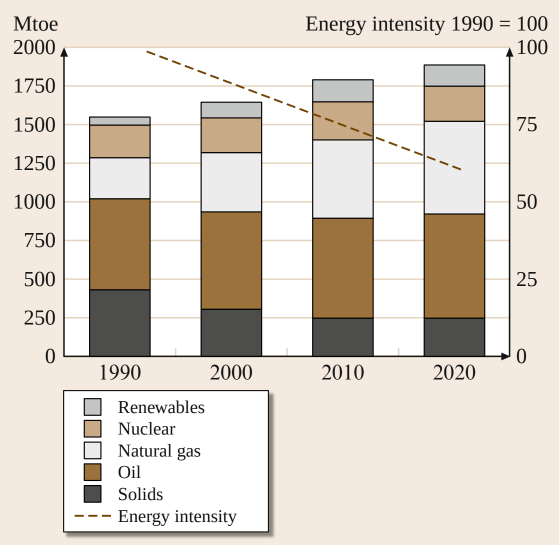


Fig. 41.8 Estimated total energy consumption by fuel and energy intensity 1990–2020 of the 25 EU member states [41.38]

41.4 Emerging Trends

41.4.1 Distributed Collaborative Engineering

Supporting cost-effective *human–human collaboration* in networked enterprises is a challenge for cost-oriented automation. With the trend to extend the design and processing of products over different and remotely located factories, the problem arises of how to secure effective collaboration of the involved workforce. Usual face-to-face work will be replaced at least partly if not totally by computer-mediated collaboration. The development and implementation of information and communication technology, suitably adapted to the needs of the workforce and facilitating remotely distributed collaborative work, is a challenge to engineers. Information mediated only via vision and sound is insufficient for collaboration. In designing and manufacturing it is often necessary to have the parts in your hands. To grasp a part at a remote site requires force (haptic) feedback in addition to vision and sound. Consider, for example, remote service for maintenance.

Bruns et al. [41.11, 39, 40] developed low-cost devices based on *mixed-reality concepts* for web-based learning as a first step to distributed collaborative work.

Mixed-reality environments as defined in [41.41] are those in which real-world and virtual-world objects are presented together on a single display. Mixed-reality techniques have proven valuable in single-user applications. Meanwhile, research has been done on applications for collaborative users. Mixed reality could be useful for collaborative distributed work because it addresses two major issues: seamlessness and enhancing reality [41.42].

Bruns [41.11] notes that most existing collaborative workspaces strictly separate reality and virtuality; for example, when controlling a remote process, one can sense and view specific system behavior, control the system by changing parameters, and observe the process by video cameras. The process, as a flow of energy – controlled by signals and information – is either real or completely modeled in virtuality and simulated. In mixed-reality distributed environments, information flow can cross the border between reality and virtuality in an arbitrary bidirectional way. Reality may be the continuation of virtuality, or vice versa, which provides a seamless connection between the two worlds. This bridging or mixing of reality and virtuality opens up some new perspectives for learning or training environments [41.12] as well as for distributed work environments.

The connection between the real and the virtual world is mediated through an *energy interface* called a *hyperbond*. In dynamic systems the system components are connected through energy (or power) transfer.

If a real dynamic system is to be extended digitally with software running on a computer (virtual dynamic system) analog sensor signals have to be converted into digital values for the software side of the interface. Flow in the opposite direction requires digital values from the software to be converted into analog signals that generate effort and flow to the real dynamic system.

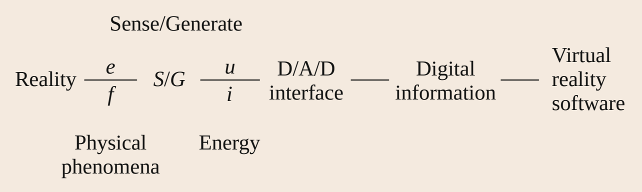

Fig. 41.9 Architecture of a hyperbond connection

Figure 41.9 describes in general the interface between the real and the virtual world: Effort (e) and flow (f) are sensed (S) (or generated (G)), providing voltage (u) and current (i) (or effort and flow in the opposite), an analog-to-digital (A/D) converter provides digital information for the software, or a digital-to-analog (D/A) converter converts digital information into analog signals to drive a generating mechanism for effort and flow to the real world.

The interface generates or dissipates energy (or power). The power, provided through the real system, has to be dissipated, because the virtual continuation with software requires nearly negligible power. In the opposite direction, the digital information provided through the software has to generate the power necessary to connect to the real system.

Application for a Discrete-Time Event System

Electropneumatic components installed at a real workbench are connected to a virtual workbench with electropneumatic components stored in a library. Because the valves can only be open or closed, the cylinders only on or off, one has only discrete events. The energy interface, called the hyperbond, receives digital information from the virtual workbench and generates air pressure and air flow as well as voltage and current for the solenoid valves and cylinders at the real workbench (Fig. 41.10). In the opposite direction the energy interface senses air pressure and air flow as well as electrical signals to convert into digital signals. No feedback control within the energy interface is necessary unless it is desired.

The *virtual and real workbench* can be located either at a local site or at remote sites connected via the Internet. Also virtual workbenches may be distributed at different sites connected via the Internet to the (only) real workbench. The software of the virtual workbench allows access by many users at the same time. Therefore students or workers distributed at different locations can solve tasks together at their virtual workbenches and export it on the real workbench to test their common solution in reality.

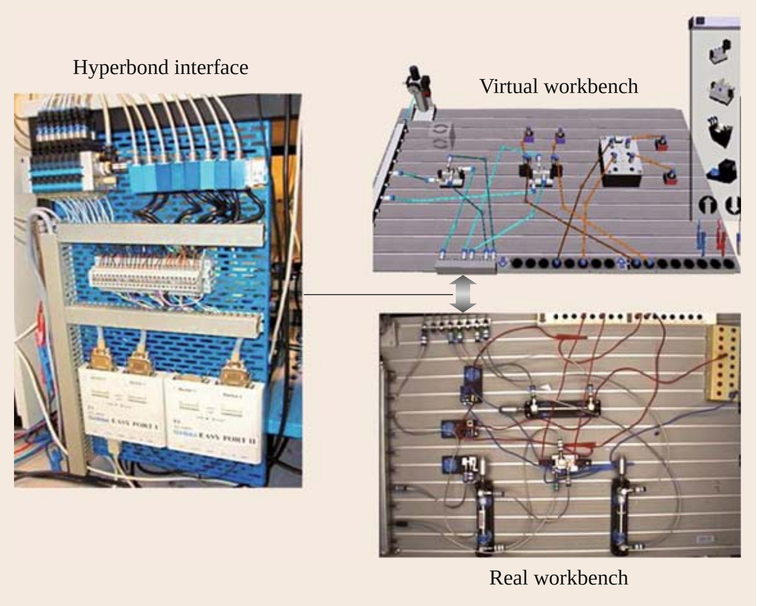

Fig. 41.10 Real and virtual pneumatic workbench connected with an energy interface (hyperbond)

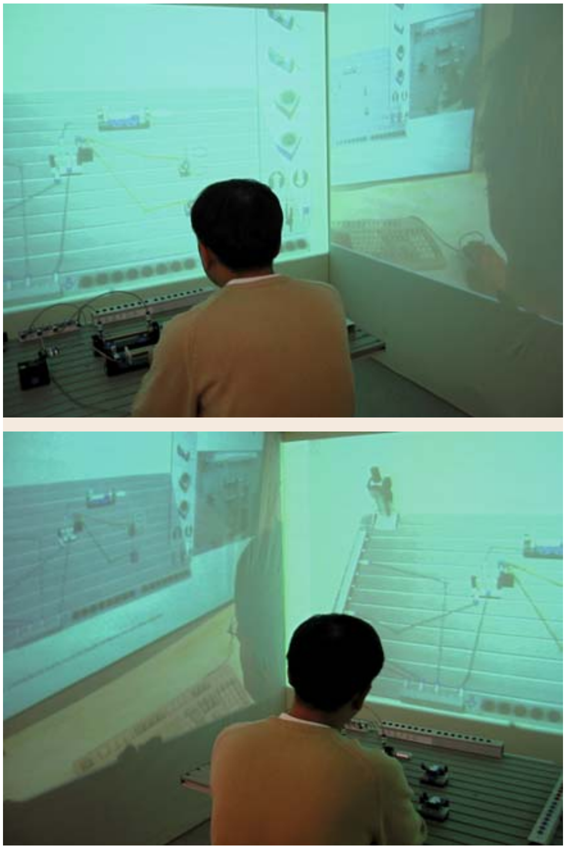

The connected workbenches are located in computer animated virtual environment (CAVE)-like constructions. CAVEs consist of scaffoldings with canvases onto which the images of other workspaces with the people working on them are beamed (Fig. 41.11).

The example presents distributed workbenches for discrete events (valves, cylinders, on/off). *Yoo* and *Burns* [41.39] enhanced this application with a generally described energy interface for the connection of real (continuous-time dynamic) and virtual (discrete-time dynamic) systems. *Yoo* [41.43] developed this interface with low-cost components for examples with haptic feedback.

41.4.2 e-Maintenance and e-Service

Among the main cost factors responsible for the performance of a plant is the availability of machines and equipment. Therefore maintenance takes an important part in plant automation. Avoiding downtime, or at least minimizing it, is the goal. *Advanced maintenance strategies and services* are candidates for cost savings. These integrate information processing and the processing of physical objects. e-Maintenance is an emerging concept, generally defined as a maintenance

Fig. 41.11 Workspace with the real workbench and the virtual one in front, and the remote collaborators projected onto the left and right canvases

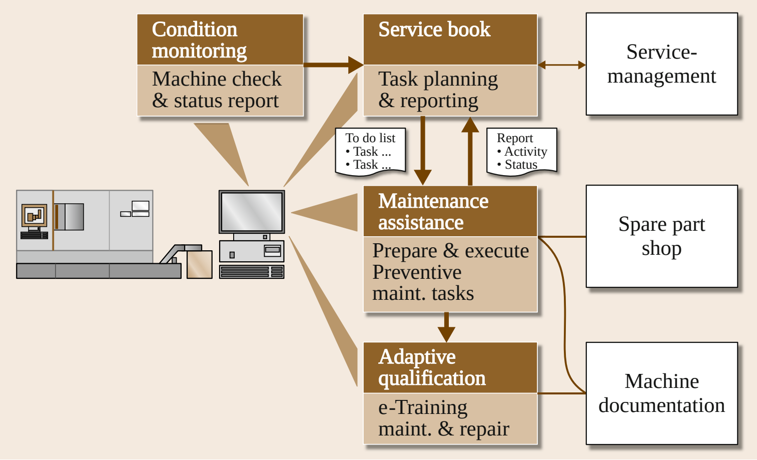

Fig. 41.12 Platform for web-based maintenance service [41.5]

management strategy in which assets are monitored (conditioned-based monitoring) and action is synchronized with the business process through the use of web-enabled and wireless infotronics technologies [41.4,44]. Despite the development of new maintenance strategies (Fig. 41.12) and the efforts of service providers one should not underestimate the knowledge and experiences of the operators of automation systems, and use their expertise if possible. Here one has to find a compromise between the cost of service from outside or specialists from inside and the cost of qualified operators and their permanent training. To empower people effectively depends on confidence between management and shop floor. It is not easy for the management, but this problem is solvable if it reduces costs and everybody understands it. *e-Maintenance* strategies were developed for the automotive industry. Many small enterprises still rely on preventive maintenance or even on breakdown maintenance. The challenge is to make e-Maintenance available for these enterprises for affordable cost.

Tele-service was developed to support small enterprises to enhance their productivity at affordable cost. The principal goal is to minimize trouble-shooting costs by allowing service personnel the flexibility to work from a distance. The main advantage for the machine operator lies in reducing machine downtime. e-Services go beyond such conventional concepts. *e-Service* is considered to include support of customer service via information and communication components and services. e-Service makes the installation and start-up of machines and plants possible, as well as trouble-shooting, the transfer of new software versions, the provision of replacement parts, and ordering spare parts on time. In the future, e-Service will also find application in process support and customer consultation [41.5].

Two emerging areas have been described with respect to their influence of cost savings. Some others that should be mentioned are:

1. *Semi-automated disassembly* of electronic waste, such as mobile phones, will gain more importance in the near future: a flexible, modular system for the development of semi-automatized, intelligent disassembly cells including stationary robots and especially a *low-cost*, hierarchical control structure [41.45].
2. *Harrison* and *Colombo* [41.46] propose *collaborative automation* in manufacturing. Their approach is to define a suitable set of basic production functions and then to combine these functions in different arrangements. This approach creates more complex production activities and saves costs of reconfiguration of rigid automation in manufacturing.

41.5 Conclusions

Low-cost automation was considered under two aspects: cost-oriented automation as a strategy to reduce the cost of ownership of an automation system, and affordable automation focused on the needs of small and medium-sized enterprises to enhance productivity and thereby competitiveness.

In the first case the life cycle of a production system was discussed, and design and maintenance/reconfiguration were identified as the main cost drivers. Recent developments of e-Maintenance as emerging trends are promising for cost saving. Maintenance was discussed holistically regarding the overall performance of a production system. Life cycle engineering with its different facets for cost savings was described, and further developments were suggested. Also human–human collaboration (including support for human–machine collaboration) has been considered with respect to cost. Mixed-reality concepts with application in learning environments to train for cost-effective collaborative work over remote sites has also been presented.

In the second case, examples of affordable automation for old and new developments of automatic control such as smart devices were presented. Web based e-Services to solve maintenance problems and to avoid downtime of machines have recently been provided by machine manufacturers. It is a challenge to the automatic control community to transfer their developments in modern control design and theory to make them applicable for affordable automation projects; for example, embedded control systems (see Chap. 43), are promising cost-oriented solutions.

Energy saving and its automatic control was briefly discussed for electrical energy generation in large-scale power plants. Wastage of primary energy occurs as unused heat. A possible energy-saving solution could be decentralized generation of electricity so that heat could be used more easily for heating buildings and processes in plants. The main consumers of energy are the residential and commercial building sectors. Building automation systems are being developed to save energy. The challenge is to make a possible sophisticated control understandable for the operators. To summarize, energy saving is not only a matter of technology but also depends on people's habits.

42. Reliability, Maintainability, and Safety

Gérard Morel, Jean-François Pétin, Timothy L. Johnson

Within the last 20 years, digital automation has increasingly taken over manual control functions in manufacturing plants, as well as in products. With this shift, reliability, maintainability, and safety responsibilities formerly delegated to skilled human operators have increasingly shifted to automation systems that now *close the loop*. In order to design highly *dependable* automation systems, the original concept of design for reliability has been refined and greatly expanded to include new engineering concepts such as availability, safety, maintainability, and survivability. Technical definitions for these terms are provided in this chapter, as well as an overview of engineering methods that have been used to achieve these properties. Current standards and industrial practice in the design of dependable systems are noted. The integration of dependable automation systems in multilevel architectures has also evolved greatly, and new concepts of control and monitoring, remote diagnostics, software safety, and automated reconfigurability are described. An extended example of the role of dependable automation systems at the *enterprise level* is also provided. Finally, recent research trends, such as automated verification, are cited, and many citations from the extensive literature on this topic are provided.

Industrial automation systems are intensively embedding infotronics and mechatronics technology (IMT) in order to fulfil complex applications required by the increasing customization of both services and goods [42.2–6]. The resulting behavior of these IMT-based automation systems is shifting system dependability responsibility [42.7] from the human operator to the automation software.

Management, engineering, and maintenance personnel have a primary responsibility to assure reliability [42.8, 9], maintainability, and safety of all automated systems, and manufacturing systems in particular. Therefore, safety, reliability, and availability as performance attributes to access the dependability of a system are threatened by a rapid growth in software

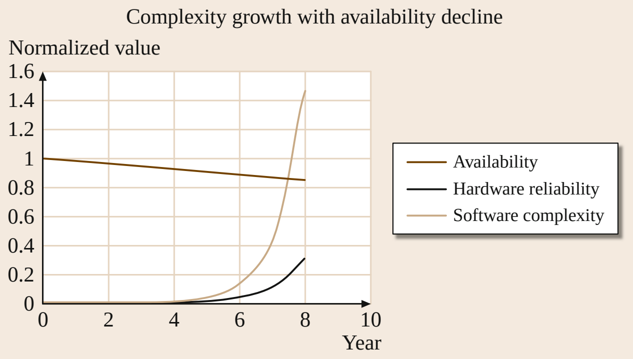

Fig. 42.1 Growth of software complexity and its impact on system availability (after [42.1])

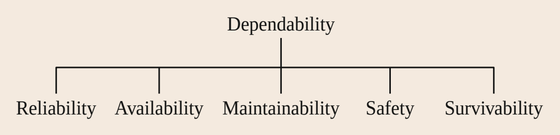

Fig. 42.2 The dependability tree (after [42.10])

complexity that could limit further automation progress (Fig. 42.1).

Section 42.1 provides definitions of dependability key concepts (Fig. 42.2) that enlarge reliability, maintainability, and safety (RMS) concepts [42.11, 12] by characterizing the ability of a device or system to deliver the correct service that can justifiably be trusted by all stakeholders in the automated process.

Then, methods for design of highly dependable automation systems are outlined in Sect. 42.2. Section 42.3 discusses the methods for achieving long-term dependable operation for an existing system.

Finally, dependability has evolved from reliability/availability concerns to information control concerns, as an outgrowth of the technological deployment of information-intensive systems and the economical pressure for cost-effective automation [42.13]. Section 42.4 concludes with challenges, trends, and open issues related to system resilience, aiming to cope with system dependability in the presence of active faults, i. e., system survivability. Chapter 39 of this handbook contains information related to the concepts covered in this Chapter.

42.1 Definitions

Dependability is an integrative concept that encompasses required attributes (qualities) of a system assessed by quantitative measures (reliability, maintainability) or qualitative ones (safety) in order to cope with the chain of fault–error–failure threats of an operational system, by combining a set of means related to fault prevention, fault tolerance, fault removal, and fault forecasting [42.14].

Reliability is the ability of a device or system to perform a required function under stated conditions for a specified period of time. This property is often measured by the probability $R(t)$ that a system will operate without failure before time t, often defined according to the failure rate ($\lambda(t)$) as

$$R(t) = \exp\left(-\int_0^t \lambda(u)\,\mathrm{d}u\right) ,$$

meaning

$$R(t) = \Pr(\mathrm{TTF} > t) ,$$

where TTF is the time to failure.

This definition of reliability is concerned with the following four key elements:

1. First, reliability is a probability. This means that there is always some chance for failure. Reliability engineering is concerned with achieving a specified probability of success, at a specified statistical confidence level.
2. Second, reliability is predicated on *intended function*. The system requirements specification is the criterion against which reliability is measured.
3. Third, reliability applies to a specified period of time. In practical terms, this means that a system has a specified chance that it will operate without failure before a final time (e.g., $0 < t < T$).
4. Fourth, reliability is restricted to operation under stated conditions. This constraint is necessary because it is impossible to design a system for unlimited conditions. Both normal and abnormal operating environments must be addressed during design and testing.

Maintainability is the ease with which a device or system can be repaired or modified to correct and prevent faults, anticipate degradation, improve performance or adapt to a changed environment. Beyond simple physical accessibility, it is the ability to reach a component to perform the required maintenance task: maintainability should be described [42.15] as the characteristic of material design and installation that determines the requirements for maintenance expenditures, including time, manpower, personnel skill, test equipment, technical data, and facilities, to accomplish operational objectives in the user's operational environment. Like reliability, maintainability can be expressed as a probability $M(t)$ based on the repair rate ($\mu(t)$) as

$$M(t) = 1 - \exp\left(-\int_0^t \mu(u)\,\mathrm{d}u\right) ,$$

meaning

$$M(t) = \Pr(\mathrm{TTR} < t)\,,$$

where TTR is the time to repair.

Availability characterizes the degree to which a system or equipment is operable and in a committable state at the start of a mission, when the mission lasts for an unknown, i. e., random, time. A simple representation for availability is the proportion of time a system is in a functioning condition, and this can be expressed mathematically [42.17] by

$$A(t) = \frac{\mu}{\mu+\lambda} + \frac{\lambda}{\mu+\lambda}\,\mathrm{e}^{-(\mu+\lambda)t}\,,$$

where λ is the constant failure rate and μ the constant repair rate, meaning

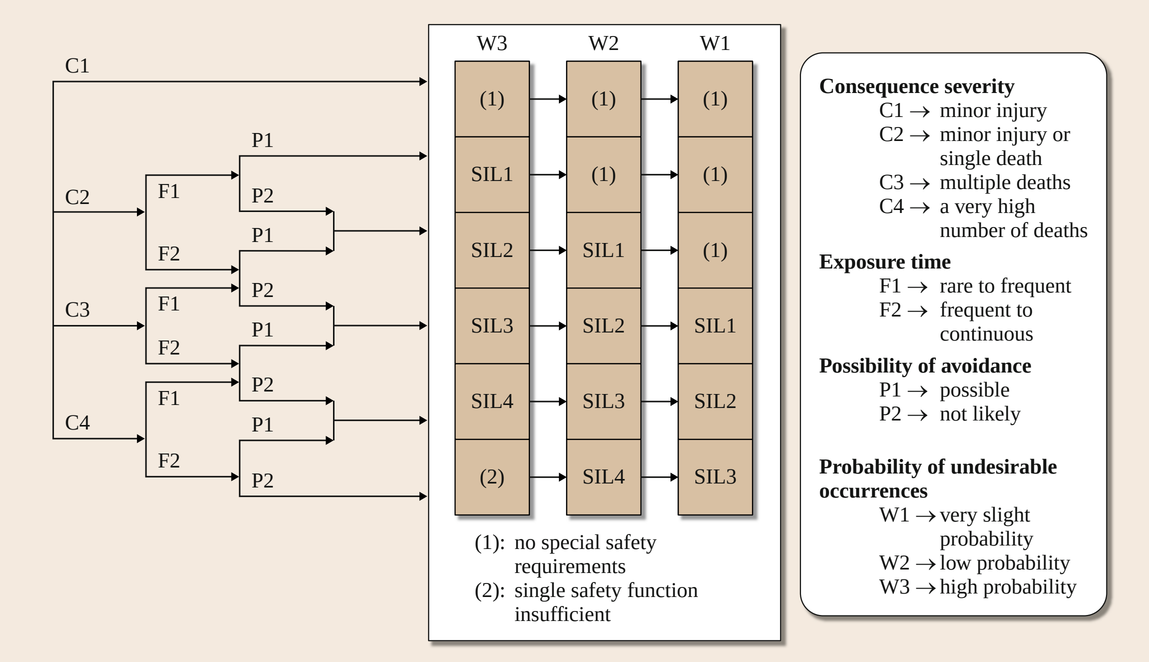
$$A(t) \equiv \Pr(Z(t) = 1)\,,$$

with

$$Z(t) \equiv \begin{cases} 1 & \text{if the system is up at time } t \\ 0 & \text{if the system is down at time } t\,. \end{cases}$$

System availability is important in achieving production rate goals, but additional processes must be invoked to assure a high level of product quality. Historically (before 1960), a *quality laboratory* would draw samples from the production line and subject them to a battery of material, dimensional, and/or functional tests, with the objective of verifying that quality was being attained *for a typical part*. In recent years, the focus has shifted from assurance of average quality to assurance of quality of *every part produced*, driven by consumer product safety concerns. *Deming* [42.18] and others were instrumental in developing methods for statistical process control, which focused on the use of quality control data to adjust process parameters in a *quality feedback loop* that assured consistently high product quality; these techniques were developed and perfected in the 1970s and 1980s. Still more recently, sensors to measure critical quality variables online have been developed, and the *quality feedback loop* is now often automated (algorithmic statistical process control). At the same time, the standards for product quality have moved up from about two sigma (1 defective product in 100) to five or six sigma (about 1 defective product in 100 000).

Increasing availability consists of reducing the number of failures (reliability) and reducing the time to repair (maintainability) according to the following for-



W3	W2	W1
(1)	(1)	(1)
SIL1	(1)	(1)
SIL2	SIL1	(1)
SIL3	SIL2	SIL1
SIL4	SIL3	SIL2
(2)	SIL4	SIL3

(1): no special safety requirements
(2): single safety function insufficient

Consequence severity
C1 → minor injury
C2 → minor injury or single death
C3 → multiple deaths
C4 → a very high number of deaths

Exposure time
F1 → rare to frequent
F2 → frequent to continuous

Possibility of avoidance
P1 → possible
P2 → not likely

Probability of undesirable occurrences
W1 → very slight probability
W2 → low probability
W3 → high probability

Fig. 42.3 Determining safety integrity level according to IEC [42.16]

mula

$$A(\infty) = \frac{\text{MTBF}}{\text{MTBF}+\text{MTTR}}$$

as the asymptotic value of $A(t)$, where MTBF is the mean time between failures and the MTTR is the mean time to repair.

Safety is the state of being safe, the condition of the automated system being protected against catastrophic consequences to the user(s) and the environment due to component failure, equipment damage, operator error, accidents or any other undesirable abnormal event. Safety hazard mitigation can take the form of being protected from the event or from exposure to something that causes health or economical losses. It can include protection of people and limitation of environmental impact.

Industrial automation standards (Fig. 42.3), introduce engineering and design requirements that vary according to the safety integrity levels (SIL). SIL specifies the target level of safety integrity that can be determined by a risk-based approach to quantify the desired average probability of failure of a designed function, probability of a dangerous failure per hour, and the consequent severity of the failure. Combining these criteria for a given function leads to four levels of SILs that can be associated with specific engineering guidelines and architecture recommendations; for example, SIL 4 is the most critical level and the use of formal methods is strongly recommended to handle the complexity of software-intensive applications and to prove safety properties. To achieve RMS properties over the lifecycle of an automated system, two complementary activities must be undertaken:

- During the system development and design phase, the occurrence of faults should be prevented by using appropriate models and methods: quantitative approaches based on stochastic models can be used to perform a predictive RMS analysis, and qualitative approaches focusing on engineering process (e.g., Six Sigma) can be used to improve the quality of the automated system and its products.
- During the operational life of the automated system, personnel should avoid or react to undesired situations by deploying appropriate safety architectures, maintenance procedures, and management methods.

Survivability is the quantified ability of a system to continue to fulfil its mission during and after a natural or manmade disturbance. In contrast to dependability studies, which focus on analysis of system dysfunction, resilience for survivability focuses on the analysis of the range of conditions over which the system will survive.

42.2 RMS Engineering

42.2.1 Predictive RMS Assessment

To evaluate and measure the various parameters that characterize system dependability, many methods and approaches have been developed. Their goal is to provide a structured framework to represent failures qualitatively and/or quantitatively. They are mainly of two types: declarative and probabilistic.

Declarative methods are designed to identify, classify, and bracket the failures and provide methods and techniques to avoid them. Most classical models use graphical classification of failure, causes, and criticality (failure mode, effects and criticality analysis (FMECA), hazardous operation (Hazop), etc.), block diagrams, and fault trees to provide a graphical means of evaluating the relationships between different parts of the system (Fig. 42.4). These models incorporate predictions based on parts-count failure rates taken from historical data. While the predictions are often not very accurate in an absolute sense, they are valuable to assess relative differences in design alternatives.

Probabilistic methods are designed to measure, in terms of probability, some RMS parameters. Models are mainly based on the complete enumeration of a system's possible states, including faulty states. These models use state-transition notation involved in the classical stochastic models of discrete event systems such as Markov chains and Petri nets [42.19]. The benefit of Markov and stochastic Petri net approaches relies on their capability to support quantitative analysis of the models, but these models suffer from the combinatoric explosion of the states that occurs when modeling complex industrial systems. Moreover, all of these analytic approaches assume that the stochastic processes can be modeled using a constant exponential law. For industrial processes that do not fit with this strong Markovian hypothesis, the definition of simulation models, such as Monte Carlo simulation, remains the only way to evaluate the RMS parameters.

Whatever the kind of used approaches, models for predictive RMS evaluation rely upon system data collection that does not always reflect the system reality due to a gap between real and estimated states. This limitation reinforces the need to establish reliable gates between RMS engineering and system deployment to update the RMS model data with real-time information provided by the automated system.

42.2.2 Towards a Safe Engineering Process for RMS

Automation techniques have proven their effectiveness in controlling the behavior of complex systems, based on the use of suitable mathematical relationships involving feedback system dynamics during the design process. Nevertheless, the process of automating a system, as addressed by *system theory* for *automatic control*, also deals with qualitative phases [42.19] that require intuitive modeling of real phenomena (a quantity of material, energy, information, a robot, a cell, a plant, etc.) to be controlled for achieving end-user goals. The modeler's intuition remains important [42.20, 21] to build the model as an abstraction of the real system by identifying the appropriate input, output, and state variables in order to logically define the required system behavior. The main difficulty is to handle the quality of the automation engineering pro-

Table 42.1 Capability maturity model [42.24]

Level 1: Initial	The software process is characterized as ad hoc and occasionally even chaotic. Few processes are defined and success depends on individual effort.
Level 2: Repeatable	Basic project management processes are established to track cost, schedule, and functionality. The necessary process discipline is in place to repeat earlier successes on projects with similar applications.
Level 3: Defined	The software process for both management and engineering activities is documented, standardized, and integrated into a standard software process for the organization.
Level 4: Managed	Detailed measures of the software process and product quality are collected. Both the software process and product are quantitatively understood and controlled.
Level 5: Optimizing	Continuous process improvement is enabled by quantitative feedback from the process and from piloting innovative ideas and technologies.

cesses from definition and development to deployment and operation of the target system by standardization and use of best practices that are generic to well-identified problem classes and whose quality has been established by experience. *Capability maturity models* (CMM) [42.22], and *validation–verification* methods, guide engineers to combine prescriptive and descriptive models in order to meet system requirements such as RMS, but without any formal proof of accuracy of the resulting system model. Finally, the present trend to compose automation logic by assembling standardized, configurable, off-the-shelf components [42.23] strengthens the need to first better relate the modeling process and the system goals and then to preserve them through the transformation of models of the automation engineering chain. The CMM, was developed as a means of rating the thoroughness of a software development process, by the Carnegie Melon University Software Engineering Institute in the 1990s.

To pave the way toward CMM level 5, there is a growing demand for formalized methods for assuring dependability in industrial automation engineering, in order to compensate for the increasing complexity of software-intensive applications [42.25]. In particular, high levels of safety integrity, as addressed by the International Electrotechnical Commission (IEC) 61508 standard, should be formally checked and proven by mathematically sound techniques in order to verify the required completeness, consistency, unambiguity, and finally correctness of the system models throughout the definition, development, and deployment phases of the engineering lifecycle [42.26, 27].

The conformance measure of system models with regards to the requirements, and especially RMS features, can be obtained using:

- Assertion methods that include the properties to be checked in the system models proceed to an a posteriori verification using automatic techniques such as model checking [42.28].
- Refinement methods that start with the formalization of a requirement model and progressively enrich this model until a concrete model of the system that fulfils, by construction, the identified requirements is obtained. They can be based on:
  - Semiformal mechanisms that identify and classify RMS requirements and then allocate those requirements to the function, components, and equipment of the automated system. In this case, classical models combine computer-science approaches such as unified modeling language (UML) with discrete-event analysis models.
  - Formal mechanisms [42.29] that allow a sequence of formal models to be systematically derived while preserving the link between formal models and required properties (goals): an extension of the spiral method for software engineering.

All of these techniques may be combined to contribute to RMS issues [42.30, 31], but the emphasis on correct system definition is then shifted to earlier requirements analysis and elicitation phases.

42.3 Operational Organization and Architecture for RMS

Taking advantage of technological advances in the field of communications (web services embedded in programmable logic controllers) or in the field of electronics and information technology (radiofrequency identification (RFID), sensor networks, software embedded components, etc.), automated systems now include an increasing part of information technology and communication distributed at the very heart of production processes and products. However, this automation comes at a price: the complexity of the control system in terms of both heterogeneous material (dedicated computers, communications networks, supply chain operations and capture, etc.) and software functions (scheduling, control, supervisory control, monitoring, diagnosis, reconfiguration, etc.) that it houses (Fig. 42.5).

This section deals with the operational architectures and organizations required to enable active dependability of the automated system by providing information processing, storage, and communication capabilities to anticipate undesired situations or to react as effectively as possible to fault occurrences.

42.3.1 Integrated Control and Monitoring Systems

In order to maintain an acceptable quality of service, dependability should no longer be considered redundant, but should be integrated with production systems in order to be an asset in the business competitive environment. This leads to integration of additional monitoring functions with the classical control functions of an automated system in order to provide the system with the ability to reconfigure itself to continue some or all of its missions. The main idea is to avoid a complete shutdown of the system when a failure (with a consequent reduction in the productive potential of the system) occurs. Considering the system's intrinsic flexibilities, the aim is to promote system reconfiguration using a reflex loop including:

- Failure detection reports about the normal or abnormal behavior of the system. These are mainly based on a theoretical model of the functional and dysfunctional behavior of the devices involved in the automated system.

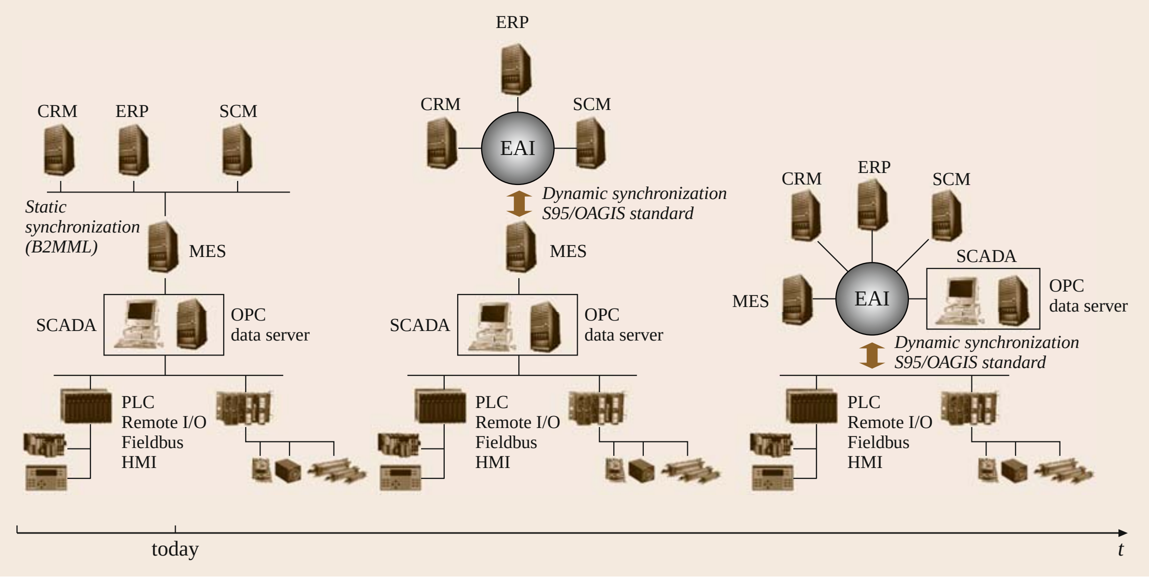

Fig. 42.5 Evolution of automated system architecture (CRM – customer relationship management, ERP – enterprise resource planning, SCM – system configuration maintenance, MES – manufacturing execution system, OPC – online process control, PLC – programmable logic controller, SCADA – supervisory control and data acquisition, EAI – enterprise architecture interface, HMI – human machine interface, OAGIS – open applications group integration specification)

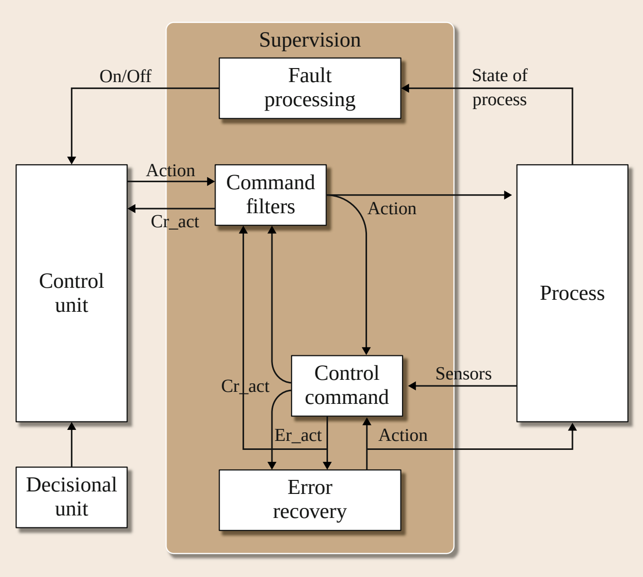

Fig. 42.6 Integrated control and monitoring systems (after [42.32])

- Diagnosis is mandated to establish a causal connection between an observed symptom and the failure that occurred, its causes, and its consequences. This function involves failure localization to isolate the failure to a subarea of the system and/or devices, failure identification to precisely determine the causes that brought about the default, and prognosis to determine whether or not there are immediate consequences of the failure on the plant's future operation.
- Reconfiguration concerns reorganization of hardware and/or software of a control system to ensure production within a timeframe compatible with the specifications. This function involves decision-making activities to define the most appropriate control policy and operational activities to implement the reconfigured control actions.

Integration of monitoring [42.33, 34], diagnosis [42.35] or even prognosis into control for manufacturing systems have been widely explored for discrete-event systems (Fig. 42.6) and today provide material for identifying degradation or failure modes where control reconfiguration may be required [42.36].

Reconfiguration exploits the various flexibilities of the automated system (functional and/or material redundancies). In this way, it aims to satisfy fault-tolerance properties that characterize the ability of a system (often computer-based) to continue operating properly in the event of the failure of some of its components. One of the most important design techniques is replication – providing multiple identical instances of the same system or subsystem, directing tasks or requests to all of them in parallel, and choosing the correct result on the basis of a quorum – and redundancy – providing multiple identical instances of the same system and switching to one of the remaining instances in case of a failure. These techniques significantly increase system reliabil-

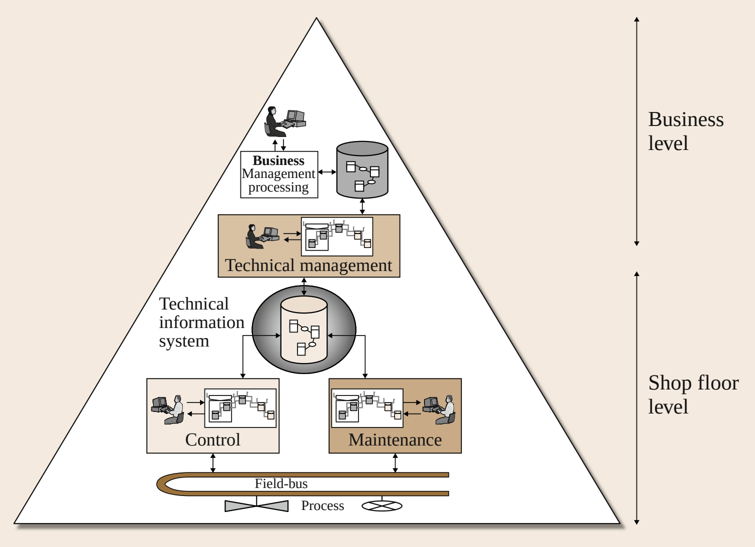

Fig. 42.7 Integrated control, maintenance, and technical management: layers of automation

ity, and are often the only viable means of doing so. However, they are difficult to design and expensive to implement, and are therefore limited to critical parts of the system.

While automation of these functions is obviously necessary for ensuring the best reactivity of the industrial production system to failure occurrence, it is nevertheless true that system stoppage is often performed by the human operator, who must act manually to put it back into a admissible state. This justifies the use of supervision and supervisory control and data-acquisition (SCADA) systems that help human operators for plant monitoring and decision-making related to the various corrective actions to be performed in order to get back to a normal functioning situation (reconfiguration, management of operating mode). Given the ever-increasing complexity of industrial processes, the burden itself tends to become difficult or even impossible. For these reasons, much research is aimed at developing and proposing solutions aimed at assisting the human operator in the phases of reconfiguration.

42.3.2 Integrated Control, Maintenance, and Technical Management Systems

Further developments of integrated control and monitoring systems have lead European projects in intelligent actuation and measurement [42.37–40] to demonstrate the benefit of integrating control, maintenance, and technical management (CMTM) activities [42.41]:

- To optimize control activities by exploiting the plant as efficiently as possible and taking into account real-time information about process status (device and function availability) provided by monitoring and maintenance activities
- To optimize the scheduling of the maintenance activities by taking into account production constraints and objectives
- To optimize, by technical management based on validated information, the operation phase by modifying control or maintenance procedures, tools, and materials

Applying this principle at the shop-floor level of the production system consists of integrating the operational activities of the CMM *agents* responsible for the plant and its lower-level interfaces with the system devices. They are also linked with the business level of the enterprise (enterprise resource planning, etc.) for business-to-manufacturing integration issues (manufacturing execution system (MES)). These operational activities are based on collaboration between human stakeholders and technical resources that support schedule management, quality management, etc., but also process management and maintenance management, which are more dependent on the e-*Connectivity* of the supporting devices.

The expected integrated organization for shop-floor activities requires that information is made available for use by all the operational activities (MES or CMM). In this way, *intelligence* embedded in field devices (e.g., devices such as actuators, sensors, PLCs (programmable logic controllers), etc.) and digital communication provide a solution to an informational representation of the production process as efficiently as possible: the system provides the right information at the right time and at the right place. In other words, the closer the data representation (e.g., in an object-oriented system) to the physical and material flows, the better the semantics of its informational representation for integration purposes (Fig. 42.7).

At the shop-floor level, local intelligence (software) allows distribution of information processing, information storage, and communication capabilities in field devices and adds to their classical roles new services related to monitoring, validation, evaluation, decision making, etc., with regard to their own operations (increased degree of autonomy) but also their application context (increased degree of component interaction).

42.3.3 Remote and e-Maintenance

Modern production equipment (manufactured by original equipment manufacturers, OEMs) is highly specialized; for example, a semiconductor manufacturing plant may have over 200 specialized production stages and over 100 equipment suppliers. In a serial process of this type, all 200 steps must operate within specification to produce an operational semiconductor at the end of the line. This type of process requires extraordinarily high reliability (and availability) of the OEM production equipment. When such equipment must be taken out of service, it is not uncommon to incur production loss rates of over 100 000 $/h, and therefore accurate diagnosis and rapid repair of equipment are essential. Since the year 2000, OEMs have increasingly provided network-capable diagnostic interfaces to equipment, so that experts do not have to come to the site to make a diagnosis or repair, but can guide plant personnel in doing this, and can order and ship parts overnight. This is often termed *e-Diagnostics*, and is crucial to maintaining high availability of production equipment. Using e-Diagnostics, a manufacturer may maintain remote service contracts with dozens of OEM suppliers to assure reliable operation of an entire production process.

In some processes, where production equipment is subject to wear or usage that is predictably related, for example, to the number of parts produced, it is possible to forecast the need for inspection, repair, or periodic replacement of critical parts, a process called *prognostics*. Although some statistical methods for prognostics (such as Weibull analysis) are well known, the ability to accurately predict the need for *service of an individual part* is still not well developed, and is not yet widely accepted. One goal of this type of analysis is *condition-based maintenance* (CBM), the practice of maintaining equipment based on its condition rather than on the basis of a fixed schedule [42.43].

Proactive maintenance is a new maintenance policy [42.44] based on prognostics, and improves on condition-based maintenance (CBM). CBM acquires real-time information in order to propose actions and to repair only when maintenance is necessary. CBM consists of equipment health monitoring to determine the equipment state; CBM is a kind of *just-in-time maintenance*. CBM is not able to predict the future state of equipment. The prognostic capability of the proactive maintenance is based on the history of the equipment operation, its current state, and its future operating conditions. The objective of proactive maintenance is to know if the system is able to accomplish its function for a given time (for example, until the next plant maintenance shutdown).

Information from control systems (distributed or not), automation, data-acquisition systems, and sensors makes it possible to measure variables continuously in order to produce symptoms or indicators of malfunction, to acquire the number of cycles of production, the time of production, the energies consumed, etc., in order to correlate this information with the diagnosis and assess the probabilities of root cause. Based on these monitoring and diagnosis functions, proactive maintenance, thanks to prognosis, propagates the drift of system behavior through time, taking into account the future exploitation conditions. Based on this

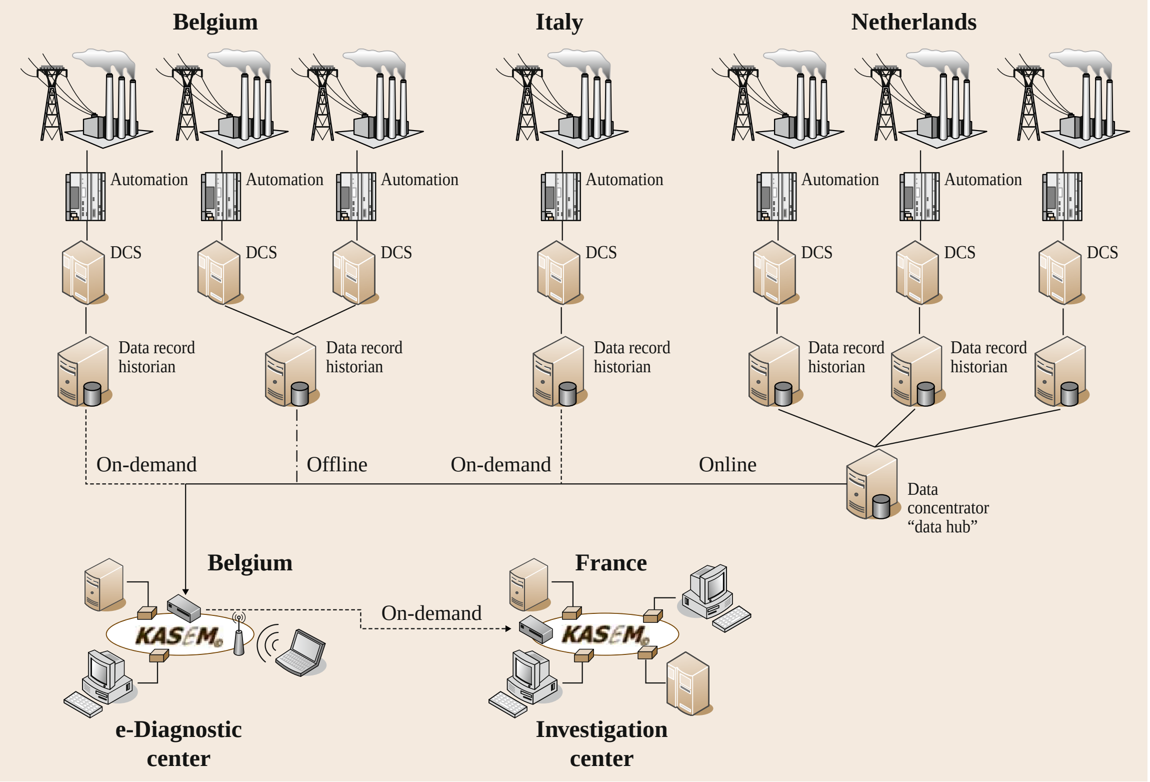

Fig. 42.8 Distributed e-Maintenance infrastructure in a power energy plant [42.42] (DCS – distributed control system)

extrapolation, prognostics can be used to evaluate the time when the drift will exceed a threshold and to propose a time before next potential failure. In this way, proactive maintenance can optimize maintenance actions and planning in order to minimize production downtime.

Proactive maintenance allows a maintenance action improvement (mean availability), to follow the degradation tendency (quality of service), to avoid the occurrence of dangerous situations (safety), and finally to support the operator with knowledge oriented to the degradation cause and effect (maintainability).

e-Maintenance is an organizational point of view of maintenance. The concept of e-Maintenance comes from remote maintenance capabilities coupled with information and communication capabilities. Remote maintenance was first a concept of remote data acquisition or consultation. Data are accessible during a limited time. In order to realize e-Maintenance objectives data storage must be organized to allow flexible access to historical data.

In order to improve remote maintenance, a new concept of e-Maintenance emerged at the end of the 1990s. The e-Maintenance concept integrates cooperation, collaboration, and knowledge-sharing capabilities in order to evolve the existing maintenance processes and to try to tend towards new enterprise concepts: extended enterprise, supply-chain management, lean maintenance, distributed support and expert centers, etc. Based on web technologies, the e-Maintenance concept is nowadays available and industrial e-Maintenance software platforms exist. e-Maintenance platforms (sometimes termed asset management systems) manage the whole of the maintenance processes throughout the system lifecycle from engineering, maintenance, logistic, experience feedback, maintenance knowledge capitalization, optimization, etc. to reengineering and revamping. e-Maintenance is not based on software functions but on maintenance services that are well-defined, self-contained, and do not depend on the context or state of other services. So, with the advent of service-oriented architectures (SOA) and enterprise service-bus technologies [42.45], e-Maintenance platforms are easy to evolve and can provide interoperability, flexibility, adaptability, and agility. e-Maintenance platforms are a kind of *hub* for maintenance services based on existing, new, and future applications.

42.3.4 Industrial Applications

Industrial software platforms have been developed during the 1990s in order to provide the proof of concept of this RMS modeling framework before marketing off-the-shelf products. The first applications have appeared since 2000 in various sectors such as power energy, steel factory, petrochemical process, navy logistics and maintenance support, nuclear fuel manufacturing and waste treatment, etc.

A common objective of these multisector applications is to reduce operation costs by increasing the availability, maintainability, and reliability of plants and systems, and to facilitate their compliance with regulation laws. Another common objective is to elicit and save the implicit knowledge acquired by skilled operators as well as by skilled engineers when performing their tasks. Others objectives are specific to an industrial sector; for example, understanding complex phenomena to anticipate maintenance operations is critical to optimize the impact of shutdown and startup operations in process plants [42.46].

Return on investment is estimated to be at most 1 year from these industrial experiments, and leads to a distributed service-oriented e-Maintenance infrastructure to warrantee by contract a level of availability in plant operation (Fig. 42.8).

42.4 Challenges, Trends, and Open Issues

All aspects of dependability such as reliability, maintainability, and safety should be viewed in a broader context depending on both management and technical processes within the enterprise system to ensure the necessary resilience to intrinsic and extrinsic complex phenomena occurring when systems are operating in changing environments. For example, MTBF is a measure of the random nature of an event and does not predict when something will fail but only predicts the probability that a system will fail within a certain time boundary. Contrary to conventional wisdom, accidents often result from interactions between perfectly functioning components, i. e., before a system has reached its expected life as predicted by RMS analysis.

Such considerations underscore that other advanced concepts are beyond traditional RMS analyses and the individual mind-set of each engineering discipline to cope with emergent behavior as one of the results of complexity. In other words, dependability assumes that cause–effect relationships can be ordered in known and knowable ways, while resilience [42.47] should confine the contextual emergence of complex relationships within the system and between the system and its environment in unordered ways [42.48].

An initial challenge is to understand that the concept of system as the unique result of normal emergence within a collaborative systems engineering process leads to an ad hoc solution based on heuristics and normative process-driven guidelines [42.49].

A second challenge relies on weak emergence [42.50] to perceive, model, and check added behaviors due to the interactions between the component systems. This should be led by extensive model-driven requirements analysis adding more details than current practices and complementary experiments such as multiagent simulation to track self-organizing patterns in order to improve component systems' adaptability.

A third open challenge deals with the quality of the engineering process to determine whether a system can survive a strongly emergent event, as well as the adaptability of the whole enterprise to come into play in facing an inevitable systemic instability.

43. Product Lifecycle Management and Embedded Information Devices

Dimitris Kiritsis

The closed-loop product lifecycle management (PLM) system focuses on tracking and managing the information of the whole product lifecycle, with possible feedback of information to product lifecycle phases. It provides opportunities to reduce the inefficiency of lifecycle operations and gain competitiveness. Thanks to the advent of hardware and software related to product identification technologies, e.g., radiofrequency identification (RFID) technology, recently closed-loop PLM has been highlighted as a tool of companies to enhance the performance of their business models. However, implementing the PLM system requires a high level of coordination and integration. In this chapter we present the background methodologies and techniques and the main components for closed-loop PLM and how they are related to each other. We start with the concept of closed-loop PLM and a system architecture in Sect. 43.1. In Sect. 43.2 we describe the necessary components for closed-loop PLM and how to integrate and coordinate them with respect to business models, hardware, and software. In Sect. 43.3 we propose a development guide based on experiences gathered from prototype applications developed to date. In Sect. 43.4 we introduce a real case example that implements a closed-loop PLM solution focusing on end-of-life (EOL) of vehicles (ELV). Finally, Sect. 43.5 discusses some challenging issues and emerging trends in the implementation of closed-loop PLM.

43.1 The Concept of Closed-Loop PLM

Product lifecycle management (PLM) is a new strategic approach to manage product-related information efficiently over the whole product lifecycle. Conceived as an extension to product data management (PDM), its vision is to provide more product-related information to the extended enterprise over the whole product lifecycle. Its concept appeared in the late 1990s, moving beyond the engineering aspects of a product and providing a shared platform for creation, organization, and dissemination of product-related knowledge across the extended enterprise [43.1]. PLM facilitates the innovation of enterprise operations by integrating people, processes, business systems, and information throughout product lifecycle and across extended enterprise. It aims to derive the advantages of horizontally connecting functional silos in organizations, enhancing information sharing, efficient change management, use of past knowledge, and so on [43.2]. To meet this end, a PLM system should be able to monitor the progress of a product at any stage in its lifecycle, to analyze issues that might arise at any product lifecycle phase, to make suitable decisions to address problems, and to execute and enforce these decisions. In spite of its vision, PLM as defined above has not received much attention so far from industry because there are no efficient tools to gather product data over the entire product lifecycle. However, recent applications of product identification technologies in various PLM aspects [43.3–9] demonstrate that a sound technological framework is now available for PLM to implement its vision. Product identification technologies enable products to have embedded information devices (e.g., RFID tags and onboard computers), which makes it possible to gather the whole lifecycle data of products at any time and at any place. A new generation of PLM systems based on product identification technologies will make the whole product lifecycle totally visible and will allow all actors involved in the product lifecycle to access, manage, and control product-related information, especially information after product delivery to customers and up to its final destiny, without temporal or spatial constraints. During the whole product lifecycle, we can now have visibility of not only forward but also backward information flow; for example, beginning of life (BOL) information related to product design and production can be used to streamline operations of middle of life (MOL) and end of life (EOL). Furthermore, MOL and EOL information can also go back to designers and production engineers for the improvement of BOL decisions. This indicates that information flow is horizontally closed over the whole product lifecycle. In addition, based on data gathered by product embedded information devices (PEID), we can analyze product-related information and take some decisions on the behavior of products, which will affect data gathering again [43.10]. This means that information flow is also vertically closed. We call this concept and relevant systems the *closed-loop PLM*. The concept of closed-loop PLM can be defined as follows: *a strategic business approach for the effective management of product lifecycle activities by using product data/information/knowledge which can compensate PLM to realize product lifecycle optimization dynamically in closed loops with the support of PEIDs and product data and knowledge management (PDKM) system.*

The objective of closed-loop PLM is to optimize the performance of product lifecycle operations over the whole product lifecycle, based on seamless product information flow through a local wireless network of PEIDs and associated devices and through remote Internet connection [43.11] to knowledge repositories in PDKM. In addition to PEIDs, sensors can be built in products and linked to PEIDs for gathering status data [43.12]. During product lifecycle, each lifecycle actor can have access to PEIDs locally with PEID controllers (e.g., RFID readers) or to a remote PLM system for getting necessary information. Furthermore, in closed-loop PLM, decision support systems (DSS) integrated to PDKM systems may provide lifecycle actors with suitable advice or decision support at any time.

In the closed-loop PLM, all business activities performed along the product lifecycle must be coordinated and efficiently managed. Although there are a lot of information flows and interorganizational workflows, the business operations in closed-loop PLM are based on the interactions among three organizations: the *PLM agent*, *PLM system*, and *product*. The PLM agent can gather product lifecycle information quickly from each product with a mobile device such as a personal digital assistant (PDA) or a fixed reader with built-in antenna. He sends information gathered at each site (e.g., retail sites, distribution sites, and disposal plants) to a PLM system, as illustrated in Fig. 43.1.

A PLM system provides lifecycle information or knowledge generated by PLM agents through product lifecycle activities realized through the three main product lifecycle phases: BOL, MOL, and EOL.

BOL is the phase where the product concept is generated and subsequently physically realized. In the closed-loop PLM, designers and production engineers will receive feedback about detailed product information from distributors, maintenance/service engineers, customers or remanufacturers on product status, product usage, product service, conditions of retirement, and disposal of their products. The feedback information is extremely valuable for product design and production because designers and production engineers are able to exploit expertise and knowhow of other actors in the product lifecycle. Hence, closed-loop PLM can improve the quality of product design and the efficiency of production.

MOL is the phase where products are distributed, used, maintained, and serviced by customers or engineers. In the closed-loop PLM, a PEID can log the product history related to distributing routes, usage conditions, failure, maintenance or service events, and

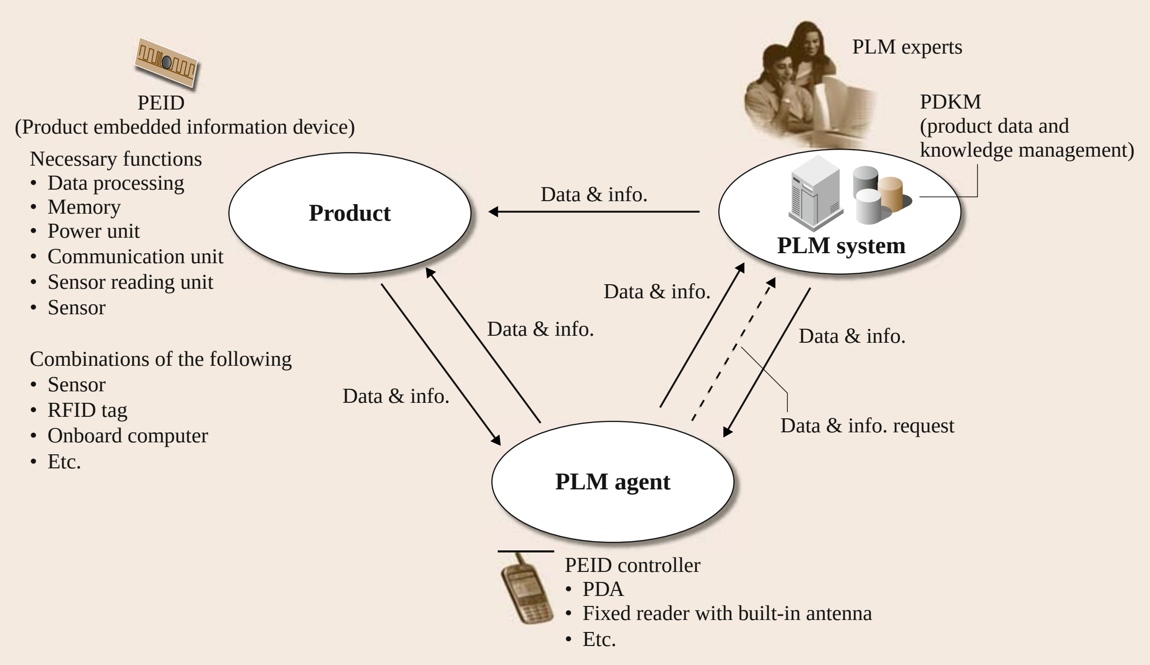

Fig. 43.1 Basic framework for PEID applications in PLM

so on. This information is later gathered into a PLM system for analysis and sharing. Thus, during MOL, an up-to-date report about the status of products and real-time assistance can be obtained from this system through the Internet or wireless mobile technology. Based on these feedbacks, predictive maintenance can be done by maintenance engineers [43.13]. Furthermore, optimizing logistics operations for maintenance and service can be facilitated.

EOL is the phase where EOL products are collected, disassembled, refurbished, recycled, reassembled, reused or disposed. It can be said that EOL starts from the time when the product no longer satisfies an initial purchaser [43.14]. In the closed-loop PLM, the use of PEIDs can greatly increase the effectiveness of EOL management; for example, material recycling can be significantly improved because recyclers and reusers can obtain accurate information about *valuable parts and materials* arriving via EOL routes: what materials they contain, who manufactured them, and other knowledge that facilitates material reuse [43.15].

43.2 The Components of a Closed-Loop PLM System

The components of a closed-loop PLM system and their relations are presented in the five layers of the system architecture schema shown in Fig. 43.2 [43.16].

These layers are mainly classified into business process, software, and hardware. PEID is an important hardware component for facilitating the closed-loop PLM concept. Furthermore, software related to applications and middleware layers, and their interfaces play important roles in closed-loop PLM. Following are some more details about the components of whole closed-loop PLM system: PEID, middleware, DSS, and PDKM.

43.2.1 Product Embedded Information Device (PEID)

PEID stands for *product embedded information device*. It is defined as a device embedded in (or attached to) a product, which contains information about the product [e.g., product identity (ID), and which is able to

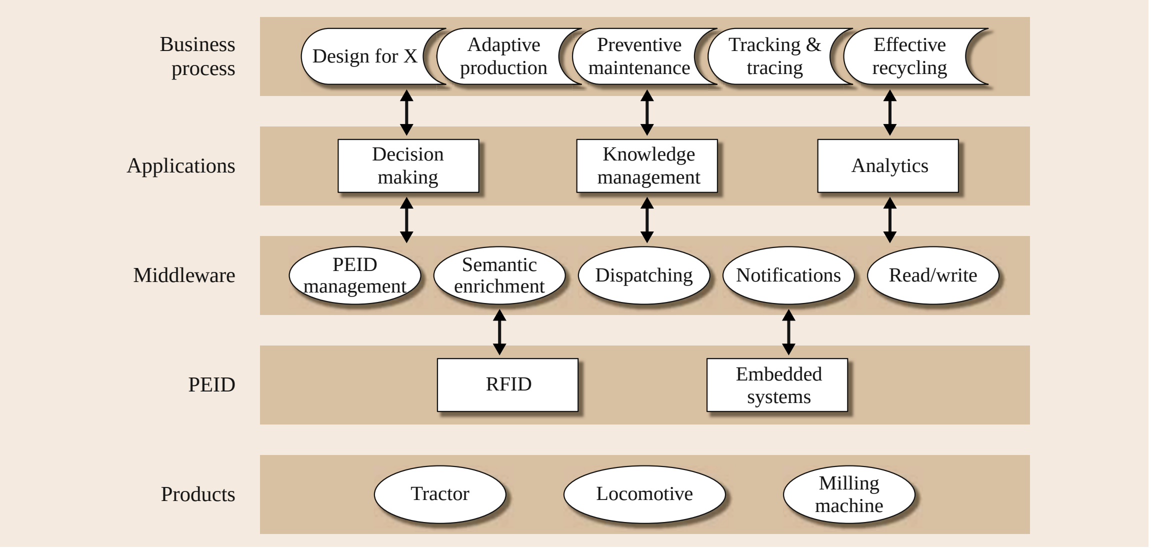

Fig. 43.2 Overall system architecture for closed-loop PLM

provide the information whenever requested by external systems during the product lifecycle. There are various kinds of information devices built in products to gather and manage product information, for example, various types of RFID tags and onboard computers. A PEID has a unique ID and provides data gathering, processing, and data-storage functions. Power management of a PEID is important to allow it to provide its functionality along the product lifecycle. Particular attention is obviously paid to the data gathering function. Over the last decade, a lot of sensor technologies have been developed to gather environmental status data of products related to mechanical, thermal, electrical, magnetic, radiant, and chemical data [43.12, 17]. These sensor technologies can be incorporated into the PEID to gather the history of product status with the data gathering function. Eventually, these functions enable a PEID to gather data from several sensors, to retain or

store them, and if necessary to analyze them or support associated decision making. In addition, it should have a communication function with external environments for exchanging data. For this, a PEID should have a processing unit, communication unit, sensor reader, data processor, and memory. Depending on the combinations of these functions, the PEID has several types such as passive RFID tag, active RFID tag, and onboard computer. In particular the manufacturing cost of the PEID is greatly affected by power management and data function specification. Hence, the PEID should be carefully designed considering application characteristics. The overall architecture of PEID is depicted in Fig. 43.3.

43.2.2 Middleware

Middleware can be considered as intermediate software between different applications. Developing middleware is one of the most challenging areas in the closed-loop PLM since it is the core technology to efficiently gather and distribute PEID data. It plays a role as the interface between different software layers, e.g., between PEIDs and PDKM, as shown in Fig. 43.4. It is used to support complex and distributed applications, e.g., applications between RFID tags and business information systems, to communicate, coordinate, and manage data by converting the data in a proper way. In the closed-loop PLM, it has a role to map the low-level data gathered from PEID readers to more meaningful data of other high-level application such as field DB/PDKM and PLM business applications. There are several issues to be resolved: data security, consistency, synchronization of data, tracking and tracing, exception handling, and so on. Figure 43.4 shows the overall architecture of the middleware developed in the PROMISE (product lifecycle management and information tracking using smart embedded systems) project (www.promise-plm.com).

43.2.3 Decision Support System (DSS)

Decision support system (DSS) software provides lifecycle actors with the ability to transform gathered data into necessary information and knowledge for specific applications. To this end, diagnosis/analysis tools for gathered data and data transformer are required. There are a lot of decision support areas which are highlighted in the closed-loop PLM, mainly transforming lifecycle information of other lifecycle phases into streamlining current lifecycle operations; for example, main areas in decision support for MOL include assisting efficient maintenance diagnosis and prognosis, whereas in EOL this includes efficient waste management. Figure 43.5 shows the overall architecture of the middleware developed in the PROMISE project (see also Chap. 87 on *Decision Support Systems*).

43.2.4 Product Knowledge and Management System (PDKM)

The PDKM manages information and knowledge generated during the product lifecycle. It is generally linked with decision support systems and data transformation software. PDKM is a process and the associated technology to acquire, store, share, and secure understandings, insights, and core distinctions. PDKM should link not only product design and development such

43.3 A Development Guide for Your Closed-Loop PLM Solution

In this section we describe the main elements of the development of a closed-loop PLM solution: modeling, selection of PEID system, data and data flow definition, PDKM, DSS and middleware.

43.3.1 Modeling

PLM has specific objectives at each phase of the lifecycle: BOL, MOL or EOL; for example, at BOL, improving product design and production quality are main concerns. During MOL, improving reliability, availability, and maintainability of products are the most interesting issues. In EOL, optimizing EOL product recovery operations is one of the most challenging issues.

It is advisable to begin the development of a closed-loop PLM solution by modeling the various characteristics of the solutions we want to develop. If, for example, we consider the EOL phase of a product, a use-case diagram such as the one shown in Fig. 43.7 below will help to identify the main actors and activities of the solution. This model shows how a PLM system,

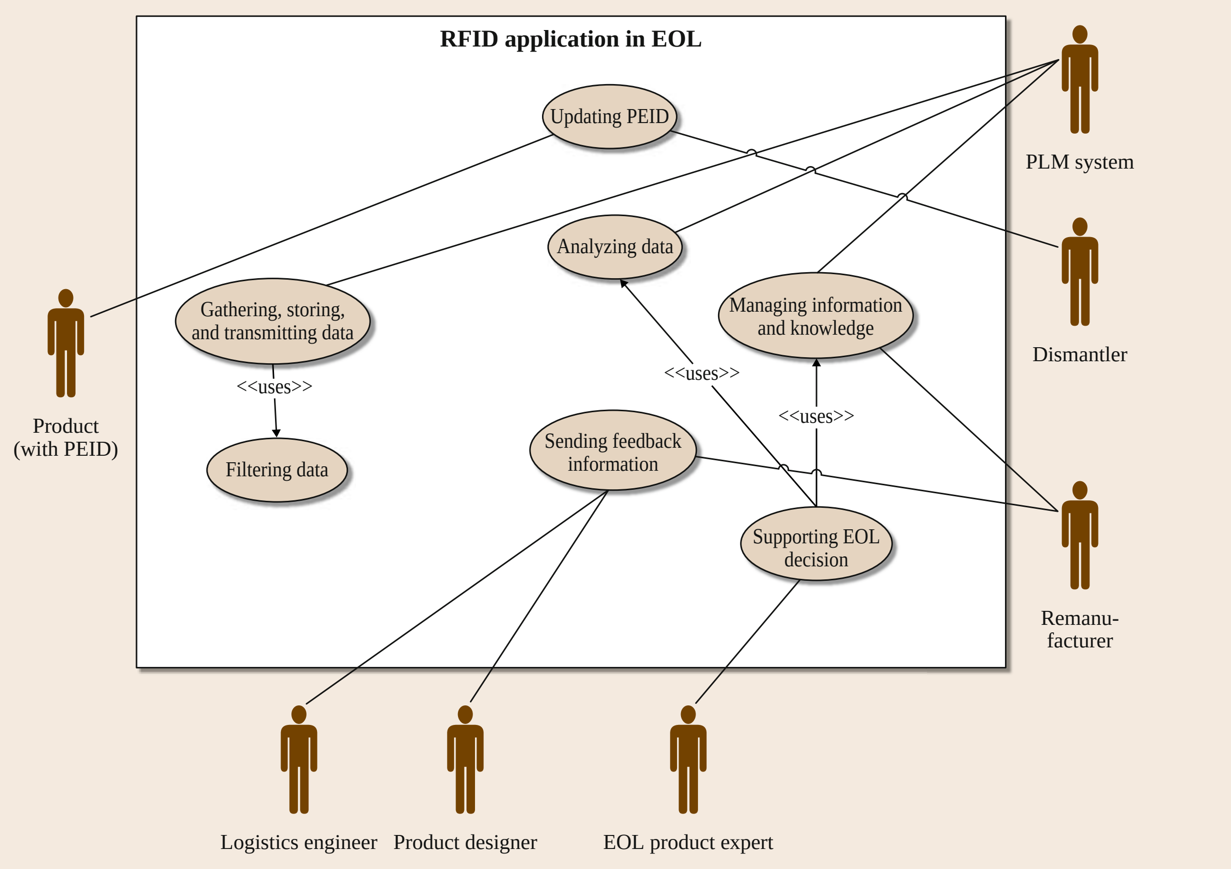

Fig. 43.7 Use case for PEID application at EOL

using PEID technology, can gather accurate data related to product lifecycle history at the collecting and dismantling phase of EOL products, e.g., which components they consist of, what materials they contain, who manufactured them, and other data that facilitate reuse of materials, components, and parts. Based on gathered data, EOL product experts in the PLM system can predict degradation status and remaining lifetime of parts or components. With this information, at the inspection phase, the dismantler can implement *EOL product recovery optimization*, in other words, deciding on suitable EOL recovery options such as recycle, reuse, remanufacturing, and disposal, with the objective of maximizing values of EOL products considering product status. This decision also provides useful information to remanufacturers for making an efficient remanufacturing plan in advance. Furthermore, logistics engineers can improve logistics at EOL (*reverse logistics*) from collecting to remanufacturing, reuse or disposal. They can obtain supply volume data for recycle, reuse, remanufacturing, and disposal products in advance from the EOL decision. In addition, EOL product recovery decision data and product status at EOL dismantling can give useful information to product designers for improving product design with several purposes, e.g., design for reliability, reuse, recycle, and so on.

The next step of modeling concerns the process and events of the solution. This is well achieved with a swim-lane chart. Figure 43.8 below shows the swim-lane chart of closed-loop application at EOL, mainly focusing on EOL product recovery optimization.

In this application, at first, the EOL collector gathers products that have lost their values. Then, the EOL dismantler inspects collected products visually. As a result, products can be simply classified into two parts: disposal, and disassembly for more detailed inspections. In disassembly, the concerned components or parts will be inspected in detail and sorted into several EOL options based on some criteria. During the inspection and sorting process, if necessary, the dismantler accesses PEIDs of the parts or components concerned to gather necessary data for inspecting and sorting the EOL products. To sort EOL products in a systematic way, the EOL dismantler asks for EOL decision support from the PLM system. EOL product experts in the PLM system estimate the remaining value of the parts or components concerned, based on accumulated data, information, and knowledge at PDKM in the PLM. Based on the estimated remaining values and other information such as costs and benefits of recycle, reuse, remanufacture, disposal, and so on, EOL product experts decide on an adequate EOL option for each part or component, i. e., which parts or components should be recycled, reused, remanufactured or disposed, under some constraints related to environmental regulation and product quality. This information will be stored in the PDKM and transmitted to dismantlers. If necessary, product designer and logistics engineer receive this information from the PLM system to improve their operations.

Based on the proposed EOL decision, dismantlers sort the parts or components. When the EOL dismantler sorts products, depending on the sorting results of EOL products, operations related to PEIDs may be different. They may be removed and replaced with new ones; or its data contents can be reset or updated without replacement for the second life of parts or components; for example, in the recycle case, PEIDs will usually be detached from products. Then, recyclable products will be sent to specific lots that have similar materials features. For each lot, a new PEID will be used for its management. Each lot will be sent to recycling companies. In the reuse case, after quality data of parts or components are updated to an existing PEID, products will be sent to a remanufacturing site or second market. In the remanufacturing case, after required information for remanufacturing such as current quality data, required quality data, product specification, and production instruction are updated, products will be sent to remanufacturing sites. In the case of disposal, after updating disposal-relevant data to each PEID and PLM system by disposal engineers, products are sent to disposal companies.

43.3.2 Selection of PEID System

Table 43.1 shows the basic functions and their corresponding components of a PEID with its specifications. Here, PEIDs can be classified into four types by their functions and specifications.

Type A is for simple applications. It contains only its own identification function. For this, it has a small-sized read-only microchip that includes its own ID, configuration parameters, and simple logics programmed for a specific application. A 1 bit transponder or simple passive RFID tag is included in this type. It does not need any power to transmit data to a PEID controller. It can be detected by a PEID controller automatically when it goes into the interrogation zone. Hence, it does not need any battery. When lifecycle actors just want to read a small amount of product identification data without

Our classification Category	Type A (1 bit transponder)	Type B (passive or semi-passive type with memory)	Type C (active type with memory and sensor)	Type D (device for smart product)
Function (corresponding component)				
Product identification (simple serial number in built-in chip)	●	●	●	●
Sensing (sensor)	–	–	●	●
Data processing (microprocessor)	–	○	○	●
Data storage (memory)	–	●	●	●
Power management (battery)	–	○	●	●
Communication (communication module)	–	–	–	●
Specification				
Memory type (RO[a], WORM[b], RW[c])	RO	WORM, RW	RW	RW
Reading distance (L[d], M[e], H[f])	L, M	M	M, H	M, H
Data rate (L, M, H)	L	L, M	M, H	M, H
Processing ability (L, M, H)	–	L	L, M	M, H
Frequency of operation (LF, HF, UHF)	LF, HF	LF, HF	HF, UHF	HF, UHF
Application level				
	Component/ item level	Component/ item or lot level	Assembly level or lot level	Product level

[a] Read only, [b] Write once and read many, [c] Read/write, [d] up to 1 cm, [e] Up to 1 m, [f] Over 1 m (L = low, M = medium, H = high)

storing additional data to a product itself during product lifecycle, this type of PEID is suitable.

Compared with type A, type B has additionally storage capability. Hence, it enables storage of necessary data in a product itself during its lifecycle. In other words, a PEID controller can update new data or information to this type of PEID, if necessary. This requires a read/write type of memory. Depending on applications, some may need processing ability to filter gathered data. Furthermore, some may need a battery because data storage requires a large amount of power. To keep not only static but also dynamic data about products (but a small amount, such as product history data within a product itself) this type is preferable. A semipassive or active tag can be used for this type of application. This type can be used in production lines or warehouses, or in supply chains for item management applications, e.g., checking item status, classifying items, tracing item history, and so on.

Type C has sensing and power management functions to gather environmental data of a product, in addition to the specifications of type B. Sensors can be installed into a RFID tag or separately, independent of a RFID tag. It should have its own battery since sensors require a large amount of power. It may also have a communication module, depending on the application. Through the communication module, it is able to transmit gathered data from sensors to back-end systems by itself. Its size is larger and its reading distance is longer than those of the previously described types. Predictive maintenance domain is a major application of this type of device. Depending on the types of sensors used, the application areas are huge, from food to machinery products.

Type D is the most complex PEID, which has additionally communication and processing ability. It can keep some amount of product status data gathered from sensors in its own memory. Furthermore, it can analyze gathered data and make some decisional processes based on them autonomously. This reduces the amount of data to be handled by the back-end systems. In addition, it can communicate with a PLM system directly without the help of PLM agents.

43.3.3 Data and Data Flow Definition

Table 43.2 describes the main data in several information flows in PLM.

Table 43.2 Main data of information flows in PLM

Information flow	Category	Main data
BOL to MOL	BOM information	Product ID, product structure, part ID, component ID product/part/component design specification, etc.
	Information for maintenance/ service	Spare part ID list, price of spare part, maintenance/service instructions, etc.
	Production information	Assemble/disassemble instruction, production specifications production history data, production routing data, production plan, inventory status, etc.
BOL to EOL	Product information	Material information, BOM, part/component cost, disassemble instruction, assembly information for remanufacturing, etc.
	Production information	Production date, lot ID, production location, etc.
MOL to EOL	Maintenance history information	Number of breakdowns, parts/components' IDs in problem, installed date, maintenance engineers' IDs, list of replaced parts, aging statistics after substitution, maintenance cost, etc.
	Product status information	Degree of quality of each component, performance definition, etc.
	Usage environment information	Usage condition (e.g., average humidity, internal/external temperature), user mission profile, usage time, etc.
	Updated BOM	Updated BOM by repairing or changing parts and components, etc.
MOL to BOL	Maintenance and failure information for design improvement	Ease of maintenance/service, reliability problems, maintenance date, frequency of maintenance, MTBF[1], MTTR[2], failure rate, critical component list, root causes, etc.
	Technical customer support information	Customer complaints, customer profiles, response, etc.
	Usage environment information	Usage condition (e.g., average humidity, internal/external temperature), user mission profile, usage time, etc.
EOL to MOL	Recycling/reusing part or component information	Reuse part or component, remanufacturing information, quality of remanufacturing part or component, etc.
EOL to BOL	EOL product status information	Product/part/component lifetime, recycling/reuse rate of each component or part, etc.
	Dismantling information	Ease to disassemble, reuse or recycling value, disassembly cost, remanufacturing cost, disposal cost, etc.
	Environmental effects information	Material recycle rate, environmental hazard information, etc.

[1] Mean time between failures, [2] Mean time to repair

43.3.4 PDKM, DSS and Middleware

PLM has emerged as an enterprise solution. Thus, all software tools/systems/databases used by various departments and suppliers throughout the whole product lifecycle have to be integrated so that the information contained in their systems can be shared promptly and correctly between people and applications [43.2]. Hence, it is important to understand how application software in a PLM fits with others

Table 43.3 Functions and specifications of main software components

Classification	Middleware	PDKM	DSS
Function	● Request-driven reading ● Event-driven reading ● Filter data ● Data transformation ● Write ● PEID management ● Service management ● Data transition	● Document management ● Field data management ● User requirement management ● Data transformation ● Communication requirement management ● Information requirement management	● Making decision ● Decision support ● Data analysis and transformation

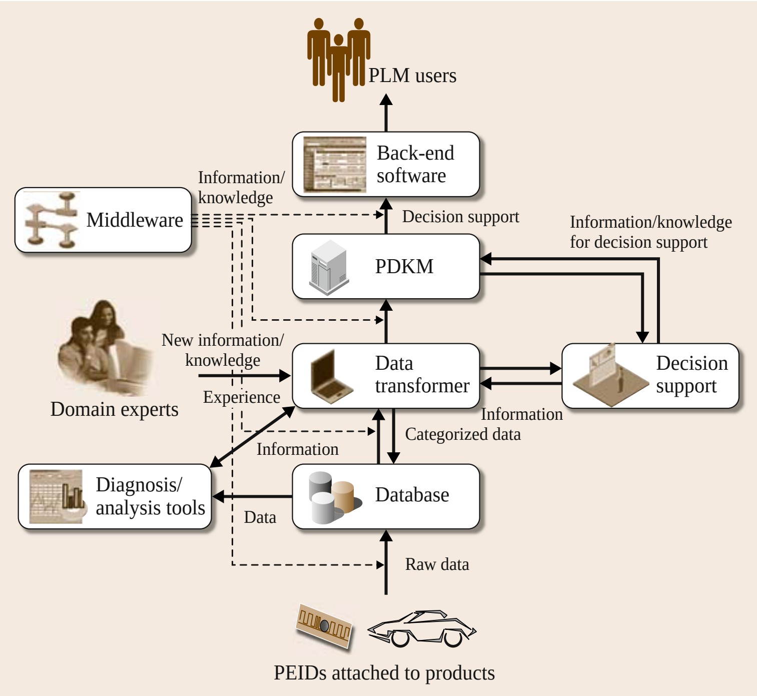

Fig. 43.9 Software architecture for closed-loop PLM

in order to manage product information and operations [43.18]. For this, a software architecture is required. Software architecture is the high-level structure of a software system concerned with how to design software components and make them work together.

Figure 43.9 shows a software architecture for closed-loop PLM. It takes a vertical approach in the sense that its structure represents a hierarchy of software of closed-loop PLM, from gathering raw data to business applications. Embedded software (called firmware) built into PEIDs plays the role of controlling and managing PEID data. The embedded software can have the ability to filter raw data gathered by various sensors, if necessary (this function can also be done in middleware). This can resolve the problem of memory size in PEIDs by removing duplicate and unnecessary data. Furthermore, firmware can do simple analyses based on the gathered data, or this function can also be implemented in other parts such as middleware, diagnosis, and analysis tools, and PDKM.

Database (DB) software is required to store processed data and manage them efficiently. A DB can be distributed or located on a central server. Regarding the format of the database, relational and object-oriented databases have been considered in the relevant research community. The configuration of the DB should be determined considering a trade-off between cost and efficiency of data management, which is different for each case.

PDKM, decision support, and middleware software components must be designed and implemented according to their description in Sect. 43.2.

Finally, back-end software can be defined as the part of a software system that processes the input from the front-end system that interacts with the user. These usually involve legacy systems of an enterprise, e.g., enterprise resource planning (ERP), supply chain management (SCM), and customer relationship management (CRM). The back-end software will support PLM users in implementing several business processes (see Chap. 90 on *Business Process Automation: CRM, SM and ERP*).

Table 43.3 presents the functions and specifications of the main software components such as middleware, PDKM, and DSS.

43.4 Closed-Loop PLM Application

The domain of application presented here is the end-of-life (EOL) phase of the product lifecycle. It specifically deals with the take back of end-of-life vehicles (ELVs) by dismantlers so that they can be reprocessed: this strategy allows for both the feedback of vital information (design information, usage statistics on components, etc.), and the materials/components themselves to the beginning-of-life (BOL) stage of the product lifecycle; as well as the take back of selected components into the middle-of-life (MOL) phase of the product lifecycle as secondhand parts.

This industrial application was developed and implemented by the Research Center of Fiat (CRF) and its partners in PROMISE, and is reported in detail in [43.19] and in the case study description A1 in [43.20]. It focuses specifically on the dismantler and the operations performed to achieve the correct removal decision [i. e., removal for reuse (BOL or MOL), removal for remanufacturing (BOL), disposal, etc.]; and the correct categorization and analysis of various environmental usage statistics associated with specific components from the ELV.

The dismantler decides on the ELV's recycling/recovery path and converts the ELV into components for reuse, remanufacturing or recycling. The dismantler's role is critical for returning ELV components and information from EOL to BOL. He retrieves from external databases the list of standard components to be removed from the car and checks if the components in the onboard diary are included in the standard list. At the same time he retrieves models (algorithms and costs) and thresholds from PDKM in order to compute wear-out level for each component and analyze the economic value of parts.

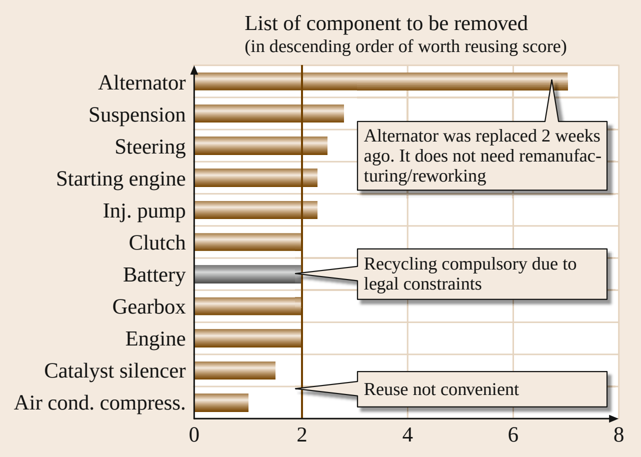

Fig. 43.10 List of EOL components of a car

In particular he decides which parts should be removed from the vehicle, how to recover (reuse or remanufacture) the removed parts, to which customers the parts should be delivered, and where to store the parts.

In the first stage, the system generates a bill of materials (BOM) of the car automatically based on the car model or identity number inputted in the background database; this BOM is used as the basis for developing a list of potentially valuable parts to remove, which also takes into account the requirements of legislation.

Using the dealer back-end system, the list of components to be removed from the car is computed. An example is shown in Fig. 43.10.

43.4.1 ELV Information and PEID Technology

In order to make these decisions properly and accurately, large amounts of information are required by the ELV dismantlers, which may be classified into six categories:

(1) Product-related information
(2) Location-related information
(3) Utilization-related information
(4) Legislative information
(5) Market information
(6) Process information

Generally the information in categories (1), (4), and (6) above is relatively easy to acquire, because the product-related information is usually obtained from the automotive producers and from other relatively static legislative bodies. However, current information systems cannot give more detailed specifications, such as usage statistics and the environmental conditions under which the ELV was used; this information can only be obtained from the ELV itself, a situation which, until recently, was only deemed to be resolvable by an experienced dismantler that could use their subjective judgement to make decisions about the present ELV based upon their knowledge of past ELVs. Naturally, this was seen as an unsatisfactory situation: the relevant knowledge required was subjective and qualitative, and, more important, linked to the personality of the dismantler. It was difficult to write down or communicate in numeric terms, and so was deemed difficult to regulate properly.

PEID technology, used as an enabler of PLM, can help to remove many of the unsatisfactory elements of the dismantling problem. By exploiting the capabilities of PEIDs, sensors embedded in particular vehicle components can collect and record relevant information about the vehicle's lifecycle, including production, usage, maintenance, and dismantling data. The dismantlers only need to read the data from the ELVs' PEID system, and can thereby obtain all the required location- and utilization-related information.

Thus, the solution suggested here removes the qualitative, subjective elements of the dismantling problem by emphasizing the use of a PEID technology infrastructure that cumulatively develops an information store of usage statistics as the ELV moves through its product lifecycle. More importantly, the use of PEIDs allows developers to remove the decision making at EOL from the experienced dismantler's hands, and allows an EOL-dedicated DSS to be developed based upon numeric usage statistics from the PEIDs in the ELV.

43.4.2 Decision Flow

The decision support for ELVs consists of two web-based process stages (Fig. 43.11). In the first stage, (1) remove decision, the system automatically generates a bill of materials (BOM) of the car based on the car model or identity number inputted and the background database; this BOM is used as the basis for developing a list of potentially valuable parts to remove, which also takes into account the requirements of legislation [that is, if there are hazardous parts, such as batteries, that must be removed by European Union (EU) law, whether valuable or not]. Once this list of parts to be removed has been generated, the user moves into the second part of the web interface: (2) recovery path, to determine what on the projected list of car parts should actually be removed and what should not be removed owing to actual damage, abnormal wear and tear or other factors that reduce the parts' value.

There are two key removal decisions involved at this point for each part in the ELV under consideration:

(1) Remove part from the vehicle for further treatment or
(2) Leave part on the vehicle to be shredded

If a part is (1) removed, it is because it is worth it: the quality of the part, the cost of labor to remove, the market conditions, and the present stock levels are assessed; if the part passes all of these thresholds then it is removed. If a part is (2) left on the ELV, it is because it is not worth removing: the value of the part does not cover its quality, the cost to remove, or the market may

Calculate customer's decision

Fig. 43.11 A schematic view of DSS for ELVs

be unfavorable or the dismantler overstocked; the part is left on the ELV to be shredded as base material for recycling.

In the second stage, (2) recovery path in Fig. 43.11, the system assumes the recovery of a number of parts from the first stage and focuses on the *recovery path* required for these removed components. The two main recovery paths that any component can now take are: remanufacturing (i. e., retooling of a part to original quality levels; normally performed at the BOL phase) or reuse (i. e., use of the part in the secondary market; the part flow path is to the MOL if this is the case). Using the information derived from the PEIDs located on the recovered parts, the DSS can direct the user to the optimal recovery path for each of the removed parts; this is performed by a set of algorithms that use the usage statistics on the PEIDs of the recovered parts to determine the correct recovery path for each component (the particular algorithms are not detailed as they are beyond the scope of this paper). Once the recovery method is issued, the system will cooperate with its back-end system to suggest a potential downstream customer and potential storage position for the component. Again, at each decision-making stage, the decision-maker has the authority to change the decision based on their judgement. When all of the decisions relating to the ELV are settled, the system records all the necessary information to the PDKM system, which is available to the BOL designers of the vehicle in question for examination.

43.5 Emerging Trends and Open Challenges

Total management of the product lifecycle is critical to innovatively meet customer needs throughout its entire lifecycle without driving up costs, sacrificing quality or delaying product delivery. For this, it is necessary to develop a PLM system in which information flow is horizontally and vertically closed, i. e., closed-loop PLM. The closed-loop PLM system provides opportunities to reduce the inefficiency of lifecycle operations and gain competitiveness.

In this chapter, we have also discussed a system architecture for product lifecycle management where information flows are closed due to emerging product identification technology over the whole product lifecycle (closed-loop PLM). To gather product lifecycle data during all product lifecycle phases, the concept and architecture of PEID has been introduced. Furthermore, necessary software components and their relations have been addressed.

The following is a list of issues to be resolved for implementing the closed-loop PLM concept:

- In the business model aspect, it is necessary to develop a good business model to apply the concept of closed-loop PLM for optimizing the profit of a company. For this, trade-off analysis for cost and effect are prerequisite. Depending on each case, partial implementation of closed-loop PLM may be cost-effective.
- Regarding the PEID, it is necessary to develop a generic concept of a PEID that can be used over the whole product lifecycle. For this, however, first, the lifecycle of the PEID, including reuse, should be modeled. Based on this design, suitable PEIDs should be designed, because the great bottleneck to deployment of PEID into business applications is their cost.
- In terms of middleware, it is a prerequisite to develop a method for managing and controlling enormous amounts of PEID event data. Methods for filtering huge amounts of event data and transforming them into meaningful information should be developed. Furthermore, PEID security and authority problems should be resolved.
- In terms of PDKM, it is a prerequisite to design the product lifecycle data schema for integrating all relevant data objects required in lifecycle operations.

Finally, the case studies developed so far in the PROMISE project show that the proposed concept can yield great benefit to product lifecycle optimization efforts.

44. Education and Qualification for Control and Automation

Bozenna Pasik-Duncan, Matthew Verleger

Engineering education has seen an explosion of interest in recent years, fueled simultaneously by reports from both industry and academia. Automatic control education has recently become a core issue for the international control community. This has occurred in tandem with the explosion of interest in engineering education as a whole. The applications of control are growing rapidly. There is an increasing interest in control from researchers from outside of traditionally control-based fields such as aeronautics, chemical, mechanical, and electrical engineering. Recently control and systems theory have had much to offer to nontraditional control fields such as biology, biomedicine, finance, actuarial science, and the social sciences as well as transportation and telecommunications networks. Complementary, innovative developments of control and systems theory have been motivated and inspired by complex real-world problems. These new developments present huge challenges in control education. Meeting these challenges will require a multifaceted approach by the control community that includes new approaches to teaching, new preparations for facing new theoretical control and systems theory problems, and a critical review of the status quo. This chapter discusses these new challenges as well as new approaches to education and outreach. This chapter starts by presenting an argument towards the future of controls as the application of control theory expands into new and unique disciplines. It provides two case studies of nontraditional areas where control theory has been applied: finance and biomedicine. These two case studies show a high potential for using powerful fundamental principles and tools of automatic control in research with an interdisciplinary nature. The chapter then outlines current and future pedagogical approaches being employed in control education, particularly introductory courses, around the world. It concludes with a discussion about the role of scholarship, teaching, and learning in control education both now and in the coming years.

44.1 The Importance of Automatic Control in the 21st Century

The field of automatic control has a rich history (Fig. 44.1), well presented in a special issue of the *European Journal of Control* [44.1]. *Fleming* [44.2] provides an assessment of its status and needs of control theory through the 1980s. A broader and more updated report is provided in [44.3–5].

At its core, control systems engineering involves a variety of tasks including modeling, identification, estimation, simulation, planning, decision making, optimization, and deterministic and stochastic adaptation. While the overarching purpose of any control system is to assist with the automation of an event, the successful application of control principles involves the integration of various tools from related disciplines such as signal processing, filtering, stochastic analysis, electronics, communication, software, algorithms, real-time computing, sensors and actuators, as well as application-specific knowledge.

The applications of control automation range from transportation, telecommunications networks, manufacturing, communications, aerospace, process industries through commercial products reaching as diverse fields of study as biology [44.6], medicine [44.7–10], and finance [44.11, 12]. New issues are already appearing in the next generation of transportation [44.13] and telecommunications network [44.14] problems, as well as in the next generation of sensor networks (particularly for applications such as weather prediction), emergency response systems, and medical devices. These are new challenges that can be solved through the careful application of control and systems theory. The impact of systems and control in the changing world is described in the 2007 Chinese Control Conference (CCC) plenary talk *Systems and Control Impact in a Changing World* delivered by Ted Djaferis, the 2007 President of the Control Systems Society [44.15]. A more thorough description of control theory for automation can be found in Chaps. 9–11.

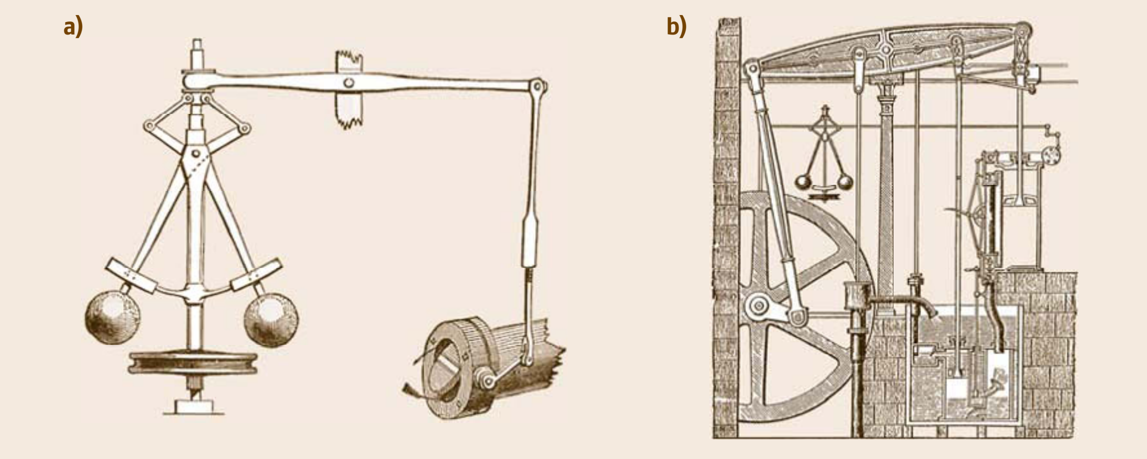

Fig. 44.1a,b The centrifugal governor **(a)** is widely considered to be the first practical control system, dating back to the 1780s. It was used in the Boulton and Watt steam engine **(b)** to regulate the amount of steam allowed into the cylinders to maintain a constant engine speed

44.2 New Challenges for Education

Marketplace pressures and advances in technology are driving a need in modern industry for well-trained control and systems scientists. With its cross-boundary nature and ever-growing application base, helping students in all disciplines of science, technology, engineering, and mathematics (STEM) to understand the power and complexity of control systems is becoming an even more critical component to the future of technical education. The need to train all STEM graduates to be comfortable with control theory generates many new challenges in control education which are extensively discussed in [44.16] as well as in the report of the National Science Foundation (NSF) and the Control Systems Society (CSS) panel on an assessment of the field [44.4] with its summary given in [44.5].

While the skills necessary for students to become successful practitioners of their craft are changing, so too is the background of our students. They are better prepared to work with modern computing technologies. The ability to interact with and manipulate a computer is second nature to today's *connected* student [44.18]. Thus the time is ripe for major renovations in control education as it applies to STEM disciplines. The first step in the renovation process is to develop cross-disciplinary examples, demonstrations, and laboratory exercises that illustrate systems and control across the entire spectrum of STEM education [44.3–5, 19].

The recent National Academy of Engineering (NAE) report [44.17] *identified the attributes and abilities engineers will need to perform well in a world driven by rapid technological advancements, national security needs, aging infrastructure in developed countries (*Table 44.1*), environmental challenges brought about by population growth and diminishing resources, and creation of new disciplines at the interfaces between engineering and science*. The systems and control community has been actively involved and engaged in taking a leading role in shaping the future automatic control engineering curriculum [44.20], as well as in educating and making nonengineering communities aware of the benefits and the power of the systems and control approaches and tools.

Table 44.1 America's infrastructure is in dire need of repair: just one of the many problems today's engineering students will be facing as they enter the workforce (after [44.17])

44.3 Interdisciplinary Nature of Stochastic Control

Stochastic adaptive control, whereby the unknown parameters of a control system are modeled as random variable or random processes [44.21, 22], can be used to illustrate the interdisciplinary nature of control. The general approach to adaptive control (Fig. 44.2) involves a splitting, or separation, of parameter identification and adaptive control. A system's behavior depends on some set of parameters, and the fact that the values of the parameters are unknown makes the system unknown. Some crucial information concerning the system is not available to the controller, and this information can be learned during the system's performance. Using that information, the system's performance can then be altered to respond. This altered response may in turn alter the previously unknown parameters. This process is repeated in a recursive manner until the system is shut down.

The described problem is the basic problem of adaptive control. A stochastic control system can be described using a stochastic differential equation or a stochastic partial differential equation. The solution to the adaptive control problem consists of showing the strong consistency of the family of estimators of an unknown parameter and the self-optimality of an adaptive control that uses the family of estimates. The disturbance, or noise, in the system is modeled by a Brownian motion or more generally by a fractional Brownian motion (more accurate for recent problems in telecommunication, finance or biomedicine) [44.11]. Industrial operation models are often described by stochastic controlled systems [44.23].

Let us describe a simple adaptive control using a simple investment model. Consider a model where an investor has a choice in investing in two assets, a simple

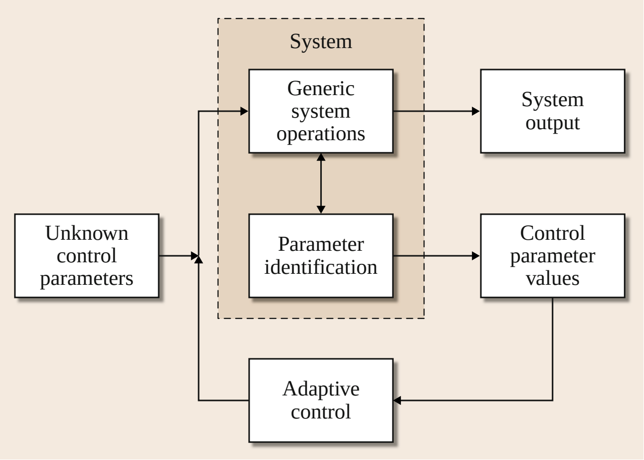

Fig. 44.2 The general structure of an adaptive control system is one where the critical input control parameters are outputs of the system. As the system operates over time, the parameters are adapted to control how the system functions in the future◀

savings account with a fixed rate of growth (say 3.5%) or shares of Microsoft stock whose growth is governed by a Brownian motion with unknown drift and variance. The investor controls his asset by transferring money between the stock and the savings account. The goal is, when the stock is expected to go down, to sell the stock and transfer the money to the savings account, but when the stock is expected to go up to repurchase the stock before it goes up. The control variable is the total amount of money transferred from the stock to the savings account and can be positive (stock has just been sold) or negative (stock is about to be purchased). The savings account is governed by a traditional differential equation and the stock is governed by a stochastic differential equation. The goal is to find the optimal control so that the expected rate of growth is maximized. The identification problem is to estimate the unknown parameters, the drift and variance of the stock's randomness, based on the available observations. The adaptive control problem is to construct the (certainty equivalence) adaptive control as a function of the current state and the current estimate of what is expected to happen.

44.4 New Applications of Systems and Control Theory

The use of systems and control theory has seen an expansion in recent years into new and emerging fields of study. This expansion functions as a control system in itself, with the unknown parameter being the number of STEM students receiving controls training. The expansion into new disciplines demonstrates the necessity of controls education for all students in STEM disciplines by showing that controls theory can be applied in a wide variety of unique places for producing solutions to some of today's most complex problems. This demonstration in turn acts as a driver for the curricular change necessary to result in more STEM students experiencing control education. As those students graduate, they too will push the boundaries of what control theory can be applied to and in turn feed the expansion cycle.

44.4.1 Financial Engineering and Financial Mathematics

Research in control methods in finance has experienced tremendous progress in recent years. The rapid progress has necessitated communication and networking between researchers in different disciplines. This area brings together researchers from mathematical sciences, finance, economics, and engineering. Together, these people work on advances and future directions of control methods in portfolio management, stochastic models of markets and pricing, and hedging of options. The finance area is highly interdisciplinary. This interdisciplinary nature comes from the necessity for a wide variety of skills and knowledge bases.

As a major impetus for the development of financial management and economics, the research in financial engineering has had a major impact on the global economy. For instance, the Black–Scholes model [44.24] and its various extensions for pricing of options [44.25] using stochastic calculus have become a standard practice nowadays and have led to a revolution in the financial industry. Incidentally, it also won Scholes and Merton the Nobel Prize for Economics in 1997 (Black had unfortunately passed away 2 years prior).

Powerful techniques of stochastic analysis and stochastic control have been brought to almost all aspects of finance and resulted in a number of important advances [44.12]. To name just a few, they include the studies of valuation of contingent claims in complete and incomplete markets, consumption–investment models with or without constraints, portfolio management for institutional investors such as pension funds and banks, and risk assessment and management using financial derivatives. At the same time, these applications require and stimulate many new and exciting theoretical discoveries within the systems and control field. Take for instance the study of arbitrage theory, risk assessment, and portfolio management, which have collectively led to new developments in martingale theory and stochastic control. Moreover, the development of financial engineering has created a large demand for graduates at both Master and Ph.D. levels in industry, resulting in the introduction of the curriculum in many universities including Kent State University, Princeton University, Columbia University, and the University of California at Berkeley.

Another contribution to the control community from financial engineering and financial mathematics was the identification and control of stochastic systems with noise modeled by a fractional Brownian motion [44.11], a process that can possess a long-range dependence. Motivated by the need for this type of process in telecommunications for models of Ethernet and asynchronous transfer mode (ATM) traffic, a new stochastic calculus for fractional Brownian motion was developed. This work in financial engineering and financial mathematics has since been successfully used in other fields such as telecommunications and medicine, in particular epilepsy analysis of brain waves [44.8, 9].

44.4.2 Biomedical Models: Epilepsy Model

Epilepsy is a condition where a person has unprovoked seizures at two or more separate times in her/his life. A seizure is an abnormal electrical discharge within the brain resulting in involuntary changes in movement, sensation, perception, behavior, and/or level of consciousness. It is estimated that 1% of the populations of industrialized countries have epilepsy whereas 5–10% of the populations of nonindustrialized countries have epilepsy. One link has been found between epilepsy and malnutrition [44.26]. In the USA the number of epilepsy cases is significantly larger than the number of cases of people who have Parkinson's disease, muscular dystrophy, multiple sclerosis, acquired immunodeficiency syndrome (AIDS) or Alzheimer's disease [44.10]. The organizers of the Third International Workshop on Seizure Prediction in Epilepsy held in Freiburg, Germany stated in the Welcome to the Workshop that:

> *The great interest of participants from all over the world and the high number of original contributions presented … instills confidence in us that seizure prediction is a promising field for the years to come.*

Epilepsy models, with their complexity, can serve as an example of interdisciplinary and multidisciplinary research for which systems and control approaches are showing considerable promise. The methods pioneered in the financial mathematics and engineering sector described above have been successfully used for detection and prediction of epileptic seizures. There is published evidence that the seizure periods of brain waves of some patients have long-range dependencies with nonseizure periods. Based on some initial work, it seems that the estimates of the Hurst parameter, which is a characterization of the long-range dependence in fractional Brownian motion, have a noticeable change prior to and during a seizure. Some of the algorithms [44.8] used in identifying the Hurst parameter use stochastic calculus for fractional Brownian motion that was developed within the financial engineering and financial mathematics sector. A new application for the Hurst parameter, real-time event detection, has recently been identified [44.9]. The high sensitivity to brain state changes, ability to operate in real time, and small computational requirements make Hurst parameter estimation well suited for implementation into miniature implantable devices for contingent delivery of antiseizure therapies.

This innovative interdisciplinary research has developed a new technology for future automated therapeutic intervention devices to lessen, abort or prevent seizures, opening the possibility of creating a brain pacemaker. The goal is, by eliminating the unpredictability of seizures, to minimize or prevent the disability caused by epilepsy and hardship it imposes on patients and their families and communities. It brings a hope to improve productivity and better quality life for those afflicted with epilepsy and their families as well as for care-givers and healthcare providers. The creation of a seizure warning device will minimize risks of injury, the degrading experience associated with having seizures in public, and the unpredictable disruption of normal daily-life activities.

Only collaborative work of engineers, computer scientists, physicists, physicians, biologists, and mathematicians can be successful in solving this type of complex problem. Based partly on the success thus far, there is a strong desire for a partnership with control engineers. The University of Kansas (KU) Stochastic Adaptive Control Group (SACG) has a long history of established collaboration in control education and research with the KU Medical Center Comprehensive Epilepsy Center and with Flint Hills Scientific, LLC (FHS). FHS has one of the largest recorded collections of long-term patient seizure data and it has used this data to develop real-time seizure prediction algorithms which have outperformed other prediction algorithms. Recently FHS has initiated electrical stimulation control with a seizure prediction algorithm to prevent the occurrence of seizures.

44.5 Pedagogical Approaches

The field of control is currently suffering from a fundamental design flaw. Because of a push from both those external to the control community (e.g., the NAE's *Engineer of 2020* reports) as well as those internal to the control community, control has become an essential component for STEM education. This has resulted in a flood of "current-state" papers describing methods and mechanisms that are currently being employed for teaching control.

The beauty of control as an area of study lies in its use of many different areas of mathematics: from functional analysis through stochastic processes, stochastic analysis, stochastic calculus of a fractional Brownian motion, stochastic partial differential equations, stochastic optimal control to methods of mathematical statistics, as well as current computational methods in stochastic differential and partial differential equations. The curse of control as an area of study lies in its use of many different areas of mathematics. Because of the broad spectrum of mathematical tools for approaching systems and control problems, it is not a subject that allows for practical understanding without some amount of deep coverage. Likewise, it is a topic that almost demands some hands-on experimentation, which can be both costly and time consuming. Several approaches are described for building adequate and appropriate control coursework into an already packed curriculum.

44.5.1 Coursework

A special pair of issues of the *Control Systems Magazine* on innovations in undergraduate education [44.28, 29] presents a variety of articles related to undergraduate controls and systems education broken down into six broad categories; Kindergarten-12th grade (K-12) education, course and curriculum development, experiment development, special projects, software and laboratory development, and lecture material.

Djaferis [44.27] describes a three-pronged approach to introducing systems and controls in a first-year engineering course. A combination of lectures, simulations, and a hands-on experiment where student develop a collision avoidance system for a model car (Fig. 44.3) are used to indoctrinate students into how control theory can be practically applied within the engineering design process. Because the only prerequisite requirement for the course is first-semester calculus, it can be offered during the spring term of the first year, allowing students the opportunity to experience control early in their education. Additionally, the author found that the early introduction to control resulted in a number of students choosing to take a more advanced course in control as well as for some to pursue graduate studies of systems and control.

An example of a new introductory control course for both engineers and general scientists is described in [44.30]. The course was taught for over 10 years at Sweden's Lund University. The goals for the course include:

- Demonstrating the benefits of control and the power of feedback
- Describing the role of control in the design process and the importance of integrated systems

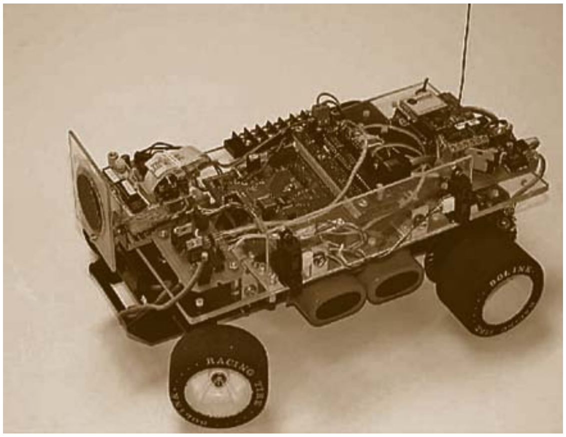

Fig. 44.3 Control laboratory experiment for first-year engineering students (after [44.27])

- Introducing the language of systems and control
- Introducing the basic ideas and concepts of control
- Explaining fundamental limitations
- Explaining how to formulate, interpret, and test specifications
- Exploring computational tools such as MATLAB and Simulink [44.32] to compute time and frequency responses
- Developing practical experience of sketching Bode diagrams and performing calculations using the associated plots.

The challenge is to teach students sufficient information for understanding the validity of the information contained in computer plots and to appreciate how to achieve a satisfactory design that meets the specifications and necessary criteria. One of the curricular design ideas that fueled the course's creation was to provide a course that functioned as both an introduction for those that elected to continue their control studies as well as a functionally complete overview for students who would only take one course on control.

One approach for demonstrating and appreciating the importance of the dynamics of a system is the use of the bicycle discussed in detail in [44.33] and proposed for use in an introductory course. Because of the universal familiarity of the bicycle, it represents a highly approachable problem context. It also presents a wide variety of unique control- and dynamics-related problems; for example, the fact that when at rest it is an unstable system but when in motion it exhibits aspects of stability presents a unique problem situation for students to understand. The problem can also be extended into issues of rear-wheeled steering and other assorted complexity inducing issues. Finally, the scope of the problem is such that other non-control-related problems can be introduced, such as discussions of the elemental physics of motion and the theoretical aspects of design.

In response to the National Academy of Engineering report [44.17, 20] in which interdisciplinary system engineering is cited as an increasingly important aspect of modern engineering and of the education of future engineers projects that integrate elements of mechanical design, modeling, control system design, and software implementation were developed at the University of Illinois at Urbana-Champaign [44.34]. In these projects, control design becomes an integral part of the larger systems engineering problems and must be carried out in conjunction with design and optimization of structural members, choice and placement of sensors and actuators, electronics, power considerations, modeling, simulations, identification, and software developments.

44.5.2 Laboratories as Interactive Learning Environments

Understanding systems and control demands hands-on experience. It is nearly impossible to appreciate the complexities and interactions of a physical system without witnessing it. Therefore a good control laboratory is important for control education. Advances in technology have reduced the cost of developing laboratories significantly. Numerous courses currently utilize the Lego Mindstorms kits which include a variety of sensors and a programmable computer capable of interpreting the sensor's raw value [44.35–39]. While the majority of those courses utilize the Lego system as a vehicle for learning programming concepts or mechanical design principles, the sensor capabilities open the door for use in a systems and control course.

The Intelligent Control Systems Laboratory [44.16] at Australia's Griffith University demonstrates con-

Fig. 44.4 Autonomous vehicles competing in the DARPA Grand Challenge [44.31]

trol through cooperative driverless vehicles. The idea of intelligent vehicles has brought with it promises of heightened safety, reliability, and efficiency. In 2004, the Defense Advanced Research Projects Agency (DARPA) held the first of three DARPA Grand Challenge prize competitions for driverless vehicles [44.31] (Fig. 44.4). The first year, the best vehicle drove only 7.36 miles of the 150 mile desert course. In 2006 at the second challenge, five vehicles completed the course and all but one of the 23 participating teams achieved a distance greater than the maximum 7.36 miles obtained during the first challenge. In 2007, the third challenge required participants to navigate a more urban setting. Six of the 11 participating teams rose to the challenge and successfully drove through the 60 mile urban course.

Finally, the number of interactive tools for education in automatic control is growing rapidly. Many examples are provided [44.40–43]. A sample plain talk presented below provides other examples of creative, interesting, and important modern control engineering education laboratories.

44.5.3 Plain Talk on Control for a Wide Range of the Public

The IEEE Control Systems Society Technical Committee on Control Education has been in the process of developing a series of short presentations prepared for a wide range of the public demonstrating the power, beauty, and excitement of systems and control. These presentations were given at the workshops for high-school teachers and students, sponsored by the National Science Foundation and the Control Systems Society. They are presented in [44.44, 45].

The following is a sample of such talks that were presented at the 2007 Control and Decision Conference in New Orleans:

- T. Djaferis: *The Power of Feedback* (University of Massachusetts Amherst)
- C. G. Cassandras: *Joys and Perils of Automation* (Dept. of Manufacturing Engineering and Center for Information and Systems Engineering Boston University)
- R. M. Murray: *Control Education and the DARPA Grand Challenge* (Control and Dynamical Systems, California Institute of Technology)
- P. R. Kumar: *The Next Phase of the Information Technology Revolution* (University of Illinois, Urbana-Champaign)
- C. Tomlin: *Controlling Air Traffic* (University of California, Berkeley)
- M. Spong: *Control in Mechatronics and Robotics* (University of Illinois, Urbana-Champaign)
- W. S. Levine, D. Hristu-Varsakelis: *Some Uses for Computer-Aided Control System Design Software in Control Education* (University of Maryland)
- I. Osorio: *Application of Control Theory to the Problem of Epilepsy* (University of Kansas Medical Center and Mark Frei Flint Hills Scientific, LLC)
- D. Duncan, T. Duncan, B. Pasik-Duncan: *Random Walk around Some Problems in Stochastic Systems and Control* (Yale University, University of Kansas)
- K. Furuta: *Understanding Phenomena through Real Physical Objects–Controlling Pendulum* (Tokyo Denki University, Japan)
- J. Baillieul: *Risk Engineering–Past Successes and Future Challenges* (Intelligent Mechatronics Laboratory, Boston University)

Developing plain talks that can be used by members of the control community for noncontrol communities in different settings is very important and has become a major goal for the control education committees. It is through these talks that the general population, particularly children and young adults, can learn to appreciate control and potentially pursue further study of the topic.

44.5.4 New Approaches to Cultivating Students Interest in Math, Science, Engineering, and Technology at K–12 Level

The IEEE CSS Technical Committee on Control Education together with the American Automatic Control Council (AACC) and the International Federation of Automatic Control (IFAC) Committees on Control Education has organized a series of workshops for middle- and high-school students and teachers on *The Power, Beauty, and Excitement of Control* at all major control conferences sponsored by CSS, AACC, and IFAC in the USA and around the world since 2000 [44.46]. The model for these workshops was created and developed at the University of Kansas (KU) 15 years ago. The university organized semiannual half-day workshops for fifth- and sixth-graders from local schools to promote STEM disciplines. They became very successful and played a major role in establishing an important partnership between K-12 and KU [44.47]. Another important outreach activity for encouraging young people to consider a career in control was the workshop organized for girls at the International Symposium on Intelligent Control/Mediterranean Conference on Control and Automation (ISIC/MED) conference [44.48].

The purpose of NSF/CSS workshops is to inspire interest from youth towards studies in control systems and to assist high-school teachers in promoting the discipline of control systems among their students. It is composed of several short but effective presentations, as listed in Sect. 44.5.3, on various problems from the real world that have been solved by using control engineering methods, techniques, and technologies. The workshops bring together all-star teams of some of the most eminent senior control researchers and some of the most prominent younger researchers involved in new technologies to present control systems as an exciting and intellectually stimulating field. The attractiveness and excitement of choosing a career in control engineering has been addressed at workshops. Live interaction between the presenters and the audience has been an important feature of the workshops. The workshops have become very popular, with the last one in San Diego bringing over 650 students and teachers. Additional information on the workshops can be found in [44.49, 50].

44.6 Integrating Scholarship, Teaching, and Learning

The integration of scholarship, teaching, and learning into the classroom can be subdivided in many ways. An important subdivision is *horizontal integration* versus *vertical integration* [44.51]. Horizontal integration deals with institutional integration, drawing perspectives from across the institution, whereas vertical integration is programmatic, drawing perspectives from throughout a specific school, department, or program. Both are important for success.

To increase horizontal integration, faculty from different disciplines work together in teaching a single course. Faculty in different disciplines often work on similar topics and each one can provide his or her particular insights for understanding the material and assimilating the information. Their combined efforts result in a variety of advantages. First, they develop cross-disciplinary ties which often boost collaboration. Second, students learn a topic from multiple perspectives, which increases their potential ability to understand the topics, as they are more likely to hear at least one explanation that they will understand, as well as increasing their interactions with a wider variety of faculty members.

Vertical integration incorporates students and researchers at different levels in the teaching activity, that is, there is involvement of senior high-school students, undergraduates, graduates, and postdoctoral students. Often a student is more likely to discuss various questions with someone near to his or her educational level, and these educationally close people can often identify more easily the causes of difficulty. The Stochastic Adaptive Control Group (SACG) research group at the University of Kansas has successfully implemented the approach [44.46, 49, 52].

44.7 The Scholarship of Teaching and Learning

No modern educational discussion would be complete without some discussion of the scholarship of teaching and learning (SoTL). While the wording of SoTL is similar to that of Sect. 44.6, there is a careful distinction. Integrating scholarship, teaching, and learning is about using research (scholarship) in the classroom to enhance teaching and learning. SoTL is about analyzing and reflecting on teaching and learning using the same scholarly processes (literature review, testing, data collection, statistics, as well as more qualitative measures such as systematically coded interviews) used in other scholarly work. Illinois State University defines SoTL to be "systematic reflection on teaching and learning made public" [44.53].

What makes aspects of SoTL interesting for control educators is that the process of *systematically reflecting* can itself be a type of control problem. We learn about our students each time we teach and we adapt the course and methods of teaching to this particular class. It can be considered a stochastic system; stochastic because there is a lot of noise in the system, but typically also having some degree of consistency. Sometimes referred to as *action research*, the process involves an iterative cycle of *planning, action, and fact-finding about* *the result of the action* [44.54]. With each new set of facts, a new plan is formed, upon which action is taken and new facts emerge. The process then begins anew. Over time, a lesson is refined, with the best approaches and attributes of the lesson being used, while the weakest elements are systematically removed or replaced. *Boyer* refers to this as "scholarship in teaching" [44.55].

Education should be regarded as a stochastic process that changes over time, a process with several components such as vision, design, data collection, and data analysis. As instructors, we should collect information, build a portfolio, analyze our reports and data after every class, and want to do better each time. We should want to apply the same rigor to our teaching that we do to our other scholarly endeavors.

44.8 Conclusions and Emerging Challenges

The control field is an exciting field. It has a cross-boundary nature. Many nontraditional disciplines recognize the power and the need for systems and control approaches, principles, and technologies. Control education of tomorrow is a collaborative effort integrating scholarship, teaching, and learning. This collaborative effort needs to include K-12 teachers, students, and scholars. They need to work together as partners who are learners in the process of control education. A classroom should be treated as a scientific laboratory, actively engaged in SoTL.

Similarly, instructors must learn to integrate their scholarship into their teaching and learning by building ties both across a discipline and across an institution. It is important for control instructors to build bridges with mathematics, computer science, and science. A future control engineer has to integrate engineering with computations, communications, mathematics, and science.

This is an extraordinary time for control, with extraordinary opportunities. Several special sessions on control educations have been organized at major control conferences, bringing together leading control scholars from academia and industry. Those important discussions have been well documented [44.16]. Every issue of the *IEEE Control Systems Magazine* is either devoted fully or has an article on control education. The biggest challenge is to attract young people to engineering and, in particular, systems and control engineering. It is important for all control communities to be involved in outreach programs. It is important to build new bridges with other disciplines. It is important to focus on good communication and writing and it is most important to be passionate and enthusiastic about systems and control, and pass on this passion and enthusiasm to young people, in particular women and minorities, encouraging them to pursue and stay in the control profession, which has so much to offer, both now and as control expands into more and more new and unique disciplines.

Future engineers must be well prepared for the complex technical, social, and ethical questions raised by emerging disciplines and technologies. To be successful, students will need to be broadly educated. Teachers and students need to understand the full range of problems covering requirement, specifications, implementation, commissioning, and operation that is reliable, efficient, and robust. They need to understand that new materials and devices are made possible through advanced control of manufacturing processes. They need to recognize that control theories can be used for achieving breakthroughs in highly diverse settings, including biomedicine and finance. As the NSF/CSS panel report summarizes [44.3]:

> ... *perhaps most important is the continued development of individuals who embrace a system perspective and provide technical leadership in modeling, analysis, design and testing of complex engineering systems.*

45. Software Management

Peter C. Patton, Bijay K. Jayaswal

This chapter is an introduction to software management in the context of automation. It recognizes how software and automation are intertwined and have been mutually enabling in enhancing the reach and seemingly unimaginable applications of these two disciplines. It further identifies software engineering as application of various tools, techniques, methodologies, and disciplines to produce and maintain an automated solution to a problem and how software management plays a central role in making it possible. We recognize that software must be managed like any other corporate or organizational resource albeit as a virtual rather than an actual or tangible entity. In this chapter we restrict ourselves to three crucial issues of software management in the context of software as a component in automation and how it enhances its value and availability by effective software distribution, asset management, and cost estimation. It presents current best practices in software automation, distribution, asset management, and cost estimation.

45.1 Automation and Software Management

Automation and software are remarkably intertwined. As organized disciplines, they have independent origins but are deeply interlocked now. Software, as an integral component of computers, is an essential tool for automation of a wide range of industrial, enterprise, educational, scientific, military, medical, home, entertainment, and personal devices, processes, and equipment. On the other hand, automation software, compilers, and a range of computer-assisted software engineering (CASE) tools are crucial for estimating, developing, testing, maintaining, and integrating all kinds of software, especially large and complex ones. CASE

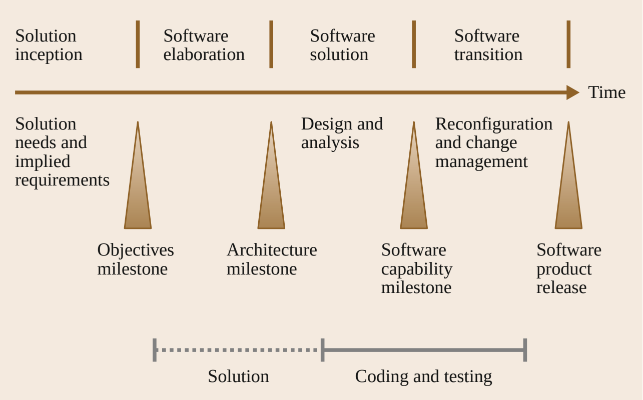

Fig. 45.1 Phases and milestones of software development

automation tools are nothing but computer programs that assist software analysts, engineers, and coders during all phases of the software and system development lifecycle (Fig. 45.1). They are used to automate software development process and to ease the task of coordinating various events in the development cycle. CASE tools are usually divided into two main groups: those that deal with the upstream parts of the system development lifecycle (preliminary estimating, investigation, analysis, and design) are referred to as front-end CASE tools, and those that deal mainly with the implementation and installation are referred to as back-end CASE tools [45.1]. Thus software is indispensable for automation and automation software tools are essential for developing reliable and cost-effective software.

In its earliest applications, automation was mechanization of certain operation or a series of mechanical tasks and operations that would be done manually otherwise. While automation developed initially to meet the challenges to automate mechanical and manual operations in industries, software's origins could be traced to solving (computing) military and subsequently, scientific and business-related data-based problems. It is amazing what a crucial role software has come to play in computing, automation, and other numerous applications, given that it was actually an afterthought to hardware. The term software was not even used until 1958 almost two decades after the invention of the ENIAC computer in 1940s.

45.1.1 Software Engineering and Software Management

Software as a tool in automation has enabled a quantum leap in improving quality, reliability, cost, precision, safety, and security of a large number of products and systems and in expanding automation to seemingly unimaginable applications in the last several decades. Software has enabled applications such as the Internet and mobile platforms that have transformed our lives. However, there are huge intellectual, resource, and research challenges to deliver and control complex systems involving systems of systems, networks of networks, and agents of agents. They create huge intellectual control and software management problems [45.2]. Automation and component technology would play a critical role in meeting these software management challenges.

Software consists of computer programs, procedures, and (possibly) associated documentation and data pertaining to the operation of a computer system [45.3]. It is important to note that software is not just codes or even programs. Further, software runs on hardware and has been, relatively speaking, a laggard as regards quality, delivery, and cost relative to hardware part of computers. Software is thus the crucial element to be addressed in determining cost and performance of a large number of computer applications. Often computers operate as part of communication networks, increasingly the web and the Internet, that provide connectivity for importing and exporting data for a wide variety of commercial, military, educational, entertainment, and public services. The limits of software availability and trustworthiness are similarly determining factors as regards effectiveness and viability of an increasingly large number of automation applications.

Software engineering, on the other hand, could be described as the application of tools, techniques, methodologies, and disciplines to produce and maintain an *automated* solution to a problem. Designing and delivering trustworthy software is one of the great technological challenges of our times. It would require, among others, the implementation of a lifecycle approach to software development that addresses software trustworthiness at upstream phases of the software development process [45.3].

That brings us to the subject of software management. What exactly is software management? An inclusive view of a software business should include organizational, strategic, and competitive contexts of an enterprise processes and technologies that are used in developing software. That is a vast area and beyond the scope of this Handbook and indeed this chapter. Even the software development process is a large discipline consisting of tools, techniques, and methodologies that aid planning, estimating, staffing, organizing, and controlling the software development process [45.3, 4]. In this chapter we would restrict ourselves to three crucial issues of software management in the context of software as a component in automation and how it enhances its value and availability by effective *software distribution*, *asset management*, and *cost estimation*.

45.2 Software Distribution

45.2.1 Overview of Software Distribution/Software Delivery

Software distribution is a generic term used to describe automated or semiautomated distribution or delivery of software, usually on a network including the Internet. Such facilities enable software providers to distribute, fix, and update software packages to clients and servers on an organization's network. It is usually configured to install software with no user intervention and as such can be used to keep organization's network up to date with minimum disruptions. Enterprises face the challenges of maintaining security and compliance requirements while keeping pace with meeting regulatory and technological changes. The information technology (IT) staff has to constantly manage new security threats and patches, updates as well as innovations. Business success depends on maintaining control in the face of all these changes. A smart configuration management suite must meet several requirements (Fig. 45.2) [45.5]:

1. Increase efficiency and save time with a complete hardware and software management solution for all the systems and users in your complex network environment.
2. Reduce costs and the demands on help desk resources with tools that help you securely and easily support users in any networked environment.
3. Protect user productivity and reduce resource needs by easily keeping up with patches and updates and maintaining system-level security.
4. Save time and network bandwidth with patented, ultra-efficient, and fault-tolerant software distribution technologies.
5. Decrease software licensing costs and quickly respond to audits with comprehensive software licence monitoring capabilities.
6. Increase efficiency and save time by easily migrating users and their profiles to new operating systems.

Software distribution is one of the important tools of configuration management tools. The rate and scale of change is increasing. Demands such as Microsoft Vista migrations, data center consolidation initiatives, and stringent time-to-market requirements have placed a new emphasis on the ability to execute changes effectively and efficiently. At the same time, IT is faced with resource constraints, a geographically dispersed and mobile workforce, and ongoing security threats.

HP configuration management solutions enable IT to respond to these demands through automated deployment and continuous management of software, including operating systems, applications, patches, content, and configuration settings, on the widest breadth and largest volume of devices throughout the lifecycle for:

- IT efficiency to control management costs
- Agility to bring services to customers and users faster.

Software distribution is essentially the process of making the software products and services available to users in a manner that meets their cost, quality, and delivery expectations. It means that the software provider successfully delivers the product that the users need, when they and in the form need it, and at the price they are willing to pay for it. It also implies that the

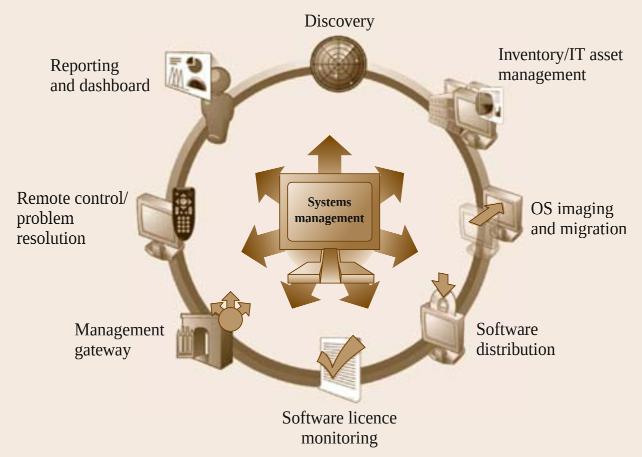

Fig. 45.2 A software management console (after [45.5] with permission)

software provider is able to do so in a cost-effective manner that is economically and competitively viable. While for many physical products we take this process for granted, for software, especially, large and complex ones, it is quite a challenge. The challenge comes often from software's complexity and the very nature of software design and use.

In addition to what was stated above regarding software distribution benefits it also ensures ubiquity and currency of software updates, and allows for certain compliance with all licensing provisions, as well as economy as just licences currently in use will be paid for.

45.2.2 Software Distribution in MS Configuration Manager 2007

Microsoft's System Center Configuration Manager (MSCCM) is a state-of-the-art toolset for software distribution and management in a networked organization. We cite this product extensively as an exemplar of technology available today without loss of generality, even though it is a particular proprietary product [45.6]. Other quality software distribution products in this general area include LANDesk [45.7], and Akamai [45.8]. Microsoft System Center is a suite of IT management solutions that help IT departments proactively plan, deploy, manage, and optimize the software lifecycle of a networked IT environment.

Planning Software Distribution

Planning is the first step in effectively upgrading the network server infrastructure. During this phase, the IT department must collect critical information about server infrastructure, including:

- Assessing the current state of the server infrastructure and datacenter
- Identifying each asset that comprises the infrastructure
- Identifying the purpose of each asset.

For most organizations, collecting accurate information about server assets within the datacenter is easier said than done. Networked datacenters grow increasingly complex daily as companies introduce and implement new technology to enhance business performance. This makes it difficult for the IT department to maintain accurate records of server assets, which also makes it difficult to plan upgrades and enhancements to server infrastructure. Microsoft System Center (MSCC) delivers capabilities that make it easier for the IT organization to collect information needed for in-depth knowledge of existing infrastructure.

The first step of planning a server upgrade is to identify all the assets that make up the network. The IT department needs a centralized management solution that automatically identifies software assets. Microsoft System Center Configuration Manager 2007 (MSCCM 2007) simplifies this task with hardware and software inventory capabilities that identify hardware and software assets, catalog who is using those assets, and understand where they are located. Through asset intelligence, MSCCM 2007 presents a clear picture of IT assets by providing identification and categorization of the servers, desktops, laptops, mobile devices, and software installed across both physical and virtual environments. Within the datacenter, this provides a fast method for understanding what server devices are in use today and who is using them. A new feature available in the first service pack for MSCCM 2007 also enables asset intelligence to identify new and changing systems and notify IT administrators of changes. This can reduce time spent identifying and tracking assets during and after an upgrade project.

As IT organizations move through the phases of the infrastructure optimization model, planning a server upgrade presents an opportunity to cut both medium- and long-term costs by optimizing the use of server resources within the datacenter. Virtualization is one of the most important trends that can impact server resource optimization by changing how an IT department manages servers and workloads. Virtual machine technology decouples the physical hardware from software so that the IT department can run multiple virtual machines on a single physical server.

Microsoft System Center Operations Manger 2007 and Microsoft System Center Virtual Machine Manager 2007 help the IT department identify how servers are being used, how each server is performing, and how each server can be used to its fullest potential. System Center Operations Manager 2007 monitors server health and stores vital performance information in a database that System Center Virtual Machine Manager 2007 can access and analyze. Virtual Machine Manager 2007 then generates a consolidation report that provides an easy-to-understand summary of the long-term performance of a workload. This information helps project teams make informed decisions about which servers would be ideal candidates for consolidation. Also, information about the performance of the hardware running virtualized applications provides data that decision-makers need to smartly move those applications off one server onto another, re-image the server, and then return the applications while maintaining full availability of the datacenter resources.

Microsoft System Center Data Protection Manager 2007 helps companies plan a server upgrade with confidence by enabling the IT department to back up existing data. System Center Data Protection Manager 2007 was built to protect and recover:

- Microsoft SQL Server
- Microsoft Exchange Server
- Microsoft Office SharePoint Server
- Microsoft Virtual Server
- Microsoft Active Directory directory service
- Windows file services.

Configuring Software Distribution

When the IT department has created an accurate inventory of server assets, it can then design the datacenter and determine which changes should be made to guarantee the most cost-efficient infrastructure. Then further steps will enable the department to successfully deploy the Windows Server 2008 operating system, Microsoft SQL Server 2008, and Exchange Server 2007 SP1 and transform the datacenter into a strategic asset. During the configuration or build phase, the IT department must create server images, convert physical servers to virtual servers, create a disaster recovery plan, and monitor the testing process. The build phase offers an opportunity for IT departments to identify areas for reducing costs, improving efficiency, and supporting compliance efforts. One way to accomplish this is by creating standardized server images for all server components, for both physical and virtual machines. System Center Operations Manager 2007 and System Center Virtual Machine Manager 2007 facilitate this process.

The task sequencer, driver packages, and dynamic driver catalog included with Configuration Manager 2007 significantly reduce the number of server images that the IT organization must create and be deployed to either physical or virtual machines. IT administrators can create a simple generic image and dynamically add the necessary drivers during the build. In addition, by integrating vendor-provided tools, Configuration Manager 2007 can automate the setup of redundant array of independent disks (RAID), storage area network (SAN), and Internet small computer system interface (iSCSI) hard-drive configurations as part of the task sequence. This can have a favorable impact on the amount of work required later as upgrades are issued. Upon creation of the server images for physical machines, Virtual Machine Manager 2007 converts the appropriate images for virtual machines. Traditionally, this task can be slow and disrupt business operations, but Virtual Machine Manager 2007 uses the volume shadow copy service, which helps administrators create virtual machines without interrupting the source physical server. Virtual Machine Manager 2007 also simplifies this whole process by providing a task-based wizard that helps guide administrators. Once images are created, Virtual Machine Manager 2007 supports a complete library that organizes and manages all the *building blocks* of the virtual datacenter within a single interface.

Data Protection Manager 2007 helps prevent the IT department from losing critical business data when upgrading server infrastructure. By integrating a point-in-time database restore with existing application logs, Data Protection Manager can deliver nearly zero data loss recovery for Microsoft Exchange Server, SQL Server, and SharePoint Server, eliminating the need to replicate or synchronize data. Data Protection Manager also uses both disk and tape media to enable fast restore from disk and supports long-term data retention and off-site portability with disks.

Before deploying upgrades to the server environment, the IT department must perform tests to ensure business continuity when the new server products go live. System Center Operations Manager 2007 makes it easy to access the results of these tests, much in the same way that it monitors the overall health of the server infrastructure. An IT department can also create scenarios that act like the end-user of a specific service to monitor success and failure rates and performance statistics results that can help identify potential deployment issues. In addition, administrator-simulated end-users can access Virtual Machine Manager by way of a web portal that is designed for user self-service. This portal enables test users and development users to quickly provision new virtual machines for themselves, according to the controls set by the administrator. Not only can IT personnel quickly test new configurations, but they can also uncover problems before deployment.

Managing Software Distribution

During deployment, IT departments must quickly roll out new products while remaining agile so they can respond to changes. Costs must also be kept to a minimum and business operations must not be disrupted. In the past, deploying new server software required someone to sit down at each server and complete the upgrade. This manual process took significant resources and did not guarantee that servers were deployed with consistent configurations. Determining which virtual and physical machines to link together was also difficult because companies did not have the data, such as workloads, performance metrics, and network capacity, to create optimal arrangements. Companies often risked losing vital company data during the migration process. System Center helps alleviate these challenges.

With Configuration Manager 2007, IT administrators can roll out new servers rapidly and consistently by automating operating system deployments and task sequences. IT administrators can fully deploy and configure servers from previous states, either by updating or replacing original equipment manufacturer (OEM) builds, or by installing the operating system and applications on new computers. Preboot execution environment protocol and Windows deployment services also make it easier to deploy servers that have no operating system installed: just plug in the server and turn it on.

The task sequencer in Configuration Manager 2007 fully automates the end-to-end deployment process, enabling zero-touch to near-zero-touch deployments. This means that the process of building servers, which can include more than 80 steps, including image loads, driver loads, update loads, and multiple reboots, can be handled by Configuration Manager automatically.

IT departments can also maintain visibility of the state of the infrastructure throughout the entire datacenter deployment and management process. Configuration Manager 2007 generates detailed reports about the deployments and provides information about those that have failed. This information helps the IT department resolve problems quickly, easily, and proactively. To maximize server utilization, it is critical that IT administrators select the appropriate virtual machine host for a given workload. Virtual Machine Manager 2007 helps IT departments with this complex task of *intelligent placement*. Virtual Machine Manager 2007 uses a holistic approach to selecting the appropriate hosts based on four factors:

1. The resource consumption characteristics of the workload
2. Minimum central processing unit (CPU), disk, random-access memory (RAM), and network capacity requirements
3. Performance data from virtual machine hosts
4. Preselected business rules and models associated with each workflow that contain knowledge from the entire lifecycle of the workload.

After the analysis, Virtual Machine Manager 2007 produces an intelligent placement report that helps the IT department select the appropriate host for a given workload.

As IT administrators migrate information to an updated server platform, it is critical that data is not lost or corrupted. Once the new platform is in place, Data Protection Manager 2007 will identify the new server environment and enable customers to quickly and easily restore the data where it needs to go. Administrative delays associated with restores are also reduced by using a restore user interface that is based on the calendar, robust media management functionality, and disk-based end-user recovery. With Data Protection Manager 2007, restoring information takes seconds and involves simply browsing a share and copying directly from Data Protection Manager to the production server. By enabling customers to restore data from disk, Data Protection Manager significantly shortens the amount of time it takes to recover data, allowing customers to recover data in minutes versus the hours it takes to recover from tape. Data Protection Manager also minimizes the risk of failure that is associated with recovering data from tape.

Monitoring Software Distribution

After successfully upgrading the server infrastructure with next-generation server technology from Microsoft, the IT department must continue to monitor the infrastructure to ensure technology and licences are up to date, the network is secure, and commitments to meet service level agreements for performance and availability are met. In addition, the IT department must ensure consistency within server configurations, for example, guaranteeing that every exchange server has the same configuration and that server resources are being used with maximum efficiency to derive the most value from existing resources. Meeting these goals was once a challenge because the IT department did not have a solution that enabled the management of the entire server infrastructure from a central location.

System Center Server Management Suite Enterprise not only simplifies and speeds the deployment of new server software, it also eases the ongoing task of managing the entire server infrastructure on a day-to-day basis. Centralized Management of Server Networks System Center offers many ways for IT departments to proactively manage the state of IT infrastructure regardless of its complexity; for example, System Center Operations Manager 2007 provides an easy-to-use management environment that can oversee thousands of servers and applications, delivering a comprehensive view of the health of the datacenter. System Center Operations

Manager 2007 also comes with over 60 management packs, which extend management capabilities to the operating systems, applications, and other technology components that make up the datacenter. With these management packs, IT departments have access to best-practice knowledge about specific Microsoft products and can more easily discover, monitor, trouble shoot, report on, and resolve problems for a specific technology component. Consequently, they can keep their datacenter running smoothly and efficiently. System Center Operation Manager also has a high-availability architecture that can leverage the latest network load-balancing and clustering capabilities to help ensure the datacenter is managed day and night.

To help guarantee that the infrastructure has the right configurations across all required server components, IT administrators can use System Center Configuration Manager 2007. The *desired configuration management* feature in Configuration Manager 2007 allows IT administrators to automatically assess how computers comply with predefined configurations; for example, an IT department can monitor the health of a configuration implemented for Microsoft Exchange Server or Windows Server and are alerted when a server's configuration drifts from the standard configuration.

Configuration Manager also ships with configuration packs, which provide predefined, optimized configurations for a range of servers. In addition, one of the most time-consuming aspects of ongoing management of the datacenter can be automated and managed by using Configuration Manager. Updating servers with patches, drivers, etc. within enforced maintenance windows remains a key challenge for IT departments. The desired configuration management feature can automate this process, ensuring that servers are maintained, available, and compliant with organizational standards.

Improve Disaster Recovery Capabilities. The IT department cannot prevent organizational disasters, but can take the appropriate steps to ensure that data is protected by developing and implementing a well-planned backup and recovery strategy for network outages. Data Protection Manager 2007 delivers the best possible recovery experience because it features continuous data protection with traditional backup, disk-based recovery, tape-based storage, database synchronizations, and log shipping. Consequently, with just a few mouse clicks the IT administrator can restore a SQL Server database directly back to the original server, restore data to a recovery database on the original server, or copy database files to an alternate server or disk.

Software Management Lifecycle

As the IT department updates and maintains datacenter server infrastructure and transitions to a dynamic IT infrastructure, Microsoft System Center can play a major role at each step. Because System Center is an integrated solution for the datacenter, IT departments can derive the most value in the shortest time. Every capability is built on a common framework and design, so IT departments can smoothly transition from one phase of the lifecycle to the next. Some examples of these transitions include:

- The ability to configure, deploy, and monitor server images, automatically, and then patch or update these images as required
- The ability to monitor datacenter applications and servers (such as Microsoft SQL Server 2008), be alerted to failures, and then recover from backup data
- The ability to report server performance, identify problem servers, backup servers, and convert to a virtual form to allow uninterrupted service while switching to new hardware.

System Center delivers the capabilities the IT department needs for the complete distributed software management lifecycle, and even offers specific licensing to support the evolution of the datacenter with the Server Management Suite Enterprise.

45.2.3 On-Demand Software

Microsoft's chairman Bill Gates recently provided a glimpse into the software giant's strategy for the future. In a widely circulated memo, Gates indicated that Microsoft will shift its focus from packaged software to the software as a service (SaaS), or *on-demand*, model. Instead of buying software outright and installing it on desktops or servers, businesses would rent applications on a per-user, per-month basis. Other enterprise software vendors have long been testing similar SaaS offerings as well. For small businesses, the on-demand model promises to reduce costs and complexity while at the same time increase the level of software functionality available to them. There are no packaged applications or hardware to buy upfront, and no dedicated personnel needed to install and maintain software. What's more SaaS will unleash a wave of service applications and that will dramatically change the nature and cost of solutions deliverable to enterprises or small businesses.

In this case as with the web a decade ago the revolution started without Microsoft, since other companies have been selling on-demand software for years. However, a push by the world's most powerful software maker will certainly accelerate the trend, and it is noteworthy that the immediate target of the new Microsoft Office Live on-demand platform is small business. Prerelease or beta versions of e-Mail, project management, collaboration, website design, and analytics programs will be available in early 2006. Microsoft aims to offer some services to small businesses for free; the basic version of Microsoft Office Live, will be supported by advertisers and will allow small businesses to establish a domain name, complete with a hosted web site with 30 MB of storage, among other services.

45.2.4 Electronic Software Delivery

Distributing software over the Internet is becoming an increasingly popular means to distribute software to users. Electronic software delivery (ESD) refers to such distribution and particularly the practice of enabling users to download software from the Internet. In fact, ESD is the future of software distribution, sales, invoicing, payment, maintenance, and customer service and support. It is already an efficient and preferred way for vendors and buyers to distribute/acquire a wide range of software including music, videos, productivity software, and increasingly texts and books. Compared with physical distribution involving compact disks (CDs), digital video disks or digital versatile disks (DVDs), and paper formats, ESD offers dramatic improvements in cost, delivery time, and convenience.

The trend toward ESD is irreversible. Nearly all software vendors offer electronic delivery options, and many new companies choose online downloads as their only vehicle for software delivery. An increasingly large proportion of consumer software and enterprise software are being delivered electronically.

Major Challenges of Electronic Software Delivery System

ESD however has a long way to go as regards quality, reliability, and security of delivery. The following constitute the major challenges that ESD faces [45.8]:

a) *Ensuring robust download performance* to promote user satisfaction, avoid costly physical fulfillment, and prevent lost sales
b) *Providing high-performance infrastructure* that meets highly unpredictable demands in a cost-effective manner
c) *Measuring and understanding download results* and completion rates to gain insight into customer base and ESD efficacy
d) *Identifying specific geographic regions* where end-users are downloading from and controlling/restricting access accordingly.

45.3 Asset Management

45.3.1 Software Asset Management and Optimization

Typically the investment in software amounts to 20% of an organization's IT budget. The portfolio of software development and maintenance tools and its enterprise applications may be licensed from third-party vendors, developed in-house, or in some cases be open-source system software such as Linux, or open-source applications such as Apache or EMACS. In any case the IT organization must take full systems responsibility including currency, interoperability, and local support for all of the software in its portfolio, managing these as the organization would any other asset. In the case of in-house developed application packages the organization has conventional ownership of the asset; in the case of third-party systems or application software the organization has a lease-like licence for the use of the software and perhaps a maintenance service subscription; for open-source software the situation is less clear but can be sufficiently unambiguous that any risk of use is vastly outweighed by the technological and economic benefits of use.

Depending on the size of the organization and its IT commitment, the human and financial resources required to manage software as an asset may vary widely. At an IBM conference for IT directors in Atlanta recently one of the authors sat next to a senior technical person from Bell-South. As the presenter went around the room of 30 IT directors asking for their titles and affiliation, he got to my seat mate who declared he was a Unix system administrator. The others looked at him in disgust, wondering how a low-level *grunt* like him got into this august gathering of senior managers. The fellow went on to finish his sentence saying that he managed 6700 Unix servers for Bell-South. Their expressions quickly turned from disgust to admiration as he probably had the biggest and most critical IT responsibility in the group. The complexity that the software asset manager must deal with comes in two flavors: first the inherent complexity of the software functionality itself, but second the number of desktop or laptop workstations that must be dealt with. Two decades ago most chief information officers (CIOs) avidly avoided taking responsibility for small computers outside their immediate purview, but since then the proliferation of client–server computing organization has long insisted that they take responsibility for them without the mandate of *ownership*. This introduces the complexity of numbers or volume, similarity to the complexity of a 1000 piece jigsaw puzzle, which is more than twice as difficult to assemble as a 500 piece puzzle. Few IT administrators are responsible for 6700 servers, but many are responsible for the effective operation of 10 000 or more client workstations remotely attached to the mainframe(s) or servers for which they do have *ownership*. As client–server technology as grown along with the third-party software vendor industry, so has the need for automation in software asset management. A glance at the Internet will reveal dozens of packages designed to aid the software asset manager in his or her task. We will not attempt to catalog this dynamic market here but rather only mention the availability and capability of such support software packages and describe what you might expect from one.

45.3.2 The Applications Inventory or Asset Portfolio

The director of development in the IT organization usually takes responsibility for what is called the applications portfolio of all the software systems, application packages, and tools licensed, owned, or used to fulfill the organization's functions. In larger organizations the responsibility may be divided between a director of systems for system software and a director of applications for applications software. An organization supporting thousands of client platforms may have a third person responsible for the management of client hardware asset leasing, software asset licensing, and end-user support. As in any other IT function these managers must walk a tightrope to avoid too slow incorporation and support of new technology and too rapid incorporation of new technology. In the former case their end-users lose competitive advantage because they do not have access to current software features and functions, and in the latter they lose competitive advantage due to unreliability of early release software, and perhaps even end-user training problems.

The software asset portfolio should include all environmental, legal, functional, and resource requirements information about any program system, application, or tool, whether licensed from the hardware vendor, a third-party software vendor, open source or locally developed. During the preparation for addressing year 2000 (Y2K) computer compliance one of the most often asked questions about a perfectly working but not Y2K compliant COBOL75 program to the IT manager was: Do you have current source code? If the answer was "yes" the second question was: Do you still have an archived copy of your COBOL75 compiler? All too often the answer to the second question was that it had long ago been discarded *because it was no longer supported by the vendor*. It was very easy (and relatively inexpensive) to help those IT managers who saved everything and knew exactly where it all was. As the prophet Isaiah once said, "my people go into exile (or captivity) for lack of knowledge" (Isaiah 5:13). The requirements for a software portfolio are relatively simple:

- Know what software you are using and its source and environmental requirements
- Know which of your users needs it, how often, and what their applications are
- If still supported by a vendor, know who to contact at the vendor for emergency support
- If not supported, maintain a current copy of the source code and a compiler that will compile it
- Know the legal or licensing constraints of the software and any sublicensed components that may be used within it
- Maintain a current source code file if possible; if not, insure that one is escrowed for you by the vendor
- Archive software that is no longer used; it is amazing how often someone very high up in the organization will need it one more time.

45.3.3 Software Asset Management Tools

The issues that software asset management (SAM) tools offer to handle for an organization concern IT managers, financial managers, and corporate legal staff. For IT managers the issues of concern are:

- Manage site licences for software by user and workstation
- Get more out of underutilized assets by moving unused software to new users rather than purchasing more licences
- Manage unlicensed and open-source software anywhere in the system
- Summarize entitlement information
- Reconcile installations to entitlements
- Provide user services high-level access to vendor support as required
- Monitor lifecycles and proposed upgrades of all licensed software
- Ensure uniform corporate-wide installation of upgrades and support.

For financial managers:

- Know whether all the software in firm is licensed and legal
- Avoid compliance fines and fees
- Ensure that site licences are sufficient but also at lowest cost
- Maximize underused software assets by redistributing existing licences to new users
- Minimize overall cost of licensed software.

For corporate legal staff in support of IT and financial management:

- Ensure absolute compliance with site licence provisions
- Inform all staff and department heads about the risks of using unlicensed software
- Inhibit maverick departments and personnel from downloading or sharing unlicensed software
- Limit corporate liability by ensuring that unauthorized or illegal (e.g., off-shore gaming, pornographic, child pornography, etc.) software is never installed on corporate desktops or laptops.

While managing these issues calls for little more than the application of common sense, doing so in a large corporation, university, or government organization with several hundred servers and 15 000 or more workstations and laptops is best done in a rigorous and disciplined way. One of the most pervasive problems is easiest solved; when CIO at a research university one of the authors had difficulty discouraging some faculty, research staff, and department personnel from downloading and sharing nonlicensed, non-open-source software that they felt entitled to use without licence. A short conversation with the general counsel solved the problem with a single joint memo informing such users and department that, in the event they were sued for such noncompliance, they would have to pay the legal fees for their defense and any fines out of personal or departmental budgets, since the university would not be doing so. As for the latter, more sensitive and even higher risk issue, making sure everyone in the organization knows the consequences of noncompliance with corporate standards is usually sufficient.

A somewhat larger issue is that software licensing agreements are not all the same. Site licences for colleges and universities are often more lenient, and may for example allow a faculty person to use two copies of the software, one on a desktop and the other on a laptop, providing that only one of them is being used at a time. Provisions such as this may require invoking a bit of the honor system but are usually manageable without undue risk.

45.3.4 Managing Corporate Laptops and Their Software

Laptops have a special set of problems due to their mobility and susceptibility to shock-related damage. Many organizations support both personal computer (PC) and Mac laptops and thus may have to license the same software in more than one way. As laptop hard drives are more subject to shock damage and consequent loss of both system and application software as well as data, an inventory of the software licensed to each laptop may be critical. The mobility of laptops introduces hazards beyond shock in terms of theft or just loss of the whole machine. Corporate data may be seriously compromised in these situations so security and backup is especially important for laptops. If an organization has thousands of laptop users it may require a full-time person to maintain currency and security of both laptop hardware and software. Now that many organizations issue only laptops and not a desktop computer as well, a special focus on laptop computing assets beyond just SAM generally is worthy of consideration.

45.3.5 Licence Compliance Issues and Benefits

As every personal computer user well knows, if you do not agree to the license agreement, the software will not install and open for you. Thus, the first benefit from licensing compliance is access. At the beginning the user was forced to actually read the licence before the installer would accept their agreement, but users never read these things (licences and contracts are written by lawyers and therefore only read by lawyers). When the vendors realized that everyone (except lawyers) was just scrolling to the end and clicking on the accept radio button, they began to allow the user to just hit the button and install. The licence is a form of contract and thus protects both the vendor and the user. Software is no longer bought and sold; rather the use of it or access to it is guaranteed by the vendor to purchaser of a licence. This means that, if it does not work as delivered, you can insist on certain fixes and upgrades, although you may have to pay an additional sum for the upgrades. After spending a great deal of creative effort building a system of application, it is some comfort to know that it will not be arbitrarily dropped or made unavailable to you. In such a case the end-user may need to finally read the licence agreement to determine his or her rights and what remedies may be available. If you build a complex application without benefit of licence and something goes wrong then you have no recourse. In a large organization this is very important and careful management of site licences may be an important business continuity consideration if a real disaster happens.

45.3.6 Emerging Trends and Future Challenges

The trend in personal computing and information sharing is definitely towards mobility. As WiFi wireless networks proliferate beyond today's local-area networks (LANs) and small digital assistants, including enhanced cell phones, become more popular, one may expect to see the corporations computing, software, and information assets spread ever more widely. As in any other management situation it is necessary to know where everything is, how it is being used, and to minimize risk.

45.4 Cost Estimation

45.4.1 Estimating Project Scope

One of the major problems in computer systems development is estimating the time and cost of a development project. It has often been said that the next major development in hardware technology forecast to be available in 10 years arrives in about half that time, but the time forecast to build a new software system takes twice as long and costs at least twice as much as the initial forecast. The field of software development is strewn with disasters and abandoned projects because the scope of the project was not understood from the beginning or was expanded beyond the time and resources available during development. A few tragic examples are given in the book *Design for Trustworthy Software* [45.3, p. 536].

One of the earliest and best contributions to the solution of this problem was *Prof. Barry Boehm*'s magisterial work entitled *Software Engineering Economics* [45.9]. The constructive cost model (COCOMO) which he developed for estimating the cost and development time for large mainframe software projects has been updated for the current client–server era and will be discussed below. While there are other similar development models and methodologies, COCOMO has long since become the gold standard for such methods and is available in several commercial versions. Here we will briefly review the COCOMO suite and a recent product, SEER-SEM, which is based on it. These are typical of the software estimation packages available to the software developer today.

45.4.2 Cost Estimating for Large Projects

Large software development projects have an unfortunate history of time and cost overruns and the largest and more complex of them have often been abandoned after several years and many millions of dollars invested. It is also true that some large software projects do finish, on time, within budget, and satisfy their users. *Capers Jones*, the dean of software estimation, did a study of both 59 manual and 50 automated estimates for large projects (e.g., in the 5000 function-point range) [45.10]. The manual estimates were created by managers using conventional methodologies and the automated ones by commercially available estimating tools. The manual estimates yielded lower costs and shorter times than actually experienced and only 4 of the 50 were within 10% of actual. Only one of the automated estimates was optimistic, most were much too conservative, but 22 were within 10% of actual experience. Curiously, both were fairly accurate estimating the actual coding involved, but the manual estimates were much too optimistic for the nonprogram-

Table 45.1 Relative software development activities and effort by genre (after [45.10, p. 3])

Activity	WWW %	MIS %	Outsource %	Commercial %	System %	Military %
Requirements	5	7.5	9	4	4	7
Prototype	10	2	2.5	1	2	2
Architecture		0.5	1	2	1.5	1
Planning		1	1.5	1	2	1
Func design		8	7	6	7	6
Tech design		7	8	5	6	7
Design review			0.5	1.5	2.5	1
Coding	30	20	16	23	20	16
Reuseability	5		2	2	2	2
Package purchase		1	1		1	1
Code inspection				1.5	1.5	1
Verification and validation						1
Config management		3	3	1	1	1.5
Integration		2	2	1.5	2	1.5
Documentation	10	7	9	12	10	10
Unit testing	30	4	3.5	2.5	5	3
Functional testing		6	5	6	5	5
Integration testing		5	5	4	5	5
System testing		7	5	7	5	6
Field testing				6	1.5	3
Acceptance testing		5	3		1	3
Independent testing						1
Quality testing			1	2	2	1
Training		2	3		1	1
Project management	10	12	12	11	12	13

ming parts of the project such as design, documentation, rework, testing, project management, etc. Jones notes that, for projects with fewer than 1000 function points (or about 125 000 C source LOC), programming is the major cost driver, but for projects above 10 000 function points (or about 1 250 000 C source LOC), testing and bug removal, plus documentation are much more costly than the programming or actual implementation cost. The dynamic of software development cost estimation is that developers tend to be conservative, especially those who have survived one or more unsuccessful project *death marches*, but their customers, i. e., the senior managers who need the application tend to be optimistic about both cost and time and crowd the developers toward more optimistic estimates. If the developer is too cautious and conservative the manager will simple not *buy* the project. Any estimate, whether it turns out to be optimistic or conservative in the end, must be defensible and is best based on experience with previous projects of the same size and complexity.

As software development projects get larger and the specter of later abandonment becomes more threatening, the need for more accurate estimates has prompted the development of a whole new software development service industry to provide quality tools. Some of the estimating tools on the market today are COCOMO II, CoStar, CostModeler, CostXpert, KnowledgePlan, PriceS, SEER, SLIM, and SoftCost [45.10, p. 2]. Some of the first generation of tools are still in use but are no longer being supported or sold. Jones reports that the basic kernel of functions supported by such tools includes:

- Sizing logic for specifications, source code, and test cases
- Phase-level, activity-level, and task-level estimation
- Schedule adjustments for holidays, vacations, and overtime
- Local salary and burden rate adjustments
- Adjustments for military, systems, and commercial standards

- Metrics support for function points and/or LOC
- Support for maintenance and enhancement.

More advanced features available in some estimating systems include quality and reliability estimates, risk and value analysis, return on investment (ROI), models to collect historical data, statistical analysis, and currency conversion for overseas development. Table 45.1 summarizes Jones experience with six different application genres. While he styles the table as merely illustrative it certainly fits one of the author's more than 50 years developing software in all six of these genres.

The new class of automatic software estimating tools may not be perfect but they are very good and may prompt the user to include factors he or she might otherwise overlook. As always in any complex human endeavor, there is no substitute for experience.

45.4.3 Requirements-Based a priori Estimates

Of course it is easier to estimate a large software project if this is the tenth one you have done just like it, but that is rarely the case. Developers who managed to do two or three projects fairly well are often promoted to chief software architect or director of MIS. What can be done when you need to create a requirements-based estimate and the requirements are not completely known yet? Amazing as it may seem to an engineer, this case occurs very often in software development, and can be tolerated because software is not manufactured like other systems and products designed by engineers. A software development project is the result of a negotiation and, like any other negotiated decision, can be renegotiated. Software is simply designed, redesigned, and redesigned again as it is implemented. The only software implementation analog to hard goods manufacturing is the almost completely error-free process of copying a computer file on to one or more CD-ROMs.

The hardware designer would think that the software engineer would follow the logical process of requirements discovery, functional design, technical design, implementation, testing, documentation, and delivery; however, the more common case in software development is that the first truly known and understood parameter is the delivery date to the customer. Hence, the software developer's commonly employed process, known as *date-driven estimation* [45.11]. So at this point we now when the project is to be completed but as yet do not know what is to be delivered. In traditional engineering one makes the estimate after design but in software engineering one must make the estimate *before* design since, for software, design replaces manufacturing. This places a tremendous burden on requirements discovery [45.12] and on the subsequent specification process. It has long been conventional wisdom in software development that one could write a precise functional specification (i. e., precise to *both* the implementers *and* the end users). Efforts to do so have greatly improved in the current era of object-oriented programming analysis and design, and have given new hope for the decades-long search for the holy grail of software development: specification-based programming [45.3, p. 502–506]. New technologies coming on to the market today such as Lawson Software's Landmark and Wescraft's Java refactoring system, inter alia promise a high degree of programming automation for Java-based software [45.3, p. 501]. Moreover, since the precise functional specification is written by domain specialist(s) and the Java code produced automatically by a metacompiler, what you as domain expert or allele for the end-user specify is truly what you get. This innovation in programming will dramatically change the way software is designed, implemented, and maintained, but it also will put even more burden on the requirements discovery and specification part of the project, which according to *Dekkers* are already the source of 60–99% of the defects delivered into implementation [45.12]. We have long known that defects are written into software, just like villains are written into melodramas, and with similar high drama and anxiety we see as we approach the end of the project, i. e., the well-known and very precise date of delivery.

In our opinion the best way to deal with this commonly occurring situation is the analytic hierarchy process (AHP) developed by *Saaty* [45.13], which naturally prioritizes the user requirements as they are identified. Clearly, the most critical and time-consuming requirements come first to the user's mind and are the most important to the user's ultimate satisfaction with the end result of the software development project. A description and overview of AHP together with examples of its application is given in [45.3, Chap. 8].

45.4.4 Training Developers to Make Good Estimates

The need to train developers to make precise estimates is an artifact of the conventional software design process, in which requirements and functional designers write in one *language*, technical or detail designers in another, testers in yet another, and the end-user in even yet another, but a bit more similar to the first language in the sequence. Understanding software design documents (including the actual source code) going from one stage to the next in the process seems to involve an inherent *language translation* effort which can be the source of many defects in the end result; for example, functional specification writers tend to think in terms of effort units, placing the project in a cost and resource framework. Developers however, tend to describe size and complexity in terms of the things they will have to make to implement the requirements [45.14]. Commercial estimation packages need either concrete measures such as source LOC or abstract measures such as function points as input, but are *encoded* with sufficient industry experience to translate back and forth between such measures.

Putnam and his associates, the developers of SLIM, have developed a process for mapping *units of need* into *units of work* which is able to train estimators to take best advantage of the new software estimation tools coming onto the market. As an alternative to the conventional software development process, one determines the size of the software components by analyzing them into common low-level software implementation units; creating a model-based first-cut estimate using known experiential productivity assumptions, project size, and critical components; performing what-if modeling until an agreed-upon (i. e., negotiated) estimate has been developed; and finally creating a detailed plan for the project [45.14]. The what-if modeling part of this alternative employs the estimation tool (SLIM in his example) in a feedback loop as well as a feedforward process and provides a powerful learning experience for the estimator. The intermediate units, for example, would include forms, new reports, changed reports, table changes, job control language (JCL) changes, and SQL procedures, and for each such unit of work a qualitative measure of effort, e.g., simple, average or complex. This is a more analytical and finer-grained approach than the conventional method of estimating the number of reports, estimating the number of forms, then the number of transactions per component, and then the number of database accesses, etc. Highly experienced COBOL programmers of yesteryear could use the time-honored conventional approach to estimate a project's source LOC to within a few percent using conventional methods and experience, but object-oriented analysis, design and programming (OOAPD)-based design begs for a more analytical and finer-grained modeling as proposed and implemented by Putnam.

45.4.5 Software Tools for Software Development Estimates

In the late 1970s and early 1980s Barry Boehm developed the original COCOMO system mentioned above to support the first generation of true software engineers in estimating the cost of mainframe software development. By 2000 the need for a version this tool able to handle object-oriented programming (OOP) and client–server software development led to COCOMO II. There is also a large suite of collateral but genre or methodology specific variations and derivatives of COCOMO models and packages available today [45.15, p. 2]. The major variations are COCOMO II, COINCOMO, and DBA COCOMO, which are fundamentally the same model but tailored for different development situations. Commercial version of COCOMO such as Costar (http://www.softstarsystems.com) and CostXpert (http://www.CostXpert.com) provide even further cost estimation capability (see also http://sunset.usc.edu/).

The basic logic of COCOMO models is based on the general model or formula

$$\mathrm{PM} = A \times \left(\sum \mathrm{Size}\right)^{\sum B} \times \prod \mathrm{EM}\,,$$

where PM is person months, A is a calibration factor, Size is a measure of functional size for a software model that has an additive effect on the software development effort, B are scale factors that have an exponential of nonlinear effect on software development effort, and EM are effort multipliers that influence software development effort.

Clearly this is an experience-based model or formula, not merely an equation to be evaluated. Each factor in the equation can be represented by either a single or multiple values depending on the purpose of the factor; for example, Size may be measured in either source LOC or function points, and EM may be used to describe development environment factors such as software complexity or software reuse. COCOMO II has 1 additive, 5 exponential, and 17 multiplicative factors, but other models in the suite have a different number depending on the scope of the effort and software genre being estimated by that model [45.15]. Boehm's current research at the University of Southern California (USC) is directed toward a unification of the COCOMO suite of models in order to provide a comprehensive estimate for the development of a software system to help developers make more precise cost and time estimates for their projects.

SEER-SEM is a cousin of COCOMO since both followed the early work of both Jensen method and Halstead's software science. As in most other models the development environment is characterized by parameters. The architecture of a software cost estimation model is characterized by the way it answers the following questions [45.16]:

- How large is the project?
- How productive are the developers?
- How much effort and time are required to complete the project?
- How does the outcome change under resource constraints?
- How much will the project cost?
- What is the expected quality of the outcome?
- How much effort will be required to maintain and upgrade the system in the field?

While the model can estimate program size in either LOC or function points we will display only the source LOC formula here

$$\begin{aligned} S_\mathrm{e} = {} & \mathrm{NewSize} + \mathrm{ExistingSize} \\ & \times (0.4 \times \mathrm{Redesign} + 0.25 \times \mathrm{Reimpl} \\ & + 0.35 \times \mathrm{Retest})\,, \end{aligned}$$

where S_e increases in direct proportion to the amount of new code being added, but by a lesser amount for the redesign, implementation, and retesting of existing code [45.16, p. 1]. This pragmatic approach reflects the fact that today's programmer rarely starts with a blank piece of paper (or a blank screen, as it were), but rather is redesigning or upgrading some existing system or application package to run in a new or enhanced environment.

The formula for effort in SEER-SEM is

$$K = D^{0.4}(S_\mathrm{e}/C_\mathrm{te})^{1.2}\,,$$

where S_e is effective size, and C_te is effective technology, a composite metric capturing factors relating to development efficiency or productivity, based on an extensive set of experiential people, process, and product parameters. D is staffing complexity, which depends on how quickly qualified staff can be added to the project [45.16]. Once effort is obtained, the time to implement can be found from

$$t_\mathrm{d} = D^{-0.2}(S_\mathrm{e}/C_\mathrm{te})^{0.4}\,.$$

The exponent on the critical ratio reflects the fact that as the project size increases so does the time to complete, however at a lesser rate.

45.4.6 Emerging Trends and Future Challenges

The future of software development may be a very interesting revolutionary one rather than the evolutionary one we have experienced for the past 50 years. The emergence of very high-quality open-source software such as Linux and Apache raises the natural question as to why management should pay large sums and wait long times to develop custom proprietary software when open-source alternatives are available. Of course the answer to this question is they do not need to: if a time- and industry-tested alternative is available it should be added to the portfolio, but managed in a somewhat different way. We should only write software when we have to, and this principle is leading to a restructuring of the software industry from a vertical to a horizontal model. In the future most software vendors will sell their products to other software vendors, similar to the structure of today's automobile industry. Henry Ford began his company with an extremely vertically integrated business model like those of European manufacturers: he had his own taconite mines in Minnesota to feed his own steel mills, his own sand mines in New Mexico for producing glass windows, his own sheep ranches in Montana to produce the wool for upholstery, etc. Today, every small engineering and machining firm in Windsor, Ontario produces part for Ford. We think the same development is happening in software, aided by OOP and the functional componentization and consequent reusability of software. Many firms will write software but only a few of them will deliver it to end-users.

The computer revolution has produced a hardware performance gain of more than 10^{10} in the 60 years since the ENIAC was announced in 1946; however, the productivity gain in software development has been much less impressive. Countess Ada Lovelace invented the idea of the program loop in 1844 while watching Jacquard loom operate; Betty Holberton invented the sort–merge generator at the Harvard Computation Laboratory 100 years later; a decade later Dr. Grace Hopper left Harvard to build the first compilers, Math-Matic and FlowMatic at Univac, while Mandaly Grems at Boeing was creating sophisticated scientific programming interpretive systems for the IBM 701.26. The progression of programmer-oriented languages such as COBOL, FORTAN, and ALGOL in the second software generation led to a factor of 10–20 in programming productivity. Third- and fourth-generation software added additional increase by at least an order of magnitude each, but three or four orders of magnitude overall is much smaller than ten orders of magnitude.

The future of software development belongs to pattern languages. Christopher Alexander is a building architect who discovered the notion of a pattern language for designing and constructing buildings and cities. In general, a pattern language is a set of patterns or design solutions to some particular design problem in some particular domain. The key insight here is that design is a domain-specific problem that takes deep understanding of the problem domain and that, once good design solutions are found to any specific problem, we can codify them into reusable patterns. A simple example of a pattern language and the nature of domain specificity is perhaps how farmers go about building barns. They do not hire architects but rather get together and, through a set of *rules of thumb* based on how much livestock they have and storage and processing considerations, build a barn with certain dimensions. One simple pattern is that, when the barn gets to be too long for doors only at the ends, they put a double door in the middle. Only with a powerful design or pattern language – and in general a domain-specific design language (DSDL) – can we overcome the inherent limitations we have in our ability to comprehend the working of some complex system, to model it, and then automate those portions which can be mechanized [45.17]. Lawson Software's experience with Richard Patton and Richard Lawson's Landmark [45.3, p. 501] DSDL has not only shown more than another order of magnitude in business enterprise software development, but in the first year of delivering accounting, supply chain, and human resources (HR) applications only one bug has been reported. This is the future of software development.

46. Practical Automation Specification

Wolfgang Mann

This chapter specifies equipment-based control system structures for complex and integrated systems and describes the approach to and implementation of an equipment-based control strategy. Based on a view of subsystems in a production, process or a single machine the control system has to abstract the subunits in an object-oriented manner to obtain their methods and properties. The base subunits will run as separate state machines (either on centralized or decentralized control devices) representing themselves to the next control hierarchy level only by said methods and properties. These base subunits form functional subsystems in the same way.

Advantages of such a modular specification are: easy replacement of different base units with the same functionality to the next hierarchy level, high efficiency in construction kit engineering of systems, easy integration of systems to vertical integration attempts – especially in the field of networking and data concentration. The challenge is the implementation on standard industrial programmable logic controller (PLC) systems with a standard industrial-like programming language (e.g., EN 61131). An example demonstrates the implementation in a modern test stand for heat meters for the German Physikalisch-Technische Bundesanstalt (PTB) institute, a system with about 1000 physical input/output (I/O) and measurement points.

46.1 Overview

Complex systems with many dozens of subsystems become increasingly challenging in terms of programming, interfacing, and commissioning, in both operation and maintenance.

The reasons for this intricacy are multifarious and include [46.1]:

1. Product lifecycles getting shorter, and even technological cycles getting shorter.
2. Orders to stock are replaced by short orders to delivery.
3. Change form self-production to integration of sub-suppliers.

4. Decentralized stock and service.
5. High price pressure.
6. Change form manually process integration to integrated processes.
7. Change from product supplier to system supplier.
8. Production processes control multiple enterprises.
9. e-Commerce and quality management systems additionally produce enormous quantity of data and force the introduction of data management throughout the company.

These requests can be covered by a horizontal and vertical integration of process and production systems and subsystems within the company and extending the network to suppliers and even customers. So the systems become more complex, open, distributed, and heterogeneous. Dataflow often has to be implemented throughout the complete enterprise hierarchy form the shop floor area to enterprise management level.

To address these attempts, new software concepts have to be implemented throughout the complete information chain within an enterprise, starting at the I/O level of the production line.

Although there are well-developed methods and strategies to produce well-structured, reusable, and sophisticated code in the information technology (IT) personal computer (PC)-based environment, industrial control at its base level is still done using standard PLC systems with EN 61131-like programming language using functional blocks, structured text or instruction lists at large scale [46.2].

As long as the projects are small and centralized a programming technique limited to the I/Os of industrial controllers and their periphery is applicable, with some restrictions.

However, with the above-stated imperative demands in mind, conventional I/O-based engineering attempts leads to unstructured, error-prone code, resulting in cost overruns during installation and operation.

We consider the traditional PLC programming style more as an expression of old-fashioned thinking, having its tradition as far back as relay-based times, rather than an exigency coming from existing hardware and in particular software systems.

Before the implementation strategy is described, we look for the *must-haves* to overcome the shortcomings of traditional industrial control programming.

46.2 Intention

Many of the following topics have been implemented for years on IT-based systems using C++, Java or other object-oriented (OO) languages. Some of these have found their way into the International Electrotechnical Commission (IEC) 61499 function blocks (with a lack of practical implementations untill now), but actually the bulk of industrial control applications is still done on EN 61131-based systems. So, in the following, focus is placed on the implementation on these existing systems [46.3].

46.2.1 Encapsulation

The most important part of changing the thinking in the traditional control programming approach is to leave the physical I/O connections as the primary way of composition and interaction of systems.

Normally an object in the real world is experienced by humans through its properties, attributes, features (however named), and the possibilities it offers or what we can do with this object (called methods). In general we realize this object only in a certain abstracted layer. The level of this abstraction is chosen according to our actual demands.

As an example we take a human being (a car mechanic). If our car is broken, we abstract him as an object: human with the attributes educated, skilled on certain brand, available, etc., and his methods: takes order, repairs car, renders account, etc. We are not interested in how the blood flows through his veins, how his heart functions, etc. His doctor on the other hand is interested in exactly these methods and attributes. He will abstract him as object: human with the attributes: sex, age, blood pressure, etc. and methods: sees, smells, tastes, etc.

Coming back to automation. We are interested in automated systems for production and processes, control and testing, etc. Usually complex systems are built as a network of subsystems (objects) based again on a network of subsystems.

In our namespace these subsystems are called equipment. The term *equipment* could lead to some unaesthetic grammar constructs in the following, but we have chosen it intentionally: firstly, equipment expresses things we need for some activities, especially in production, and secondly it is already a plural expression, although it could be a single device or the whole factory. So it represents the modularity of the method down to the smallest base modules (that in general again consist of parts).

We differentiate between base equipment and abstracted equipment. A motor, a valve or a pump is a single base equipment. A pump station, for example, is a single abstracted equipment.

What is the definition of base equipment in contrast to abstracted equipment? A base equipment implements interface access via physical I/Os to the real world, whereas an abstracted equipment implements interface access to physical I/Os only via base equipment. Nevertheless base equipment can of cause host other base equipment (see Sect. 46.2.2 as well).

The intention for building equipment is to encapsulate the actual physical implementation of one subsystem from the collaboration with other subsystems, as well as to support the abstraction of these systems for different service subscribers (with different interests, e.g., production, service, and management) to its methods and/or properties.

The encapsulation consists of three layers: the interface layer (providing abstracted methods and properties), the implementation layer (running the algorithms, the event routines, and the exception routines), and the base layer. The base layer is the interface to the physical I/Os and the access to the implementation layer of subequipment for base equipment and the same without direct access to physical I/Os for abstract equipment.

Access from one single equipment to another is allowed only by use of its interface layer. This strict access method allows one to change the implementation layer as well as the base layer of equipment without affecting how it is accessed.

46.2.2 Generalization (Inheritance)

In the implementation of object-oriented languages the method of inheritance is an important feature. It describes the deployment from more generic objects to more specialized ones. As in the following implementation we have no special software tools in standard EN 61131-based systems for constructing strict inheritance (as is possible in C++), we talk about generalization and bear in mind the underlying ideas. So, for our needs, generalization allows hierarchical structures and establishes a relationship between a more general equipment and a more specific one, without redefining all the specific methods and properties, although if required it is possible to override the generic methods and properties of the generic equipment with more specific ones.

To follow our first example, a woman inherits all the methods and properties of the object human, but has of course more specific attributes and methods, most importantly to give life to new humans. We will give more technical examples in the implementation section.

46.2.3 Reusability

Probably it is the basic idea of every engineer to built up a system (whichever) out of already existing, used, and tested parts coming from a toolbox (as children do when playing Lego) to create new systems and projects. By doing this an engineer mostly thinks about saving time, lowering risks, and reducing overall costs.

The basis for doing this is encapsulation and the concept of instances. As a single equipment is the implementation of methods and at the same time its abstraction, and the base layer is the interface to the physical world, it is only a general construct. The base equipment, e.g., is brought to life when it is connected via its interface to defined physical I/O points and placed as a defined instance in the state machine call (see the implementation section); for example, we define an equipment pump with all its methods and properties, but only when we have certain pumps (FreshwaterPump01, WasteWaterPump01, ...) instantiated in our project will water flow.

So with these concepts we are able to forget the internal details of the equipment for all future implementations of the same sort of pump and can concentrate on the method and property interface.

46.2.4 Interchangeability

Interchangeability has a strong relation to reusability as it is based on the same concepts, although it describes another topic.

Reusability refers to the ability to use the same equipment without major efforts again in the same or another project. Interchangeability applies when we want to replace existing equipment with another type of equipment, but with the same functionality. According to our encapsulation approach, equipment with the same functionality should have the same interface layer, although the implementation layer and the base layer are different. We advise strict application of this rule, at least for base equipment.

Consider, for example, that one has to change a pump with all its control and monitoring periphery for any reason (customer demand, unavailability, etc.) with one from another manufacturer. It is evident that often the physical implementation of the machine will be different, even though it has the same functionality.

Having two equipments describing the two pump systems with the same interface layer makes software changes possible in a matter of minutes.

46.2.5 Interoperability

As long as the defined equipment runs on a centralized system, communication between them leads to no trouble. As we pointed out in the Introduction systems nowadays are highly complex and distributed, so we need implementation concepts to simplify access between equipment even in high-grade networked and heterogeneous environments, starting at low control levels with existing equipment.

We will not describe all the systems and attempts in hardware and software that exist or are in development, which could fill books. We only want to focus on the way we structure the issue.

As pointed out in the paragraph on encapsulation, the only way of accessing other equipment is by using the interface layer. As a fetch-ahead of the implementation, we will see that this interface is not part of the equipment functions, but is a separate, generally available data structure. For the time being, this data structure is only composed of basic data types.

As a paradigm we do not allow the implementation layer of a single equipment to be spread over several controllers. This seems like a strong restriction on first reflection, but it enforces well-elaborated encapsulation, and good and fine-structured systems. As an additional advantage, it simplifies equipment communication, which is one of our aims.

46.3 Strategy

46.3.1 Device Drivers

As we defined in the paragraph on encapsulation the basis of every system is its base equipment – the equipment connected directly to the physical world. We consider this equipment like device drivers in the PC environment. In the same way that a program in Windows does not care about the actual physical mouse type connected to the computer, but only the abstracted events, other base or abstracted equipment does not care about the physical implementation of the accessed equipment.

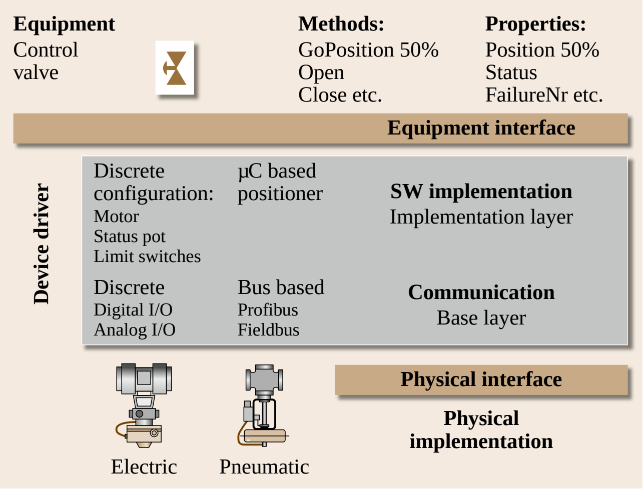

Fig. 46.1 Example of a single base equipment (control valve)

All base equipment, at least, is implemented in the implementation layer as a state machine, executing the functions necessary to the actual state and checking all allowed transitions to switch to another. Typically another cycle is used to catch all possible exceptions.

Figure 46.1 shows the example of a control valve (base equipment) with two possible physical and software implementations. The left column in the implementation part depicts a discrete built-on electric valve with a motor, a potentiometer providing feedback, and limit switches for the end positions. In this case the implementation layer has to build up the complete functionality of the valve, such as the control of the motor, the control loop with the feedback potentiometer, etc. In the right column a micro controller (µC) positioner-based pneumatic valve is represented. Here the implementation layer has to manage mainly the communication to the µC positioner, as the control itself is done by the external logic.

Additionally the independency of the physical implementation is visible. As the electrical valve is

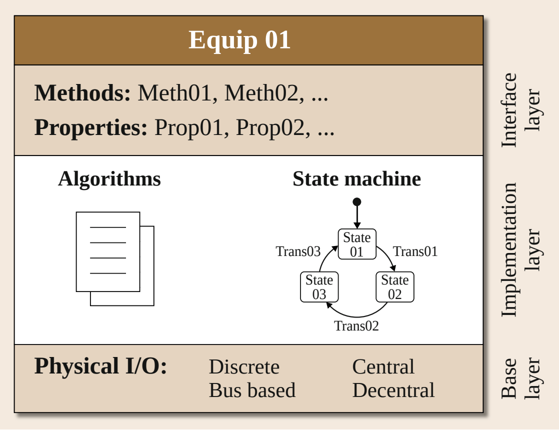

Fig. 46.2 Example of a specifying single base equipment (equipment block diagram); Equip01 does not use other equipment, accessing only physical I/O

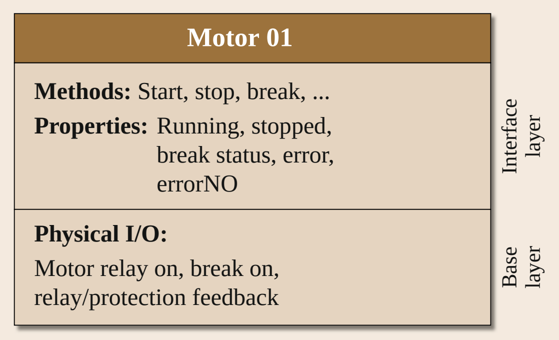
connected via the base interface to discrete I/O, the pneumatic valve is running on a bus system.

Nevertheless the interface layer is the same, and we can control both valve types from higher-level equipment with a handful of methods and properties. So we fulfill at least the demands for encapsulation, reusability, and interchangeability.

46.3.2 Equipment Blocks

To model a complex system a graphical representation of its equipment is helpful. We choose a unified modeling language (UML) class-like representation, although the diagram has an additional area for the base layer [46.4].

Figure 46.2 shows an equipment block for a single base equipment interfacing the base layer singly to physical I/O and not to other equipment. The implementation layer is not a must for the diagram representation, but can be used for clarification of the actual execution of the equipment.



Motor 01
Methods: Start, stop, break, ...
Properties: Running, stopped, break status, error, errorNO
Physical I/O:
Motor relay on, break on, relay/protection feedback
Interface layer
Base layer

Fig. 46.3 Specifying implementation of single base equipment (relay/motor protection controlled motor)

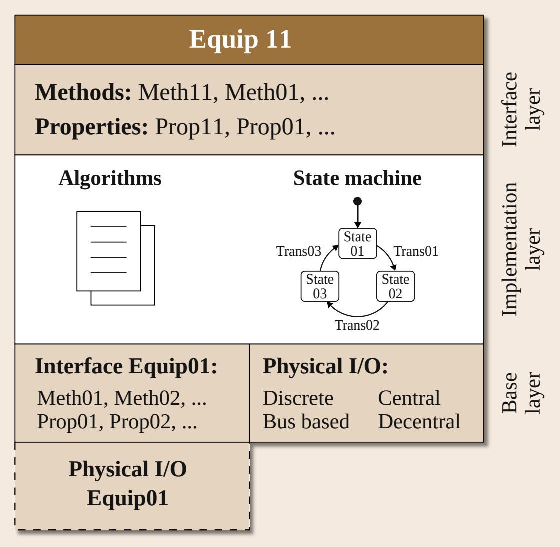


Fig. 46.4 Specifying generalization of single base equipment

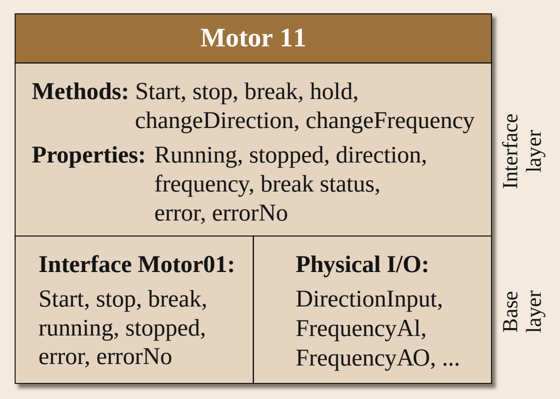
Figure 46.3 depicts the diagram for a simple motor with a brake controlled only by a relay–motor protection switch combination with feedback contacts.

Figure 46.4 shows a more specific equipment *inherited* from a general one. Equip11 will use the methods and properties of Equip01, adding some specific new methods and properties by implementing additional



Motor 11
Methods: Start, stop, break, hold, changeDirection, changeFrequency

Interface Motor01:
Start, stop, break, running, stopped, error, errorNo
Physical I/O:
DirectionInput, FrequencyAI, FrequencyAO, ...
Interface layer
Base layer

Fig. 46.5 Specifying implementation of single base equipment based on generalized base equipment (motor controlled by frequency converter)

physical IO and/or by implementing new algorithms and transitions in the interface of Equip01.

Figures 46.4 and 46.5 demonstrate the generalization (inheritance) of equipment in general based on the example of a more sophisticated implementation of the motor controlled by a frequency converter unit. Bear in mind that there are no automatic mechanisms for inheritance in EN 61131 as in object-oriented programming (OOP) languages. Nevertheless, we implement the underlying idea and call the method generalization to indicate the difference.

Equip11 can forward the interface layer of Equip01 to its own interface layer or can override certain methods and properties of Equip01 as its own implementation.

Figure 46.5 depicts a motor controlled via an intelligent frequency converter. It is derived from the more general Motor01 shown in Fig. 46.3. Depending on the actual implementation, the interface of Motor01 can be forwarded directly to the interface layer of Motor11, or some methods and/or properties have to be overridden.

Figure 46.6 represents a single abstract equipment, built up on two sublevels, as Equip02 accesses another equipment. Euip21 is abstract, as it does not access physical I/O directly.

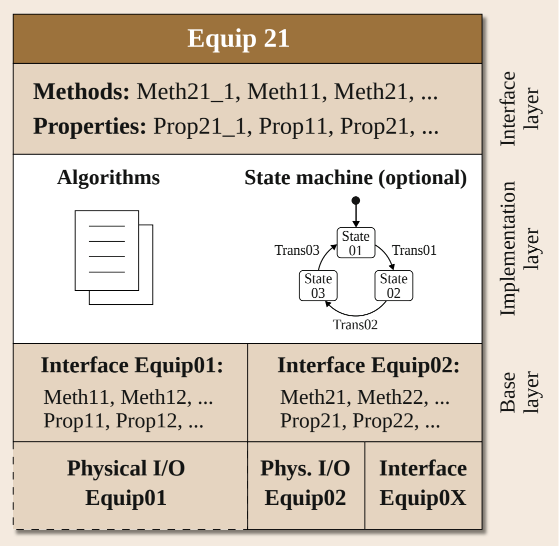

Fig. 46.6 Abstract equipment (does not access physical I/O directly)

46.3.3 Communication

As stated above, communication between equipment is allowed only through use of the interface level. For communication between equipment on the same control unit, shared data blocks are used in general. For homogenous distributed systems all open or proprietary transfer mechanisms are allowed, ensuring coherent data transfer.

For data communication between heterogeneous distributed systems a standardized communication protocol has to be used. As object linking and embedding (OLE) for process control (OPC) data access (DA) is widespread, we normally use this protocol. As version 2 of this protocol does not support well-structured data, the interface layer data has to built up by basic data types only when using OPC DA 2.

With broad distribution of OPC DA 3 or OPC extensible markup language (XML) data access (OPC XML-DA) this constriction will vanish in the foreseeable future, reducing implementation time for the interface communication [46.5].

Special attention has to paid to access to the interface layer of a single equipment by another equipment. As indicated in Figs. 46.4 and 46.6, in general, a single subequipment is embedded into another equipment only via connecting the interface layer of subequipment to the base layer of the accessing equipment. In this way we will obtain a well-structured and strictly hierarchical system.

An exception to this rule has been implemented for accessing data of interest to a group of equipment, bypassing this strict hierarchical system. A separate handler extracts filtered data from the interface layer of defined equipment, stores it in separated data blocks, and present these to a certain interface of the implementation layer. In general we use this outlier only for exception handling.

46.3.4 Rules

As the following implementation will be done on standard EN 61131-based systems, the following rules have to be implemented as a design guide, as these existing systems do not force the engineer to act in an equipment-oriented way. On the other hand, only by using a C++ compiler, nobody is barred from writing unstructured code in an objectless method. The rules are:

1. Encapsulation is a must: no direct access to the physical level other than by distinctive base equipment.
2. Abstraction has to be forced to the highest level possible, which makes especially interchangeability simple.
3. Interequipment communication has to be done only by use of the interface level (methods and properties).
4. Generalization has to be used whenever possible.
5. The use of abstract equipment should be done in the lowest possible level.
6. Implementation of one single equipment on a single controller (no implementation of algorithms or state machines in the implementation layer via more then one controlling unit).

46.4 Implementation

As pointed out at the beginning, in this chapter we want to focus on the implementation of the topics elaborated so far for EN 61131-based PLCs, since this poses a particularly challenge.

We have chosen the implementation in instruction list form, as the flexibility of this method in general is the largest for most control systems. Nevertheless one can use structured text or function block diagrams; ladder diagrams or sequential function charts are not adequate [46.2].

All equipment is implemented in function blocks; each instance of the function block represents a physical unit for base equipment or a certain virtual or composed unit for abstract equipment.

The base layer is represented by the function block's own encapsulated data block, whereas the interface layer is represented by a separate, general data block, unique for each implementation of the equipment. This allows simple data communication and easy multiple access for different higher-level equipment.

For base equipment a state-machine implementation is a must, although abstract equipment should also use this method if it makes sense.

All base equipment function block are called cyclically by a service routine and run their state-machine functions. Implementing this approach, at least error handling is done for all devices, independently of whether the device is actually used or not. This is a major advantages for early failure detection. The way of connecting physical I/O to base equipment is not limited and could be either discrete on a centralized unit or via fieldbuses, Ethernet or even wireless for decentralized peripherals.

As mentioned earlier, one homogenous control unit is responsible for implementing the algorithms and state-machine functions for a single equipment, i. e., such a control unit can of course host a large number of equipments, but the implementation layer of one single equipment cannot be executed by several control devices.

So, considering the communication aspect, even in heterogeneous networked systems different communication methods simply have to map the interface data blocks to the participating control units in a coherent manner.

Practically we use system-specific communication methods, as long we are working in homogenous platforms, because they are in general more efficient. If we leave the homogenous domain, we normally use OPC DA and OPC AE (alarms and events) [46.5].

Because we do not mix data with data communication in our strategy, functional engineering and data communication setup can be handled separately.

46.5 Additional Impacts

46.5.1 Vertical Integration and Views

In the Introduction of this chapter we found that vertical integration of processes is an answer to many of the demands of modern business [46.6]. Figure 46.7 represents the business as well as the communication pyramid in a contemporary enterprise. Nowadays the control level is the domain of PLCs, whereas

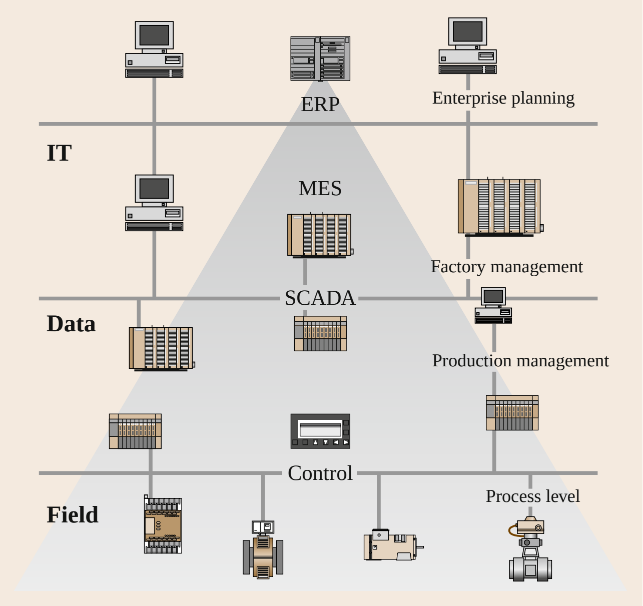

Fig. 46.7 Business and communication pyramid in a modern enterprise

supervisory control and data acquisition (SCADA), manufacturing execution systems (MES), and enterprise resource planning (ERP) are the domains of PC-based devices [46.7].

With the implementation of an equipment-based programming structure at the control level we overcome the existing gap between the field and the data/IT level.

As many enterprise MES and ERP solutions are already object oriented, equipment-based control structures can easily be mapped to objects in higher-level applications, as the equipment constructs are built up in a class-like manner [46.7].

The hierarchical structure of the equipment implementation follows the natural business pyramid, and the encapsulation and abstraction support the inherent enforcement of data reduction in the lower field level.

46.5.2 Testing

A major part of resources during the development of a system is spent on testing its functionality and exception handling. By using software strategies with a clear hierarchical structure, a modular concept with a strictly defined interface layer architecture, these resources can be dramatically reduced, concurrently increasing performance and stability.

46.5.3 Simulation

Another attempt to reduce testing resources is the simulation of systems or subsystems of a project. If a simulation is connected to real hardware, we speak of *hardware in the loop* simulation. In testing developed equipment, one can differentiate between two cases. The higher-level equipment accessing the part to be tested is simulated, or a lower-level part we want to access is simulated.

In both cases the concept of equipment-based structures simplifies the simulation part. Firstly, most simulation tools are object oriented, so we are able to map our equipment easily to their classes. Second the simulation environment has to model only the abstracted interface layer of the simulated subsystem, rather than simulating all the necessary I/Os.

46.6 Example

Profactor, amongst others, has been a supplier of test stands for heat and flow meters for 20 years; additionally the automation group of ARC-sr delivers innovative automation solutions for the process and production industry and also develops new automation processes for a couple of sectors [46.8].

In 2000 Profactor was put in charge of building one of the largest and most modern test stands for heat meters in Berlin. The customer was the well-known Physikalisch Technische Bundesanstalt (PTB) [46.9].

In addition to building up the mechanics and measurement system, challenging the frontiers of today's realizability, the test stand had to be embedded into an overall test administration system. This started with the management of customers, test orders, and devices under test, and ended with management of test reports and quality management for the test stand with its own subsystems.

As the system for the PTB was the most complex test stand ever, incorporating about 1000 physical I/O and measurement points, including dozen of subsystems, and has to be vertically integrated into the testing hierarchy of the PTB, Profactor decided to implement the described system for the actual and future system as well as for other complex systems in their field of activities [46.10].

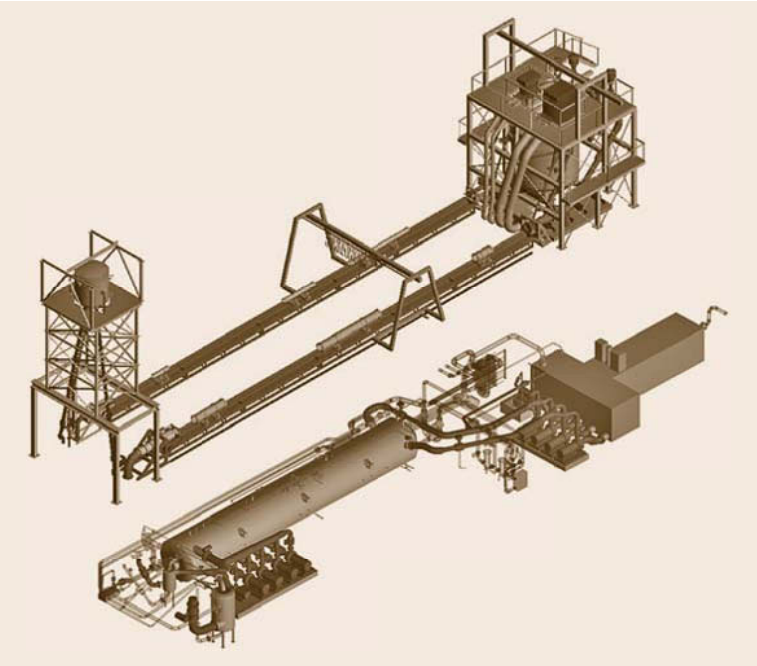

Fig. 46.8 Layout of the test stand for flow and heat meters

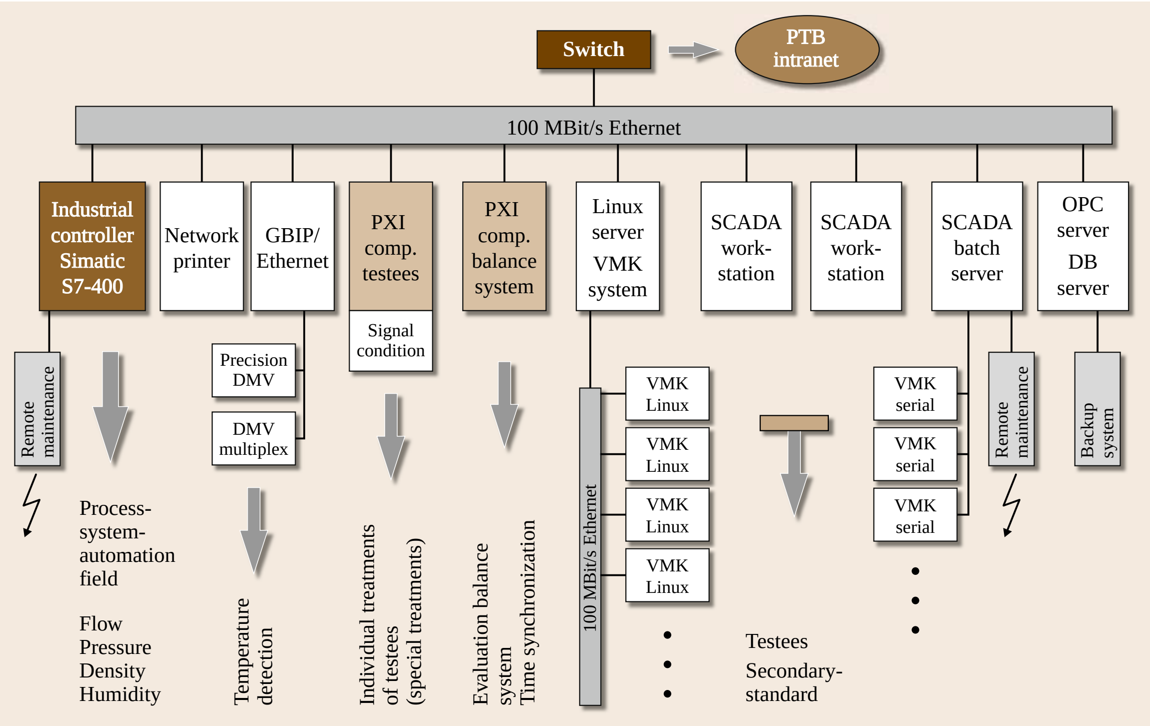

Fig. 46.9 Specifying subsystems and their communication implementation (Seibersdorf Research) (VMK – measurement interface, GBIP – general purpose interface bus, PXI – PCI extensions for instrumentation)

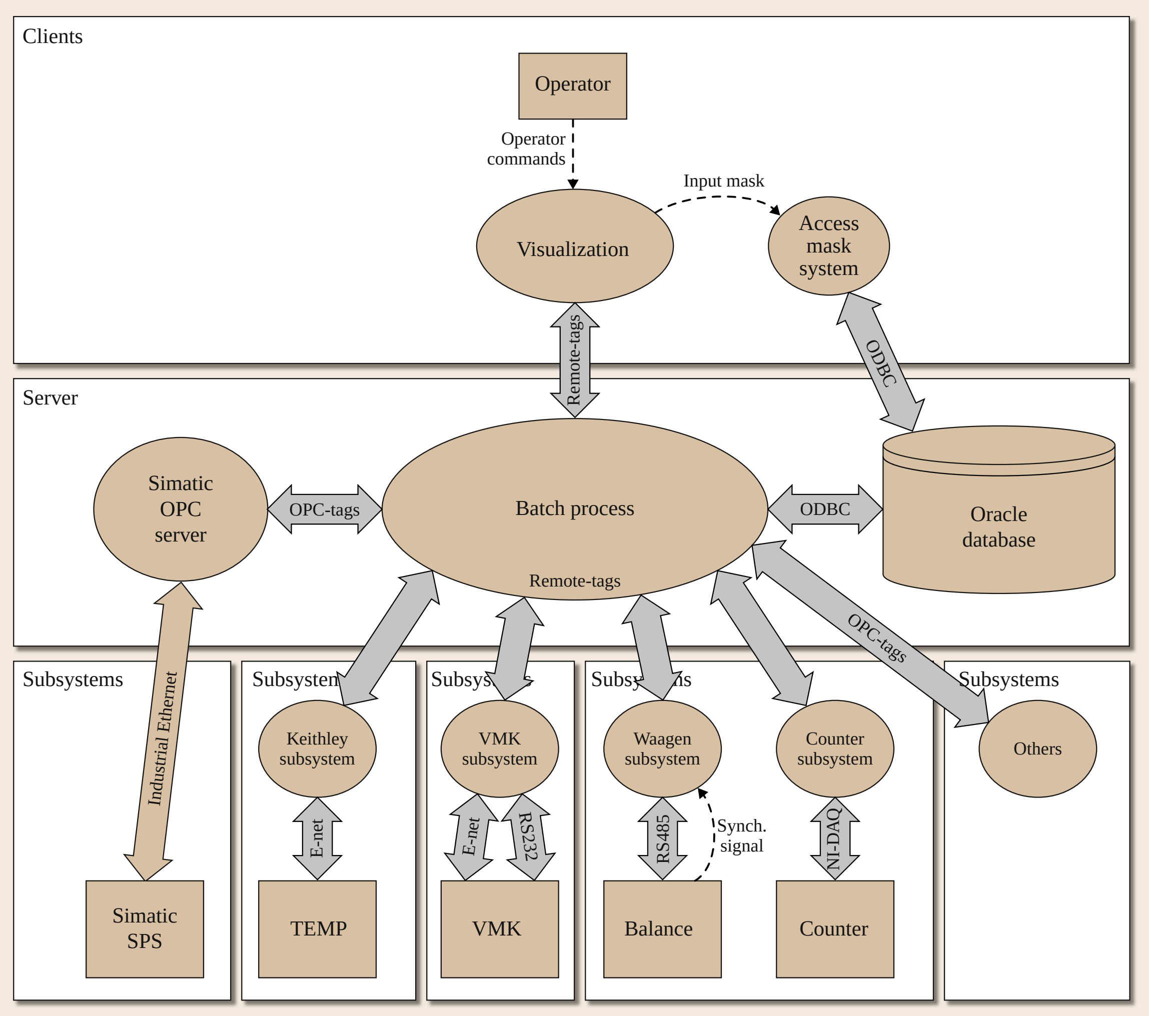

Fig. 46.10 Specifying communication pyramid of the test stand (ODBC – open database connectivity, SPS – PLC, NI-DAQ – national instruments – data acquisition)

46.6.1 System

Figure 46.8 depicts the layout of the test stand. The facility is built up on two floors. The upper floor houses the test bench itself, the balance device with its self-calibration unit, the diverter unit, and the elevated tank. The pressure tank, compensation tank, pumping stations, and electrical heating device are installed on the lower floor. Auxiliary equipment such as the gas heating unit and air cooling systems as well as compressor-based cooling systems are in separate locations and are not shown in the figure.

To get an impression of the dimensions, the linear expansion of the system as depicted in Fig. 46.8 is about 40 m. The maximal testing flow rate is 1000 m^3/h. The operation temperature is between 3 °C and 90 °C with an installed heating capacity of 680 kW h, an air cooling capacity of about 1000 kW h, a compressor-based cooling capacity of about 380 kW h, and an installed pump capacity of about 350 kW h.

The technical requests for the commissioning were at the limit of technical feasibility:

- Stability of temperature in all operating points $< 0.1\,\text{K}$
- Stability of flow (up to $1000\,\text{m}^3/\text{h}$) $< 1\%$
- Stability of pressure (in pressure mode) $< 3\,\text{mbar}$
- Accuracy of balance unit $< 50\,\text{g}$ (on 20 t of load)
- Overall measurement uncertainty $< 4 \times 10^{-4}$.

These demands resulted in highest efforts to the control and measurement system.

The key factor for the integration request was the integration of the test stand management database (Oracle or MS SQL server (Microsoft structured query language)) with its user front-end in the production database that organizes the test routines and is responsible for the storage of real-time trend data from the testing process [46.11].

In these databases not only the test and test management data is stored, but also the complete setup and control parameters as well as the calibration data of the test stands measurement devices.

For exact repetition of tests all setup and control parameters of the complete facility can be reloaded to the subsystems automatically by recalling a certain date or test order from the database. In additionally providing the necessary automatic documents for quality control the customer owns not only one of the most modern test stands in measuring technology, but also in terms of data management.

Figure 46.9 shows the communication of the subsystems. The control of the test stand itself and its auxiliary systems is realized by an EN 61131-like PLC system. This PLC system alone manages about 800 physical I/O points on a centralized and decentralized basis. The programming strictly follows the described equipment structure.

46.6.2 Impacts

The first PLC implementation of this concept required more effort and expense compared with traditionally programming, but major benefits were observed already during start of operation and integration into the vertical environment.

46.6.3 Succession

Subsequently Profactor was put in charge of building another, smaller test stand for a major German power authority. Although Profactor was forced to use a lot of different components compared with the PTB installation, the decrease of time, efforts, cost, and failures was significant.

46.7 Conclusion

By following the described methods of implementing an equipment-based control system structure, the system designer is able to deliver software with a clear hierarchical structure and a modular concept with strictly defined interface layer architecture, simultaneously decreasing the required resources and increasing performance, stability, and openness.

It is possible to implement a lot of concept features normally only supported by object-oriented languages. Most importantly, the engineer can use existing software and hardware platforms that have been available for many years and anywhere.

47. Automation and Ethics

Srinivasan Ramaswamy, Hemant Joshi

Should we trust automation? Can automation cause harm to individuals and to society? Can individuals apply automation to harm other individuals? The answers are yes; hence, ethical issues are deeply associated with automation. The purpose of this chapter is to provide some ethical background and guidance to automation professionals and students. Governmental action and economic factors are increasingly resulting in more global interactions and competition for jobs requiring lower-end skills as well as those that are higher-end endeavors such as research. Moreover, as the Internet continually eliminates geographic boundaries, the concept of doing business within a single country is giving way to companies and organizations focusing on serving and competing in international frameworks and a global marketplace. Coupled with the superfluous nature of an Internet-driven social culture, the globally-distributed digitalization of work, services and products, and the reorganization of work processes across many organizations have resulted in ethically challenging questions that are not just economically, or socially sensitive, but also highly culturally sensitive. Like the shifting of commodity manufacturing jobs in the late 1900s, standardization of information technology and engineering jobs have also accelerated the prospect of services and jobs more easily moved across the globe, thereby driving a need for innovation in design, and in the creation of higher-skill jobs. In this chapter, we review the fundamental concepts of ethics as it relates to automation, and then focus on the impacts of automation and their significance in both education and research.

47.1 Background

> *To educate a man in mind and not in morals is to educate a menace to society.* (Theodore Roosevelt)

In this chapter we attempt to address a key issue facing people from industry and academia, especially with the rapid pace of globalization and technological advancement related to automation. Why is ethics, and what makes studying and understanding ethics and its link to automation important; both the inculcation of it among our present and future colleagues, employees, and public services, and understanding it within the context of academic, government, and corporate research. After describing the ethical issues related to automation, we focus our presentation on two specific areas, education and research, respectively. In the section on education, we present a mechanism whereby the inculcation of ethics can, and should, be integrated within a student's curricular program and learning experience, instead of the simpler one-course approach that is taken by educational institutions today, in response to the mandatory requirement of *teaching* ethics as sought by employers and accreditation agencies such as ABET. The section on research could have been written on many levels – from ethics in workplace, personal ethics, to social and professional perspectives of what can be considered ethical behavior in research. Since these topics are widely covered elsewhere (references are given below), we have chosen to illustrate and explore the critically emerging issues of user profiling by logging user activities on a network (the Internet and automation networking in general). This illustration is important because this issue is beginning to assume a greater degree of significance in today's world, with the ability of people and organizations to use advanced automation to gather, store, mine and analyze enormous amounts of data, very cheaply. Hence, addressing this issue will likely prompt ethical questions (not just limited to what we present here) across all the above different perspectives.

47.2 What Is Ethics, and How Is It Related to Automation?

> *New and emerging automation technologies and solutions pose significant new challenges for ethical individuals, organizations, and policy-makers.* (Automation Scholars)

Ethics is a set of principles of right and wrong that individuals apply when making decisions influencing their behavior. Many decisions can clearly be recognized by most people as being wrong or immoral, including violations of the law, dishonesty, and any other behaviors that conflict with common behavioral norms and societal values. The role of ethics, ethical thinking, is important especially when there are no clear-cut guidelines, for example, when individuals encounter conflicts between objectives and their principles, and as often happens with the emergence of new technology, including automation technology [47.1–7]. As new choices and new experiences become available to individuals and organizations, they face dilemmas between risks and benefits, short-term benefits against long-term risks, risks to individuals versus benefits to a group, and so on. A major challenge to ethical behavior is the fact that not only changes in technological abilities over time pose new ethical dilemmas, but that ethics is deeply rooted in local and domain cultures, hence, it requires adjustments and calibration in the interfaces and exchanges. This dual challenge for inter-cultural ethical behavior over time and location has been evident throughout history, and is particularly sharp at the edges during our age of tremendous automation innovations coupled with intensifying global exchanges (Fig. 47.1).

Automation has several particular impacts on ethics:

1. Automation enables unethical behavior, e.g., applying automatic imaging to monitor private situations violates privacy rights, but may be necessary for security and prevention of theft.
2. Automation simplifies unethical behavior by obscuring its source, e.g., people blaming automation for mistakes, delays, inefficiency, and other weaknesses (*It's not me; it's this dumb computer*).
3. Automation increasingly enables unethical behavior related to information and communication, e.g., recording conversations and proprietary knowledge; maintaining and visiting web-sites with illegal, violent, or hateful contents.
4. Automation enables replacement of labor, e.g., by robots, automated sorting, and automatic inspection.
5. Automation affords anonymous access over and to private or restricted property.

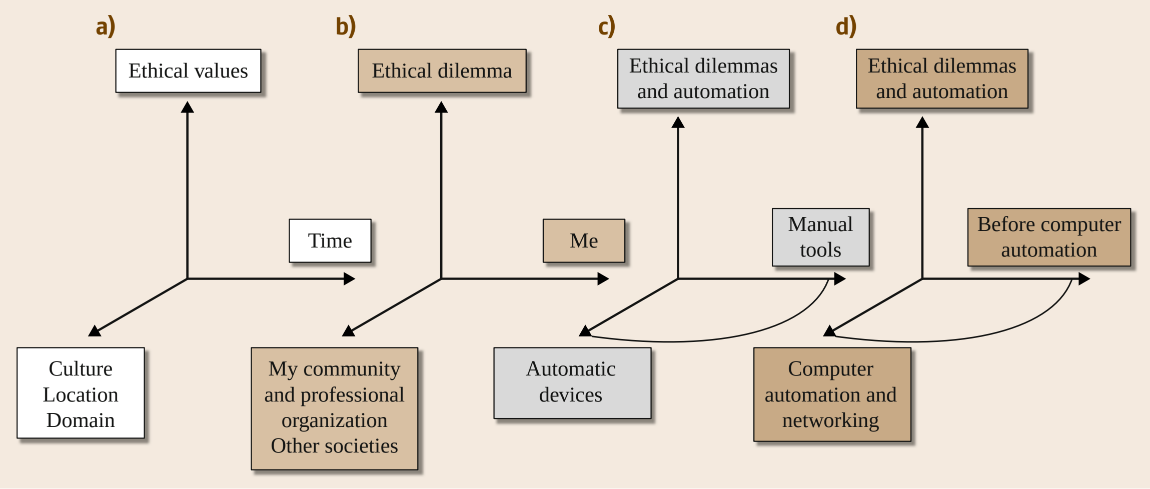

Fig. 47.1a–d Ethics values and dilemmas: **(a)** Ethics of today may not be the same as ethics of yesteryears due to changes in cultural and technological evolution (changes) around the globe. **(b)** Ethical dilemmas are conflicts between individual's or groups of individuals' rights, benefits, and rewards versus community, organization, and society at large gains and sustainability. **(c)** Major ethical dilemmas emerge when changing from manual tools and procedures to automated and automatic devices, e.g., remote imaging, banking automation, and Internetworking. **(d)** Major ethical dilemmas further emerge, more frequently and with farther impact when automation evolves and with computers and worldwide network communications advancements

6. Automation enables cyber-crime, cyber-terrorism, information hiding or obscuring, forgery, identity theft, or identity hiding.

Some of these examples overlap with criminal and other illegal behavior [47.6, 8, 9]. But there are many examples where the situations are ambiguous, or ambivalent. When society realizes the severity and damage caused by some such cases, laws are developed and implemented. Often, however, ethical issues emerge and require urgent individual and organizational responses in the face of far-reaching ethical dilemmas.

47.3 Dimensions of Ethics

Dimensions of ethics can be considered in multiple aspects, which are inter-related (Table 47.1): From the *aspect of automation technology*, how and what it enables in challenging ethical behaviors, e.g., financial crimes through banking automation; from the *aspect of impacts on individuals, on communities, and on society*, e.g., hate crimes through the Internet. From the *aspect of automation security*, how automation's own security can be breached with unethical schemes and outcomes, e.g., by intentionally or unintentionally disabling software safety functions. In all dimensions, however, it is clear that people are responsible, directly or indirectly, intentionally or unintentionally, for their ethical decisions, behaviors, and the outcomes; furthermore, people, not automation, are the potential misusers and abusers of automation in the context of ethics.

Ethics and automation can also generally be divided into ethical issues involving information-focused automation [47.1, 2, 4, 10], e.g., information security and privacy; and automatic device/systems ethic [47.7, 9, 11–13], e.g., ethics of robotics (sometimes called roboethics), for instance, trust in tele-surgery by robots. There are, of course, overlapping ethical dimensions, for instance, when information systems are hacked (security breach) to disrupt automatic traffic and aviation control (impact dimension), or to dysfunction automatic power distribution (technology and impact dimensions) [47.5, 14–16].

Table 47.1 Aspects and dimensions of ethical concerns with automation

Aspect of ethical dimensions	Scope	Main ethical dimensions	Sample references
Technology aspect	Ethical challenges enabled and raised by automation functions and abilities	● Cyber-ethics (a.k.a. e-Ethics) ● Robo-ethics	[47.3, 7, 8, 11–15, 17–20]
Impact aspect	Ethical impacts on individuals, communities, and society	● Privacy ● Property ● Quality ● Accessibility	[47.1,2,4,6,10,14, 16,19,21–23]
Automation security aspect	Ethical issues of man-made (malicious and erroneous) and natural disasters causing security threats through automation, and vulnerabilities caused by automation	● Information security ● Technical failures ● Cyber-crime ● Cyber-terrorism ● Cyber-warfare; robo-warfare	[47.2,4,6,7,12–15, 20,24–30]

Consider the four main automation areas (Chap. 3, Fig. 3.2):

1. Automation with just computers – Data processing and decision support, e.g., enterprise resource planning, accounting services
2. Automation with various automation platforms and applications, but without robots, meaning automation with devices, sensors, and communication, e.g., weather forecasting, air-traffic control
3. Automation applying also robotics, e.g., fire safety including alarms and robotic sprinklers
4. Automation with robotics, e.g., robot painting, robotics in microelectronics fabrication and assembly

Each of these automation areas involves ethical decisions and behaviors, along the dimensions indicated in Table 47.1, by managers, operators, maintenance personnel, and designers, who have to adhere to ethical values to enable sustainable services and viable society. Additional examples follow below.

Another common view of ethics and automation has been the view from the aspect of impacts on individuals, on communities, and on society. Four main dimensions of ethics in this context, as related to automation, are privacy, property, quality, and accessibility.

Privacy: Privacy issues are related to gathering, maintaining, distributing, analyzing, and mining information about individuals. For example:

- What rights do individuals have to their own information and its protection?
- What information about themselves do individuals have to share with others?
- Who is responsible for the security of private information about individuals when it is maintained in a database?
- What rights to surveillance over individuals do organizations and government services have?

Property: Issues involving ownership of physical and intellectual property. For example:

- Can corporate automation equipment be used for personal purposes?
- How should software, music, and other media piracy be handled?
- Who is accountable and liable for damage caused by automation?
- How will intellectual property be traced and accounted for, when automation enables its easy and rapid copying and transfer?
- Who is responsible and accountable for backup records?

Quality: Quality of automation implies its integrity and safety of functions, fidelity, authenticity and accuracy. For example:

- Can an individual trust an automatic device, e.g., in medical diagnostics and treatment?

- What quality standards are needed to protect society's and individuals' safety and health, also including long-term environmental concerns?
- What quality standards and protocols concerning automation and information are required to protect individuals' rights?
- Who is responsible, accountable, and liable for the accuracy and authenticity of information and of automatic functions?
- Who is responsible, accountable, and liable when functions relying on automation fail?

Accessibility: Accessibility issues involve the right to access and benefit from automation, the authority of who can and cannot access certain automation assets and resources, and the increasing dependency on automation. For example:

- What skills and what values should be preserved and maintained in a society increasingly relying on automation?
- What about loss of judgment due to such reliance?
- Who is authorized to use automation and access automation resources?
- How can such access be managed and controlled?
- Can employees or clients with disabilities be provided with access to automation, for their work, healthcare, learning, and entertainment?
- How and under what conditions should access to automation be priced and charged?
- Can automation limit political freedom?
- Does automation cause addiction and isolation from family and community?

47.3.1 Automation Security

Automation security involves security of computer and controller software and hardware; of information and knowledge stored, maintained, and collected by automation, e.g., the Internet, imaging satellites, and sensor networks; and of automation devices, appliances, systems, networks, and other platforms. Most of the ethical concerns in automation security overlap the previous aspects and dimensions, but have certain unique security related dimensions. Some of the ethical issues associated with automation security are:

- What are the vulnerabilities of automation security that impact on privacy, property, quality, and accessibility ethical dimensions, and who is responsible for overcoming them? For recovering from them?
- With increasing automatic interconnections and automatic interactions between various automation systems and devices, how can security levels be maintained, shared, and warranted over entire services? Who is responsible for tracking, tracing, and blocking the instigators and initiators of the security shortcomings causing unsatisfactory service?
- Who is responsible and who is liable in the case of harmful and damaging security breaches, such as trespassing, espionage, sabotage, information extortion, data acquisition attacks, cyber-terrorism, cyber-crime, compromised intellectual property, private information theft, and so on? What would be the difference between breaches caused by unintentional human error versus malicious, unethical acts?
- Who is responsible and who is liable when there are automation software attacks, e.g., software viruses, worms, Trojan horses, denial of service, phishing, spamware, and spyware attacks?

Governments, national and international organizations, and companies have already advanced various measures of defenses and protection mechanisms against security breaches. Examples are the Business Software Alliance (www.bsa.org), the cyber consequences unit in the US Department of Homeland Security, computer and information security enterprises such as www.cybertrust.com, and university centers such as CERIAS (Center of Education and Research in Information Assurance and Security, www.cerias.purdue.edu), and CERT (Computer Emergency Response Team, www.cert.org). Yet, automation security poses complex and difficult challenges because of the high cost of preventing hazards, associated with the difficulty to justify such controls, the difficulty to protect automation networks that cross platforms, organizations, countries, and continents, and the rapid automation advances, which render new security measures obsolete. More about automation security can be found in [47.25–30].

The ethical dilemmas discussed above and their dimensions illustrate some of the ethical questions raised by developing and applying automation, and by its rapid advancement and influence over our society, from automatic control devices, robots and instruments, to the computing, information, communication, and Internet applications.

47.3.2 Ethics Case Studies

Ethics is best taught and explained through case studies and examples [47.2, 3, 5, 14, 21, 31, 32]. In Table 47.2, examples of ethical issues related to automation are described. Some examples are clear ethical dilemmas. Some of them are more subtle ethical problems. As often is the case in ethical dilemmas, solutions are usually not simple.

Table 47.2 Examples of ethical issues in automation and their dimensions ▶

47.4 Ethical Analysis and Evaluation Steps

> *What is hateful to you, do not do to your fellow human.* (Hillel the Elder, Talmud, Shabbat 31a)

How can one rationalize situations and decisions involving ethical conflicts? And how can automation systems be designed and operated with assurance that intended ethical imperatives and decisions would indeed be followed?

Some of the earliest thinking about ethics and automation, in the area of robotics, is attributed to Isaac Asimov, a prominent scientist and science fiction author, who wrote in his book *I, Robot*, [47.33] and also in *Looking Ahead* [47.34] *The Three Laws of Robotics*:

1. A robot may not injure a human being, or, through inaction, allow a human being to come to harm.
2. A robot must obey the orders given it by human beings except where such orders would conflict with the First Law.
3. A robot must protect its own existence as long as such protection does not conflict with the First or Second Law.

Substituting *an automation system* for *a robot* in the three laws above would still make a lot of sense in any context of automation, including the threat of automation singularity (see Chap. 3). But a critical issue is how to implement it during the design and activation of any automation functions. While this challenge is still open to research and discoveries, ethics educators and scholars recommend a five-step approach, as follows [47.1–8, 18, 19]:

Step 1 *Characterize and Specify the Facts*
Establish the stakeholders and events involved, including the *6 Ws*, who, what, when, why, to whom, and where.
Notes:
a) Sometimes, just clarifying the facts results in simplifying the resolution and the decision.
b) Often getting multiple parties, even those in conflict, to agree on the facts may help resolve the ethical conflict.
c) Often the clarification of facts sharpens and simplifies the realization of an ethical imperative, leading one or more of the participants to share the facts with authorities (known as the *whistle blower*), thus leading to a resolution of the ethical dilemma.

Step 2 *Formulate the Dilemma and Conflict (or Conflicts), and Find the Involved Values*
Ethical issues are always linked with values; the parties in conflict usually claim their motivation as the pursuit of high values, such as fairness, freedom, protection of privacy and property, saving resources and the environment, and increasing quality.

Step 3 *Clarify Who Would Benefit and Who Would Be Harmed by the Given Ethical Issue*
Beyond the facts established in Step 1, including the stakeholders, analyzing and finding who may benefit and who may be harmed can be useful in clarifying and understanding which solution, or solutions, may be effective and feasible and practicable.

Step 4 *Weigh and Balance the Resolution Options*
Ethical dilemmas and conflicts are characterized by having complex variables and dependencies, and rarely present a simple solution. Usually, not every one of the stakeholders and other involved individuals, organizations, and society members can be satisfied. Moreover, the thorny realization is that there would almost always be some who may suffer or would consider themselves harmed under any given decision. In some cases, there may not be any optional strategies that could balance the consequences to all the involved parties.

Step 5 *Analyze and Clarify the Potential Outcome of the Ethical Decision*
Certain options of ethical strategy and policy to resolve a given ethical dilemma may satisfy our principles and values, yet they may be harmful from other aspects. For example, a policy

Ethical case	Dimensions of ethical issues			
	Privacy	Property	Quality	Accessibility
1. Company database highlights employees' personal attributes, e.g., nearing retirement, potentially being discriminatory. Furthermore, who needs to know this information? Who is authorized to access it?	✓			✓
2. Service providers monitor employees' access to certain websites. Employees cannot prevent being monitored while using company computers; employers may abuse the gathered private information.	✓	✓		✓
3. Organization audits individuals' use of unauthorized software, either to create policies, protect itself from property lawsuits, or monitor individual private behavior.	✓	✓		
4. Company is using automated imaging technology to replace employees. This case illustrates a typical conflict between economy, accuracy, and efficiency goals achievable with automation, and the loyalty to dedicated employees (who will lose access to work with automation).			✓	✓
5. New automatic sorter has hidden design deficiencies that are too costly to repair after deployment of thousands of such devices. This case is common, as evident by some ethical companies occasionally recalling defective automation equipment for upgrade and repair. If there is no recall in such cases, clients and users are denied access to better quality and safer equipment.			✓	✓
6. A robot controller, under certain undisclosed conditions, will cause substantial chemical waste and pollution. This multi-dimensional ethical problem, involving issues of significant potential damages to life, life quality and property, possibly denying access to inflicted areas and properties, and potentially costing also in major remedial and recovery efforts, is illustrated by cases of whistle blowers, ethical individuals who risked their employment to warn about imminent hazards.		✓	✓	✓
7. Company has superior medical automation technology but will not produce it for several years till it recovers all previous investments in the inferior product currently being marketed to hospitals. This case is similar to Case 6, except it is a different scenario.		✓	✓	✓
8. A vending machine delivers (a) the right item, but returns too much change; (b) the wrong item, and no change. Ethical dilemmas are caused by automation's dysfunctional quality.			✓	
9. A manager blames automation for faulty packaging. Is automation to blame, or is it its designer/implementer/user?			✓	
10. A student blames the school's computer for lost homework. Ethical challenges concerning work quality (and computer automation quality) are posed to both the student and the instructor.			✓	
11. (Think of an ethical dilemma with your home automation.)				
12. (Think of an ethical dilemma unique to your organization's use of automation.)				

Table 47.3 Examples of conflicts between ethical values and principles

Values/Principles in conflict	Illustration
1. Short versus long term	Software patch solving security problems now but causing hazards later
2. Individual versus community	Wasteful exploitation of resources harming later generations
3. Justice versus mercy	Charging for mass email to prevent spamming
4. Privacy versus convenience	Reading the fine details of use-contracts for each downloaded software
5. Loyalty versus truth	Divulging harmful private or proprietary information gained in confidence
6. Loyalty to present versus former organization (employer)	Sharing knowledge about relative advantages or shortcomings of design or applications
7. Efficiency versus safety	Higher speed limits and lower weight versus automobile accidents' severity

that works well for some situations may not work well, or may work only partially well for the same situations under different conditions (it is a conditional solution); or not work well at another time period (it is a time-dependent solution). In analyzing potential outcomes, one may consider the conflicts arising between wrong and right solutions or decisions, between two wrong solutions or decisions, and between two right solutions or decisions. Examples of such ethical conflict analyses are illustrated in Table 47.3.

In analyzing ethical conflicts, usually the conflicts between two or more right solutions, or between two or more right values, pose the most complicated dilemmas. For example, decisions in examples 1 and 5, which may be relatively simple when the potential hazard is enormous. The situations are also relatively more complex when multiple conflicts combine, e.g., individual versus community for short versus long term implications. Additional guidance is offered by ethics principles.

47.4.1 Ethics Principles

Numerous ethics principles have evolved since ancient times, and have been suggested by ethics philosophers and scholars. Seven of the well known principles are listed in Table 47.4.

Principles (1) and (2) are considered the *individual fairness* principles. Principle (3) is similar to (2), but stated from a group aspect. Principle (4) represents the

Table 47.4 Seven ethics principles

Principle's name	Ethical principle imperative/lesson
1. Hillel the Elder's principle	Do not do to others what you do not want to be done to you.
2. *The Golden rule*	Do to others what you would accept if done to you.
3. Immanuel Kant's categorical imperative	If an action is not right for everyone (in a team, or group, or community) to take, then it is not right for anyone.
4. Descartes' rule of change	If an action cannot be taken repeatedly (e.g., a small action that may snowball out of control), it is wrong to take it at any time.
5. Utilitarian principle	Decide on the action that leads to the higher, or greater, or more significant value (if values can be prioritized, and if consequences can be predicted).
6. Risk aversion principle	Decide on the action that leads to the least damage, or the smallest hazard.
7. *No Free Lunch* rule	Respect the ownership of tangible and intangible assets, and if ownership is unknown to you, assume somebody owns assets that do not belong to you.

impact of time and changes over time (at least those changes that are predictable. Principle (5) addresses the issue of conflict between several objectives and principles, and maximizing the value of consequences. Principle (6) is similar to (5) but from the aspect of minimizing damage. Finally, principle (7) addresses the value and concern for intellectual property protection, on par with physical property protection, as a fair principle for a globally sustainable society.

The above principles provide some guidance for initial analysis. Often, however, they may point to conflicting strategies, and individuals still need to carefully weigh their decisions and take responsibility for each of their decisions. On the other hand, these basic principles offer clear tests for actions and decisions that should not be followed if they fail these tests.

47.4.2 Codes of Ethics

To address the complexities of ethical issues, corporations and organizations define, accept, and publicize their code of ethics [47.10, 21–23]. Such a code prescribes values to which the organization or corporation members are supposed to adhere. The typical structure of a code of ethics closely related to automation is illustrated in the Appendix. Examples of codes of ethics in different countries are included on the USA National Academy of Engineering site ([47.21], http://onlineethics.org). Values that may be incorporated in a code of ethics include:

- Care for others
- Compliance with the law
- Consideration of cultural differences
- Courtesy
- Fairness
- Honesty
- Integrity
- Loyalty
- Reliability
- Respect for sustainable environment
- Trustworthiness
- Waste avoidance and elimination.

General moral imperatives that are included in a code of ethics are listed as follows:

- Follow fairness principles
- Contribute to society and human well-being and sustainability
- Avoid harming others
- Be honest and trustworthy
- Honor property rights including copyrights and patents
- Give proper credit to intellectual property
- Access automation resources only when authorized
- Respect the privacy, diversity, and rights of others.

47.5 Ethics and STEM Education

> *I didn't know I was a slave until I found out I couldn't do the things I wanted.* (Frederick Douglass)

Rapid advancements in automation have led to significant challenges, as indicated earlier in this chapter. Automation has also influenced changes to demographics, and the creeping of problems associated with student and employee recruitment, retention, and *focused* funding. Good educational preparation in the science, technology, engineering, and mathematics (STEM) disciplines is one of the primary means available to prepare the workforce to compete globally for highly skilled technology-based and automation-based jobs. In their current work environments, not only do students need to understand and deal with the increased knowledge expectations from the workforce, but they need to also understand and deal with the pervasive and dominant role of automation technology within their chosen fields, and operate effectively in an increasingly multi-cultural and multi-ethnic, global environment. In these jobs, softer skills, which relate to *how we go about getting things done*, being language, society, and culture-sensitive, are becoming equally important as the hard functional skills (e.g., programming, problem solving, techniques selection, modeling) that have traditionally defined what it means to be competent in a chosen professional field. The widespread globalization of the job market calls for future employees to be adaptive, curious, and nurturing so as to work effectively in a team, which may be either co-located or geographically separated.

47.5.1 Preparing the Future Workforce and Service-Force

I cannot tell anybody anything; I can only make them think. (Socrates)

Many organizations, for profit and not-for-profit, now realize that hiring workers who have been trained to understand international issues, specifically from an ethical and cultural perspective, will provide their businesses and services the necessary competitive-sustainable advantage in a global society and global market. For example, conducting transactions in another country can be riddled with cultural issues that require deft personal touch, such as demonstrating appropriate hospitality, and respecting cultural and religious diversity. Thus, the future in many professional disciplines is not in merely a collective ability to prepare and graduate good designers, programmers, practitioners, managers, and technologists – these skills have now become commodities that can be outsourced. It lies is in the ability to prepare entry-level employees and continuing education employees who are highly comfortable with the theory, can appropriately blend it with necessary practice and possess an understanding of both the business culture and the social issues involved, while being able to effectively share, communicate, articulate, and advance their ideas for an innovative product or solution. Hence, how we educate students to become such successful employees and entrepreneurs, while acting ethically in the global economy and society is an important consideration, often better taught through the use of appropriate case studies.

The rapidly emerging and evolving, and highly sensitive global economy is profoundly affecting the employment patterns and the professional lives of graduates. Thus educating the future workforce to understand such issues in a global context is becoming a highly sought-after experience and a critical differentiator in their employability, often testing their ability to bridge discipline-specific theoretical research issues with real-world practice, including addressing and resolving ethical dilemmas, as reflected by the inundation of single and multi-semester capstone projects in many disciplines. While it has been widely reported that despite intensifying competition, off shoring between developed and developing countries can benefit both parties, many students from western countries have shunned STEM careers because they fear that job opportunities and salaries in these fields will decline. Thus, education is confronted with needing to provide students with higher-order technological skills aptly blended with the consideration of emerging social needs across the globe to provide much needed experiences to thrive in the future, as well as be frontline contributors to the technologically and ethically savvy workforce.

A fundamental change in the education of future workforce and service-force is necessary to assure that we are well prepared for the increasingly more professionally demanding roles. These demands relate to success in the job market, responsibilities toward employers, customers, clients, community and society, and responsibilities as developers of powerful and pervasive automation technologies. In addition to strong technical and management skills, future software and automation designers need the skills to design customized products and integrated services that meet the diverse needs of a multi-cultural, multi-ethnic, and increasingly smaller world united by rapid scientific and technological advances, and facing globally and tightly inter-related hazards and challenges. These trends come with unforeseen social and ethical challenges and tremendous opportunities.

47.5.2 Integrating Social Responsibility and Sensitivity into Education

Effectively integrating social-responsibility, sensitivity and sustainability into our educational curricula has become essential for employers and organization leaders [47.32, 35–37]. See also, for example, the IEEE and ACM model curricula in the context of automation (IEEE.org, ACM.org). Students, trainees, and employees need the diverse exposure to problems and ideas to develop a broad, yet pragmatic vision of the technologically-shifting employment and business landscape. A case study-based approach to teaching, training, and inculcating ethical behavior can provide adequate opportunities to develop the necessary soft skills for being successful in the global service and workplace. Such an exposure can vastly benefit those who may very well be charged with developing policies, priorities, and making investments that can help regions and nations to remain competitive and integrated in the global automation systems and services industry.

Many STEM curricula, in response to these growing industry needs, have placed emphasis on team-based projects and problem-based instruction styles. However, these projects have their own bag of pit falls; for example, in project-based software development classes students often epitomize software development as building the best solution to address customers' requirements. In the following section, a dilemma-based case study approach that goes beyond a project-based curriculum is described. It encourages students to reflect upon the social and ethical ramifications of technology, expanding the narrow, functional-focused tunnel vision that currently (subliminally) exists across many computing and automation curricula, and the automation and software industry, in particular. This is an attempt to address some specific concerns that arise out of such a problem/project focused curricula. With respect to automation and software-related issues, some of these concerns include:

1. In today's post-scandal business climate, additional scrutiny, public condemnation, and possible legal consequences could result if individuals and companies continue to violate accepted ethics and fairness standards. While it is often difficult, if not impossible to predict the future, or the negative consequences of a creation, is ignoring such possible consequences on individuals not ethically questionable?
2. Is it responsible automation development practice, when creating a new technology, and is it ethically sound enough with regard to any possible negative consequences of the new creation and its effects on society?

47.5.3 Dilemma-Based Learning

> *Education is what remains after one has forgotten what one has learned in school.* (John Dryden)

Case-based learning has long been used in management and business schools [47.38, 39]. It has also proved to be highly effective in other disciplines [47.40–42]. According to [47.43], "Students change profoundly in their ability to undertake critical analysis and discuss issues intelligently". Case-based instruction offers a number of advantages and is effective for increasing student motivation [47.40, 41]. In summary, it is thought to be more effective than didactic teaching methods because real-world cases:

1. More accurately represent the complexity and ambiguity of problems
2. Provide a framework for making explicit the problem-solving processes of both novices and experts
3. Provide a means for helping students develop the kind of problem-solving strategies that practicing professionals need [47.44].

Problem-based learning, a case-based derivative, is also widely used, where students are required to learn and apply assimilated knowledge [47.45]. It is reported to broaden students' views and causes a new awareness of their own ideologies and capabilities, and effects growth, questioning, or affirmation [47.42].

In *dilemma-based learning* [47.31, 37], another case-based derivative, a story or game is used to communicate the feeling of real-life dilemmas, while challenging its users to learn from the results of their actions. Dilemmas are chosen for their relevancy to complex and costly situations that are difficult for people to comprehend. For example, dilemmas may reflect the complexities of network implementations or the impact of blame on team productivity and project costs. Dilemmas in the classroom challenge learners to balance trade-offs between short-term rewards and long-term results [47.37]. In prior work, it has been noticed that discussions on real-world topics through dilemma-based case studies that couple logical investigative thinking of the problem-based approaches with strategic needs assessments – cost, performance metrics, etc., make appropriate sense in motivating CS students [47.32, 35, 37].

The use of enthusiasm, empathy, and role-play by students has also been shown to be beneficial in improving overall student attitude and encouraging more participation by women students and minorities [47.36, 46]. It helps develop learning communities and other forms of peer support structures, while emphasizing the positive social benefits of automation and computing. It instills a good feeling among students and motivates them to be participative [47.47, 48]. Hence, a secondary effect of this approach is to help student retention efforts, as they explore related technology issues and interests in the various domains based upon their own personal analogical contexts and experiences. Thus, a recurring dilemma-based approach integrated into multiple automation and computing classes could help increase retention of acceptable ethical standards among students regarding automation technology and help them better understand different ethical issues and perspectives.

Dilemma-based learning, by adopting and building upon themes that dominate our everyday lives, in introductory level classes can not only have the greatest impact on subsequent classes, but also help correct the bad blame-driven rapport that the engineering and computing disciplines have received since the 2001 market crash. Progressive refinement of knowledge gained through more dilemma-based cases in different classes throughout the curriculum provide the natural progression necessary for the retention of ethical issues, while allowing for reinforcement learning through similar dilemmas, but with increasing technical content of cases.

Currently, for interested educators, there are several archival case resources (this is a partial set of references to such material) on ethics with appropriate real-world cases that can be adapted to the needs of a particular class (e.g., [47.1–7, 21, 50, 51]). They can serve as resources to start the building of dilemma-based case studies across several core classes in automation-related curricula.

47.5.4 Model-Based Approach to Teaching Ethics and Automation (Learning)

Several *model-based approaches to teaching* ethics and automation have been developed and implemented effectively. For example, in [47.21] a model for teaching information assurance ethics is presented. The model is composed of four dimensions:

1. The moral development dimension
2. The ethical dimension
3. The security dimension
4. The solutions dimension.

The ethical dimension explores the ethical ramifications of a topic from a variety of perspectives. The security dimension includes ways in which an information assurance topic manifests to information assurance professionals. The solutions dimension focuses on remedies that individuals, groups of individuals, and society have created to address security problems and associated ethical dilemmas. The moral development dimension describes the stages and transitions that humans experience as they develop morally, and as they develop their own personal beliefs and behaviors about right and wrong.

Another model-based approach [47.49] is the IDEA model, described next.

The IDEA model presents how dilemma-based learning can be accomplished. There are two primary players and four steps to the IDEA model (Fig. 47.2). The players include the teachers involved in teaching the courses and the participating students. The four steps are, in turn, specific to these players. The four steps are explained in more detail and illustrated next.

IDEA Step 1: Involve and Identify

From the teacher's perspective, the 'I' in IDEA stands for *involve* and from the students' perspective it stands for identify. The teacher begins by engaging in a discussion of specific cases that are related to the topic being discussed in the class. For example, in an introductory programming course the discussion may be based on a case that is related to the issue of outsourcing. The teacher presents various concerns with respect to the case in question while at the same time engaging the students' interest through discussions (several societal

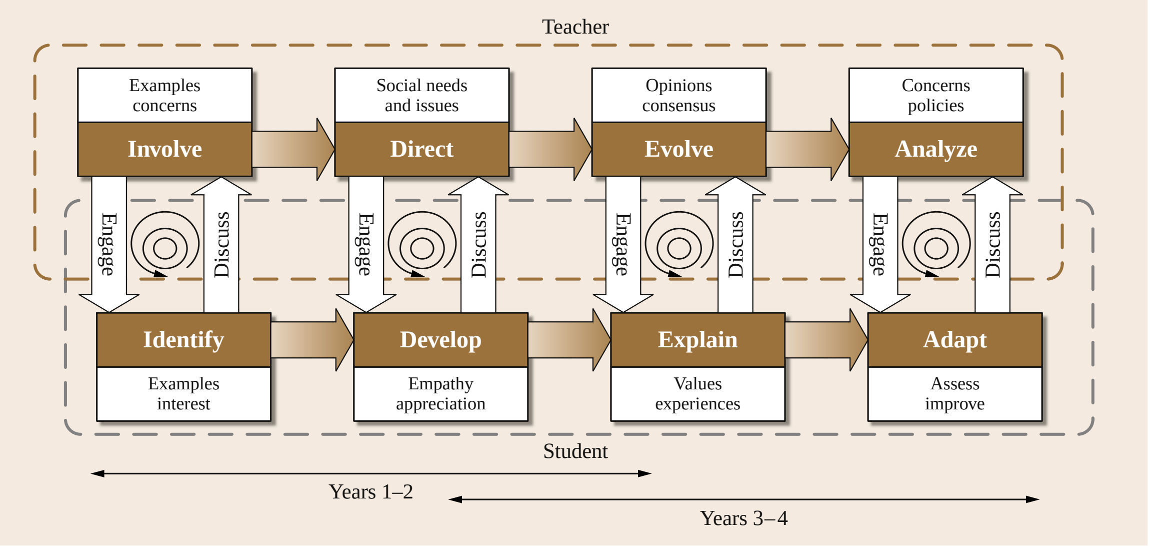

Fig. 47.2 The IDEA Model (after [47.49])

issues can be discussed here: job loss, immigration issues, changing business culture, companies relocating to other countries, etc.).

By engaging the students in the identification of appropriately interesting cases, they become active participants in the class discussions and hence are more likely to engage in investigating the case study further from various socially-interesting perspectives.

A case study on outsourcing provides the ideal opportunity to dispel some of the pervasive myths that students seem to be swayed by, in their choice of automation and computing as a career choice. Current world news information is critical to involving students in the topic of discussion.

For example, at the time of writing this chapter, in the current state of the economy (August 2008), according to the CIO magazine, the unemployment rate for people in the IT industry is less than 3%, while that for the entire USA is 5.9%. Such information opens up the classroom for engaging discussions on IT-driven outsourcing myths and realities. In the rest of this section, we use outsourcing as an engaging example to illustrate the IDEA model. However, this example is by no means meant to be restrictive; other relevant examples may be issues of poor GUI design, issues with electronic voting machines (especially in years of national elections), issues of multi-language support in browsers, issues of robots in tele-surgery, issues with automation for earthquake rescue and refugee survival, automation innovations for energy production, distribution, and delivery, etc.

IDEA Step 2: Direct and Develop

In step 2, most possibly in a follow up class, the student is directed (guided) by the teacher to explore some specific issues of the case further to develop a deeper understanding of the various issues involved. Following the outsourcing case study identified earlier, say an automation assembly language programming class, students can be engaged in a discussion of software outsourcing for embedded systems, say the development of software modules such as drivers that are further integrated into everyday automation systems. Issues of security and privacy that are affected by these low-level software modules, which may be produced in any part of the world, can be discussed and articulated. It has been observed that students participate in such engaging topics with great enthusiasm. This enthusiasm allows learners and trainees to develop a mental model of the entire issue, as well as understand some of the subtle issues in the globalized system of automation software development, as well as appreciate the finer details of even studying a subject such as assembly language programming and its need within an automation and computing-based curriculum.

Often, students tend to develop a *follow the herd* mentality and are swayed by what they see and hear as requisite *job skills*. Students may often espouse the clouded view that they need to spend most of their time in the program learning *marketable* skills – such as the next hot programming language or system. By association, they may believe they should not spend time learning issues that may not be directly related to their immediate future jobs. This learning misconception has indeed been the observation of instructors and trainers in many disciplines.

Hence, although highly relevant to learning the fundamentals of automation, or computer science, courses such as assembly language programming, evoke less interest among current-day students. Integrating such a dilemma-oriented case study driven discussion can help assure the students of the need for focusing on such fundamental courses as well as understanding its high relevance to societal needs – for example, helping build privacy and security in I/O drivers and embedded automation devices and systems.

IDEA Step 3: Evolve and Explain

> *The mediocre teacher tells. The good teacher explains. The superior teacher demonstrates. The great teacher inspires.* (William Ward)

In step 3, the ‘E’ in IDEA stands for *evolve* from the teacher’s perspective, and *explain* from the students’ perspective. The student, in the same (automation programming/digital design/assembly language) or a follow up class (say a database systems class that normally appears in a junior/senior year of the curriculum) is guided by the teacher to explore more details of the case to understand the magnitude and implications of the various issues involved. Again, on the issue of outsourcing, the teacher can engage the students in cases such as *credit card sales and marketing* (or cellular communication devices, etc.), whereby the jobs of identifying and seeking *likely* customers are outsourced to BPO companies (business process outsourcing).

Foreign governments are offering significant fiscal and non-fiscal incentives to attract such foreign direct investments into their respective countries and hence it is difficult for a business to ignore such compelling benefits. Experts who see the growing global demand for BPO (estimated to be at US$180 billion in 2010) indicate a shift from cost-effectiveness to issues of skills, quality, and competence. Issues of personal, professional, and business ethics would definitely be factored as we move towards meeting such expectations, often driven by concerned citizens whose personal data is at stake as part of such BPO decision processes in multinational organizations.

In a course such as database systems, the teacher can guide discussion on how such practices effect the compilation, sharing, and administration of the data contained in large-scale distributed databases in question, their effect on issues of an individual's privacy, which possibly is no longer within the geographical confines of the source country, and issues of checks and bounds verifications that need to occur for such business arrangements between business operating in across different countries that are culturally different.

How is an individual's right to privacy different across cultures and what does *privacy* mean in a different society? What are the issues a business needs, or service needs, to be concerned with respect to the laws of the country? How can the business or service contain and secure the assimilation and sharing of such data? Instructors can promote discussions that can actually engage the student in understanding core values that may be viewed differently across cultures and grow by discussing cases that involve such experiences.

IDEA Step 4: Analyze and Adapt

Through the use of the three earlier steps, students would have incrementally developed the mental and subject-level maturity needed to understand the various issues, their interrelatedness and the socio-cultural effects of the various aspects of automation and computing. In an appropriate junior/senior level course, say systems analysis and design, software engineering or a capstone automation course, where students normally develop large-scale projects to demonstrate their deep understanding of their career subject, students can focus on better understanding the design and development, or process; issues that need to be enforced for guaranteeing globally standardized automation development practices when dealing with data and signals that can be potentially misused.

Students will also be better prepared to understand and discuss issues of professional codes of ethics, since they would have been exposed to and have developed a deeper understanding of the need for them in a globalized sense. In addition, they may have actually gained the necessary skills to analyze and assess ethical dilemmas and conflicts, good versus evil ideas and policies, and issues of sensitivity to social and global sustainability concerning the design and enforcement of such policies for globally-distributed services and businesses.

47.6 Ethics and Research

Collectively this book provides a wealth of automation-related research topics: sensor networks, cybernetics, communication, automatic control, soft computing, artificial intelligence, evolutionary automation, etc. All these automation research topics may serve as valid, timely topics for ethical concerns related to research; highly appropriate for this section. For the purposes of demonstration of emerging issues that can be ethically-sensitive vis-á-vis research, we focus specifically on the ethical issues related to research aided by the exponential growth of the World Wide Web and the information it could offer research about Internet users [47.52].

In order to advance research and serve the users of their products, many Internet companies keep web access logs, search history logs, or transaction logs. Why is this perspective of *logs* important? On bulletin boards, peer-to-peer and social networks, e-Commerce sites, and the Internet in general, individuals can behave and operate with certain anonymity in the absence of the presentation of self. Individuals online have a sense of complete autonomy and anonymity. Often the learnt social norm from such interactions is that there is little incentive to feel responsible for one's own actions or sensitivity to the open public and community, in general, if *the community* does not provide some kind of *instantaneous* visible reward or tangible penalty.

47.6.1 Internet-Based Research

The scaling up of web content as well as users has resulted in increased difficulty in searching for information over the web. The ever increasing number of pages that match any given set of query words compel users to modify their queries a number of times before obtaining the required information. This repeated, inefficient search results in increased traffic on the network and in a spiraling effect, which in turn results in higher resource consumption and overload. Search engines have made it possible for anyone to look up information from any corner of the world on the Internet.

In an unprecedented decision statement a judge in New Zealand banned online media from publishing the names of two people accused of murder [47.53]. All other news media such as TV, printed media, etc. were allowed to publish the names except the Internet media. This distinction was based on the concern that information about the accused is available on Internet for a long time even after the trial is over.

This case poses a dilemma about the information available on the Internet and in search engine logs much longer after the validity of the information has expired. The availability of query log datasets such as AOL has opened up the doors for carrying out exploratory research on searching user query logs and coming up with possible solutions to make the user search sessions more productive with the intent to provide better search experience for users. While AOL seems to have not taken adequate measures to hide personally identifiable information, the availability of the data set itself poses interesting ethical questions.

Several related developments can be summarized about research and internet-based search, which may shed light on ethical concerns and conflicts in this domain:

- In order to encourage research with user search query logs, Microsoft announced that it would avail its dataset to selected research organizations upon signing agreements. Such safeguards are necessary to protect user privacy and advance research, while developing better tools to help search engine users. Users' *opt-in* and *opt-out*, meaning personally selective, optional acceptance or rejection of sharing their personal information, have become common as part of *codes of privacy* [47.4].
- Users' web searching behavior has been an interesting research area for some time now. Researchers have studied the overall nature of *information behavior*, including information seeking behavior [47.54], *information retrieval* (IR) with *hidden behavioral patterns* and semantically *superconcepts* [47.55,56]. Sometimes, the thirst for information and convenience influence human searchers (as well as purchasers on the web researching available options) to willingly compromise, at least in part, their principled sensitivity to protect their privacy.
- Privacy rights and protection privileges are also associated with the availability of user search query log datasets. Included are multi-faceted logs coupled with relevant information such as time spent on the web page clicked on, web pages opened, printed and/or bookmarked, and whether the user's true or at least intended information needs are satisfied. Potential ramifications or lack of such query logs dataset vis-á-vis user privacy issues are outlined in [47.57–59] and are subject to further research.

Addressing privacy rights and issues and Internet-based research requires review boards, as described also in the next section. Ethical thinking in this direction includes, for example:

- Setting up a review board for release of query log data for research purposes, while adhering to certain guidelines of ethical practices [47.60].
- Classifying sensitive queries in the query log dataset from a privacy perspective; for example, by partial anonymization of queries [47.61].
- Specific methods of anonymizing sensitive queries in the AOL and similar such datasets [47.62, 63]. For instance:
  a) applying threshold cryptography systems that eliminate highly identifying queries in real time, and
  b) dealing with a set of aggregated queries that are overly identifying, and addressing issues of tradeoff between privacy and utility of the query log data.

47.6.2 More on Research Ethics and User Privacy Issues

While internet users' search session data availability for research and other exploitation illustrates serious ethical issues, some of which are described above, other privacy, property, quality, and accessibility ethical concerns need to be addressed. These concerns need to be appropriately handled, including: fair use of information, ethics of anonymity, and critical need for carefully enabling selective access to private information and behavioral research for specific goals of information for safety, health, security, and other essential public needs [47.64].

Privacy and Accessibility Rights Versus Significant Public Service

What about limiting research on behavior patterns, which may result in losing the opportunity to obtain unique results for targeted services that are significantly beneficial to society, even critical for sustainability? For example, health, safety, and security related issues may need Internet-based and mobile phone-based research. An emerging optional way is to have informed consent from the users at appropriate instances, to enable the fair use of behavior information for agreed upon and selectively chosen research activities. This area is being addressed already by different industry segments and is handled by various legal means.

Policies for Conducting Research Based on Automation

Policies for research based on knowledge obtained by automation have been developed and are still emerging to address ethical concerns, e.g., [47.65]. Initiatives have emerged and need to be strengthened and widened to satisfy World Wide Web media related issues, as such data may become increasingly available for organizations to mine for gaining competitive advantage in the market place, e.g., [47.33]. A consortium for university researchers, industries, government agencies, and other concerned organizations to discuss policy and other related issues of conducting such research is being developed.

The Myth About User Privacy with Automation

One myth about privacy of automation-users is that protecting privacy rights is the onus of the user. In today's world, where information systems security management is a discipline that is fast emerging, its peripheries are yet to be well defined. Who are the gatekeepers?

- Internet service provider (ISP) are burdened with the responsibility of being gatekeepers of their users' privacy; they have to regularly compromise with governmental agencies trying to gain access to ISP user data in order to prevent crime or conduct data forensics.
- Search engine services have a similar responsibility, though they are not burdened with the bulk of keeping the identity of their users private (exceptions being Google or Yahoo! users who may opt to log in before conducting a web-based search).

Neither of these entities, the ISP and the search engine service, would like to be burdened with the bulk of the responsibility of protecting the identity of a user, when the user performs web-based searches. But the fact is that the necessary interface for Internet access is provided to the user by the ISP. This fact lays the primary responsibility of user identity obfuscation squarely on the ISP. ISP employees may be able to gain access to searches conducted by their users and may be able to exploit these details in various unethical or ethical ways. This risk is higher in smaller communities that have populations less than 50 000 and are typically serviced by a few local ISPs.

Policies on Data Mining for Efficiency

Automation data preservation, analysis and indexing are important for web-based search engines and other Internet companies and automation services to perform efficiently, since correlating diverse user searches and interactions are the modus operandi of enhancing performance results. This information can be useful for automation design and architecture evolution. However, this data mining can also be misused by the automation service provider. Self regulations should be supported by clearly defined policies on how the data is collected, accessed, and distributed even for research purposes.

Institutional Review Boards

As common with any research involving human subject, universities and research organizations need to follow strict review board scrutiny. The Internet data research initiatives undertaken by universities and research organizations should also go through institutional review boards' (IRB) formal approval process to make sure human interests, rights, and privacy are protected. Since the review, scrutiny and approval procedures can also be automated, Internet service providers and companies should set clearly defined guidelines and policies for its researchers and users. Many companies already focus on establishing a working group of individuals from privacy, legal, IRB, and security teams to discuss various aspects of the problem and proposed solutions. Such working groups study problems on a case by case basis ensuring a company's competitive advantage without compromising on the ethical issues (if any) involved in the research.

The ethical issues about research and automation will undoubtedly be addressed as organizations and society learn the pitfalls and find methods to resolve the ethical dilemmas that have been mentioned. At the same time, it is clear (as indicated in Fig. 47.1) that newly developed and far reaching automation functions will continue to pose tremendous ethical challenges to individuals, organizations, and society at large.

47.7 Challenges and Emerging Trends

In this chapter, ethical challenges, dilemmas, and conflicts related to automation and enabled or introduced by automation have been highlighted. The context of automation and internationalization, or globalization of services and businesses bring further need for rational, acceptable, and sustainable ethical sensitivities and behaviors. These should continue to be the responsibility of individuals, and of individuals within organizations, but should also be supported, monitored, and maintained by automation mechanisms. Therefore, the increasing attention being paid to ethics in the context of automation, specifically from the perspective of education and research, has been explained. Challenging ethical issues have been presented and illustrated relative to the dimensions of technology, security, privacy, property, quality, and accessibility.

For education and training, the model-based approach for integrating ethics and socially responsible automation/computing into the undergraduate curricula, as well as training courses, has been presented. Examples from automation and computing curricular perspective have been used, and can be adapted to other science and technological disciplines, and commercial and service organizations. For the effective application of this approach, or similar programs, one needs the participation of several multi-disciplinary members, instructors or trainers. However, the attractiveness of such an approach is in its ability to engage the students and trainees meaningfully while still undertaking the primary task of learning the skills and techniques they would need to be successful upon graduation or completion.

For research, certain open challenges in gathering, mining, and observing user information-seeking behavior, while maintaining individuals' privacy rights have been highlighted. Policies, including review boards, have been and are being developed to address these ethical concerns. In such situations a strong rational balance between advanced research and user privacy must be maintained at all times. While the research community at large would come up with the solutions, privacy, anonymity, and fair use issues need to be effectively addressed to demonstrate the innumerable benefits that such research work can yield for the great benefits of individuals and of society. Marketing and information dissemination in a digital world represent an emerging area of research that can be timely and exciting for students, for users, for organizations, and for the public – for example, issues such as cookies leaving digital trail mixes on people's machines, in light of protecting society, while also protecting individual freedom and individual rights.

47.7.1 Trends and Challenges

Ethical issues, dilemmas, and conflicts, and unethical behaviors, some of which are horrendous and tragic, are unfortunately an integral part of the proliferation of computers and automation in our lives. Major concerns range from privacy, copyrights, and cyber crime issues, to the global impact of computers and communication, online communities and social networks, and effects of virtual reality. Articles, books, conferences, on-line resources, social and political processes have evolved and continue to grow in importance and influence, contributing to ethics expertise in diverse disciplines. The breadth of multi-disciplinary scope allows students and professionals to learn, understand, and evaluate the individual, social, and ethical issues brought about by computer and automation technologies.

Some specific trends to consider:

International Policies

Impact of digitized information on individuals, communities, organizations, and societies, including continued discussions and necessary development of international policies on:

- Privacy
- Automation quality and reliability
- Automation security
- Copyrights and intellectual property
- Collaborative protocols for rational automation control, equality of access under authorization procedures, and trust and authentication agreements

Frameworks and Regulations

Development of ethical frameworks and regulatory processes are needed for substantial treatment of the interrelated automation issues of cyber-ethics: accessibility, free speech and expression, property, privacy, and security.

Self-Repair and Self-Recovery

Research and development of automatic self-repair and self-recovery are needed to address the risks associated with unexpected computer and automation break-downs, disasters, and failures that open up vulnerabilities to unethical, unsustainable scenarios.

Ethical Automation

Research and development are needed of *inherently* ethical software and ethical automation (including ethical robotics) able to automatically handle and automatically help resolve issues such as media copying, file sharing, infringement of intellectual property, security risks and threats, Internet-based crime, automation-assisted forgery, identity theft, unethical employee surveillance, individual privacy, and compliance with ethical and professional codes.

Ethics of Robotic Automation

Major advancements are needed in robo-ethics to address the fact that (1) robots and robotic automation are increasingly more capable, and (2) there are humans that will increasingly abuse these powerful capabilities, deploying them in ethically questionable situations and environments (e.g., in schools, hospitals, etc.) where ethically wrong robotic automation conduct could have disastrous impacts on humans.

- We must develop ways to ensure that automation, without robots and with robots, will always behave in an ethically correct manner.
- We need to be able to trust that automation, through software-inherent ethics-rationale reflecting ethical human logic (preferably specified in natural languages) will always behave under strict ethical constraints. These constraints must follow previously defined ethical codes, and be able to limit their actions and behavior under these constraints, always reflecting ethical humans' instructions, even without human supervision.

The dual challenge in front of us is that as we develop more powerful, intelligent, and autonomous automation, we must also be careful it is not and cannot be abused by unethical people against us and against other people; we must also be careful that this powerful automation does not assume independence to, on its own, hurt people and inflict damage. The challenge for automation scientists, designers, and managers is that we need to consider how to ethically control the behavior of automation and how to ethically restrict its autonomy – because automation is all around us and because we are so dependent on it.

47.8 Additional Online Resources

Source materials relevant to ethics and automation are available from the ACM and IEEE model curricula, national societies such as ACM, IEEE, AAAS, ASEE, AAES, AIS, and others, for guidelines on ethics; groups such as ACM SIGCAS, CERIAS, CPSR, EFF, EPIC, and other professional organizations that promote responsible behavior. Their conferences, journals and materials provide rich, additional topics on automation and ethics. In addition, the following are several online resources relevant for ethics and automation:

47.A Appendix: Code of Ethics Example

ACM (Association for Computing Machinery) Code of Ethics and Professional Conduct

Adopted by ACM Council 10/16/92.

Preamble

Commitment to ethical professional conduct is expected of every member (voting members, associate members, and student members) of the Association for Computing Machinery (ACM).

This Code, consisting of 24 imperatives formulated as statements of personal responsibility, identifies the elements of such a commitment. It contains many, but not all, issues professionals are likely to face. Section 47.A.1 outlines fundamental ethical considerations, while Sect. 47.A.2 addresses additional, more specific considerations of professional conduct. Statements in Sect. 47.A.3 pertain more specifically to individuals who have a leadership role, whether in the workplace or in a volunteer capacity such as with organizations like ACM. Principles involving compliance with this Code are given in Sect. 47.A.4.

The Code shall be supplemented by a set of Guidelines, which provide explanation to assist members in dealing with the various issues contained in the Code. It is expected that the Guidelines will be changed more frequently than the Code.

The Code and its supplemented Guidelines are intended to serve as a basis for ethical decision making in the conduct of professional work. Secondarily, they may serve as a basis for judging the merit of a formal complaint pertaining to violation of professional ethical standards.

It should be noted that although computing is not mentioned in the imperatives of Sect. 47.A.1, the Code is concerned with how these fundamental imperatives apply to one's conduct as a computing professional. These imperatives are expressed in a general form to emphasize that ethical principles which apply to computer ethics are derived from more general ethical principles.

It is understood that some words and phrases in a code of ethics are subject to varying interpretations, and that any ethical principle may conflict with other ethical principles in specific situations. Questions related to ethical conflicts can best be answered by thoughtful consideration of fundamental principles, rather than reliance on detailed regulations.

47.A.1 General Moral Imperatives

As an ACM member I will. . .

Contribute to Society and Human Well-Being

This principle concerning the quality of life of all people affirms an obligation to protect fundamental human rights and to respect the diversity of all cultures. An essential aim of computing professionals is to minimize negative consequences of computing systems, including threats to health and safety. When designing or implementing systems, computing professionals must attempt to ensure that the products of their efforts will be used in socially responsible ways, will meet social needs, and will avoid harmful effects to health and welfare.

In addition to a safe social environment, human well-being includes a safe natural environment. Therefore, computing professionals who design and develop systems must be alert to, and make others aware of, any potential damage to the local or global environment.

Avoid Harm to Others

Harm means injury or negative consequences, such as undesirable loss of information, loss of property, property damage, or unwanted environmental impacts. This principle prohibits use of computing technology in ways that result in harm to any of the following: users, the general public, employees, employers. Harmful actions include intentional destruction or modification of files and programs leading to serious loss of resources or unnecessary expenditure of human resources such as the time and effort required to purge systems of *computer viruses*.

Well-intended actions, including those that accomplish assigned duties, may lead to harm unexpectedly. In such an event the responsible person or persons are obligated to undo or mitigate the negative consequences as much as possible. One way to avoid unintentional harm is to carefully consider potential impacts on all those affected by decisions made during design and implementation.

To minimize the possibility of indirectly harming others, computing professionals must minimize malfunctions by following generally accepted standards for system design and testing. Furthermore, it is often necessary to assess the social consequences of systems to project the likelihood of any serious harm to others. If system features are misrepresented to users, coworkers, or supervisors, the individual computing professional is responsible for any resulting injury.

In the work environment the computing professional has the additional obligation to report any signs of system dangers that might result in serious personal or social damage. If one's superiors do not act to curtail or mitigate such dangers, it may be necessary to *blow the whistle* to help correct the problem or reduce the risk. However, capricious or misguided reporting of violations can, itself, be harmful. Before reporting violations, all relevant aspects of the incident must be thoroughly assessed. In particular, the assessment of risk and responsibility must be credible. It is suggested that advice be sought from other computing professionals. See principle 2.5 regarding thorough evaluations.

Be Honest and Trustworthy

Honesty is an essential component of trust. Without trust an organization cannot function effectively. The honest computing professional will not make deliberately false or deceptive claims about a system or system design, but will instead provide full disclosure of all pertinent system limitations and problems.

A computer professional has a duty to be honest about his or her own qualifications, and about any circumstances that might lead to conflicts of interest.

Membership in volunteer organizations such as ACM may at times place individuals in situations where their statements or actions could be interpreted as carrying the *weight* of a larger group of professionals. An ACM member will exercise care to not misrepresent ACM or positions and policies of ACM or any ACM units.

Be Fair and Take Action not to Discriminate

The values of equality, tolerance, respect for others, and the principles of equal justice govern this imperative. Discrimination on the basis of race, sex, religion, age, disability, national origin, or other such factors is an explicit violation of ACM policy and will not be tolerated.

Inequities between different groups of people may result from the use or misuse of information and technology. In a fair society, all individuals would have equal opportunity to participate in, or benefit from, the use of computer resources regardless of race, sex, religion, age, disability, national origin or other such similar factors. However, these ideals do not justify unauthorized use of computer resources nor do they provide an adequate basis for violation of any other ethical imperatives of this code.

Honor Property Rights Including Copyrights and Patent

Violation of copyrights, patents, trade secrets and the terms of license agreements is prohibited by law in most circumstances. Even when software is not so protected, such violations are contrary to professional behavior. Copies of software should be made only with proper authorization. Unauthorized duplication of materials must not be condoned.

Give Proper Credit for Intellectual Property

Computing professionals are obligated to protect the integrity of intellectual property. Specifically, one must not take credit for other's ideas or work, even in cases where the work has not been explicitly protected by copyright, patent, etc.

Respect the Privacy of Others

Computing and communication technology enables the collection and exchange of personal information on a scale unprecedented in the history of civilization. Thus there is increased potential for violating the privacy of individuals and groups. It is the responsibility of professionals to maintain the privacy and integrity of data describing individuals. This includes taking precautions to ensure the accuracy of data, as well as protecting it from unauthorized access or accidental disclosure to inappropriate individuals. Furthermore, procedures must be established to allow individuals to review their records and correct inaccuracies.

This imperative implies that only the necessary amount of personal information be collected in a system, that retention and disposal periods for that information be clearly defined and enforced, and that personal information gathered for a specific purpose not be used for other purposes without consent of the individual(s). These principles apply to electronic communications, including electronic mail, and prohibit procedures that capture or monitor electronic user data, including messages, without the permission of users or bona fide authorization related to system operation and maintenance. User data observed during the normal duties of system operation and maintenance must be treated with strictest confidentiality, except in cases where it is evidence for the violation of law, organizational regulations, or this Code. In these cases, the nature or contents of that information must be disclosed only to proper authorities.

Honor Confidentiality

The principle of honesty extends to issues of confidentiality of information whenever one has made an explicit promise to honor confidentiality or, implicitly, when private information not directly related to the performance of one's duties becomes available. The ethical concern is to respect all obligations of confidentiality to employers, clients, and users unless discharged from such obligations by requirements of the law or other principles of this Code.

47.A.2 More Specific Professional Responsibilities

As an ACM computing professional I will…

Strive to Achieve the Highest Quality, Effectiveness and Dignity in Both the Process and Products of Professional Work

Excellence is perhaps the most important obligation of a professional. The computing professional must strive to achieve quality and to be cognizant of the serious negative consequences that may result from poor quality in a system.

Acquire and Maintain Professional Competence

Excellence depends on individuals who take responsibility for acquiring and maintaining professional competence. A professional must participate in setting standards for appropriate levels of competence, and strive to achieve those standards. Upgrading technical knowledge and competence can be achieved in several ways: doing independent study; attending seminars, conferences, or courses; and being involved in professional organizations.

Know and Respect Existing Laws Pertaining to Professional Work

ACM members must obey existing local, state, province, national, and international laws unless there is a compelling ethical basis not to do so. Policies and procedures of the organizations in which one participates must also be obeyed. But compliance must be balanced with the recognition that sometimes existing laws and rules may be immoral or inappropriate and, therefore, must be challenged. Violation of a law or regulation may be ethical when that law or rule has inadequate moral basis or when it conflicts with another law judged to be more important. If one decides to violate a law or rule because it is viewed as unethical, or for any other reason, one must fully accept responsibility for one's actions and for the consequences.

Accept and Provide Appropriate Professional Review

Quality professional work, especially in the computing profession, depends on professional reviewing and critiquing. Whenever appropriate, individual members should seek and utilize peer review as well as provide critical review of the work of others.

Give Comprehensive and Thorough Evaluations of Computer Systems and Their Impacts, Including Analysis of Possible Risks

Computer professionals must strive to be perceptive, thorough, and objective when evaluating, recommending, and presenting system descriptions and alternatives. Computer professionals are in a position of special trust, and therefore have a special responsibility to provide objective, credible evaluations to employers, clients, users, and the public. When providing evaluations the professional must also identify any relevant conflicts of interest, as stated in imperative 1.3.

As noted in the discussion of principle 1.2 on avoiding harm, any signs of danger from systems must be reported to those who have opportunity and/or responsibility to resolve them. See the guidelines for imperative 1.2 for more details concerning harm, including the reporting of professional violations.

Honor Contracts, Agreements, and Assigned Responsibilities

Honoring one's commitments is a matter of integrity and honesty. For the computer professional this includes ensuring that system elements perform as intended. Also, when one contracts for work with another party, one has an obligation to keep that party properly informed about progress toward completing that work.

A computing professional has a responsibility to request a change in any assignment that he or she feels cannot be completed as defined. Only after serious consideration and with full disclosure of risks and concerns to the employer or client, should one accept the assignment. The major underlying principle here is the obligation to accept personal accountability for professional work. On some occasions other ethical principles may take greater priority.

A judgment that a specific assignment should not be performed may not be accepted. Having clearly identified one's concerns and reasons for that judgment, but failing to procure a change in that assignment, one may yet be obligated, by contract or by law, to proceed as directed. The computing professional's ethical judgment should be the final guide in deciding whether or not to proceed. Regardless of the decision, one must accept the responsibility for the consequences.

However, performing assignments *against one's own judgment* does not relieve the professional of responsibility for any negative consequences.

Improve Public Understanding of Computing and Its Consequences

Computing professionals have a responsibility to share technical knowledge with the public by encouraging understanding of computing, including the impacts of computer systems and their limitations. This imperative implies an obligation to counter any false views related to computing.

Access Computing and Communication Resources only when Authorized to Do so

Theft or destruction of tangible and electronic property is prohibited by imperative 1.2–*Avoid harm to others*. Trespassing and unauthorized use of a computer or communication system is addressed by this imperative. Trespassing includes accessing communication networks and computer systems, or accounts and/or files associated with those systems, without explicit authorization to do so. Individuals and organizations have the right to restrict access to their systems so long as they do not violate the discrimination principle (see 1.4). No one should enter or use another's computer system, software, or data files without permission. One must always have appropriate approval before using system resources, including communication ports, file space, other system peripherals, and computer time.

47.A.3 Organizational Leadership Imperatives

As an ACM member and an organizational leader, I will...

Background Note: This section draws extensively from the draft IFIP Code of Ethics, especially its sections on organizational ethics and international concerns. The ethical obligations of organizations tend to be neglected in most codes of professional conduct, perhaps because these codes are written from the perspective of the individual member. This dilemma is addressed by stating these imperatives from the perspective of the organizational leader. In this context *leader* is viewed as any organizational member who has leadership or educational responsibilities. These imperatives generally may apply to organizations as well as their leaders. In this context *organizations* are corporations, government agencies, and other *employers*, as well as volunteer professional organizations.

Articulate Social Responsibilities of Members of an Organizational Unit and Encourage Full Acceptance of Those Responsibilities

Because organizations of all kinds have impacts on the public, they must accept responsibilities to society. Organizational procedures and attitudes oriented toward quality and the welfare of society will reduce harm to members of the public, thereby serving public interest and fulfilling social responsibility. Therefore, organizational leaders must encourage full participation in meeting social responsibilities as well as quality performance.

Manage Personnel and Resources to Design and Build Information Systems that Enhance the Quality of Working Life

Organizational leaders are responsible for ensuring that computer systems enhance, not degrade, the quality of working life. When implementing a computer system, organizations must consider the personal and professional development, physical safety, and human dignity of all workers. Appropriate human-computer ergonomic standards should be considered in system design and in the workplace.

Acknowledge and Support Proper and Authorized Uses of an Organization's Computing and Communication Resources

Because computer systems can become tools to harm as well as to benefit an organization, the leadership has the responsibility to clearly define appropriate and inappropriate uses of organizational computing resources. While the number and scope of such rules should be minimal, they should be fully enforced when established.

Ensure that Users and Those Who Will Be Affected by a System Have Their Needs Clearly Articulated During the Assessment and Design of Requirements; Later the System Must Be Validated to Meet Requirements

Current system users, potential users and other persons whose lives may be affected by a system must have their needs assessed and incorporated in the statement of requirements. System validation should ensure compliance with those requirements.

Articulate and Support Policies that Protect the Dignity of Users and Others Affected by a Computing System

Designing or implementing systems that deliberately or inadvertently demean individuals or groups is ethically unacceptable. Computer professionals who are in decision making positions should verify that systems are designed and implemented to protect personal privacy and enhance personal dignity.

Create Opportunities for Members of the Organization to Learn the Principles and Limitations of Computer Systems

This complements the imperative on public understanding (2.7). Educational opportunities are essential to facilitate optimal participation of all organizational members. Opportunities must be available to all members to help them improve their knowledge and skills in computing, including courses that familiarize them with the consequences and limitations of particular types of systems. In particular, professionals must be made aware of the dangers of building systems around oversimplified models, the improbability of anticipating and designing for every possible operating condition, and other issues related to the complexity of this profession.

47.A.4 Compliance with the Code

As an ACM member I will…

Uphold and Promote the Principles of this Code

The future of the computing profession depends on both technical and ethical excellence. Not only is it important for ACM computing professionals to adhere to the principles expressed in this Code, each member should encourage and support adherence by other members.

Treat Violations of this Code as Inconsistent with Membership in the ACM

Adherence of professionals to a code of ethics is largely a voluntary matter. However, if a member does not follow this code by engaging in gross misconduct, membership in ACM may be terminated.

This Code and the supplemental Guidelines were developed by the Task Force for the Revision of the ACM Code of Ethics and Professional Conduct: Ronald E. Anderson, Chair, Gerald Engel, Donald Gotterbarn, Grace C. Hertlein, Alex Hoffman, Bruce Jawer, Deborah G. Johnson, Doris K. Lidtke, Joyce Currie Little, Dianne Martin, Donn B. Parker, Judith A. Perrolle, and Richard S. Rosenberg. The Task Force was organized by ACM/SIGCAS and funding was provided by the ACM SIG Discretionary Fund. This Code and the supplemental Guidelines were adopted by the ACM Council on October 16, 1992.

This Code may be published without permission as long as it is not changed in any way and it carries the copyright notice. Copyright 1997, Association for Computing Machinery, Inc.

Part F Industrial Automation

Industrial Automation. Part F Industrial automation is well known and fascinating to all of us who were born in the 20th century, from visits to plants and factories to watching movies highlighting the automation marvels of industrial operations and assembly lines. This part begins with explanation of machine tool automation, including various types of numerical control (NC), flexible, and precision machinery for production, manufacturing, and assembly, digital and virtual industrial production, to detailed design, guidelines and application of automation in the principal industries, from aerospace and automotive to semiconductor, mining, food, paper and wood industries. Chapters are also devoted to the design, control and operation of functions common to all industrial automation, including materials handling, supply, logistics, warehousing, distribution, and communication protocols, and the most advanced digital manufacturing, RFID-based automation, and emerging micro-automation and nano-manipulation. Industrial automation represents a major growth and advancement opportunity, because as explained in this part, it can provide significant innovative solutions to the grand challenges of our generation, including the production and distribution capacity of needed goods and equipment, as well as food, medical and other essential sustenance supplies for the quality of life around the globe.

48. Machine Tool Automation

Keiichi Shirase, Susumu Fujii

Numerical control (NC) is the greatest innovation in the achievement of machine tool automation in manufacturing. In this chapter, first a history of the development up to the advent of NC machine tools is briefly reviewed (Sect. 48.1). Then the machining centers and the turning centers are described with their key modules and integration into flexible manufacturing systems (FMS) and flexible manufacturing cells (FMC) in Sect. 48.2. NC part programming is described from manual programming to the computer-aided manufacturing (CAM) system in Sect. 48.3. In Sect. 48.4 and Sect. 48.5, following the technical innovations in the advanced hardware and software systems of NC machine tools, future control systems for intelligent CNC machine tools are presented.

Numerical control (NC) is the greatest innovation in the achievement of machine tool automation in manufacturing. Machine tools have expanded their performance and ability since the era of the Industrial Revolution; however all machine tools were operated manually until the birth of the NC machine tool in 1952. Numerical control enabled control of the motion and sequence of machining operations with high accuracy and repeatability. In the 1960s, computers added even greater flexibility and reliability of machining operations. These machine tools which had computer numerical control were called CNC machine tools. A machining center, which is a highly automated NC milling machine performing multiple milling operations, was developed to realize process integration as well as machining automation in 1958. A turning center, which is a highly automated NC lathe performing multiple turning operations, was also developed. These machine tools contributed to realize the flexible manufacturing system (FMS), which had been proposed during the mid-1960s. FMS aims to perform automatic machining operations unaided by human operators to machine various parts.

The automatically programmed tool (APT) is the most important computer-assisted part programming language and was first used to generate part programs

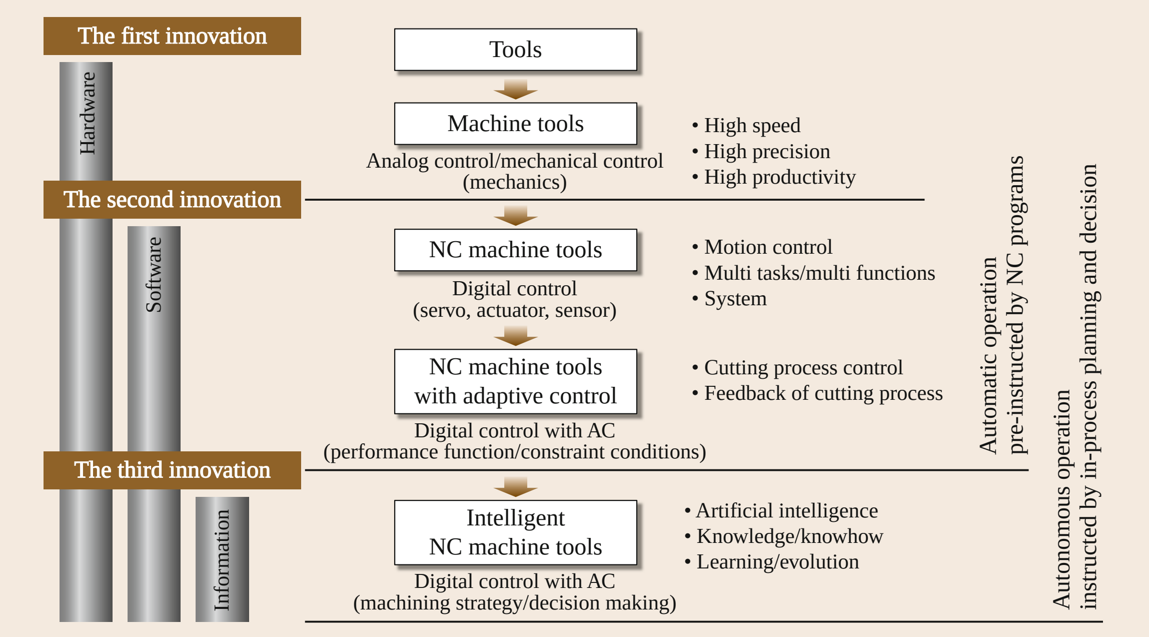

Fig. 48.1 Evolution of machine tools toward the intelligent machine for the future

in production around 1960. The extended subset of APT (EXAPT) was developed to add functions such as setting of cutting conditions, selection of cutting tool, and operation planning besides the functions of APT. Another pioneering NC programming language, COMPACT II, was developed by Manufacturing Data Systems Inc. (MDSI) in 1967. Technologies developed beyond APT and EXAPT were succeeded by computer-aided manufacturing (CAM). CAM provides interactive part programming with a visual and graphical environment and saves significant programming time and effort for part programming. For example, COMPACT II has evolved into open CNC software, which enables integration of off-the-shelf hardware and software technologies. NC languages have also been integrated with computer-aided design (CAD) and CAM systems.

In the past five decades, NC machine tools have become more sophisticated to achieve higher accuracy and faster machining operation with greater flexibility. Certainly, the conventional NC control system can perform sophisticated motion control, but not cutting process control. This means that further intelligence of NC control system is still required to achieve more sophisticated process control. In the near future, all machine tools will have advanced functions for process planning, tool-path generation, cutting process monitoring, cutting process prediction, self-monitoring, failure prediction, etc. Information technology (IT) will be the key issue to realize these advanced functions. The paradigm is evolving from the concept of autonomy to yield next-generation NC machine tools for sophisticated manufacturing systems.

Machine tools have expanded their performance and abilities as shown in Fig. 48.1. The first innovation took place during the era of the Industrial Revolution. Most conventional machine tools, such as lathes and milling machines, have been developed since the Industrial Revolution. High-speed machining, high-precision machining, and high productivity have been achieved by these modern machine tools to realize mass production.

The second innovation was numerical control (NC). A prototype machine was demonstrated at MIT in 1952. The accuracy and repeatability of NC machine tools became far better than those of manually operated machine tools. NC is a key concept to realize programmable automation. The principle of NC is to control the motion and sequence of machining operations. Computer numerical control (CNC) was introduced, and computer technology replaced the hardware control circuit boards on NC, greatly increasing the reliability and functionality of NC. The most important functionality to be realized was adaptive control (AC). In order to improve the productivity of the machining process and the quality of machined surfaces, several AC systems for real-time adjustment of cutting parameters have been proposed and developed [48.1].

As mentioned above, machine tools have evolved through advances in hardware and control technologies. However, the machining operations are fully dominated by the predetermined NC commands, and conventional machine tools are not generally allowed to change the machining sequence or the cutting conditions during machining operations. This means that conventional NC machine tools are allowed to perform only automatic machining operations that are pre-instructed by NC programs.

In order to realize an *intelligent* machine tool for the future, some innovative technical breakthroughs are required. An intelligent machine tool should be good at learning, understanding, and thinking in a logical way about the cutting process and machining operation, and no NC commands will be required to instruct machining operations as an intelligent machine tool thinks about machining operations, and adapts the cutting processes itself. This means that an intelligent machine tool can perform autonomous operations that are instructed by in-process planning made by the tool itself. Information technology (IT) will be the key issue to realize this third innovation.

48.1 The Advent of the NC Machine Tool

48.1.1 From Hand Tool to Powered Machine

It is well known that John Wilkinson's boring machine (Fig. 48.2) was able to machine a high-accuracy cylinder to build Watt's steam engine. The performance of steam engines was improved drastically by the high-accuracy cylinder. With the spread of steam engines, machine tools changed from hand tools to powered machines, and metal cutting became widespread to achieve modern industrialization. During the era of the Industrial Revolution, most conventional machine tools, such as lathes and milling machines, were developed.

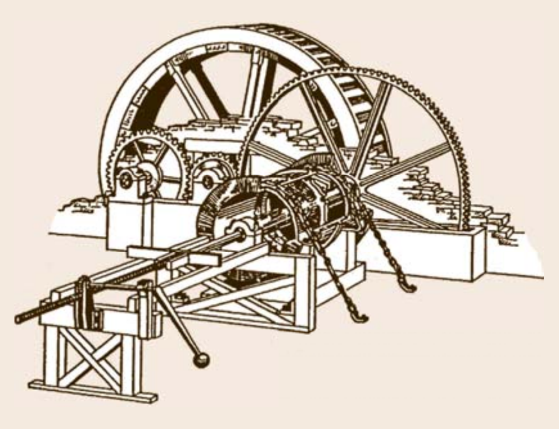

Fig. 48.2 Wilkinson's boring machine (1775)

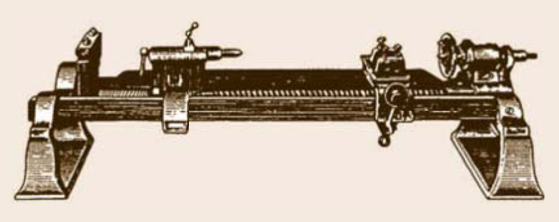

Fig. 48.3 Maudsley's screw-cutting lathe with mechanized tool carriage (1800)

Maudsley's screw-cutting lathe with mechanized tool carriage (Fig. 48.3) was a great invention which was able to machine high-accuracy screw threads. The screw-cutting lathe was developed to machine screw threads accurately; however the mechanical tool carriage equipped with a screw allowed precise repetition of machined shapes. Precise repetition of machined shape is an important requirement to produce many of the component parts for mass production. Therefore, Maudsley's screw-cutting lathe became a prototype of lathes.

Whitney's milling machine (Fig. 48.4) is believed to be the first successful milling machine used for cutting plane of metal parts. However, it appears that Whitney's milling machine was made after Whitney's death. Whitney's milling machine was designed to manufacture interchangeable musket parts. Interchangeable parts require high-precision machine tools to make exact shapes.

Fitch's turret lathe (Fig. 48.5) was the first automatic turret lathe. Turret lathes were used to produce complex-shaped cylindrical parts that required several operating sequences and tools. Also, turret lathes can perform automatic machining with a single setup and can achieve high productivity. High productivity is an

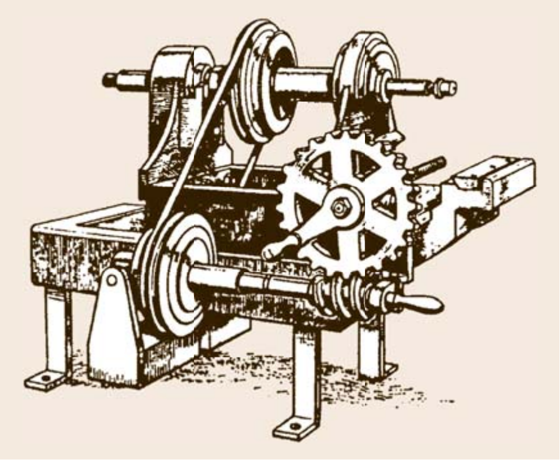

Fig. 48.4 Whitney's milling machine (1818)

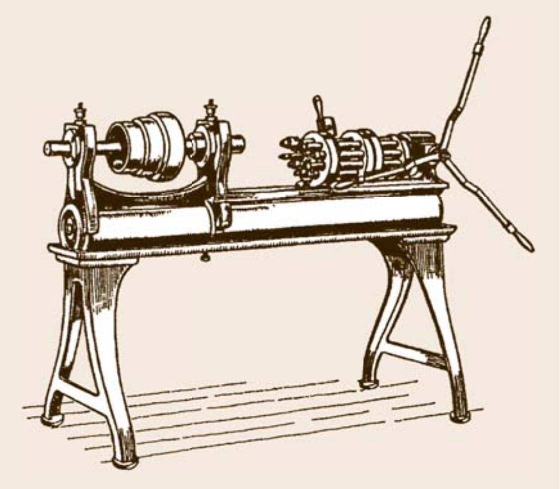

Fig. 48.5 Fitch's turret lathe (1845)

important requirement to produce many of the component parts for mass production.

As mentioned above, the most important modern machine tools required to realize mass production were developed during the era of the Industrial Revolution. Also high-speed machining, high-precision machining, and high productivity had been achieved by these modern machine tools.

48.1.2 Copy Milling Machine

A copy milling machine, also called a tracer milling machine or a profiling milling machine, can duplicate freeform geometry represented by a master model for making molds, dies, and other shaped cavities and forms. A prove tracing the model contour is controlled to follow a three-dimensional master model, and the cutting tool follows the path taken by the tracer to machine the desired shape. Usually, a tracing prove is fed by a human operator, and the motion of the tracer is converted to the motion of the tool by hydraulic or electronic mechanisms. The motion in Fig. 48.6 shows an example of copy milling. In this case, three spindle heads or three cutting tools follow the path taken by the tracer simultaneously. In some copy milling machines the ratio between the motion of the tracer and the cutting tool can be changed to machine shapes that are similar to the master model.

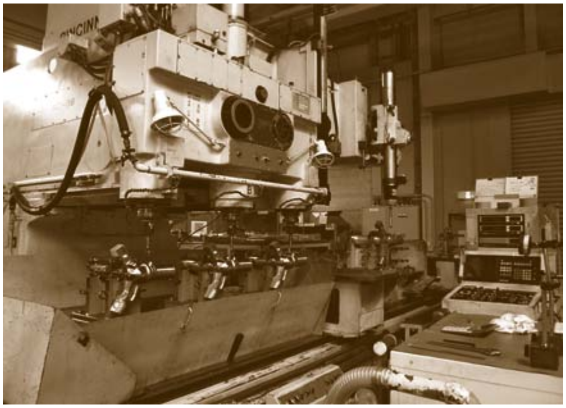

Fig. 48.6 A copy milling machine

Copy milling machines were widely used to machine molds and dies which were difficult to generate with simple tool paths, until CAD/CAM systems became widespread to generate NC programs freely for machining three-dimensional freeform shapes.

48.1.3 NC Machine Tools

The first prototype NC machine tool, shown in Fig. 48.7, was demonstrated at the MIT in 1952. The name *numerical control* was given to the machine tool, as it was controlled numerically. It is well known that numerical control was required to develop more efficient manufacturing methods for modern aircraft, as aircraft components became more complex and required more machining. The accuracy, repeatability, and productivity of NC machine tools became far better than those of machine tools operated manually.

The concept of numerical control is very important and innovative for programmable automation, in which the motions of machine tools are controlled or

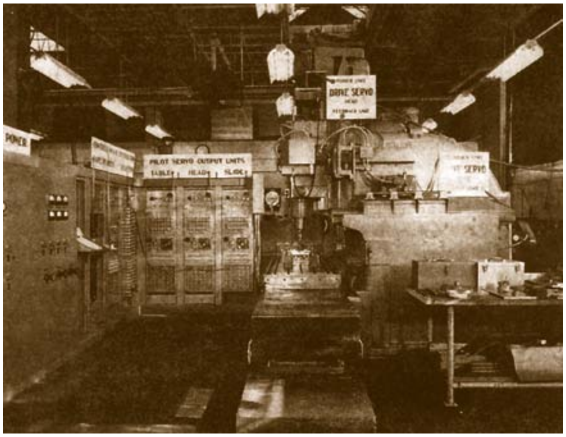

Fig. 48.7 The first NC machine tool, which was demonstrated at MIT in 1952

instructed by a program containing coded alphanumeric data. According to the concept of numerical control, machining operation becomes programmable and machining shape is changeable. The concept of the flexible manufacturing system (FMS) mentioned later required the prior development of numerical control.

A program to control NC machine tools is called a part program, and the importance of a part program was recognized from the beginning of NC machine tools. In particular, the definition for machining shapes of more complex parts is difficult by manual operation. Therefore, a part programming language, APT, was developed at MIT to realize computer-assisted part programming.

Recently, CNC has become widespread, and in most cases the term NC is used synonymously with CNC. Originally, CNC corresponded to an NC system operated by an internal computer, which realized storage of part programs, editing of part programs, manual data input (MDI), and so on. The latest CNC tools allow generation of a part program interactively by a machine operator, and avoid machine crash caused by a missing part program. High-speed and high-accuracy control of machine tools to realize highly automated machining operation requires the latest central processing unit (CPU) to perform high-speed data processing for several functions.

48.2 Development of Machining Center and Turning Center

48.2.1 Machining Center

A machining center is a highly automated NC milling machine that performs multiple machining operations such as end milling, drilling, and tapping. It was developed to realize process integration as well as machining automation, in 1958. Figure 48.8 shows an early machining center equipped with an automatic tool changer (ATC). Most machining centers are equipped with an ATC and an automatic pallet changer (APC) to perform multiple cutting operations in a single machine setup and to reduce nonproductive time in the whole machining cycle.

Machining centers are classified into horizontal and vertical types according to the orientation of the spindle axis. Figures 48.9 and 48.10 show typical horizontal and vertical machining centers, respectively. Most horizontal machining centers have a rotary table to index the machined part at some specific angle relative to the cutting tool. A horizontal machining center which has a rotary table can machine the four vertical faces of boxed workpieces in single setup with minimal human assistance. Therefore, a horizontal machining center is widely used in an automated shop floor with a loading and unloading system for workpieces to realize machining automation. On the other

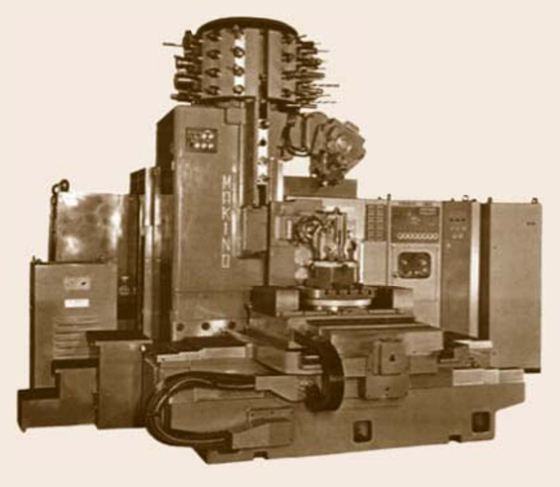

Fig. 48.8 Machining center, equipped with an ATC (courtesy of Makino Milling Machine Co. Ltd.)

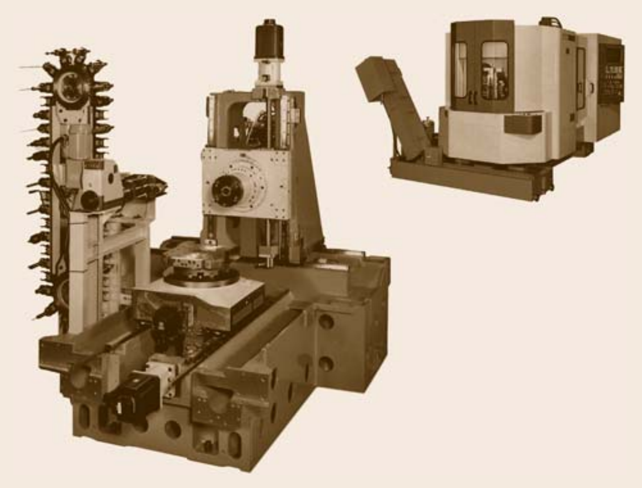

Fig. 48.9 Horizontal machining center (courtesy of Yamazaki Mazak Corp.)

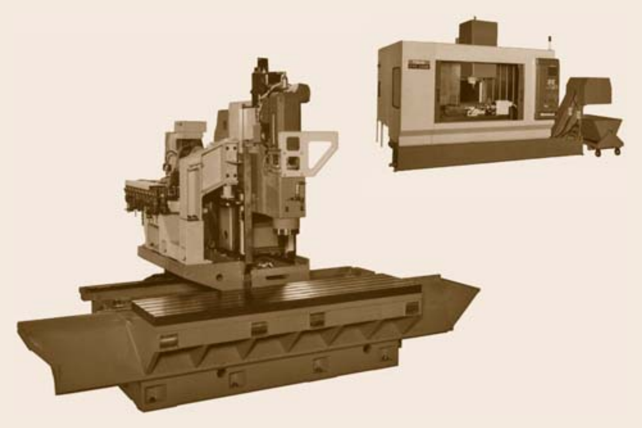

Fig. 48.10 Vertical machining center (courtesy of Yamazaki Mazak Corp.)

hand, a vertical machining center is widely used in a die and mold machine shop. In a vertical machining center, the cutting tool can machine only the top surface of boxed workpieces, but it is easy for human operators to understand tool motion relative to the machined part.

Automatic Tool Changer (ATC)

ATC stands for automatic tool changer, which permits loading and unloading of cutting tools from one machining operation to the next. The ATC is designed to exchange cutting tools between the spindle and a tool magazine, which can store more than 20 tools. The large capacity of the tool magazine allows a variety of workpieces to be machined. Additionally, higher tool-change speed and reliability are required to achieve a fast machining cycle. Figure 48.11 shows an example of a twin-arm-type ATC driven by a cam mechanism to ensure reliable high-speed tool change.

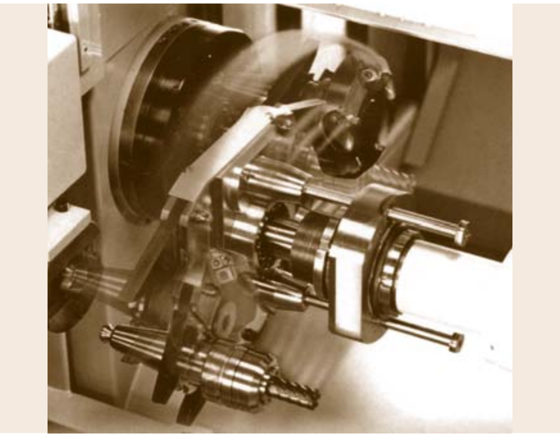

Fig. 48.11 ATC: automatic tool changer (courtesy of Yamazaki Mazak Corp.)

Automatic Pallet Changer (APC)

APC stands for automatic pallet changer, which permits loading and unloading of workpieces for machining automation. Most horizontal machining centers have two pallet tables to exchange the parts before and after ma-

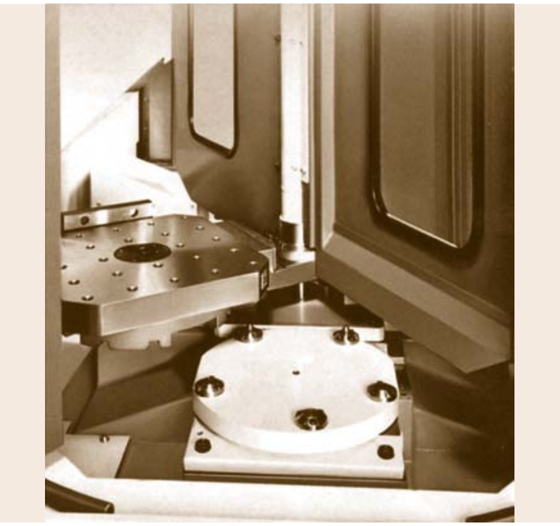

Fig. 48.12 APC: automatic pallet changer (courtesy of Yamazaki Mazak Corp.)

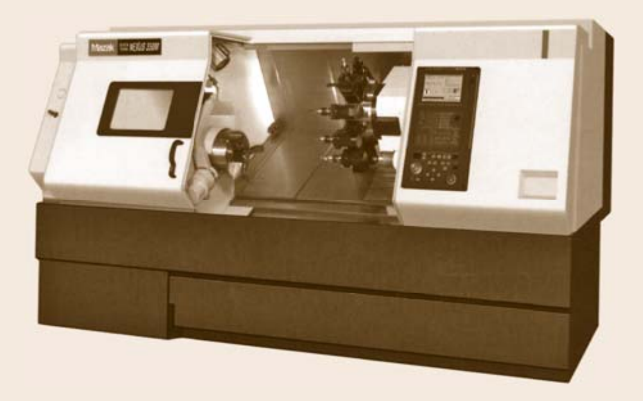

Fig. 48.13 Turning center or CNC lathe (courtesy of Yamazaki Mazak Corp.) ▶

chining automatically. Figure 48.12 shows an example of an APC. The operator can be unloading the finished part and loading the next part on one pallet while the machining center is processing the current part on another pallet.

48.2.2 Turning Center

A turning center is a highly automated NC lathe to perform multiple turning operations. Figure 48.13 shows a typical turning center. Changing of cutting tools is performed by a turret tool changer which can hold about ten turning and milling tools. Therefore, a turning center enables not only turning operations but also milling operations such as end milling, drilling, and tapping in a single machine setup. Some turning centers have two spindles and two or more turret tool changers to complete all machining operations of cylindrical parts in a single machine setup. In this case, the first half of the machining operations of the workpiece are carried out on one spindle, then the second half of the machining operations are carried out on another spindle, without unloading and loading of the workpiece. This reduces production time.

Turret Tool Changer

Figure 48.14 shows a tool turret with 12 cutting tools. A suitable cutting tool for the target machining operation is indexed automatically under numerical control for continuous machining operations. The most sophisticated turning centers have tool monitoring systems which check tool length and diameter for automatic tool alignment and sense tool wear for automatic tool changing.

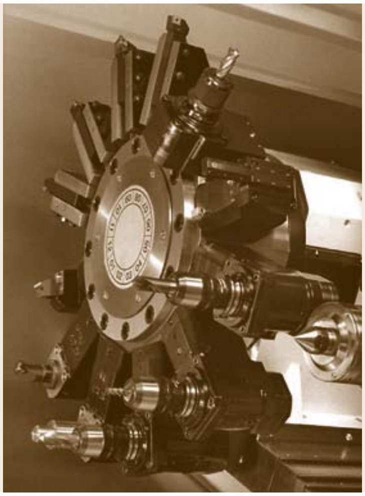

Fig. 48.14 Tool turret in turning center (courtesy of Yamazaki Mazak Corp.)

48.2.3 Fully Automated Machining: FMS and FMC

Flexible Manufacturing System (FMS)

The concept of the flexible manufacturing system (FMS) was proposed during the mid-1960s. It aims to perform automatic machining operations unaided by human operators to machine various parts. Machining centers are key components of the FMS for flexible machining operations. Figure 48.15 shows a typical FMS, which consists of five machining centers, one conveyor, one load/unload station, and a central computer that controls and manages the components of the FMS.

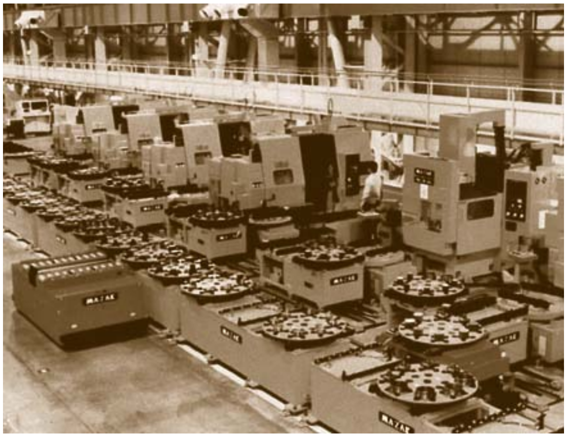

Fig. 48.15 Flexible manufacturing system (courtesy of Yamazaki Mazak Corp.)

No manufacturing system can be completely flexible. FMSs are typically used for mid-volume and mid-variety production. An FMS is designed to machine parts within a range of style, sizes, and processes, and its degree of flexibility is limited. Additionally, the machining shape is changeable through the part programs that control the NC machine tools, and the part programs required for every shape to be machined have to be prepared before the machining operation. Therefore a new shape that needs a part program is not acceptable in conventional FMSs, which is why a third innovation of machine tools is required to achieve autonomous machining operations instead of automatic machining operations to achieve true FMS.

An FMS consists of several NC machine tools such as machining centers and turning centers, material-handling or loading/unloading systems such as industrial robots and pallets changer, conveyer systems such as conveyors and automated guided vehicles (AGV), and storage systems. Additionally, an FMS has a central computer to coordinate all of the activities of the FMS, and all hardware components of the FMS generally have their own microcomputer for control. The central computer downloads NC part programs, and controls the material-handling system, conveyer system, storage system, and management of materials and cutting tools, etc.

Human operators play important roles in FMSs, performing the following tasks:

1. Loading/unloading parts at loading/unloading stations
2. Changing and setting of cutting tools
3. NC part programming
4. Maintenance of hardware components
5. Operation of the computer system.

These tasks are indispensable to manage the FMS successfully.

Flexible Manufacturing Cell (FMC)

Basically, FMSs are large systems to realize manufacturing automation for mid-volume and mid-variety production. In some cases, small systems are applicable to realize manufacturing automation. The term flexible manufacturing cell (FMC) is used to represent small systems or compact cells of FMSs. Usually, the number of machine tools included in a FMC is three or fewer. One can consider that an FMS is a large manufacturing system composed of several FMCs.

48.3 NC Part Programming

The task of programming to operate machine tools automatically is called NC part programming because the program is prepared for a part to be machined. NC part programming requires the programmer to be familiar with both the cutting processes and programming procedures. The NC part program includes the detailed commands to control the positions and motion of the machine tool. In numerical control, the three linear axes (x, y, z) of the Cartesian coordinate system are used to specify cutting tool positions, and three rotational axes (a, b, c) are used to specify the cutting tool postures. In turning operations, the position of the cutting tool is defined in the x–z plane for cylindrical parts, as shown in Fig. 48.16a. In milling operations, the position of the cutting tool is defined by the x-, y-, and z-axes for cuboid parts, as shown in Fig. 48.16b.

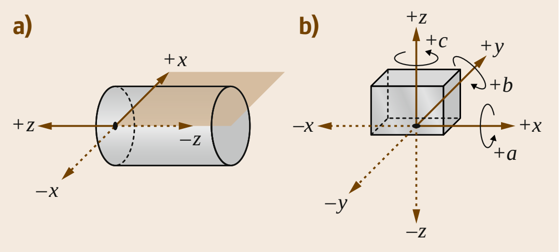

Fig. 48.16a,b Coordinate systems in numerical control. **(a)** Cylindrical part for turning; **(b)** cuboid part for milling

Numerical control realizes programmable automation of machining. The mechanical actions or motions of the cutting tool relative to the workpiece and the control sequence of the machine tool equipments are coded by alphanumerical data in a program. NC part programming requires a programmer who is familiar with the metal cutting process to define the points, lines, and surfaces of the workpiece, and to generate the alphanumerical data. The most important NC part programming techniques are summarized as follows:

1. Manual part programming
2. Computer-assisted part programming – APT and EXAPT
3. CAM-assisted part programming.

48.3.1 Manual Part Programming

This is the simplest way to generate a part program. Basic numeric data and alphanumeric codes are entered manually into the NC controller. The simplest commands example is shown as follows:

```
N0010   M03       S1000       F100       EOB
N0020   G00       X20.000     Y50.000    EOB
N0030   Z20.000   EOB
N0040   G01       Z – 20.000  EOB
```

Each code in the statement has a meaning to define a machining operation. The "N" code shows the sequence number of the statement. The "M" code and the following two-digit number define miscellaneous functions; "M03" means to spindle on with clockwise rotation. The "S" code defines the spindle speed; "S1000" means that the spindle speed is 1000 rpm. The "F" code defines the feed speed; "F100" means that the feed is 100 mm/min. "EOB" stands for "end of block" and shows the end of the statement. The "G" code and the following two-digit number define preparatory functions; "G00" means rapid positioning by point-to-point control. The "X" and "Y" codes indicate the x- and y-coordinates. The cutting tool moves rapidly to the position $x = 20$ mm and $y = 50$ mm with the second statement. Then, the cutting tool moves rapidly again to the position $z = 20$ mm with the third statement. "G01" means linear positioning at controlled feed speed. Then the cutting tool moves with the feed speed, defined by "F100" in this example, to position $z = -20$ mm.

The positioning control can be classified into two types, (1) point-to-point control and (2) continuous path control. "G00" is a positioning command for point-to-point control. This command only identifies the next position required at which a subsequent machining operation such as drilling is performed. The path to get to the position is not considered in point-to-point control. On the other hand, the path to get to the position is controlled simultaneously in more than one axis to follow a line or circle in continuous path control. "G01" is a positioning command for linear interpolation. "G02" and "G03" are positioning commands for circular interpolation. These commands permit the generation of two-dimensional curves or three-dimensional surfaces by turning or milling.

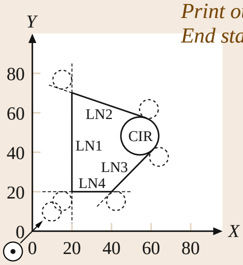

Fig. 48.17 Example program list in APT

48.3.2 Computer-Assisted Part Programming: APT and EXAPT

Automatically programmed tools is the most important computer-assisted part programming language and was first used to generate part programs in production around 1960. EXAPT contains additional functions such as setting of cutting conditions, selection of cutting tool, and operation planning besides the functions of APT. APT provides two steps to generate part programs: (1) definition of part geometry, and (2) specification of tool motion and operation sequence. An example program list is shown in Fig. 48.17. The following APT statements define the contour of the part geometry based on basic geometric elements such as points, lines, and circles:

```
LN1 =LINE/20, 20, 20, 70
LN2 =LINE/(POINT/20, 70), ATANGL, 75, LN1
LN3 =LINE/(POINT/40, 20), ATANGL, 45
LN4 =LINE/20, 20, 40, 20
 CIR =CIRCLE/YSMALL, LN2,
          YLARGE, LN3, RADIUS, 10
```

where LN1 is the line that goes through points (20, 20) and (20, 70); LN2 is the line that goes from point (20, 70) at 75° to LN1; LN3 is the line that goes from point (40, 20) at 45° to the horizontal line; LN4 is the line that goes through points (20, 20) and (40, 20); and CIR is the circle tangent to lines LN2 and LN3 with radius 10. Most part shapes can be described using these APT statements.

On the other hands, tool motions are specified by the following APT statements:

```
TLLFT, GOLFT/LN1, PAST, LN2
GORGT/LN2, TANTO, CIR
GOFWD/CIR, TANTO, LN3
```

where “TLLFT, GOLFT/LN1” indicates that the tool positions left (TLLFT) of the line LN1, goes left (GOLFT), and moves along the line LN1. “PAST, LN2” indicates that the tool moves until past (PAST) the line LN2. “GORGT/LN2” indicates that the tool goes right (GORGT) and moves along the line LN2. “TANTO, CIR” indicates that the tool moves until tangent to (TANTO) the circle CIR. GOFWD/CIR indicates that the tool goes forward (GOFWD) and moves along the circle CIR. “TANTO, LN3” indicates that the tool moves until tangent to the line LN3.

Additional APT statements are prepared to define feed speed, spindle speed, tool size, and tolerances of tool paths. The APT program completed by the part programmer is translated by the computer to the cutter location (CL) data, which consists of all the geometry and cutter location information required to machine the part. This process is called main processing or preprocessing to generate NC commands. The CL data is converted to the part program, which is understood by the NC machine tool controller. This process is called postprocessing to add NC commands to specify feed speed, spindle speed, and auxiliary functions for the machining operation.

48.3.3 CAM-Assisted Part Programming

CAM systems grew based on technologies relating to APT and EXAPT. Originally, CAM stood for computer-aided manufacturing and was used as a general term for computer software to assist all operations while realizing manufacturing. However, CAM is now used to indicate computer software to assist part programming in a narrow sense.

The biggest difference between part programming assisted by APT and CAM is usability. Part programming assisted by APT is based on batch processing. Therefore, many programming errors are not detected until the end of computer processing. The other hand, part programming assisted by CAM is interactive-mode processing with a visual and graphical environment. It therefore becomes easy to complete a part program after repeated trial and error using visual verification. Additionally, close cooperation between CAD and CAM offers a significant benefit in terms of part programming. The geometrical data for each part designed by CAD are available for automatic toolpath generation, such as surface profiling, contouring, and pocket milling, in CAM through software routines. This saves significant programming time and effort for part programming. Recently, some simulation technologies have become available to verify part programs free from machining trouble. Optimization of feed speed and detection of machine crash are two major functions for part program verification. These functions also save significant production lead time.

48.4 Technical Innovation in NC Machine Tools

48.4.1 Functional and Structural Innovation by Multitasking and Multiaxis

Turning and Milling Integrated Machine Tool

Recently, a turning and milling integrated machine tool has been developed as a sophisticated turning center. It also has a rotating cutting tool which can perform milling operation besides turning operation, as shown in Fig. 48.18. The benefits of the use of turning and milling integrated machine tools are

1. Reduction of production time
2. Improved machining accuracy
3. Reduction of floor space and initial cost.

As the high performance of these machine tools was accepted, the configuration became more and more complicated. Multispindles and multiturrets are integrated to perform multitasks simultaneously. The machine tool shown in Fig. 48.18 has two spindles: one milling spindle with four axes and one turret with two axes. Increasing the complexity of these machine tools causes the risk of machine crashes during machining operation, and requires careful part programming to avoid machine crashes.

Five-Axis Machining Center

Multiaxis machining centers are expanding in practical applications rapidly. The multiaxis machining center is applied to generate a workpiece with complex geometry with a single machine setup. In particular, five-axis machining centers have become popular for machining aircraft parts and complicated surfaces such as dies and molds. A typical five-axis machining center is shown in Fig. 48.19. Benefits to the use of multiaxis machining centers are

1. Reduction of preparation time
2. Reduction of production time
3. Improved machining accuracy.

Parallel Kinematic Machine Tool

A parallel kinematic machine tool is classified as a multiaxis machine tool. In the past years, parallel kinematic machine tools (PKM) have been studied with interest for their advantages of high stiffness, low inertia, high accuracy, and high-speed capability. Okuma Corporation in Japan developed the parallel mechanism machine tool COSMO CENTER PM-600 shown in Fig. 48.20. This machine tool achieves high-speed and high-degrees-of-freedom machining operation for practical products. Also, high-speed milling of a free surface is shown in Fig. 48.20.

Ultraprecision Machine Tool

Recently, ultraprecision machining technology has experienced major advances in machine design, performance, and productivity. Ultraprecision machining was successfully adopted for the manufacture of computer memory discs used in hard-disk drives (HDD), and also

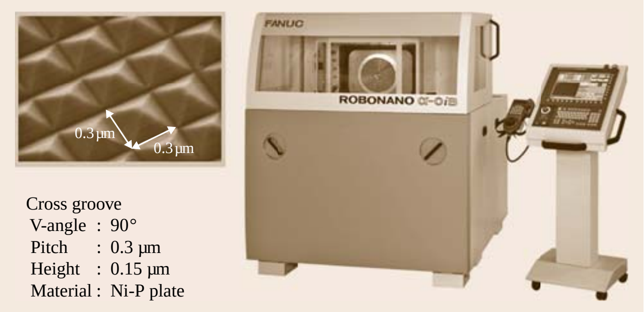

Fig. 48.21 Ultraprecision machine tool (courtesy of Fanuc Ltd.)

photoreflector components used in photocopiers and printers. These applications require extremely high geometrical accuracies and form deviations in combination with supersmooth surfaces.

The FANUC ROBONANO α-0iB is shown in Fig. 48.21 as an example of a five-axis ultraprecision machine tool. Nanometer servo-control technologies and air-bearing technologies are combined to realize an ultraprecision machine tool. This machine provides various machining methods for mass production with nanometer precision in the fields of optical electronics, semiconductor, medical, and biotechnology.

48.4.2 Innovation in Control Systems Toward Intelligent CNC Machine Tools

The framework of future intelligent CNC machine tools is summarized in Fig. 48.22. A conventional CNC control system has two major levels: the servo control (level 1 in Fig. 48.22) and the interpolator (level 2) for the axial motion control of machine tools. Certainly, the conventional CNC control system can achieve highly sophisticated motion control, but it cannot achieve sophisticated cutting process control. Two additional levels of control hierarchy, levels 3 and 4 in Fig. 48.22, are required for a future intelligent CNC control system to achieve more sophisticated process control.

Machining operations by conventional CNC machine tools are generally dominated by NC programs, and only feed speed can be adapted. For sophisticated cutting process control, dynamic adaptation of cutting parameters is indispensable. The adaptive control (AC) scheme is assigned at a higher level (level 3) of the control hierarchy, enabling intelligent process monitoring, which can detect machining state independently of cutting conditions and machining operation.

Level 4 in Fig. 48.22 is usually regarded as a supervisory level that receives feedback from measurements of the finished part. A reasonable index to evaluate the cutting results and a reasonable strategy to improve cutting results are required at this level. For this purpose, the utilization of knowledge, knowhow, and skill related to machining operations has to be considered. Effective utilization of feedback information regarding the cutting results is very important.

Additionally, an autonomous process planning strategy, which can generate a flexible and adaptive working

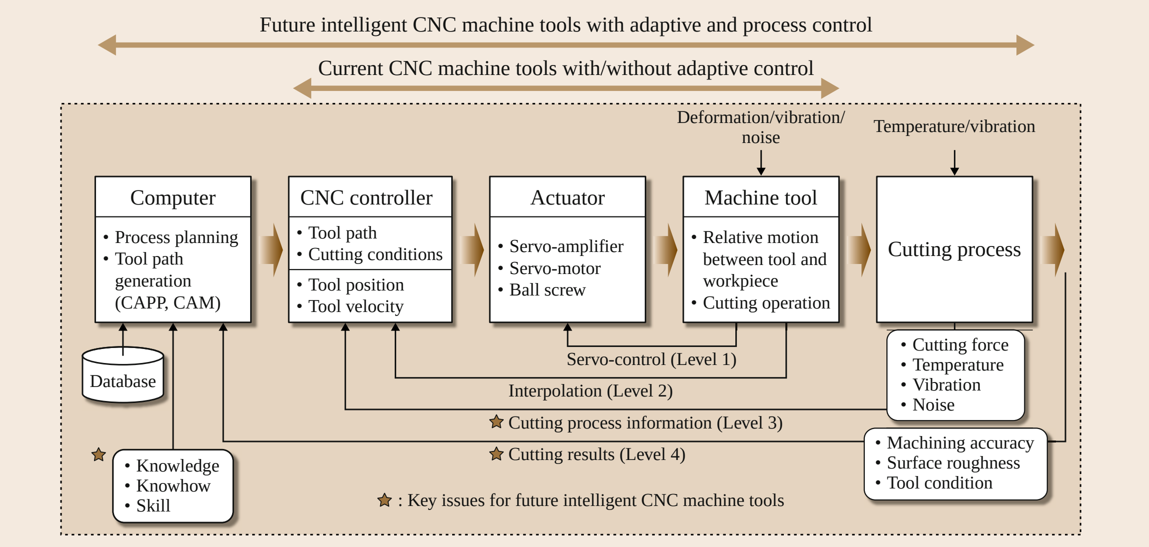

Fig. 48.22 Framework of intelligent machine tools (CAPP – computer aided process planning)

plan, is required as a function of intelligent CNC machine tools. It must be responsive and adaptive to unpredictable changes, such as job delay, job insertion, and machine breakdown on machining shop floors. In order to generate the operation plan autonomously, several planning and information processing functions are needed. Operation planning, cutting tool selection, cutting parameters assignment, and tool-path generation for each machining operation are required at the machine level. Product data analysis and machining feature recognition are important issues as part of information processing.

48.4.3 Current Technologies of Advanced CNC Machine Tools

Open Architecture Control

The concept of open architecture control (OAC) was proposed in the early 1990s. The main aim of OAC was easy implementation and integration of customer-specific controls by means of open interfaces and configuration methods in a vender-neutral standardized environment [48.2]. It provides the methods and utilities for integrating user-specific requirements, and it is required to implement several intelligent control applications for process monitoring and control.

Altintas has developed a user-friendly, reconfigurable, and modular toolkit called the open real-time operating system (ORTS). ORTS has several intelligent machining modules, as shown in Fig. 48.23. It can be used for the development of real-time signal processing, motion, and process control applications. A sample tool-path generation using quintic spline interpolation for high-speed machining is described as an application, and a sample cutting force control has also been demonstrated [48.3].

Mori and *Yamazaki* developed an open servo-control system for an intelligent CNC machine tool to minimize the engineering task required for implementing custom intelligent control functions. The conceptual design of this system is shown in Fig. 48.24. The software model reference adaptive control was implemented as a custom intelligent function, and a feasibility study was conducted to show the effectiveness of the open servo control [48.4]. Open architecture control will reach the level of maturity required to replace current CNC controllers in the near future. The custom intelligent control functions required for an intelligent machine tool will be easy to implement with the CNC controller. Machining performance in terms of higher accuracy and productivity will thereby be enhanced.

Feedback of Cutting Information

Yamazaki proposed TRUE-CNC as a future-oriented CNC controller. (TRUE-CNC was named after the following key words. T: transparent, transportable, transplantable, R: revivable, U: user-reconfigurable, and E: evolving.) The system consists of an information service, quality control and diagnosis, monitoring, control, analysis, and planning sections, as shown in

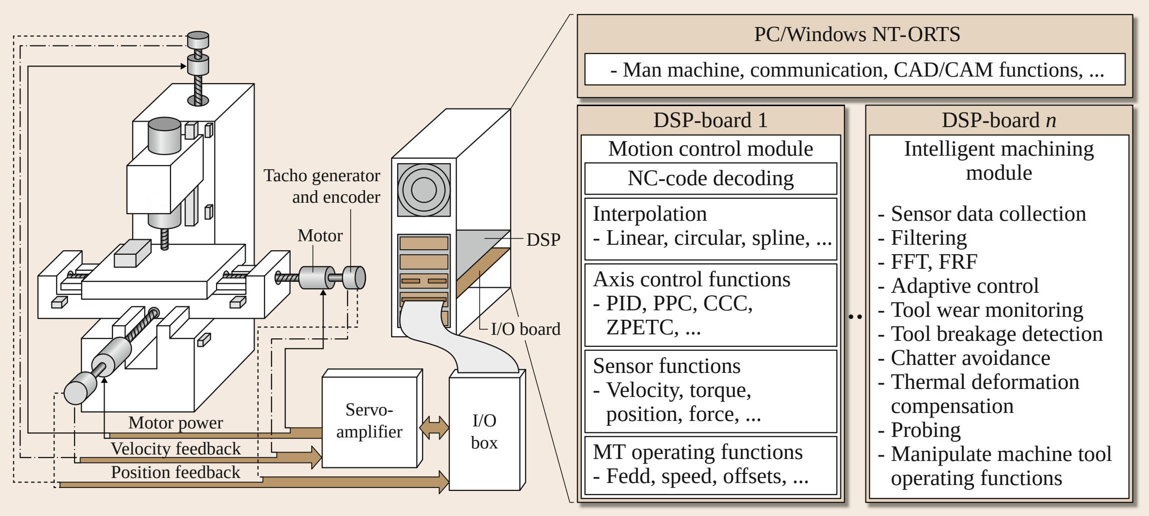

Fig. 48.23 Application of ORTS on the design of CNC and machining process monitoring (after [48.3]) (DSP – digital signal processor, FFT – fast Fourier transform, FRF – frequency response function, PID – proportional–integral–derivative controller, PPC – pole placement controller, CCC – cross coupling controller, ZPETC – zero phase error tracking controller, I/O – input/output, MT – machine tool)

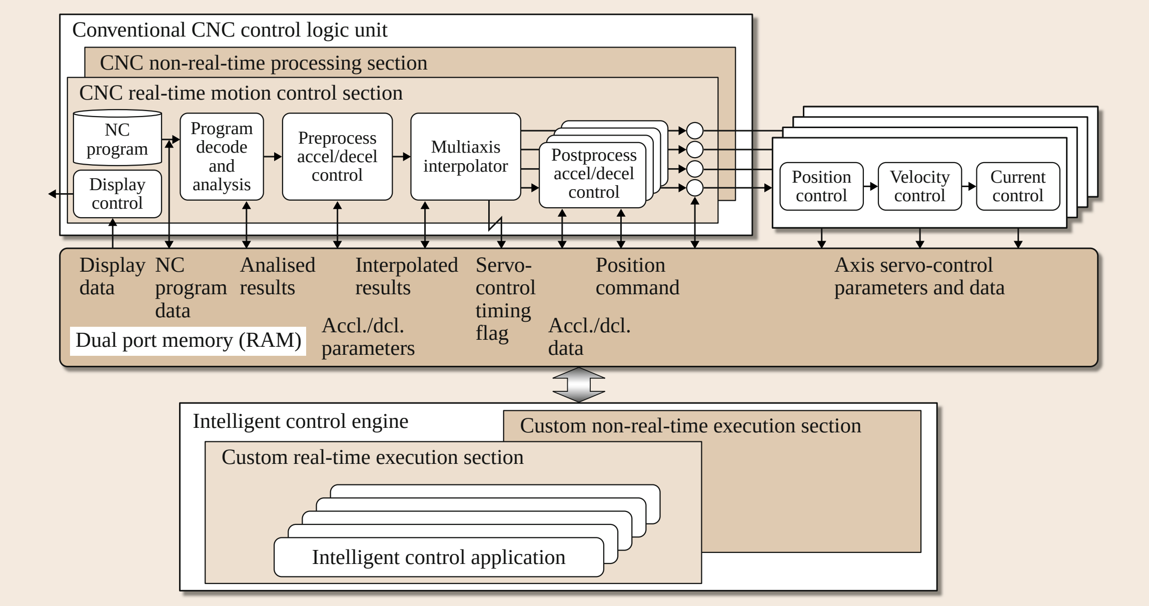

Fig. 48.24 Conceptual design of open servo system (after [48.4])

Fig. 48.25 [48.5]. TRUE-CNC allows the operator to achieve maximum productivity and highest quality for machined parts in a given environment with autonomous capture of machining operation proficiency and machining knowhow. The autonomous coordinate measurement planning (ACMP) system is a component of TRUE-CNC, and enhances the operability of coordinate measuring machines (CMMs). The ACMP generates probe paths autonomously for inline measurement of machined parts [48.6]. Inspection results

or measurement data are utilized to evaluate the machining process to be finished and to assist in the decision-making process for new operation planning. The autonomous machining process analyzer (AMPA) system is also a component of TRUE-CNC. In order to retrieve knowledge, knowhow, and skill related to machining operations, the AMPA analyzes NC programs coded by experienced machining operators and gathers machining information. Machining process sequence, cutting conditions, machining time, and machining features are detected automatically and stored in the machining knowhow database [48.7], whihc is then used to generate new operation plans.

Mitsuishi developed a CAD/CAM mutual information feedback machining system which has capabilities for cutting state monitoring, adaptive control, and learning. The system consists of a CAD system, a database, and a real-time controller, as shown in Fig. 48.26 [48.8]. The CNC machine tool equipped with a six-axis force sensor was controlled to obtain the stability lobe diagram. Cutting parameters, such as depth of cut, spindle speed, and feed speed, are modified dynamically according to the sequence for finding stable cutting states, and the stability lobe diagram is obtained autonomously. The stability lobe diagram is then used to determine chatter-free cutting conditions. Furthermore, *Mitsuishi* proposed a networked remote manufacturing system which provides remote operating and monitoring [48.9]. The system demonstrated the capability to transmit the machining state in real time to the operator who is located far from the machine tool. The operator can modify the cutting conditions in real time depending on the machining state monitored.

Five-Axis Control

Most commercial CAM systems are not sufficient to generate suitable cutter location (CL) data for five-axis control machining. The CL data must be adequately generated and verified to avoid tool collision with the workpiece, fixture, and machine tool. In general, five-axis control machining has the advantage of enabling arbitrary tool posture, but it makes it difficult to find a suitable tool posture for a machining strategy without tool collision. *Morishige* and *Takeuchi* applied the concept of C-space to generate tool-collision-free CL data for five-axis control [48.10, 11]. The two-dimensional C-space is used to represent the relation between the tool posture and the collision area, as

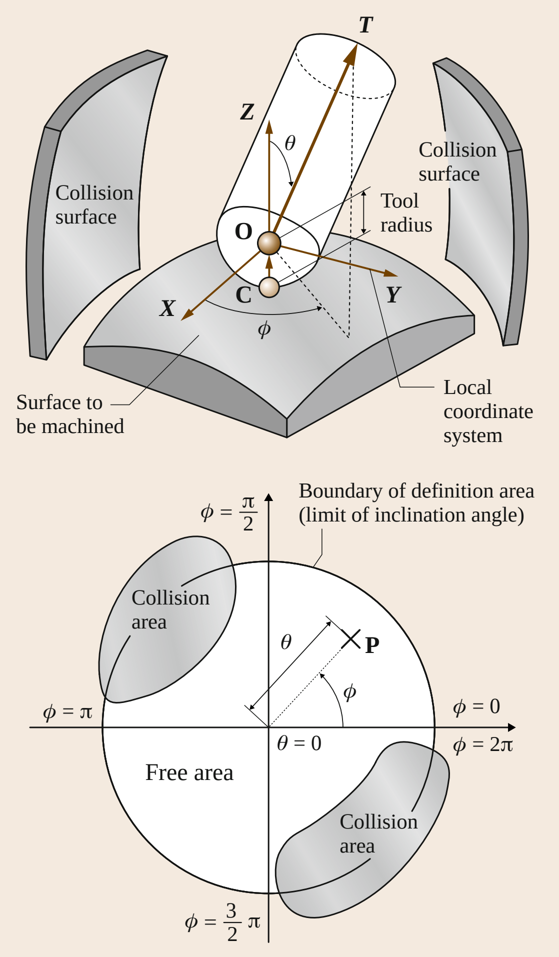

Fig. 48.27 Configuration space to define tool posture (after [48.11])

shown in Fig. 48.27. Also, three-dimensional C-space is used to generate the most suitable CL data which satisfy the machining strategy, smooth tool movement, good surface roughness, and so on. Experimental five-axis-control collision-free machining was performed successfully, as shown in Fig. 48.28.

48.4.4 Autonomous and Intelligent Machine Tool

The whole machining operation of conventional CNC machine tools is predetermined by NC programs. Once the cutting conditions, such as depth of cut and stepover, are given by the machining commands in the NC programs, they are not generally allowed to be changed during machining operations. Therefore NC programs must be adequately prepared and verified in advance, which requires extensive amounts of time and effort. Moreover, NC programs with fixed commands are not responsive to unpredictable changes, such as job delay, job insertion, and machine breakdown found on machining shop floors.

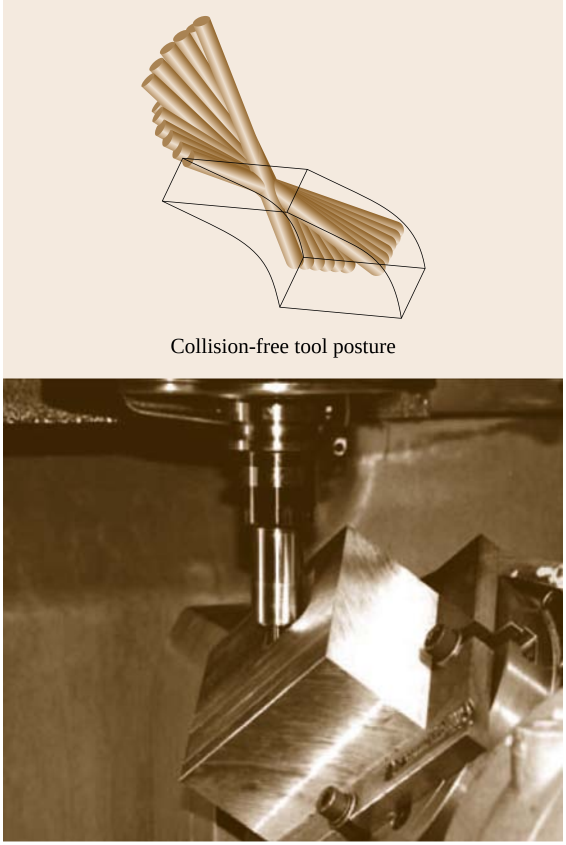

Fig. 48.28 Five-axis control machining (after [48.11])

Shirase proposed a new architecture to control the cutting process autonomously without NC programs. Figure 48.29 shows the conceptual structure of autonomous and intelligent machine tools (AIMac). AIMac consists of four functional modules called management, strategy, prediction, and observation. All functional modules are connected with each other to share cutting information.

Digital Copy Milling for Real-Time Tool-Path Generation

A technique called digital copy milling has been developed to control a CNC machine tool directly. The

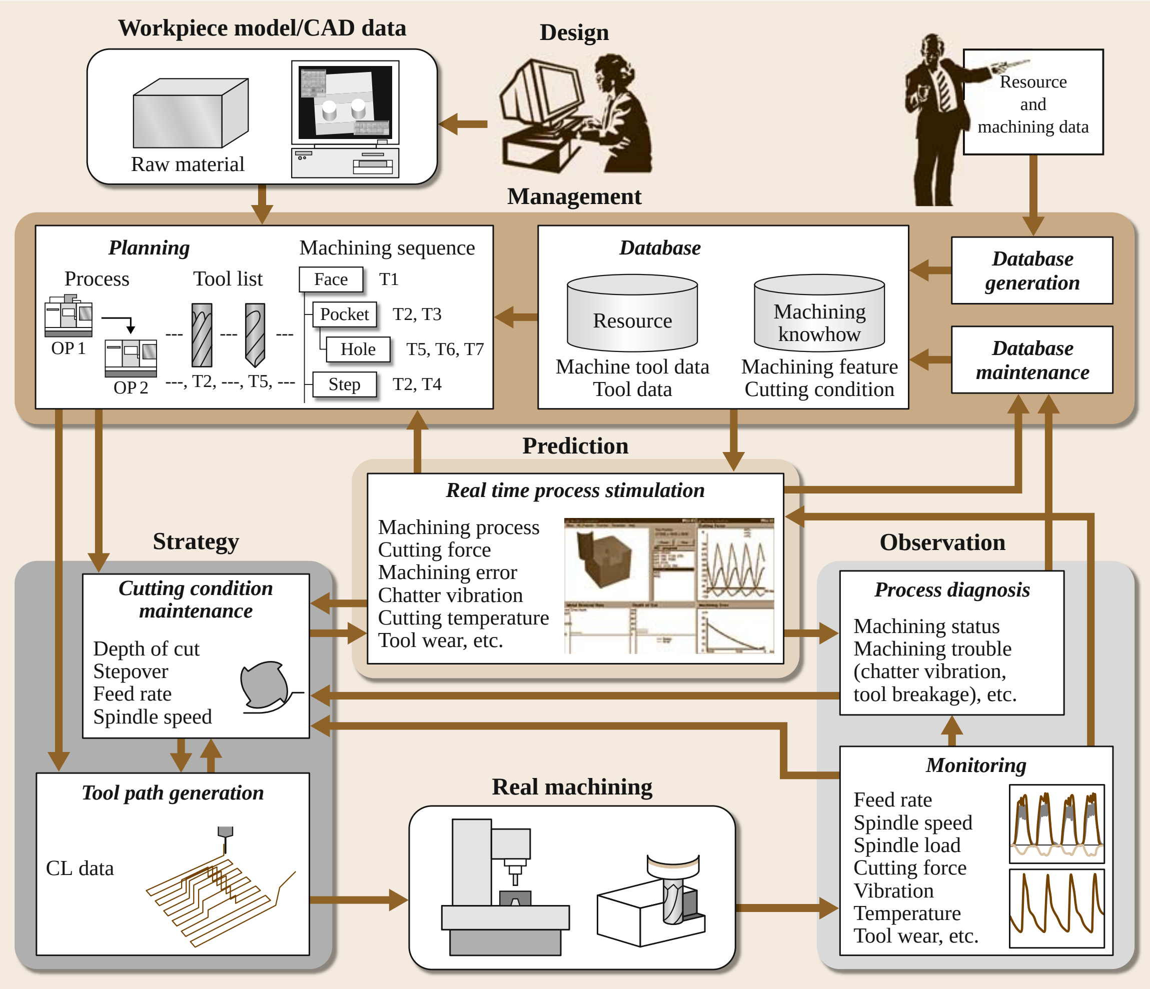

Fig. 48.29 Conceptual structure of AIMac

digital copy milling system can generate tool paths in real time based on the principle of traditional copy milling. In digital copy milling, a tracing probe and a master model in traditional copy milling are represented by three-dimensional (3-D) virtual models in a computer. A virtual tracing probe is simulated to follow a virtual master model, and cutter locations are generated dynamically according to the motion of the virtual tracing probe in real time. In the digital copy milling, cutter locations are generated autonomously, and an NC machine tool can be instructed to perform milling operation without NC programs. Additionally, not only stepover, but also radial and axial depths of cut can be modified, as shown in Fig. 48.30. Also, digital copy milling can generate new tool paths to avoid cutting problems and change the machining sequence during operation [48.12].

Furthermore, the capability for in-process cutting parameters modification was demonstrated, as shown in Fig. 48.31 [48.13]. Real-time tool-path generation and the monitored actual milling are shown in the lower-left corner and the upper-right corner of this figure. The monitored cutting torque, adapted feed rate, and radial and axial depths of cut are shown in the lower-right corner of this figure. The cutting parameters can be modified dynamically to maintain the cutting load.

Fig. 48.32 Results of machining process planning on AIMac

Flexible Process and Operation Planning System

A flexible process and operation planning system has been developed to generate cutting parameters dynamically for machining operation. The system can generate the production plan from the total removal volume (TRV). The TRV is extracted from the initial and finished shapes of the product and is divided into machining primitives or machining features. The flexible process and operation planning system can generate cutting parameters according to the machining features detected. Figure 48.32 shows the operation sequence and cutting tools to be used. Cutting parameters are determined for the experimental machining shape. The digital copy milling system can generate the tool paths or CL data dynamically according to these results and perform the autonomous milling operation without requiring any NC program.

48.5 Key Technologies for Future Intelligent Machine Tool

Several architectures and technologies have been proposed and investigated as mentioned in the previous sections. However, they are not yet mature enough to be widely applied in practice, and the achievements of these technologies are limited to specific cases.

Achievements of key technologies for future intelligent machine tools are summarized in Fig. 48.33. Process and machining quality control will become more important than adaptive control. Dynamic toolpath generation and in-process cutting parameters modification are required to realize flexible machining operation for process and machining quality control. Additionally, intelligent process monitoring is needed to evaluate the cutting process and machining quality for process and machining quality control. A reasonable strategy to control the cutting process and a reasonable index to evaluate machining quality are required. It is therefore necessary to consider utilization and learning of knowledge, knowhow, and skill regarding machining operations.

A process planning strategy with which one can generate flexible and adaptive working plans is required. An operation planning strategy is also required to determine the cutting tool and parameters. Product data analysis and machining feature recognition are important issues in order to generate operation plans autonomously.

49. Digital Manufacturing and RFID-Based Automation

Wing B. Lee, Benny C.F. Cheung, Siu K. Kwok

Advances in the Internet, communication technologies, and computation power have accelerated the cycle of new product development as well as supply chain efficiency in an unprecedented manner. Digital technology provides not only an important means for the optimization of production efficiency through simulations prior to the start of actual operations but also facilitates manufacturing process automation through efficient and effective automatic tracking of production data from the flow of materials, finished goods, and people, to the movement of equipment and assets in the value chain. There are two major applications of digital technology in manufacturing. The first deals with the modeling, simulation, and visualization of manufacturing systems and the second deals with the automatic acquisition, retrieval, and processing of manufacturing data used in the supply chain. This chapter summarizes the state of the art of digital manufacturing which is based on virtual manufacturing (VM) simulation and radio frequency identification (RFID)-based automation. The associated technologies, their key techniques, and current research work are highlighted. In addition, the social and technological obstacles to the development of a VM system and in an RFID-based manufacturing process automation system, and some practical application case studies of digital manufacturing based on VM and RFID-based automation, are also discussed.

49.1 Overview

The industrial world is undergoing profound changes as the information age unfolds [49.1]. The competitive advantage in manufacturing has shifted from the mass-production paradigm to one that is based on fast responsiveness and on flexibility [49.2]. One of the important issues in manufacturing is related to the integration of engineering and production activities. This includes integration of developers, suppliers, and customers through the entire production cycle, involving design, production, testing, servicing, and marketing. The scope of digital manufacturing includes manifesting physical parts directly from three dimensional (3-D) computer-aided design (CAD) files or data, using additive fabrication techniques such as 3-D printing, rapid prototyping from virtual manufacturing (VM) models, and the use of radiofrequency identification (RFID) for supporting manufacturing process optimization and resources planning. Examples can be found in *Red-Eye* [49.3], *Stratasys* [49.4], and *Autodesk* [49.5]. To achieve the integration, digital manufacturing, which covers all the engineering functions, information flow, and the precise characteristics of a manufacturing system are needed. Manufacturing enterprises are now forced to digitize manufacturing information and accelerate their manufacturing innovation in order to improve their competitive edge in the global market.

There are two major applications of digital technology in manufacturing. One is based on virtual manufacturing, which deals with the modeling, simulation, and visualization of manufacturing systems. The second is based on the automation of the manufacturing process and deals with the automatic *acquisition, retrieval, and processing of manufacturing data encountered in the supply chain*. In this chapter, the state of the art of digital manufacturing based on recent advances in VM and RFID-based automation is summarized. The concept and benefits of VM and RFID are presented, while the associated technologies, their key techniques, and current research work are also highlighted. The social and technological obstacles in the development of a VM system and an RFID-based manufacturing process automation system together with some case studies are discussed at the end of the chapter.

49.2 Digital Manufacturing Based on Virtual Manufacturing (VM)

49.2.1 Concept of VM

Digital manufacturing based on VM integrates manufacturing activities dealing with models and simulations, instead of objects and their operations in the real world. This provides a digital tool for the optimization of the efficiency and effectiveness of the manufacturing process through simulations prior to actual operation and production. A VM system can produce digital information to facilitate physical manufacturing processes. The concept, significance, and related key techniques of VM were addressed by *Lawrence Associate Inc.* [49.7] while the contribution and achievements of VM were reviewed by *Shukla* [49.8]. As mentioned by *Kimura* [49.6], a typical VM system consists of a manufacturing resource model, a manufacturing environment model, a product model, and a virtual prototyping model. Some active research work is found in the study of both conceptual and constructive VM systems. *Onosato* and *Iwata* [49.9] developed the concept of a VM system, and *Kimura* [49.6] described the product and process model of a VM system. Based on the concept and the model, *Iwata* et al. [49.10] proposed a general modeling and simulation architecture for a VM system. *Gausemeier* et al. [49.11] has developed a cyberbike VM system for the real-time simulation of an enterprise that produces bicycles. With the use of a VM system, people can observe the information in terms of the structure, states, and behaviors equivalent to a real manufacturing environment, in a virtual environment [49.12, 13]. Various manufacturing processes can be integrated and realized in one system so that manufacturing cost and

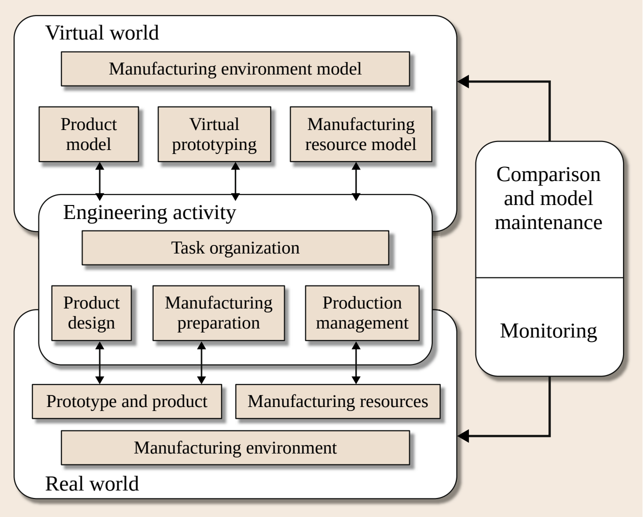

Fig. 49.1 Conceptual view of a virtual manufacturing system (after *Kimura* et al. [49.6])

time to market can be reduced and productivity can be significantly improved.

A conceptual view of a VM system according to *Kimura* [49.6] is shown in Fig. 49.1. The manufacturing activities and processes are modeled before, and sometimes in parallel with, the operations in the real world. Interaction between the virtual and real worlds is accomplished by continuous monitoring of the performance of the VM system. Since a VM model is based on real manufacturing facilities and processes, it provides realistic information about the product and its manufacturing processes, and also allows for their evaluation and validation. Since no physical conversion of materials into products is involved in VM, this helps to enhance production flexibility and reduce the cost of production as the cost for making the physical prototypes can be reduced.

Basically, the classification of a VM system is based on the type of system integration, the product and process design, and the functional applications. According to the definitions proposed by *Onosato* and *Iwata* [49.9], every manufacturing system can be decomposed into four different subsystems: a real and physical system (RPS), a real information system (RIS), a virtual physical system (VPS), and a virtual information system (VIS). A RPS consists of substantial entities such as materials, parts, and machines that exist in the real world, while a RIS involves the activities of information processing and decision making such as design, scheduling, controlling, and prediction, etc. On the other hand, a computer system that simulates the responses of a real physical system is a virtual physical system, which can be represented by a factory model, product model, and a production process model. The production process models are used to determine the interactions between the factory model and each of the product models. A VIS is a computer system which simulates a RIS and generates control commands for the RPS.

VM can be subdivided into product-design-centered VM, production-centered VM, and control-centered VM according to the product design and process design functions. The product-design-centered VM makes use of different virtual designs to produce the production prototype. The relevant information about a new product (product features, tooling, manufacturability, etc.) is provided to the designer and to the manufacturing system designers to support decision making in the product design process. Production-centered VM is based on the RPS or VPS to simulate the activities in process development and alternative process plans while the control-centered VM aims at optimizing the production cycles based on dynamic control of process parameters.

Production-centered VM, on the other hand, is based on the functional use so as to provide interactive simulation of various manufacturing or business processes such as virtual prototyping, virtual operational system, virtual inspection, virtual machining, virtual assembly, etc. Virtual prototyping (VP) mainly deals with the processes, tooling, and equipment such as injection molding processes, while virtual machining mainly deals with cutting processes such as turning, milling, drilling and grinding, etc. Finally, control-centered VM technology is used to study the factors affecting the quality, machining time, and costs based on the modeling and simulation of the material removal process as well as on the relative motion between the tool and the workpiece. Virtual inspection makes use of VM technology to model and simulate the inspection process, and the physical and mechanical properties of the inspection equipment. The aim of this is to study the inspection methodologies, inspection plans, and the factors affecting the accuracy of the inspection process, etc. In assembly work, VM is mainly used to investigate the assembly processes, the mechanical and physical characteristics of the equipment and tooling, and the interrelationship between different parts so as to predict the quality of an assembly or product cycle. It will also examine the costs as well as evaluating the feasibility of the plan of the assembly process. VM can also be used for virtual operational control, the aim of which is to evaluate the design and operational performance of the material flow and information flow system, etc. VM technology is also used for investigating the human behavior of the different workers who handle the various tasks such as assembling parts, queuing, handling documents, etc. The human factors affecting the operation of a manufacturing or business system can be predicted and evaluated.

49.2.2 Key Technologies Involved in VM

The development of VM demands multidisciplinary knowledge and technologies related to computer hardware and software, information technology, microelectronics, manufacturing, and mathematical computation. The key technological areas related to VM are:

1. *Visualization technologies*
   VM makes use of direct graphic interfaces to display highly accurate, easily understandable, and accept-

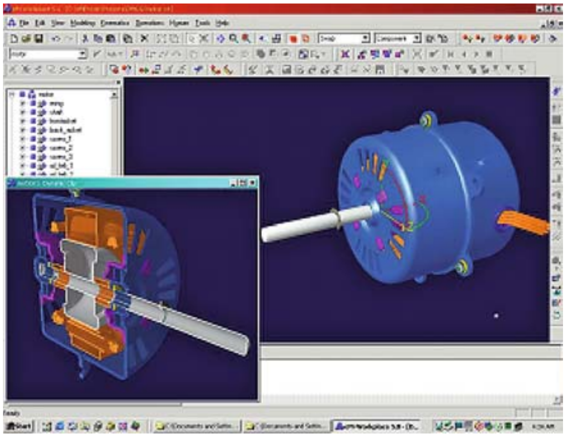

Fig. 49.2 Evaluation of product design

able input and output information for the user. This demands advanced visualization technologies such as image processing, virtual reality (VR), multimedia, design of graphic interfaces, animation, etc.

2. *Techniques for the establishment of a virtual manufacturing environment*
   A computerized environment for VM operations is vital. This includes the hardware and software for the computer, modeling and simulation of the information flow, support of the interface between the real and the virtual environment, etc. This needs the research and development of devices for VM operational environment, interface and control between the VM system and the real manufacturing (RM) system, information and knowledge integration and acquisition, etc.

3. *Information-integrated infrastructure*
   This refers to the hardware and software development for supporting the models and the sharing of resources, i.e., information and communication technologies (ICT) among dispersed enterprises.
4. *Methods of information presentation*
   The information about product design and manufacturing processes and related solid objects are represented using different data formats, languages, and data structure so as to achieve the data sharing in the information system. There is a need for research into advanced technologies for 3-D geometrical representation, knowledge-based system description, rule-based system description, customer-orientated expert systems, feature-based modeling, physical process description, etc.
5. *Model formulation and reengineering techniques*
   In order to define, develop, and establish methods and techniques which are capable of realizing the functions and interrelationships among various models in the VM system, various techniques are employed, including model exchange, model management, model structure, data exchange, etc.
6. *Modeling and simulation techniques*
   These refer to processes and methods used to mimic the real world, on the computer. Further research on the technologies related to dispersed network modeling, continuous system modeling, model databases and their management optimization analysis, validation of simulation results, development of simulation tools, and software packaging technique are much needed.
7. *Verification and evaluation*
   To ensure that the output from the VM system is equivalent to that from the RM system, related technologies such as standards of evaluation, decision tools, and evaluation methods are needed. These methods are useful for verifying and evaluating the performance and reliability of different models in VM systems and their outputs.

Some of these technologies are comparatively mature. However, most of them have to be further developed before they can be used to form an integrated VM platform.

49.2.3 Some Typical Applications of VM

1. VM can be used in the evaluation of the feasibility of a product design, validation of a production and business plan, and optimization of the product

Fig. 49.4a,b Virtual training workshop (VTW) for ultraprecision machining center

design and of the business processes. Fine-tuning of these will result in reduction of the cost of the product throughout its lifecycle.

2. As shown in Figs. 49.2 and 49.3, VM can be used to test and validate the accuracy of the product and business process designs, for example, the design of the appearance of a product, analysis of its dynamic characteristics, checking for the tool path during machining process, numerical control (NC) program validation, checking for possible collision problems in machining [49.14] and assembly [49.15].
3. With the use of VM, it is possible to conduct training (Fig. 49.4) in a distributed virtual environment for the operators, technicians, and management people on the use of manufacturing facilities. The costs of training and production can thus be reduced.
4. As a knowledge-acquisition vehicle, VM can be used to acquire continuously the manufacturing or business knowhow, traditional manufacturing or business processes, production data, etc.

49.2.4 Benefits Derived from VM

1. VM can be used not only to predict the costs of product or process development but can also be used to provide the information about the process capability [49.16]. It allows for the modeling and simulation of the activities involved in process development and also for alternative process plans. It also enables the rapid evaluation of a production plan, the evaluation of the operational status of a manufacturing system as well as of the objectives of the design of the physical system such as the degree of optimization of manufacturing resources and facilities, etc. The information generated from VM system is useful for improving the accuracy of the decisions made by the designer and the management. Possible problems in product or process development can be predicted and resolved prior to the actual operation.
2. VM can support VP, which simulates the materials, processes, tooling, and equipment in the fabrication of prototypes. The factors affecting the process, product quality, and hence the material properties, processing time, and manufacturing costs can be analyzed with the use of modeling and simulation techniques. As more computer-based product models are developed and prototyped upstream in the product development process using VM, the number of downstream physical prototypes traditionally made to validate the product models and new designs can be reduced. Hence, the product development time can be shortened.
3. With the virtual environment provided by VM [49.17], customers can take part in the product development process. Design engineers can respond more quickly to customer queries and hence provide better solutions to the customers. Discussion, manipulation, and modification of the product data model directly among personnel with different technical backgrounds are also facilitated. As a result the competitive edge of an enterprise in the market can be enhanced.

49.3 Digital Manufacturing by RFID-Based Automation

Another major application of digital manufacturing deals with the automatic acquisition and processing of manufacturing data in the supply chain. This is due to the fact that the keen competition in global manufacturing has rekindled interest in lean manufacturing, reducing inventory, and efficiency in production control. There has been growing interest worldwide in the use of RFID to digitalize the manufacturing information so as to automate the manufacturing process. As technical problems are slowly being overcome and the cost of using RFID is decreasing, RFID is becoming popular in manufacturing industries. According to industrial statistics, the worldwide market for RFID technology was US$ 1.49 billion in 2004. In the first 6 months of 2008, 6.8 billion tags were sold for these applications as well as 15.3 billion tags for pallets and cases. There is great market demand, which is ever increasing, for various RFID applications. It is predicted that RFID industry figures will increase from US$ 1.95 billion in 2005 to US$ 26.9 billion in 2015 [49.18].

The rapid increase in use of RFID technology in the retail industry has been driven by major players such as Gillette, Tesco, Wal-Mart, and Metro AG in Germany.

Wal-Mart, the world's largest retailer, has started deploying RFID applications and implementing new procedures in some of its distribution centers and stores. By January 1st, 2005, Wal-Mart required its top 100 suppliers to put RFID tags on shipping crates and pallets, and by January 1st, 2006, this was expanded to its next 200 largest suppliers. The aim of the applications is to reduce out-of-stock occurrences by providing visibility of the location of goods by using RFID tags. Out-of-stock items that are RFID-tagged have been found to be replenished three times faster than before, and the amount of out-of-stock items that have to be manually filled has been cut by 10%.

Gillette and Tesco implemented an item-level RFID project in the UK. Gillette razor blade cartridges were tagged with RFID tags and Tesco, the retailer, used an RFID reader embedded smart shelf system to search for items in the field, in order to take on-shelf inventories. Metro AG has implemented an item-level RFID trial for use in its future stores. RFID tags are attached to each pack of Gillette razor blades, Proctor and Gamble (P&G) shampoos, Kraft cream cheese, and digital versatile disks (DVDs). In addition to enhancing stock replenishment operations, consumers also benefit. Shopping trolleys which automatically update shopping lists and self-check-out systems have also been implemented using this technology. This demonstrates how RFID can revamp the retail industry and provide new customer experiences. With better tag and reader technology, declines in the cost of RFID tagging, and the release of information-sharing platforms, it is likely that RFID will be widely adopted across the entire supply chain.

In recent years, the use of RFID has enabled real-time visibility and increased the processing efficiency of shop-floor manufacturing data. RFID also supports information flow in process-linked applications. Moreover, it can help to minimize the need for reworking, improve efficiency, reduce line stoppages, and replenish just-in-time materials on the production line. RFID can assist in automating assembly-line processes and thus reduce labor and cost, and minimize errors on the plant floor. The integration of RFID with various manufacturing systems is still a challenge to many corporations. As most large retailers will gradually demand the use of RFID in the goods from their suppliers, this creates both pressure and the opportunity for small and medium sized enterprises (SMEs) to adopt this technology in their logistics operations and extend it to the control of their manufacturing processes. Some previous work [49.19] has discussed the point that RFID can be more cost effective in bridging the gap between automation and information flow by providing better traceability and reliability on the shop floor.

Traditional shop-floor control in a production environment, although computerized, still requires manual input of shop-floor data to various systems such as the enterprise resources planning (ERP) for production planning and scheduling. Such data includes product characteristics, labor, machinery, equipment utilization, and inspection records. Companies such as Lockheed Martin, Raytheon, Boeing [49.20], and Bell Helicopter have installed lean data-capture software and technologies and are in the process of converting barcodes to RFID. Honeywell was using barcodes to collect data related to part histories, inventories, and billing, and sharing data with its clients, and is accelerating its plan to switch from barcodes to RFID. The use of RFID has several advantages over barcodes, as tags that contain microchips that can store as well as transmit dynamic data have a fast response, do not require line of sight, and possess high security. RFID offers greater scope for the automation of data capture for manufacturing process control. In recent years, the cost of RFID tags has continuously decreased [49.21, 22] while their data capability has increased, which makes practical applications of RFID technology in manufacturing automation economically feasible.

For manufacturers, it is becoming increasing important to design and integrate RFID information into various enterprise application software packages and to solve connectivity issues relating to plant floor and warehousing. Real-time manufacturing process automation is dependent on the principle of closed-loop automation that senses, decides, and responds from automation to plant and enterprise operations; for example, a pharmaceuticals manufacturer [49.23] makes use of RFID to trace the route or history taken by an individual product at multiple locations along the production line. This allows the pharmaceuticals manufacturer easily to trace all final products that might have been affected by any production miscarriage. An aerospace company named Nordam Group uses RFID to track its high-cost molds. Through the use of RFID tags, they save the cost of real-time tool tracking. With growing emphasis on real-time responsiveness, manufacturers are seeking to control more effectively the production processes in real time in order to eliminate waste and boost throughput. The desire to extend supply-chain execution dispatching within a plant makes closed-loop automation an imperative. The inability to achieve true closed-loop manufacturing process automation presents one of the greatest barriers to successful real-time operation strategies. Critical elements that support manufacturing process automation include:

- Dynamic information technology (IT) systems to support high-mix, variable environments
- Dynamic modeling, monitoring, and management of manufacturing resources
- Real-time synchronization between activities in the offices, manufacturing plant, and supply chain
- Visibility of the real-time status of production resources

Although some previous studies [49.24–26] have shown that RFID technology has the potential to address these problems and has great potential for supporting manufacturing automation, critical deficiencies in the current systems in keeping track of processes under changing conditions include:

- Lack of integration of manufacturing with the supply chain
- Lack of real-time shop-floor data for predictive analysis and for decision support
- Lack of a common data model for all operational applications
- Inability to sense and analyze inputs ranging from the factory floor to the supply chain
- Ineffective integration links between manufacturing process automation and enterprise IT applications
- Inability to provide intelligent recommendations and directives to targeted decision points for quick action.

In light of these, this chapter presents a review of the RFID-based manufacturing process automation system (MPAS), which embraces heterogeneous technologies that can be applied in the manufacturing process environment with the objective of enhancing digital manufacturing at the level of automation across the enterprise and throughout the value chain. The proposed RFID-based manufacturing process automation system aims to address these deficiencies.

49.3.1 Key RFID Technologies

RFID is an advanced automatic identification technology, which uses radiofrequency signals to capture data remotely from tags within reading range [49.27, 28]. The basic principle of RFID, i. e., the reflection of power as the method of communication, was first described in 1948. One of the first applications of RFID technology was *identify friend or foe* (IFF) detection deployed by the British Royal Air Force during World War II. The IFF system allowed radar operators and pilots to distinguish automatically between friendly and enemy aircraft using radiofrequency (RF) signals. The main objective was to prevent *friendly fire* and to aid the effective interception of enemy aircraft. The radiofrequency used is the critical factor for the type of application for which an RFID system is best suited. Basically, the radiofrequencies can be classified as shown in Table 49.1.

A typical RFID system contains several components, including an RFID tag, which is the identification device attached to the item to be tracked, and an RFID reader and antenna, which are devices that can recognize the presence of RFID tags and read the information stored on them. After receiving the information, in order to process the transmission of information between the reader and other applications, RFID middleware is needed, which is software that facilitates the communication between the system and the RFID devices. Figure 49.5 shows a typical RFID system to illustrate how the pieces fit together.

As shown in Fig. 49.5, radio frequency (RF) tags are devices that contain identification and other information

Table 49.1 Comparison of RFID frequency bands and their respective applications

Frequency	Approximate read range	Data speed	Cost of tags	Applications
Low frequency (LF) (125 kHz)	< 5 cm (passive)	Low	High	Animal identification Access control
High frequency (HF) (13.56 MHz)	10 cm – 1 m (passive)	Low to moderate	Medium to low	Smart cards Payment
Ultrahigh frequency (UHF) (433, 868–928 MHz)	3–7 m (passive)	Moderate to high	Low	Logistics and supply chain Pallet and case tracking Baggage tracking
Microwave (2.45 and 5.8 GHz)	10–15 m (passive) 20–40 m (active)	High	High	Electronic toll collection (ETC) Container tracking

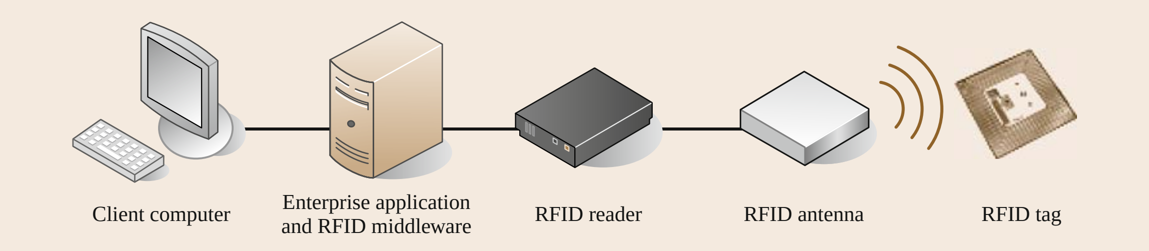

Fig. 49.5 Infrastructure for an RFID system

that can be communicated to a reader from a distance. The tag comprises a simple silicon microchip attached to a small flat aerial which is mounted on a substrate. RFID tags (Fig. 49.6) can be divided into three main types with respect to the source of energy used to power them:

1. *Active tags*: use a battery to power the tag transmitter and receiver to broadcast their own signals to readers within the life of batteries. This allows them to communicate over distances of several meters.
2. *Semipassive tags*: have built-in batteries to power the chip's circuitry, resist interference, and circumvent a lack of power from the reader signal due to long distance. They are different from active tags in that they only transmit data at the time a response is received.
3. *Passive tags*: derive their power from the field generated by the reader without having an active transmitter to transfer the information stored.

The reader is called an interrogator, and it sends and receives RF data to and from the tag via antennas.

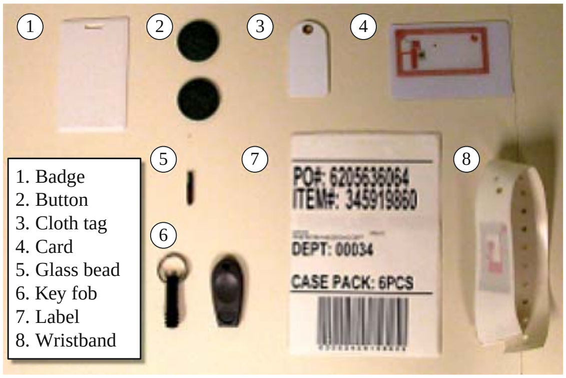

Fig. 49.6 Samples of different types of tags

Fig. 49.7 Example RFID reader

As shown in Fig. 49.7, the reader contains a transmitter, a receiver, and a microprocessor. The reader unit also contains an antenna as part of the entire system. The antennas broadcast the RF signals generated by the reader and receive responses from tags within range. The data acquired by the readers is then passed to a host computer, which may run specialist RFID software or middleware to filter the data and route the data to the correct application to be processed into useful information. Middleware refers to software that lies between two interfaces; RFID middleware is software that lies between the readers and the data collection systems. It is used to collect and filter data from readers. It can transfer those useful data, which are filtered, to the data collection system.

49.3.2 Applications of RFID-Based Automation in Digital Manufacturing

Manufacturing process automation relies heavily on efficient and effective automatic tracking of assets during manufacturing. The tracked assets include physical assets such as equipment, raw materials, work-in-progress (WIP), finished goods, etc. Efficient automatic tracking of assets is beneficial for manufacturers. One of the major challenges for manufacturers today is management of their movable assets. Managing assets includes activities such as locating assets, tracking status, and keeping a history of flow information. If the location of an asset is not effectively located, workers are required to spend much time searching for it, which results in increased process costs. As a result, manufacturers are turning to RFID to investigate whether they can use it to bring the benefits of managing assets individually, real-time location tracking of assets, and better information accuracy and automation into their business operations.

Examples can be found in the garment industry [49.23]. The manufacturer ties the RFID tags to the bundles and sends them to the sewing workstation. At each process station, the data stored in the RFID tag is captured. The real-time status of the WIP can be automatically captured during the manufacturing process. It is also interesting to note that Boeing and Airbus are moving forward and have created an RFID strategy for airplane manufacturing [49.20, 28], as a component to meet US Department of Defense mandates. The RFID tags are attached to removable parts of the airplane to aid the control of maintenance programs. In the present study, four major areas of RFID in manufacturing process automation are introduced.

49.4 Case Studies of Digital Manufacturing and RFID-Based Automation

49.4.1 Design of Assembly Line and Processes for Motor Assembly

Kaz (Far East) Limited, formerly Honeywell Consumer Product (HK) Ltd., is a multinational manufacturing company with about 45 employees in Hong Kong and around 2650 in China. Its corporate headquarters, design, sales offices, and production plants are widely dispersed in Europe, North America, and Asia, as are its key suppliers and customers. As shown in Fig. 49.8,

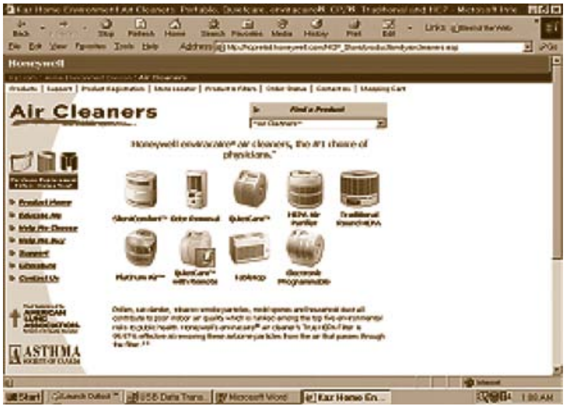

Fig. 49.8 Home comfort products from Kaz

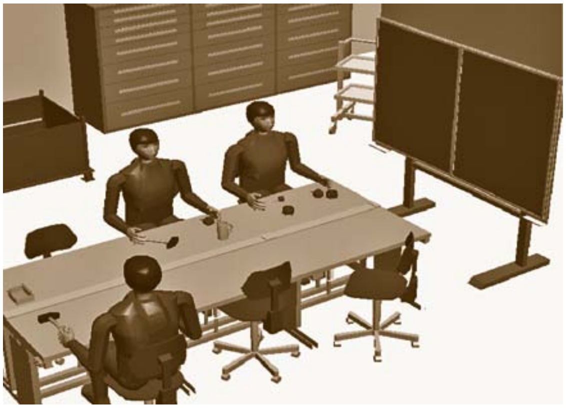

Fig. 49.9 Virtual assembly station for assembling a motor

the company has been involved in the seasonal products business which includes home comfort products such as portable air cleaners, humidifiers, heaters, fans, etc. It delivers a portfolio of innovative products and trusted brands to serve customers worldwide, though most of their products are sold to customers in North America and Europe.

The company possesses a number of assembly lines and clusters for assembling the motors for the home comfort products. For new assembly line planning, there are many factors which affect the efficiency and throughput rate. These include the design of the workplace, the investigation of the assembly process, the allocation of the resources (e.g., number of workers), and the scheduling of the assembly lines. Conventionally, the production team was essentially empowered to use their own judgment in deciding *what, when, and how* to setup the assembly lines, based on their own experience. The optimal efficiency, throughput rate, and quality for new assembly lines can only be obtained through iterative trial operations and process refinement. This is not only time consuming but also costly. With the use of the VM approach, Kaz can investigate the assembly processes and optimum utilization of resources through modeling and simulation. The feasibility of the assembly process plan (Fig. 49.9) can be evaluated prior to the actual production. As a result, the time and cost of setting up new assembly operations can be significantly reduced.

49.4.2 A VM System for the Design and the Manufacture of Precision Optical Products

The conventional approach to the design and the manufacture of precision optical products is based on a trial-and-error method. As shown in Fig. 49.10a, the optical product is designed using computer-aided optics design software (Fig. 49.11b). Then a lens prototype is made by either direct machining or injection-molding from a test mold insert machined by ultraprecision machining (Fig. 49.12). Quality tests will then be conducted on the prototype lenses or mold inserts (Fig. 49.13). It should be noted that the design, prototyping, and evaluation processes are iterative until a satisfactory mock-up is found. This is expensive and time consuming; it also creates a bottleneck for the overall process flow.

Using the VM approach, as shown in Fig. 49.10b, the iterative design, prototyping, and testing processes are accomplished by a virtual machining and inspection system (VMIS) [49.29–33]. As shown in Fig. 49.14, the VMIS has been developed with the aim of creating a virtual manufacturing environment. This is done by electronically representing the activities of optic design,

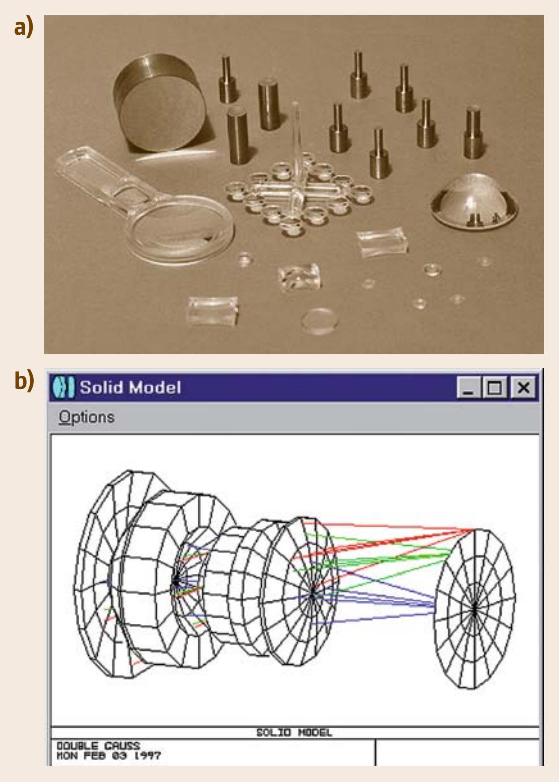

Fig. 49.11 **(a)** Precision optical products and **(b)** their computer-aided optics design

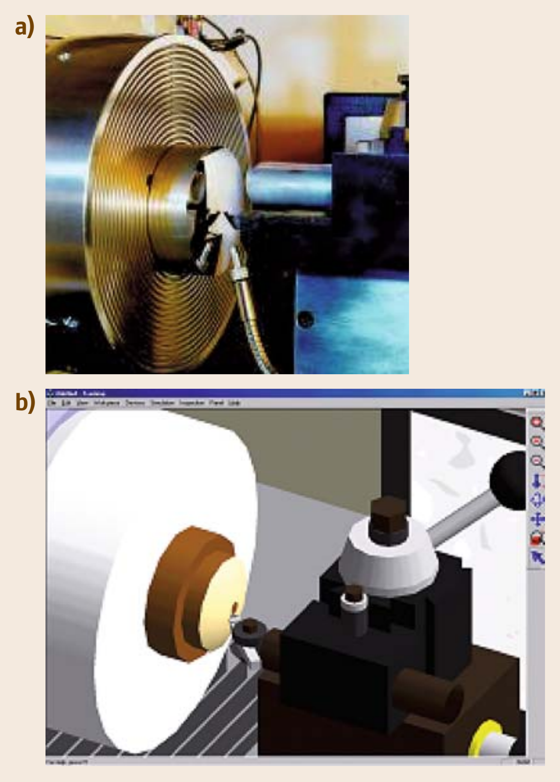

Fig. 49.12a,b Comparison between **(a)** actual and **(b)** virtual machining process

prototyping ultraprecision machining and inspection of the design, and manufacture of precision optical products. Interaction between the virtual and real worlds is accomplished by continuous training and by monitoring the performance of the VMIS system by comparing the simulation results and the real cutting test results (Fig. 49.15).

The feasibility of a product design and the optimal resources needed to turn a design into a real product can be determined prior to any manufacturing resources being committed and before any costly scrap is generated. The VMIS allows the precision optics manufacturers to evaluate the feasibility of an optical product design and a manufacturing process plan prior to actual production. This avoids the need for conducting expensive production trials and physical prototyping.

49.4.3 Physical Asset Management (PAM)

A physical asset management (PAM) program involves the tracking of physical assets such as expensive machinery and equipment, as well as returnable items such as containers and pallets. Across industries and regions, PAM is a major concern in the manufacturing industry. PAM includes engineering activities, as well as the adoption of a variety of approaches to maintenance such as reliability-centered maintenance, multiskills, total productive maintenance, and hazard and operability studies [49.34]. Manufacturing enterprises that have better PAM systems usually excel when compared with their counterparts in terms of utilization of assets in manufacturing. However, many organizations today still face significant challenges in relation to tracking the location, quantity, condition, and maintenance and depreciation status of their fixed assets.

Traditionally, a popular approach is to track fixed assets by utilizing serially numbered asset tags, such as barcodes, for easy and accurate reading. This process is often performed by scanning a barcode on a physical asset identification (ID) tag that has been affixed to the asset. However, PAM may also involve a physical asset ID tag with a human-readable number only, which

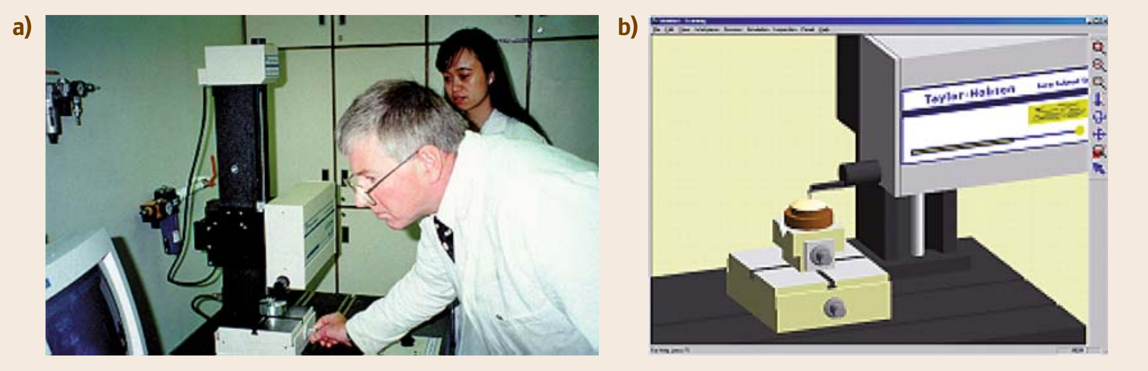

Fig. 49.13a,b Comparison between (a) actual and (b) virtual inspection of precision optics

is documented manually. The barcode approach has its limitations though, e.g., lack of automation and inability to provide real-time tracking.

To increase the utilization rate of movable equipment, manufacturing enterprises usually adopt a fluid approach to the composition of production lines. Movable equipment is shared across lines for some nonbottleneck procedures. Previously, applications for transfer of physical assets required tedious manual operations. Since most manufacturing processes were related to the requested equipment, late arrival of equipment lowered the overall efficiency of the company, which in turn impacted on the company's profit margin. Also, as the transfer records were entered into a database after a long verification process, the timeliness of the information was questionable. Worse, due to inevitable human errors, the database records were incomplete and inaccurate. Common discrepancies included asset locations, utilization, and history of maintenance and repair. As a result, equipment could not be repaired in a timely fashion and some was even lost.

To improve the overall efficiency and increase the visibility of physical assets, an RFID-enabled solution is used to track the movement of physical assets easily when they pass through antenna detection points without interfering with normal operations. It was therefore proposed that RFID antennas should be set up near the door of each production site so that the moving in and out of physical assets would be automatically recorded, as illustrated in Figs. 49.16 and 49.17.

RF signals are affected by metal because of interference and reflection from it, which affects the readability of RFID tags. Since most equipment is made of metal, this is one of the main challenges of implementing an RFID-enabled solution in the plant. To address this problem, a feasibility study was carried out to investigate the necessary settings for satisfactory RFID-enabled tracking performance. Several experiments were performed and the results are shown in Fig. 49.18. Special attention was given to the height and angle of the antennas in order to provide optimal results for autotracking.

To evaluate the feasibility of the proposed RFID-enabled PAM system, a case study was carried out in a selected company named SAE Magnetics (HK) Ltd., which is one of the world's largest independent manufacturers of magnetic recording heads for hard-disk drives used in computers and, increasingly, in consumer electronics such as digital video recorders, MP3 players, and even mobile phones. While the bulk of SAE's operations are based in two modern facilities located in mainland China, the company needs to manage large-scale warehouses for its sophisticated logistics. Differ-

ent kinds of equipment are stored in these warehouses, e.g., semiproducts, subassemblies, and equipment parts (collectively known as physical assets). It is normal for movable physical assets to be transferred from one site to another to maximize their use, e.g., production equipment and assets that are costly and advanced. In the past, SAE's warehouses adopted a pen-and-paper approach to record the transfer of physical assets. In time, this became a complicated process that generated piles of forms and involved many approval processes, which ultimately limited the company's operational efficiency.

This new method has enabled equipment or required parts and subassemblies to arrive promptly and has increased the utilization of important and valuable physical assets for the company. This system automatically tracks the transfer of physical assets and greatly reduces the processing time of equipment transfer. With the data transfer between the system and RFID devices being in real time, information about physical assets can be captured. These data are then presented in the RFID-enabled equipment tracking system in a systematic way, as shown in Fig. 49.18. The system provides the ability to track and trace the status of equipment, issue equipment transfer orders, and provides reports for asset utilization analysis. As a result, location and utilization of equipment can be easily identified using visual diagrams that help in maintenance planning and repair scheduling.

The introduction of an RFID-enabled equipment tracking system at SAE enabled the operational inefficiencies associated with the PAM approach to be targeted and allowed the equipment transfer operation and production planning at SAE to be streamlined. The system has generated great benefits for the company, and has ultimately achieved cost savings while enhancing the effectiveness of asset management.

49.4.4 Warehouse Management

Warehouse management in manufacturing enterprises usually requires much more complex and accurate systems than are required for warehouse management in other industries. Since a single company takes care of a tremendous amount of stock for multiple vendors at one time, the loading for handling the warehouse information is especially heavy. It is also common for a single warehouse to be used to store stock from different vendors so as to enhance utilization rates. Such an approach also increases the complexity of warehouse storage structures. Without an accurate, automated, and comprehensive stock transfer recording procedure, warehouse management becomes a tremendous challenge.

It is interesting to note that many warehouses in manufacturing enterprises still rely on sophisticated manual processes for validating and checking to ensure service quality, and these have been responsible for limiting the efficiency of the operation; for example, updating inventory lists in the warehouse, checking of replenishment requirements, and entering updated data into the Kerry warehouse management system (KWMS) are all manual processes. Not surprisingly, these paper-based processes are excessively time consuming and susceptible to manual errors.

Low warehouse visibility is another main area of concern. Warehouse visibility can be evaluated by measuring the discrepancy between the actual status and the system warehouse inventory status. Since the system is such that warehouse inventory status is only updated after office staff have entered all the latest information into the KWMS, there might be a discrepancy between the actual status and the system warehouse inventory status. As a result, staff might not know the real-time warehouse inventory status from the KWMS. Such information gaps could result in wrong decisions in inbound, relocation, and outbound processes. This is especially important for dialysis solutions since they have a limited period of validity. Extensive warehouse storage time causes product expiry and ultimately financial loss to the company.

To address these problems, RFID is used to increase the visibility of the warehouse and to streamline warehouse operations. Through the implementation of RFID-enabled solutions in warehouse management, instant and accurate inventory records with automatic real-time record update and physical stocktaking can be achieved. However, most of the existing RFID-enabled solutions for warehouse management are lacking in automation. In the present study, an RFID-enabled intelligent forklift is proposed to achieve a higher degree of automation for the warehouse management via RFID. Two RFID antennas were placed at the front of the forklift, as shown in Fig. 49.19, one for location scanning and the other for pallet scanning. A tailor-made application was installed in the mobile computer placed in the forklift, which is used to show the information captured by the antennas and the information stored in the database system. Forklift drivers can view the information on the vehicle-mounted computer screen.

A tag containing product storage information, including particular stock keeping unit (SKU) and lot numbers, is pasted to each pallet. At the same time, RFID tags that store unique location information are placed on the racks. When a driver has loaded a pallet onto the forklift, the pallet information is scanned automatically and that product information and its planned location are shown on the screen attached to the forklift (Fig. 49.20). After the pallet has been placed in the storage position, the forklift scans the location tag on the rack, and completes the stock-in process (Fig. 49.21).

Vehicle-mounted computer
RFID antenna and cabling
RFID antenna for location scanning
RFID antenna for pallet scanning

Fig. 49.19 The RFID-enabled intelligent forklift

With such modifications in warehouse operation, numerous benefits can be achieved. Since most paper processes are eliminated by RFID-enabled automation, both the speed and accuracy of the stock transaction process are greatly enhanced; for example, warehouse staff are no longer required to fill in put-away lists and relocation lists, neither do they need to input data manually.

To realize the capability of the RFID-enabled intelligent forklift, a case study was carried out in a selected company named Kerry Logistics (Hong Kong) Limited. Kerry Logistics (Hong Kong) Limited is part of the diversified international conglomerate, the Kuok Group, and is a subsidiary of the Hong-Kong-listed Kerry Properties Limited. Kerry's Asian logistics business has been built on more than two decades of warehousing and logistics operations in Hong Kong. Its third-party logistics (3PL) business has dramatically accelerated since 1998. Kerry Logistics now encompasses contract logistics,

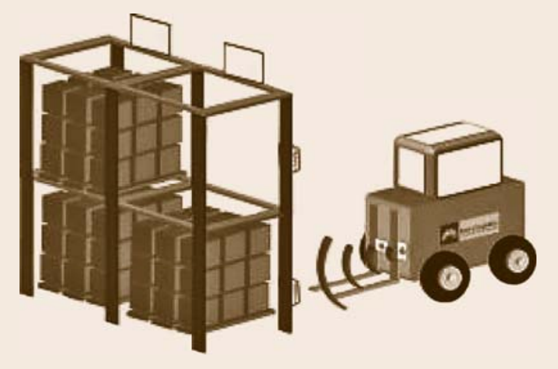

Fig. 49.20 Location RFID scanning

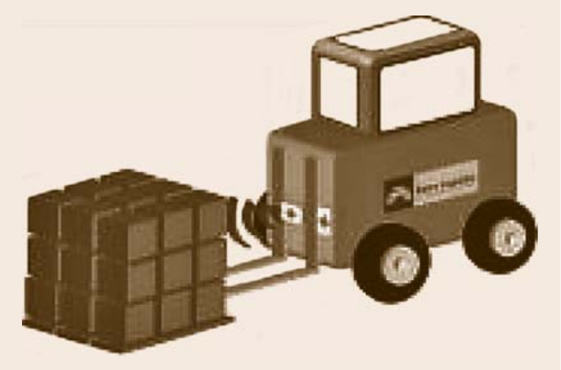

Fig. 49.21 Pallet RFID scanning

distribution centers, international air and sea freight forwarding, transportation, distribution, and value-added services.

Like most third-party logistics (3PL) service providers around the world, Kerry Logistics has recently recognized some inefficiency in the warehouse management of one of its major logistics centers located in Kwai Chung. Because of the complexity of taking care of multiple companies and products at the same time, 3PL service providers require considerable documentation to record the mass of information generated in the course of their work. One warehouse inside the logistics center stores healthcare products, especially dialysis solutions, for renal patients. To reduce human error and streamline the operation flow, an RFID-enabled intelligent forklift was developed.

With such modifications in warehouse operation, numerous benefits can be achieved. Since most paper processes are eliminated by RFID-enabled automation, both the speed and accuracy of the stock transaction process are greatly enhanced. For example, warehouse staffs are no longer required to fill in put-away lists and relocation lists, neither do they need to input location information manually into the KWMS, as this kind of activity is done automatically by the RFID system. Without tedious paper-based location mapping, the overall speed of the inbound process has improved by almost 15%, not to mention the cost saving factors of increased accuracy and reduced manpower. In addition, the RFID-enabled intelligent forklift allows for unstructured storage, which completely eliminates the relocation process. Forklift drivers can freely locate pallets of stock on the racks, and subsequently map their respective location information with only a few clicks. The flexibility of stock positioning is thus improved, resulting in better utilization of warehouse space and further shortened inbound processing time.

49.4.5 Information Interchange in Global Production Networks

The trend towards the establishment of a global production network in the manufacturing industry poses some new challenges to information interchange; for example, some components of a product may be produced in one country, some part of the product may be outsourced and made in a second country, and the final assembly of the finished product may be done a third country, before being ultimately sold somewhere else. However, apart from the obvious need for collaboration, the problems of data integration and information sharing within the supply chain are challenging. Therefore, an RFID-based intra-supply-chain information system (ISCIS) is much needed in order to streamline the supply-chain activities and form an intra-supply-chain network.

Figure 49.22 shows the architecture of a proposed RFID-based ISCIS which is basically divided into platform tiers. The system consists of the application of RFID tags to generate the data within the supply-chain network. Data from the RFID tags is scanned by readers and synchronized with the internal information systems. The RFID-based ISCIS enables the different partners in the supply chain to share real-time information.

1. Data acquisition tier: The data from the operational level on the textile supply chain are captured by RFID technology. RFID readers are installed in the warehouses of the textile and apparel manufacturers and at the retailers. Tags are placed either at the pallet level or the item level, depending on the stage in the supply chain. At the level of the individual item of merchandise it is difficult to achieve 100% reading accuracy with RFID tags. However, it is already technically feasible to track RFID tags at the pallet or carton level. As the raw materials progress through the stages of WIP to the finished goods, the tagging level changes from the pallet level to the carton level and finally to the item level.
2. Information systems tier: This integrates the RFID-based information systems with the internal information systems of the different supply-chain partners, such as enterprise resources planning (ERP) systems. The most successful new business models are probably those that can integrate information technology into all activities of the enterprise-wide value chain.

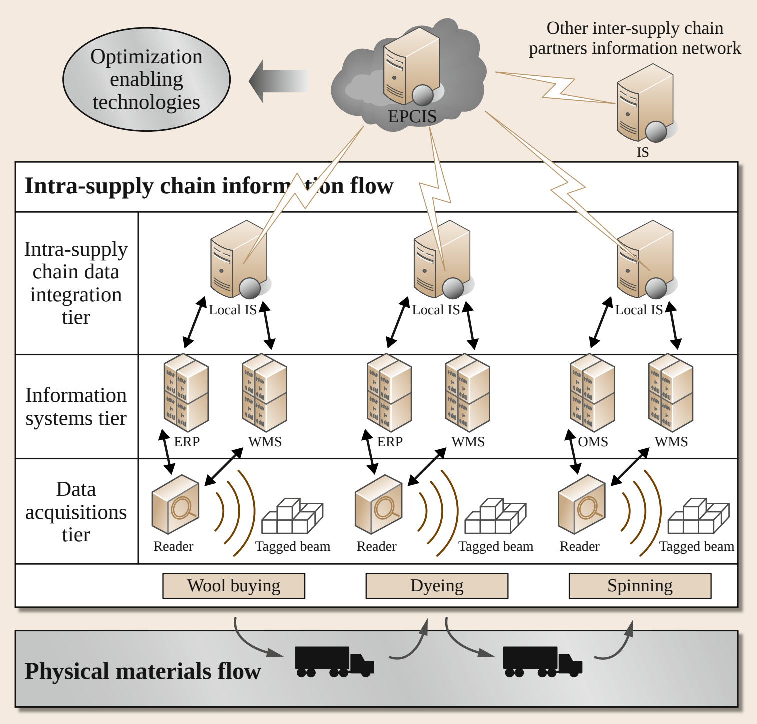

Fig. 49.22 Architecture of RFID-based ISCIS (IS – information system, WMS – warehouse management system)

3. Intra-supply-chain data integration platform: Figure 49.23 shows how the supply-chain information is shared and integrated with the different supply-chain parties. On this platform, an integrated information system is built to enable the supply-chain partners to download the information from the chain. As discussed before, the RFID gateway can act as a check-in and check-out system and synchronize the internal information systems without delay. Supply-chain partners can select the information to be shared, which will be stored in a centralized database.
4. Web-based platform: On this platform, a web-based information-sharing portal is built so that supply-

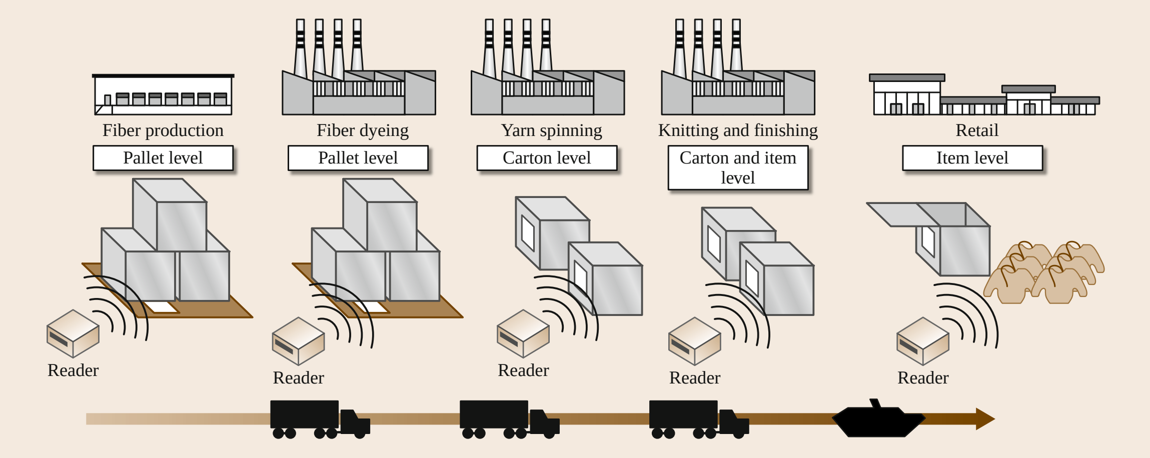

Fig. 49.23 Information sharing along the supply chain

chain partners can retrieve related supply-chain information. Intra-supply-chain partners can use the web browser to search for information about the chain. The production status, the supplier's inventory level, the delivery status, and retail sales data can be displayed on the web-based platform. The above platforms help an intra-supply-chain company to obtain data on their operations and provide an interface permitting them to share information. To facilitate the intra-supply-chain collaboration, different optimization technologies, such as intelligent agent and data mining, can be used to analyze these data.

To realize the capability of the RFID-based ISCIS, a case study was conducted in a reference site in the textile industry named Novetex. Novetex Spinners Limited was established in 1976 and, employing over 2000 people, is now recognized as the world's largest single-site woolen spinner. As part of the Novel Group, Novetex has its headquarters in Hong Kong and a factory located in Zhuhai, Southern China. The factory houses four spinning mills, a dyeing mill, and 51 production lines, resulting in an annual capacity of 7500 t of high-quality yarn. Novetex has recognized the need to be a truly global supplier and has invested in offices and agents worldwide to offer customers the most efficient service possible. The trend towards the establishment of a global production network in the textile industry poses some new challenges to Novetex; for example, fibres might be produced in one country, spun to yield yarns in a second country, woven into fabrics in a third, and sewn into clothing in yet another one, before being ultimately sold somewhere else.

Novetex has traditionally used pen-and-paper-based warehouse management processes. The recording of the inventory, storage, order picking, packaging, and stocktaking processes were heavily dependent on the efficiency of warehouse operators, who used their own judgment and perceptions to decide how, when, and where to store the goods. This heavy reliance on paperwork and on human input to update the inventory data inevitably leads to data inaccuracy. This in turn may affect the company's decisions on inventory replenishment, inventory control, and the first-in first-out (FIFO) order-picking process. Heavy reliance on pen-and-paper-based warehouse management processes has limited the operational efficiency in inventory replenishment, inventory control, and the FIFO order picking process of Novetex. These issues become more complex in the era of the global production network.

As a result, the company has implemented an RFID-enabled ISCIS. The outcomes of the implementation of the system were positive in terms of increased stock visibility and data accuracy. The textile manufacturer can synchronize the inventory status with the ERP software without any delay. The attachment of an RFID tag to each bundle of goods facilitates identification and visualization of items. The storage location of the items can be easily identified and retrieved from the ERP system. Order picking and stock relocation is easier for the warehouse.

49.4.6 WIP Tracking

RFID-based solutions have been used for a decade in manufacturing. Their applications in a manufacturing enterprise are usually tracking of parts during manufacture and tracking of assembled items, i. e., WIP. As a result, efficiency can be increased while entry errors and manpower are saved. For WIP tracking, the tags can be attached to products as they are being assembled or created along the production line [49.35]. The status of the product can be updated as it progresses along the production line via RFID readers placed above and below its path [49.36]. According to *Hedgepeth* [49.37], the history or route taken by an individual product can be ascertained from data stored on tags attached to the item, by installing RFID readers at single or multiple locations along the production line. As a result, the location as well as the flow history of any item can be recorded in the manufacturer's database. To realize the advantages of RFID-enabled WIP tracking, a case study was conducted in a precision mold manufacturing company named Nypro Tool Hong Kong Ltd.

Nypro Tool Hong Kong Ltd. is a precision injection mold manufacturer which provides high-quality molding tools globally. Since the company provides products with a wide variety, WIP items need to be transported to different workshops for various processes such as machining, heat treatment, quality checking, etc. Each of the items is accompanied by its unique drawing so that operators can refer to its required operations. Currently, Nypro is using a barcode system to monitor the flow of WIP items within the plants. For every processing operation of the WIP items, the status of the process must be captured manually so that management can check follow-up information for WIP through the database system. However, the manual process induces a lot of human errors and is time consuming. The application of RFID in WIP tracking is believed to be able to au-

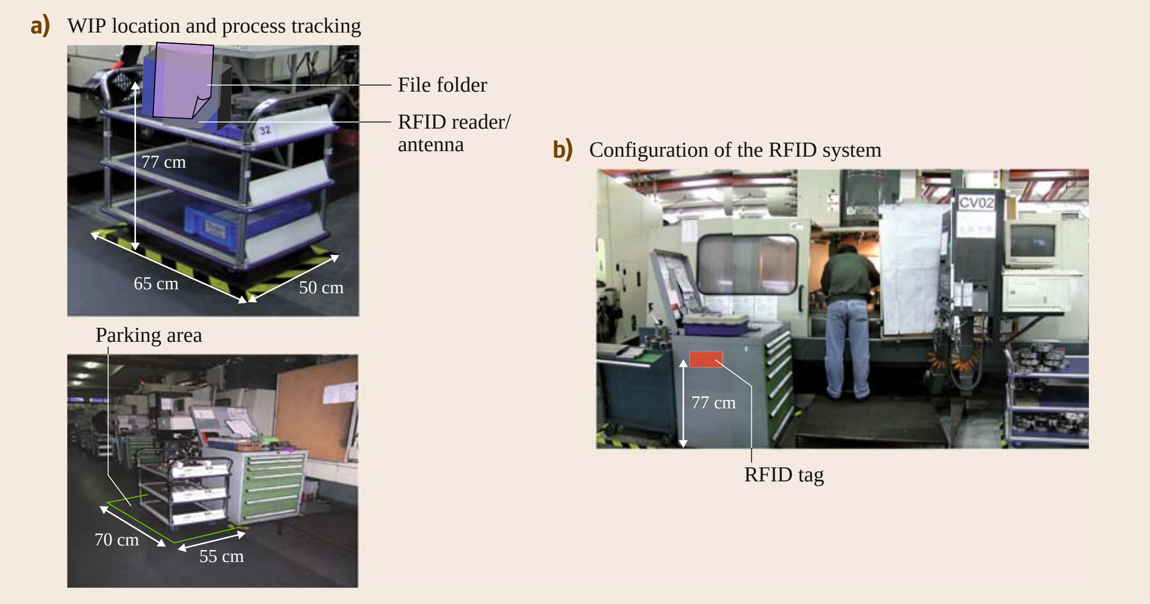

Fig. 49.24a,b RFID-based location tracking and process status tracking for WIP application **(a)** WIP location and process tracking **(b)** Configuration of the RFID system

tomate the tracking process and reduce the number of errors.

As shown in Fig. 49.24a, which shows the location tracking process, RFID gateways are set up at the entrance of the workshops. WIP items and drawings transported to the workshop are required to pass through the gateway and the tag information for the arriving item is automatically tracked when it is pulled through the gateway. Figure 49.24b shows the setup for the RFID-based process. The process is designed in such a way as to capture the machining status of the WIP items accurately and automatically. The result of the trial implementation shows that the management of the company can accurately plan job allocation during the production process through automatic and accurate capture and tracking of the information related to the flow, location, and processing status of the WIP items. In other words, visibility of WIP information can be significantly enhanced and this makes manufacturing process automation possible.

49.5 Conclusions

Digital manufacturing through virtual manufacturing simulation, and real-time tracking of production data in the supply chain, have led to improved accuracy of information, reduction of human errors, and automation of business operations. This chapter presents a study of digital manufacturing which covers computer simulation of manufacturing processes, and systems for manufacturing process automation based on real-time online capture of RFID data from the movement of materials, people, equipment, and assets in the production value chain. Various case studies are described which involve virtual assembly, VP, PAM, warehouse management, WIP management, and the management of a global production network.

Virtual manufacturing has gone beyond the graphical simulation of product and process design, has accelerated the product development cycle, and deepens the level of customer interaction in the preproduction phase of products. Combined with the growing demand for RFID technology for automatic capture, tracking, and processing of the huge amount of data available in the production of goods and services, digital manufacturing is going to revolutionize the way in which the supply chain is managed. It will also greatly change the behavior of global producers and consumers.

50. Flexible and Precision Assembly

Brian Carlisle

Flexible assembly refers to an assembly system that can build multiple similar products with little or no reconfiguration of the assembly system. It can serve as a case study for some of the emerging applications in flexible automation. A truly flexible assembly system should include flexible part feeding, grasping, and fixturing as well as a variety of mating and fastening processes that can be quickly added or deleted without costly engineering. There is a limited science base for how to design flexible assembly systems in a manner that will yield predictable and reliable throughputs. The emergence of geometric modeling systems (computer-aided design, CAD) has enabled work in geometric reasoning in the last few years. Geometric models have been applied in areas such as machine vision for object recognition, design and throughput analysis of flexible part feeders, and dynamic simulation of assembly stations and assembly lines. Still lacking are useful techniques for automatic model generation, planning, error representation, and error recovery. Future software architectures for flexible automation should include geometric modeling and reasoning capabilities to support autonomous, sensor-driven systems.

50.1 Flexible Assembly Automation

Flexible assembly automation is used in many industries such as electronics, medical products, and automotive, ranging in scale from disk drive to automotive body assembly. The ubiquitous yardstick for a flexible assembly system is the human. While dedicated machines can far exceed the speed of a human for certain applications, for example, circuit board assembly, there is no automation system than can assemble a hard disk drive one day and an automobile fuel injector the next.

A flexible assembly system must present, grasp, mate, and attach parts to each other. It may also perform quality tests during these processes. In order to be useful, it must compare favorably in terms of development cost and product assembly cost with manual alternatives. To date, automatic assembly has only been justified for applications where volumes exceed tens of thousands of assemblies per year.

Key capabilities in sensing, modeling, reasoning, manipulation, and planning are still in their infancy for automated systems. The following discussion of flexible automation for assembly will illustrate the current state of the art. Further advances in flexible automation will require machine control software architectures that can integrate complex motion control, real-time sensing, three-dimensional (3-D) modeling, 3-D model generation from sensor data, automatic motion planning from task-level goals, and means to represent and recover from errors.

50.1.1 Feeding Parts

Assembly requires picking up parts, orienting them, and fastening them together. In almost all automatic assembly systems in production today, parts are oriented and located by some means *before* the assembly system picks them up. In fact, it should be recognized that orientation has value; if part orientation is lost, it costs money to restore it. Due to this requirement for pre-oriented parts, most automatic assembly systems only deal with small parts, typically less than 10 cm^3 in volume. Traditional small part feeders include indexing tape feeders (Fig. 50.1), tray feeders, tube feeders, Gel Pack (a sticky film in a round frame for semiconductor parts) feeders, and vibratory bowl feeders (Fig. 50.2). Each of these feeders is typically limited to a fairly narrow class of parts; for example, tape feeders are sized to the width of a part; a 3 mm-wide tape cannot feed a 25 mm-wide part. Tape and tray systems have several disadvantages in addition to their cost: they are not space efficient for shipping as parts are stored at a low density, and the packing material can add several cents to the cost of each part. Larger parts are almost universally transported on pallets, or in boxes or bins, and are at best only partially oriented.

The development of machine vision systems has begun to change this situation (Fig. 50.3). Useful machine vision systems began to emerge in the 1980s. Early systems that could recognize the silhouette of a part in two dimensions cost US$ 50 000–100 000. Today, you can buy two-dimensional (2-D) vision systems for a few thousand dollars, and the price continues to drop rapidly. At the time of writing, 3-D vision systems are beginning to emerge, and in a few cases, are being installed in factories to guide robots in the acquisition of large heavy parts from pallets and even bins [50.1].

Vision systems are allowing the development of part feeders that can separate parts from bulk, inspect the parts for certain critical dimensions, and guide a robot or other automatic assembly machine to acquire the part reliably.

Several such part feeders are shown in Fig. 50.4.

These feeders utilize either conveyors or vibratory plates to separate parts from bulk and advance them under a machine vision system, which then determines if the part is in an orientation that can be picked up by the assembly machine. If not, parts are usually recirculated, since it takes a lot of time to pick them up and hand them off to a part-reorienting mechanism, and then regrasp them. These feeders can handle a wide variety of part sizes and geometries without changing the feeder. In fact, this class of feeder is increasingly being accepted in applications where parts are changed daily or several times a day.

Predicting the throughput of this type of feeder requires predicting the probability that a part will come

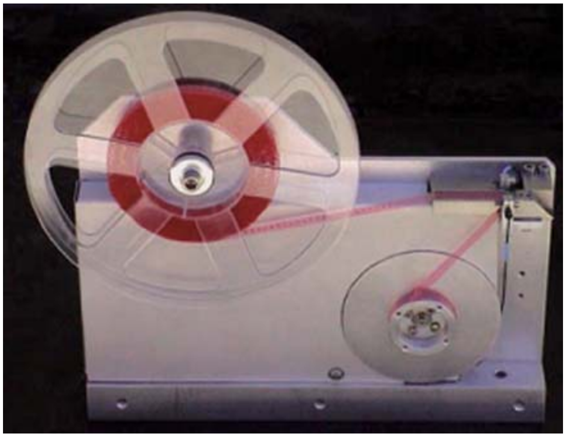

Fig. 50.1 Sticky-tape part feeder (courtesy of Pelican Packaging Inc.)

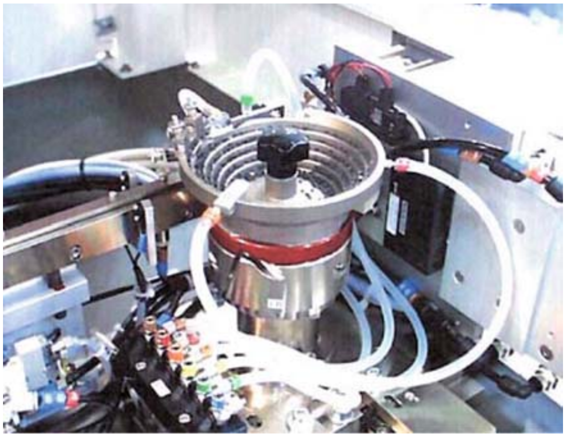

Fig. 50.2 Bowl part feeder (courtesy of Pelican Packaging Inc.)

to rest in a desired stable state (will not topple or roll) when it is separated from the other parts. The author worked with *Ken Goldberg* and others to develop a method for predicting the distribution of stable states from part geometry [50.2]. Part geometries can be complex, and the distribution of stable states may not be obvious. The part illustrated in Fig. 50.5, from a plastic camera, has 12 stable states, of which four are shown. Goldberg et al. developed an algorithm that could predict the distribution of these 12 stable states from a CAD model of the part.

The ability to simulate feeder throughput from an analysis of part geometry is an example of using modeling and geometric reasoning to help design a flexible assembly system.

It is desirable to be able to generate both 2-D and 3-D vision recognition algorithms directly from CAD models of parts. While this sounds simple for the case of 2-D parts, to date the author is not aware of any commercially available vision systems that offer this capability. Real-world challenges from lighting, reflections, shadowing, lens and parallax distortion, camera and lens geometry, etc. combine to make this a challenging task. The task becomes more challenging when 3-D vision is considered. Robust models that take into account these factors need to be developed and extensive algorithm testing done to ensure reliable real-world vision system performance from CAD-generated algorithms.

In summary, recent advances in machine vision are allowing large parts to be picked directly from bins and small parts to be picked from mechanisms that separate them under a camera. These advances allow assembly systems to be changed over quickly to new products without designing and installing new part feeders.

50.1.2 Grasping Parts

In today's commercial assembly systems almost 100% of part grasping is done by either a vacuum cup or a two-finger gripper with custom fingers designed for the particular part to be grasped. Even for systems with the vision-based flexible part feeders described above, if we change parts, we must change the part gripper. Part pick-up strategies are generated by explicit manual training or programming. Obstacle avoidance of other parts generally also requires part-specific programming. This approach works fine for systems that only have to handle one or two types of parts for an extended period of time.

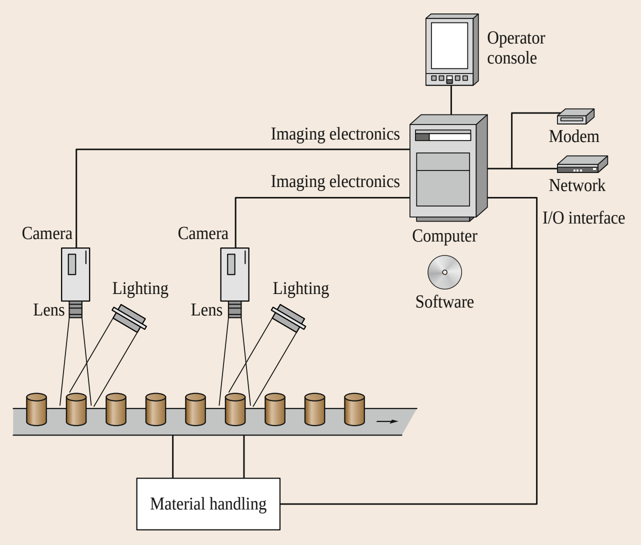

Fig. 50.3 Machine vision system (courtesy of High-Tech Digital, Inc.)

As part dimensions shrink, new considerations enter into gripper design. As part dimensions approach 1 mm, chemical attraction, static electricity or other forces may exceed the force of gravity on the part. So, while it may be possible to pick up a small part with a vacuum needle, it may be necessary to use air pressure or other means to release it. With tiny parts, it can be very difficult to grasp a part with the precision needed to place it at the desired location. Therefore, for most very small parts, machine vision is used to refine the position of the part in the gripper after it has been grasped.

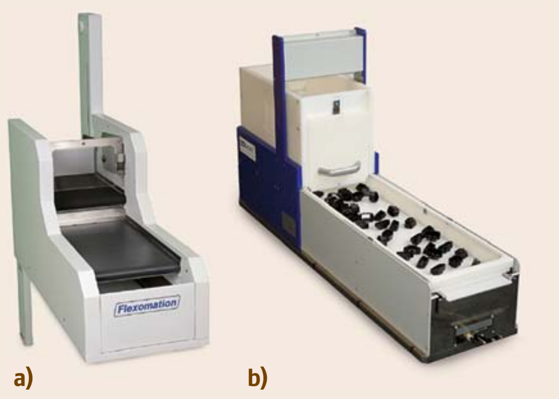

Fig. 50.4a,b Flexible part feeders. **(a)** Adept Technology [50.3], **(b)** Flexfactory [50.4]

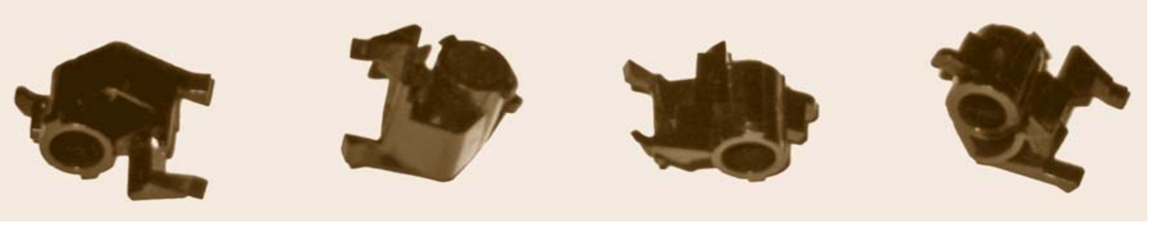

Fig. 50.5 Four of 12 stable states for a complex part

In order to maintain a stable grasp of a part, the part should be uniquely constrained, with gripper mechanical tolerances taken into account; for example, a two-finger gripper with an opposing V groove in each finger would appear to locate a round part. However, if the fingers are not perfectly aligned, the part in fact will roll between parallel plates of the opposite V grooves. For this example, one V groove opposite a flat finger would be a better solution.

In a similar manner, attempting to grasp a prismatic part with two flat fingers is a bad idea. Any slight variation in parallelism of the part or fingers will result in a poor grasp that may not resist acceleration or part mating forces. In this case three pads to define a plane on one finger and a single pad to press the part against this plane on the opposing finger is a better solution and can handle draft angle on parts, finger splay, and other tolerances.

These simple examples illustrate the more general concept of planning and achieving stable grasp in multiple dimensions, and resisting slip and torque in the dimensions important to the process.

In the popular image of a service robot, the robot performs a wide range of menial tasks, perhaps cooking and serving dinner, cleaning up after the kids or dusting the shelves. Within the next few years it is likely that machine vision technology will develop to the point where, given explicit models of objects, a robot could pick up a large variety of objects from an unstructured environment. However, this will be possible only if it can grasp them.

Multifinger prehensile hands were developed in research laboratories in the 1980s. Several companies now offer commercial versions [50.6, 7]. However, to date, we lack the sensing and control technologies to reorient a part within the hand once it is grasped, except for ad hoc preprogrammed strategies developed manually with a good deal of trial and error. Even the automatic generation of stable grasping strategies for these complex hands is still a topic for research and has not found commercial acceptance.

What is often not realized by the casual observer of these humanoid hands is that the control of these hands is far more difficult than the control of a six-axis robot arm. Planning stable grasps with humanoid hands from CAD models of objects has been the topic of numerous research papers for many years now [50.5, 8] (Fig. 50.6). *Kragic* et al. [50.8] present a typical approach to this issue and point out that having a CAD model and grasp plan are not sufficient to achieve a stable grasp. The robot must also determine the actual orientation of the object. Kragic et al. used simple objects with strong markers so that a simple 3-D vision system could determine the object orientation for the

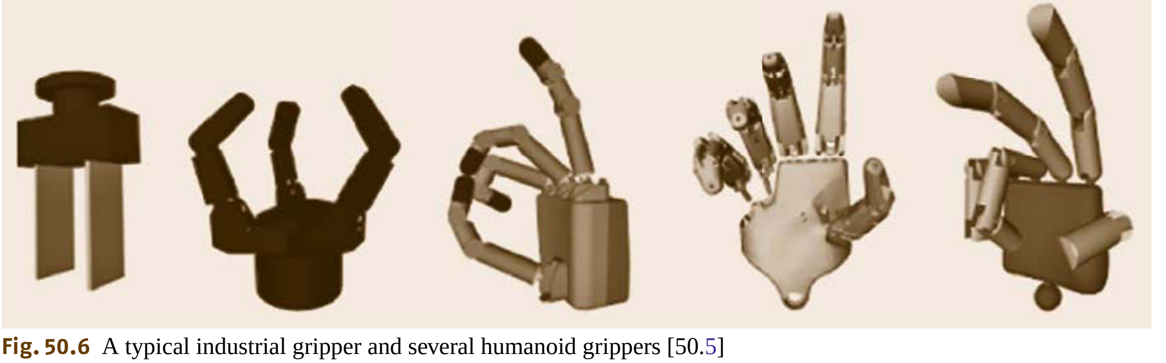

Fig. 50.6 A typical industrial gripper and several humanoid grippers [50.5]

planner to plan a grasp. Further, they point out that not all their grasp plans were stable and discuss the need for further work.

This work further emphasizes the need for a 3-D modeler integrated with the motion control system to support both the grasp planning and 3-D object recognition with machine vision.

50.1.3 Flexible Fixturing

Most assemblies are based around a larger part to which smaller parts are affixed. The larger part typically moves through several assembly stations by means of a material handling system. Each station feeds and attaches one or two smaller parts. Some sort of fixture is usually designed to hold the larger part in a desired orientation.

Current industry practice is for this fixture to be some sort of pallet, or a two- or three-jaw clamping system. In some cases fixtured parts must withstand significant assembly forces from press fits or secondary machining operations.

There is interest in reducing the time and cost to design and fabricate fixtures, and being able to use them again for a different product rather than scrap them when a product changes. This has led to various approaches to flexible part fixturing.

The simplest approach is based on a modular series of adjustable blocks and clamps that can be used to locate and support parts. This approach has been used in machining centers for some time and can provide a high degree of rigidity.

A more general approach was proposed and tested by Sandia Labs in 1996. This was a planar clamping scheme in which a geometric planner analyzed the perimeter of a part, and placed some pins in a location on a grid such that a single clamp could uniquely restrain the part from translation and rotation [50.10].

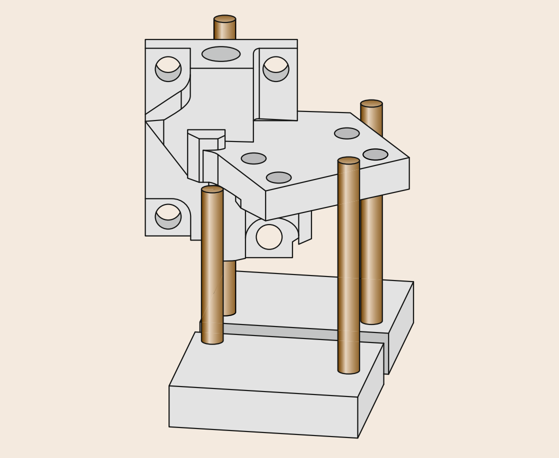

Fig. 50.7 A computer-generated fixture (after [50.9])

More recently, a team at Sandia extended this work to a 3-D planner [50.9] (Fig. 50.7). Inputs to this planner include a 3-D (ACIS) model of the part, a fixture kit specification detailing the fixture building tools and clamps, friction data for the fixture components and the workpiece, and disturbance forces to be applied to the fixtured part. The tool then outputs a series of fixture designs with a quality score for each.

For larger workpieces, one or more multiaxis robots are now being used to hold and reposition workpieces while other robots add parts to the assembly. Parallel link structures are being offered commercially for orienting larger workpieces (Fig. 50.8). In November 2007, at the International Japan Robot Exhibition in Tokyo, Yaskawa showed a two-armed robot performing assembly, with one arm holding a workpiece and a second arm inserting components. All programming for this demonstration was done manually.

Fixture design is essentially the same problem as grasping design except there is a strong commercial need for fixtures to be low cost, as for many systems there may be a large number of fixtures in the system. Generating reliable fixture designs quickly from CAD geometry and knowledge of assembly forces remains an interesting challenge. With the advent of rapid

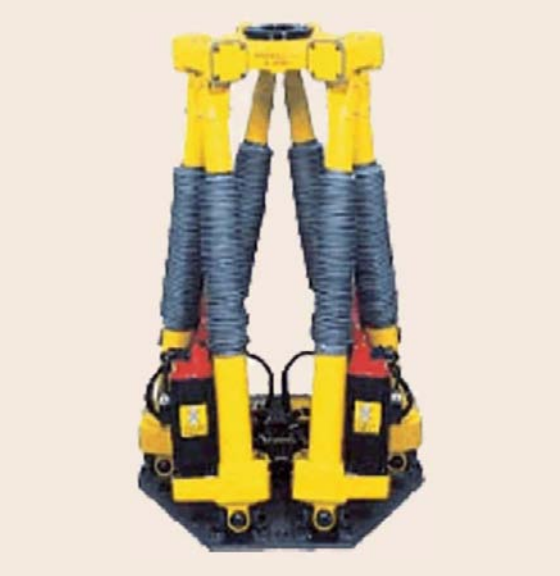

Fig. 50.8 A robot fixture

prototyping machines, it is now possible to quickly fabricate fairly complex fixture geometry. It is important that fixtures provide kinematic grasps that can withstand assembly (or machining) forces.

50.2 Small Parts

50.2.1 Aligning Small Parts

For many industries part dimensions are shrinking to a point where humans can no longer handle or assemble parts. Parts with submillimeter dimensions often have manufacturing tolerances that can be a substantial percentage of the overall part size, and may not be registered to any part dimension that can be grasped; for example, laser diodes emit light with a Gaussian intensity profile whose peak must be measured optically to position the laser diode in an optical assembly. Cancer cells in a fluid must be located optically so they can be sampled by means of a microliter pipette.

While semiautomated systems employing people looking through microscopes are currently used for many such applications, advances in integrating machine vision with motion control now allow parts to be actively steered into position, using vision to take a series of pictures to measure alignment error. The workpiece is moved into position until the alignment error falls below a threshold. Commercial applications use 2-D machine vision for this [50.11] (Fig. 50.9).

In the next several years it is likely that this work will be extended to 3-D vision. There are some significant challenges in using 3-D vision for aligning very small parts. For these applications the parts typically fill a large portion of the field of view of the camera(s). For 3-D applications this means that, as a gripper approaches a part, the part image will change dramatically in size and perspective. For applications where a number of pictures will be taken and processed, the vision system must be able to recognize these changing images without explicit programming for each image. In addition, for the case where small parts are being actively mated to each other, one part may obscure the second part so that only a few features on the second part may be visible. Lighting, reflections, and depth of field all contribute to make this work challenging.

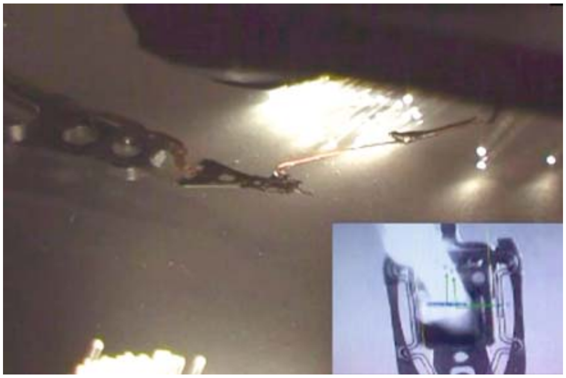

Fig. 50.9 Visual servoing: steering parts into alignment using vision in motion control loop (courtesy of Precise Automation)

Automatically generating 3-D vision recognition and part-mating algorithms is another area where the integration of a 3-D modeling system and a 3-D motion planning system with the actual online motion control system will be necessary.

50.2.2 Fastening Small Parts

There are many well-developed techniques for fastening large parts together. However, when part geometries shrink to submillimeter levels, fastening techniques are largely confined to adhesive bonding, eutectic bonding such as soldering, and welding.

Since all of these material-based fastening techniques involve physical changes in the material, they all tend to introduce dimensional changes during the fastening process; for example, in aligning laser diodes in fiber-optic transceivers, the desired optical alignment is within 10 μm. Epoxy curing and laser welding both introduce dimensional shifts equal to the desired assembly tolerance. It took the photonics industry over 5 years to improve first-pass production yields from 30% to over 90% due to this issue.

There are several approaches to dealing with this problem. One is to model and predict the dimensional change that will occur during the bonding process and offset the assembly positions to account for this. This only works if the amount of bonding material is highly repeatable and the assembly geometry is highly repeatable. Where the assembly geometry must vary due to part tolerances, for example where the peak power of a laser diode moves relative to the package outline, a fixed offset is not possible. In this case a real-time offset would need to be computed based on the alignment geometry and bonding material properties.

A second approach is to bond the parts, then measure the resulting geometry, and deform the resulting bonded structure to achieve the desired alignment. This technique is employed by the photonics industry to align laser diodes, and is referred to as *bend align*. Techniques must be used to stress-relieve the assembly after deforming so that residual stress does not affect alignment over time.

A third approach is to create a separate, rigid, kinematic support structure for the parts, which controls part alignment, and use a parallel bonding process around this support structure to place it in compression. A properly designed support structure can then resist the forces from the bonding material. The author suggested the kinematic structure in Fig. 50.10, in which a fiber is mounted in either a solid ferrule or a V-block ferrule. The ferrule rests on a hollow ceramic tube with a V notch. A solder preform is placed inside this tube. The assembly system aligns the fiber and the preform is heated, bonding the ferrule to the mounting substrate, with the ceramic tube resisting the compression forces when the solder solidifies. A sixth degree of freedom can be added by using a half-sphere instead of a cylinder for the fiber ferrule.

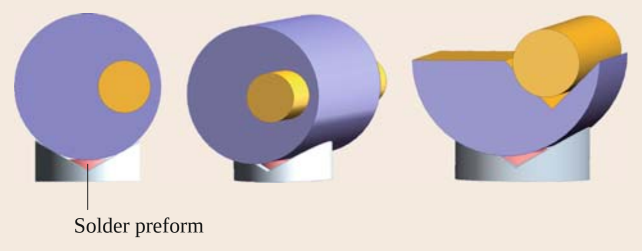

Fig. 50.10 A five-degree-of-freedom kinematic mount for optical fibers (courtesy of B. Carlisle)

A fourth approach proposed in the photonics industry is to bond parts to microservo mechanisms which can be actively controlled after bonding to align parts [50.12]. However, this approach is relatively expensive and may suffer from reliability problems over extended service periods.

In general, the stable alignment of small parts to micron or submicron tolerances remains a challenge, which will benefit from advances in modeling stresses and bonding material deformation in systems that can be linked to real-time motion systems.

50.3 Automation Software Architecture

The foregoing discussion points out the need for some new features in a flexible automation programming language. Some of these features are available in today's robot languages; some of them (3-D modeling) are available in separate packages; and some are not available yet, other than in research environments. Surprisingly, some robot vendors still do not offer general-purpose programming languages, preferring to offer application-specific programming tools. For a current state-of-the-art robotic programming language, see [50.13]. Also see Chap. 22 on *Modeling and Software for Automation*.

A general-purpose automation programming language should include the features described below.

50.3.1 Basic Control and Procedural Features

In addition to common control features such as looping, branching, multithreading, mathematical functions, and data structures, an automation language should be able to coordinate multiple mechanisms on a common time base. It should be possible to do this over a network, with a structure that allows master–slave or peer-to-peer communication and control. It should be possible to use sensor data to alter motion in real time.

50.3.2 Coordinate System Manipulation

Robots and other automation equipment are usually programmed in a Cartesian coordinate system, which may be different from the joint coordinates of the robot. Mathematical models, loosely referred to as *kinematics*, transform joint coordinates into Cartesian coordinates via matrix algebra. Modern robot languages store Cartesian positions in a format known as a homogeneous coordinate transformation. These coordinate transformations can be multiplied together to offset positions relative to a pallet, for example, or a tool. Sensor data must be transformed from the sensor coordinate system, for example, a camera frame, to the robot coordinate system. It is useful to be able to compute elements of these coordinate transformations in real time at the application level; for example, circular, elliptical, spline or other motions can be computed by a procedure in a loop that calculates the destination coordinates in a location variable and then calls a trajectory generator to compute and execute an incremental motion. Tracking a conveyor can be accomplished by using an encoder to update a base reference frame in real time.

There is increasing interest in including a 3-D model and representation of both robot and workcell geometry. Today's robot languages do not offer the ability to define the surfaces of the robot or workcell in 3-D space, other than some simple planes and cylinders. Accurate representation of 3-D surfaces would be very useful for collision avoidance, path planning, and safety systems.

There is also increasing interest in improving the absolute accuracy of robots and other automatic machines. Today's kinematic models of six-axis robots assume that the physical robot is manufactured perfectly, i. e., that right angles are perfect, link lengths are perfect, there are no deflections from gravity or loads, etc. For offline programming of robots working in complex environments, for example, spot-welding of an automobile, it is desirable for the robot motion to be one to two orders of magnitude more accurate than typical manufacturing tolerances permit. Recently, more complete models of robots have been developed in offline simulators. Actual robots can be programmed to go through a calibration routine and a more accurate model of the robot is built in the simulator. Then the simulator commands an offset path which is downloaded so the real robot will make accurate motions. This is currently an offline function. Improved robot controls will include this capability as an online function.

50.3.3 Sensor Interfaces and Sensor Processing

Machine vision, force sensors, and other sensors have been integrated with commercial robot control systems since the early 1980s. However, what is needed today is the ability for sensors to deal with 3-D geometry, and for sensor programs to be generated automatically from 3-D geometry.

In fact, it would be very useful if sensors could be used to create 3-D models when no explicit models exist. A mobile robot entering a new environment should be able to build up a model of the environment from sensor data. Extensive work in the research community has shown success building 3-D models from a series of 2-D images [50.14] as well as fusing sensor data from stereo vision and laser range finders for complex navigation tasks such as the Defense Advanced Research Projects Agency (DARPA) Grand Challenge competitions in 2006 and 2007, in which multiple teams of researchers developed vehicles that could build models and navigate through unknown outdoor environments.

Sensor-generated models must then be available to the motion planning system so the robot can plan moves, update progress through the environment, avoid collisions, and detect and recover from errors.

50.3.4 Communications Support and Messaging

Many commercially available robot controllers currently support only limited-bandwidth messaging and file handling. With the rapid development of distributed motion control where motion can be coordinated at frequencies of 1 kHz or more over a network, the technology now exists for higher-bandwidth, time-synchronized communication; for example, a mobile camera could broadcast an image to a group of mobile devices (imagine soccer-playing robots) that also exchange strategy and planning information. The automation language and operating system should be capable of handling high-bandwidth communications without interfering with other deterministic tasks such as trajectory planning, image processing, and servo loops. The ability to set time slots and task priorities in the operating system becomes very important as communication loads increase. Personal computers remain disappointing in this regard, with large, unpredictable communication delays.

50.3.5 Geometric Modeling

From much of the foregoing discussion it should be clear that the author believes that automation languages should be extended with 3-D modeling systems. One important difference though, is that robotic and other automation systems are dynamic, while many modeling systems are static, or updated at a low rate. In order to be useful, an online modeling system needs to be capable of being updated at rates similar to those in 3-D video games, as robots can make large motions in a few hundred milliseconds. It is likely that some of the simplifications and data-compression methods used in video games may be useful for real-time geometric modeling for motion control.

Eventually, it may be useful to include dynamic models as well as structural deflection models in automation languages. Today's robots are large, rigid, heavy structures with masses that exceed their rated payloads by a factor of ten or more. Lighter, more flexible robots would waste less energy, but will be harder to control and harder to program without some capability to predict their trajectories under load.

50.3.6 Application Error Monitoring and Branching

In most industrial robot applications, over 50% of the programming effort is devoted to anticipating, sensing, and recovering from possible errors. Today, much of this programming is done on site, in an ad hoc manner, and takes a long time to develop and debug. As more sensors are used, this problem becomes larger, as sensors can introduce new errors. It may not be obvious to the programmer why a sensor-driven system is not reliable. To aid debugging, data-logging features, time-stamping of data and communication messages, and single stepping of motion programs are becoming common automation language features. In assembly systems, many errors are due to poorly understood or poorly modeled part tolerances. Often weeks or even months of testing is required for a production system to meet reliability standards. This testing is used to find software bugs, make sensors reliable, and make the system robust within a statistical range of part tolerances.

However, we still do not have general methods to analyze assembly systems for errors, represent errors or generate error monitoring and recovery strategies. Work by Deming and others in statistical process control contributed greatly to understanding manufacturing process tolerances and designing products and processes for reliable production with known tolerances. However, these techniques, while used in the metal-forming and semiconductor industries, seem to be largely absent in automated assembly systems. In 1997 *Carlisle* and *Craig* developed a simulation tool [50.15] for assembly tolerance process analysis that was used by Nokia to analyze and improve cellphone production yields. However, since assembly systems vary so dramatically, there are few, if any, generally accepted practices for modeling assembly processes and part tolerances and predicting and improving yields.

It is not clear if it is productive to try to predict errors. In general, an error is a deviation from a plan. It may be more productive to detect errors quickly and for the system to have enough geometric and sensor data to make a new plan quickly to try to recover from the error. Assembly systems with this capability have yet to be demonstrated.

50.3.7 Safety Features

The cost of assembly robots and sensors is coming down quickly. At the same time the speed of these devices is increasing. Motions of 1 m in a fraction of a second are now common. As a result, robots can present a substantial danger to humans who may enter the robot workspace.

The industry approach to this issue is to create walls around the robot with sensors and interlocks to prevent people from entering the robot workspace when it is moving under computer control. This approach is both expensive and inefficient. A US$ 15 000 robot may be surrounded by US$ 5000 of screens, light curtains or safety mats. Creating cells with walls tends to require more floor space for each cell.

More generally, there are more and more applications where it is desirable to have robots work with, and in some cases touch, people. To address this issue in a general way we need control systems that can model the robot's structure as well as the environment, and sensors that can detect people entering the robot's workspace. We need motion control systems that can respond dynamically to space intrusion and modify the motion appropriately. An operator should be able to walk up to a robot workcell and load a new tray of parts in the workspace without fear of injury in the same manner that he or she would interact with a human assembler.

50.3.8 Simulation and Planning

It is time for robot simulation to move from an offline capability to an online capability, where the control system contains a real-time geometric simulation of the complete assembly system. Simulation systems are now widely used for programming robots for spot-welding, arc-welding, and some material handling tasks. However, they could be more widely used for many applications described here, including programming flexible part feeders, programming 2-D and 3-D vision systems, optimizing sensor-driven motions through workcells, detecting and recovering from errors, and allowing robots to interact safely with people.

Online simulation offers the opportunity to develop high-level representations of common tasks; for example, a task-level command such as "Drive a screw at location hole 1 to torque *X*" is much easier for an application programmer to work with than many lines of detailed programming code. However for task-level instructions to be fairly general, they should be able to access geometric and process information from databases, and a simulation system with motion planning ability and knowledge of the robot and workcell should generate the motion plan for the task. If an error occurs, the planning system should generate a new plan online.

More generally, simulation and task-level planning are necessary tools to address the broader issue of robot interoperability, and program and data sharing. Users would like to be able to move programs from one brand of robot to another. This will remain an elusive goal until robots can be instructed at a very high level of abstraction, in almost the same manner as a human is given high-level, abstract directions along with some data, and figures out how to perform the task. The instruction "Bolt down the manifold cover", given a CAD model, is far easier to translate than today's explicit low-level programs.

50.3.9 Pooling Resources and Knowledge

In the last few years it has become technically possible for people to share knowledge and collaborate remotely over the Internet. This has created the potential for open-architecture systems where many people pool knowledge to create complex systems efficiently. The Linux operating system is one example that has been widely accepted by an enthusiastic user base.

An ideal robot programming system would have a core set of functions that could support a wide range of applications, yet it would be open enough and extensible enough that users could create new capabilities that could be shared or integrated. There is an interesting balance between providing enough structure that programs from different developers can be integrated while allowing enough flexibility that users can add new features easily.

50.4 Conclusions and Future Challenges

In general, we need to raise the abstraction level of robot programming if robots are going to be able to perform increasingly complex tasks in increasingly less structured environments. Programming languages for robots need to incorporate modeling, sensing, and planning capabilities to allow libraries of tasks and actions to be compiled. These high-level tasks need to be robust and safe. We also need to think about how to pool ideas and resources from many different developers and locations, to build up the large knowledge base that will be needed for robots to move from simple, highly structured tasks to complex, unstructured tasks. A more thorough discussion on the future of flexible and precise automation is provided in Chap. Sect. 21.3 of the handbook.

51. Aircraft Manufacturing and Assembly

Branko Sarh, James Buttrick, Clayton Munk, Richard Bossi

Increasingly the manufacturing of complex products and component parts involves significant automation functions. This chapter describes a cross section of automated manufacturing systems used to fabricate, inspect, and assemble aircraft. Aircraft manufacturing cost reductions were made possible by development of advanced technologies and applied automation to produce high-quality products, make air transportation affordable, and improve the standard of living for people around the globe. Fabrication and assembly of a commercial aircraft involve a variety of detail part fabrication and assembly operations. Fuselage assembly involves riveting/fastening operations at five major assembly levels. The wing has three major levels of assembly. The propulsion systems, landing gear, interiors, and several other electrical, hydraulic, and pneumatic systems are installed to complete the aircraft structurally and, after functional tests, it normally gets painted and goes to the flight ramp for final customer acceptance checks and delivery. Aircraft manufacturing techniques are well developed, fabrication and assembly processes follow a defined sequence, and process parameters for manual and mechanized/automated manufacturing are precisely controlled. Process steps are inspected and documented to meet the established Federal Aviation Administration quality requirements, ensuring reliable functions of components, structures, and systems, which result in dependable aircraft performance.

The emergence of the industrial age brought significant changes and impacts on living conditions of human societies. Innovative product development in a free market environment, driven by a desire to improve standards of living, led to revolutionary products in computing, communications, and transportation that impacted all levels of human activities. The key enabler of this progress was improved industrial productivity, which climaxed with automation technologies, starting with hard automation (suitable for mass production of consumer goods) and evolved into intelligent automation (selectively used for batch-type single-component fabrication) using computers and software to precisely control complex processes.

Automation has successfully met the need to improve quality, reduce cost, and improve ergonomics of aircraft fabrication and assembly. The conversion to digitally defined aircraft and advancements in machine tools have enabled widespread use of automation. The trend to machine/fabricate components accurately with automated machines started with a Massachusetts Institute of Technology (MIT) demonstration of the first-ever developed numerically controlled (N/C) machine in 1952. This quickly led to a huge machine tool market that enabled rapid production of precision machined parts and accurate assembly of large aircraft structures.

51.1 Aircraft Manufacturing and Assembly Background

Aircraft manufacturing cost reductions were made possible by development of advanced technologies and applied automation to produce high-quality products, make air transportation affordable, and improve the standard of living for people around the globe [51.1–3].

Fabrication and assembly of a commercial aircraft, such as the one depicted in Fig. 51.1, involves a variety of detail part fabrication and assembly operations. A number of raw materials are machined and fabricated into detail parts, which are then assembled into various levels of structural configurations. Starting with basic assembly of detail parts into simple panels, they are then combined into super panels and higher-level assemblies to produce the fuselage, wings, and finally the complete aircraft. Integral designs and efficient production of new aircraft involve tradeoffs to optimize materials, the number of parts and size of structures, use of innovative processes, and adaptations of appropriate existing equipment and facilities.

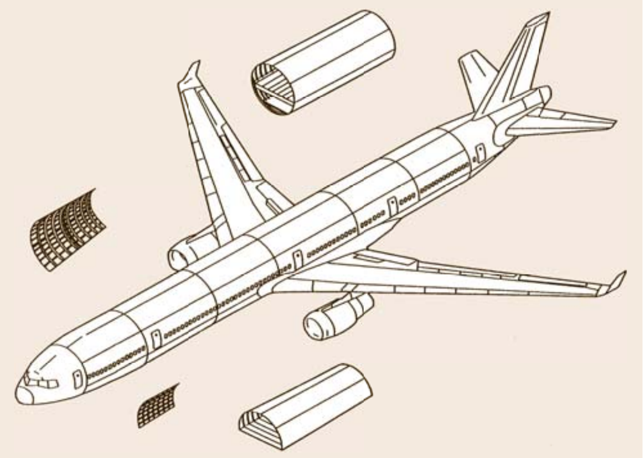

Fig. 51.1 Major aircraft fuselage and wing components layout

Fuselage assembly involves riveting/fastening operations at five major assembly levels. At the first (lowest) level, skins, doublers, longerons, and shear ties are joined to form a single panel. The size and complexity of single panels is primarily driven by aerodynamics, load requirements, and function in operation of the aircraft. At the second assembly level, several single panels are joined using additional detail parts along longitudinal and radial joints into super panels. Frames are usually attached to shear ties during this operation. Assembly of the floor grid structure (also second-level assembly) joins the floor beams and seat tracks. At the third assembly level, half shells are created by joining super panels and the floor grid is often attached to the upper or lower half-shell of the fuselage. Fourth-level assembly involves longitudinal joining of barrel halves to complete the individual barrel structures. Fifth-level (highest) assembly does the 360° radial joins which fasten the nose, forward, center, and aft fuselage barrels together. Inside these structures, multiple radial doublers, couplings, and fittings are installed to complete the aircraft's fuselage structure.

The wing has three major levels of assembly. The first (lowest) assembly level joins the upper and lower skin panels, spars, and bulkheads (consisting of N/C-machined skins, stringers, and stiffeners). At the second assembly level, spars and bulkheads are joined to form the wing grid, to which skin panels are attached to create the wing box. The third (highest) assembly level joins leading and trailing edge components to the wing box to complete the wing structure. The wing is joined to the fuselage in the appropriate sequence to complete the airframe.

The propulsion systems, landing gear, interiors, and several other electrical, hydraulic, and pneumatic systems are installed to complete the aircraft structurally and, after functional tests, it normally gets painted and goes to the flight ramp for final customer acceptance checks and delivery.

Aircraft manufacturing techniques are well developed fabrication and assembly processes that follow a defined sequence, and process parameters for manual and mechanized/automated manufacturing are precisely controlled. Process steps are inspected and documented to meet the established Federal Aviation Administration quality requirements, ensuring reliable functions of components, structures, and systems, which result in dependable aircraft performance.

All activities at aircraft factories are organized around flow of materials, parts, and structures to the final assembly line. In the early stages of aircraft manufacturing, detail parts are fabricated (involving machining, heat treatment, stretch forming, superplastic forming, chemical treatment, composite material layup, curing, trimming, etc.), followed by part inspection (x-ray, ultrasonic, etc.). The next manufacturing steps focus on the assembly of detail parts into subassemblies and larger structures using both manual assembly tasks and automated machinery (C-frame, ring riveters, etc.), and also moving lines for final aircraft assembly.

Due to economic pressures and ergonomic necessities, the majority of manual aircraft manufacturing has been replaced during past decades by mechanized and/or automated processes and systems, yielding significant process and cost saving improvements; for example, the productivity of machining processes has generally improved by a factor of ten, with some highly automated assembly processes enjoying improvements in excess of a factor of 15.

51.2 Automated Part Fabrication Systems: Examples

Automated aircraft part fabrication involves a variety of manufacturing techniques and systems, all tailored to processing specific materials and part configurations, ranging from aluminum and titanium alloys to carbon-fiber epoxy materials, using intelligent automation to produce strong, lightweight parts at affordable/competitive costs.

51.2.1 N/C Machining of Metallic Components

Process Description

Since the advent of metallic airframe construction, airplane manufacture has been machining intensive, largely because the starting material forms (i. e., plate, extrusion, die forging, etc.) were not available in near-net shapes. To minimize airplane fly-weight and ensure good fatigue life, most metallic surfaces are machined to obtain the final component configuration and achieve a specified surface finish. An important expression in the aerospace machining industry is the *buy-to-fly ratio*, which indicates the ratio of excess material removed during a given machining operation versus the remaining material that flies away on the airplane. For an average commercial aircraft N/C-machined part, this ratio is about 8 : 1.

The machining process usually employs a cutter mounted in a rotating spindle, where the spindle or part can be moved relative to one another by a numerical controller (N/C) using servo motors. The spindle revolutions per minute (RPM) may vary from 0 to 40 000, depending on the material, with the largest wing skin mills employing multiple spindles with power ratings up to 200 horsepower (HP). N/C machine tools commonly used within the aerospace industry are some of the largest machine tools in the world, with skin mill bed sizes ranging up to 24 ft wide by 270 ft long [51.4–8].

Wing Skin Mills

The wing skin mill shown in Fig. 51.2 is capable of machining two wing skins simultaneously. The aluminum plate from which the wing skins are produced is held down to the skin mill bed using a vacuum. Typically the aerodynamic outer wing surface, known as the outside mold line (OML), is machined first. Once completed, the wing skin is flipped over, the vacuum is reapplied, and machining on the inside mold line (IML) is completed. The IML contains pads and other features which mate to other wing structure components such as wing ribs and stringers. In addition, the wing skins, which are thickest near the fuselage, taper down to approximately 0.25 in thick at the outboard wing tip. Thickness tolerances for these flight critical components are typically held to ±0.005 in Mammoth gantries (weighing nearly 30 t) carrying two 200 HP machining spindles over a wing skin move with precision, while holding the necessary tolerances. Face mill cutters up to 1 ft in diameter are employed to quickly cover the vast expanse of the wing skins, generating a large volume of

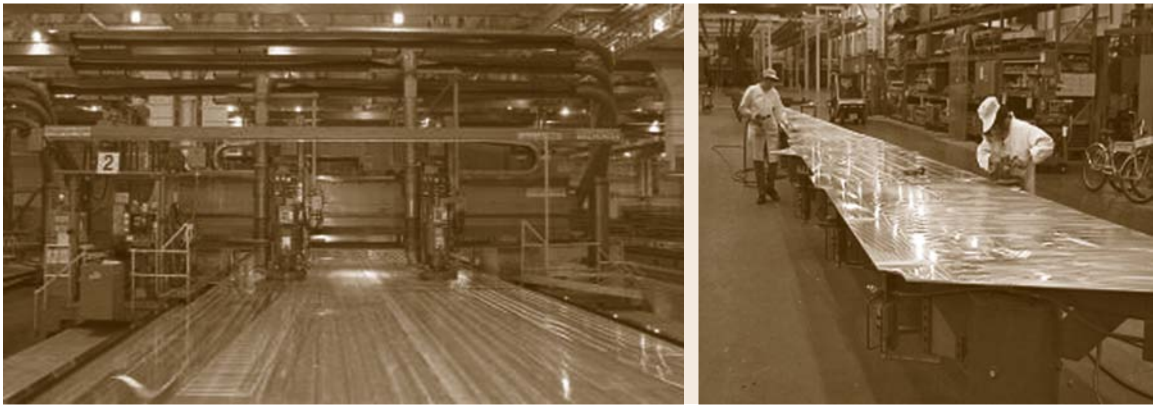

Fig. 51.2 Cincinnati milacron wing skin mill and wing skin after machining

aluminum chips, which are collected by a vacuum chip collection system requiring a 100 HP motor.

Customized Long-Bed Gantry-Style Milling Machines

Dedicated long-bed purpose-designed gantry-style milling machines have been the traditional choice for machining major wing structural components (i.e., stringers, spar chords, and channel vents). These machines employ multiple high-power (112 kW), low-RPM spindles, each capable of high material removal rates (MRR). Each wing component (upper chord, lower chord, stringers, and channel vents) for each airplane model has a dedicated part holding fixture. Large-diameter cutters mounted in steep-taper tool holders experience high cutting forces and bending moments. This technology is still appropriate when high MRR is required for long extruded parts of adequate stiffness. These machines have been regarded as the aerospace machining standard for 50 years.

The right side of Fig. 51.3 shows a typical 110 ft-long completed part after machining and a typical cross section of the extrusion that makes this part. The cross-sectional area reduction is evident in this illustration. Approximately 12 kg of material is machined away for each (1 kg) of flyaway part. When buy-to-fly ratios for various manufacturing methods are compounded by the sheer size of commercial airplanes, it becomes obvious how an airframe manufacturer can produce over 35 million pounds (16 Gg) of aluminum chips annually. This is roughly equivalent to the airframe weight of 100 Boeing 747 aircraft.

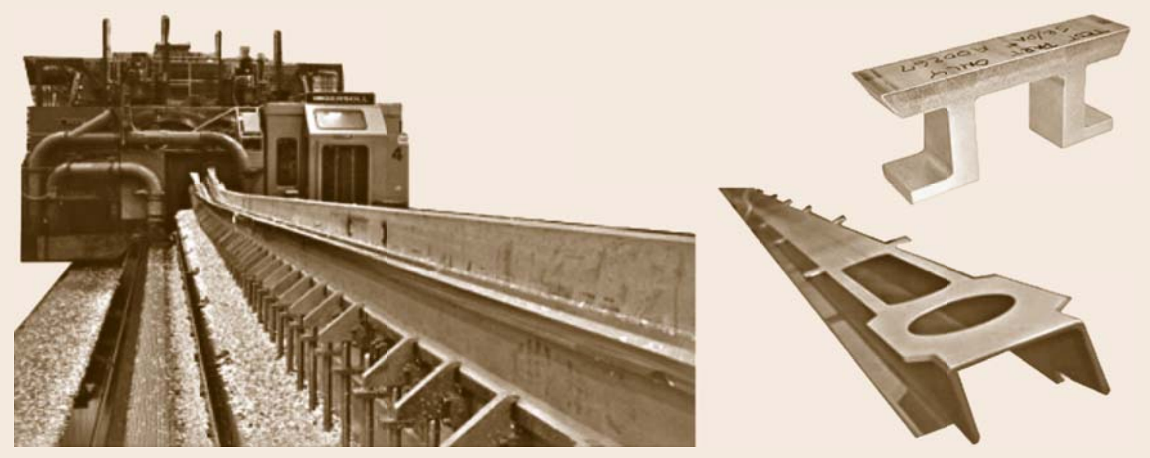

Fig. 51.3 Dedicated spar mill gantry with typical cross section and machined part

High-Performance Machining

As future airframe designs are considered, more emphasis will be placed on component producibility and manufacturing costs. Traditional built-up assemblies are being replaced by monolithic designs. Contrary to popular belief, the value for the airframe producer to utilize high-speed machining techniques does not lie solely in reduced machining cycle times. Economies of scale are gained not by machining cycle time reduction alone, but by conversion of multiple-piece assemblies to monolithic components. This ensures a more accurate final part and the elimination of assembly tooling, labor, equipment, and facilities previously required by built-up designs. High-performance machining provides designers a manufacturing process to produce thin-wall monolithic parts quickly with minimal distortion.

However, monolithic designs are placing new burdens on high-performance machining technology. Such designs often require more material be removed during the machining process than previously required for built-up or assembled sheet metal components. It is difficult to use extrusions or die forgings for monolithic airplane components that are long with significant cross-sectional changes. Components up to 110 ft (35 m) with a tapering cross-section must either be produced from multiple die forgings that are joined or machined from plate stock (if they are designed as a monolithic part). This requires removing large amounts of material, as depicted in Fig. 51.3. Increased buy-to-fly ratios will necessitate that more emphasis be placed on maximizing material removal rates in the future.

51.2.2 Stretch Forming Machine for Aluminum Skins

Machine Description

The machine depicted in Fig. 51.4 is capable of stretch-forming large contoured fuselage skins. The major machine components are:

1. A die table for supporting and moving stretch form dies (dies contain the configuration of the final skin and are placed on the table) vertically during the stretch forming process.
2. Two articulating jaws (one on each side of the table), consisting of multiple jaw segments, enabling articulation of each jaw around longitudinal and transversal axis to accommodate the contoured skin geometry. Jaw segments have built-in hydraulic clamps which firmly clamp the metallic sheets prior to the stretch-forming process. During the forming process each jaw moves longitudinally away from the die table.
3. A computerized numerical control (CNC) machine controller, which executes stretch-forming programs by activating/moving machine components [51.1–3].

Heat-Treat and Stretch-Forming Processes

Common structural materials used for fuselage skins, fuselage frames, and stringers are the high-performance aluminum alloys, namely the 2000 series and 7000 series aluminum alloys (i. e., 2024, 7075). Both of these aluminum alloys are heat-treatable for strength, toughness, and corrosion resistance. To achieve high strength,

Technical data

- Stretch forming of large contoured fuselage skins
- Machine size: $L = 20\,\mathrm{m}$; $W = 4\,\mathrm{m}$; $H = 3\,\mathrm{m}$
- Sheet size max. $t = 6\,\mathrm{mm}$; $W = 2.5\,\mathrm{m}$; $L = 12\,\mathrm{m}$
- Articulating jaws stretch force = 1500 tons
- Articulating jaws min. radius: longitudinal axis = 10 m
- Articulating jaws min. radius: transverse axis = 2 m
- Stretch die table max force = 1000 tons
- CNC controller
- All machine motions can be actuated manually or controlled by program

Fig. 51.4 Stretch-forming machine for skins

the 2024 alloy, commonly used for fuselage skins, is heat-treated in furnaces up to 496 °C. A quenching process from these elevated temperatures dissolves the alloy constituents (i. e., such as copper) in a solid state in the solid aluminum alloy. After quenching, room-temperature aging occurs, causing copper constituents to *precipitate* along the grain boundaries and along slip planes of the alloy. This action distorts the crystal lattice interferes with any smooth slip process, resulting in increased strength of the material. Immediately after quenching, the material is relatively soft and can be formed as in as-quenched (AQ) tempering. However after about 20 min the alloy will start *room*-temperature aging and strengthen to the T4 temper condition. Room-temperature aging is also referred to as *natural* aging. The final T4 strength obtained is about 96 h.

Alloy sheets are moved from the quenching system/equipment to the stretch-forming machine and laid up on the stretch die, then both ends of the sheets are pushed into the jaws and jaw segment clamps are activated, clamping onto sheet ends. Jaw segments are configured around the longitudinal axis to accommodate skin shape, dictated by the stretch die geometry, and longitudinal forces are applied to the sheet by driving jaws away from the table. At a certain point, the table is activated, moving the stretch die vertically while the jaws rotate around the transversal axis, pulling the sheet and forcing it to comply to the stretch die geometry. After sufficient stretch (plastic deformation) is achieved, the jaws and table reverse direction, relieving tension on the sheet once it has attained the desired skin geometry (and allowing for some spring-back). Ideally, aluminum skin stretch form dies are built with spring-back compensation. This is especially important for large contoured skins. Software for stretch die design tools are readily available and have proven very useful.

For many decades, the stretch forming process was (and partially still is) a black art. It requires very experienced personnel to drive machine elements (table, jaws) in linear and rotational axes while observing the skin during stretch-forming operations. Variations in skin and stretching behavior result from changes in material properties during the incubation time and make it difficult to establish precise process parameters. After years of experimentation, and collecting empirical data (required degree of stretch, etc.), the majority of skin form operations can be computer controlled or at least semi-automated, whereby the operator observing the skin behavior can make slight adjustments to the degree of stretch to compensate for material property variations. Programs can be generated offline, or recorded/stored in the teach mode on the machine during the stretch-forming process.

51.2.3 Chemical Milling and Trimming Systems for Aluminum Skins

System Description

Chemical milling is a material removing process using chemical reaction to dissolve material in certain locations to produce contoured skins with variation in cross sections (thickness), accommodating changing design load conditions along the fuselage. This process involves several subsystems:

1. Galvanic treatment tanks for cleaning and surface preparation of stretch-formed skins
2. A five-degree-of-freedom (DOF) robotic system applying a mask to the skin surface
3. A five-DOF gantry robotic system and flexible pogo fixture using a carbon-dioxide laser to scribe the mask, enabling mask removal in certain skin locations
4. Chemical milling and galvanic treatment tanks to perform metal removal (chemical milling)
5. A five-DOF CNC gantry system with a flexible pogo table to trim and drill skins [51.1–3].

Process Description

Stretch-formed skins have to be cleaned and surface prepared for the application of the chemical milling mask. A robotic system under program control automatically applies the mask of defined thickness to both

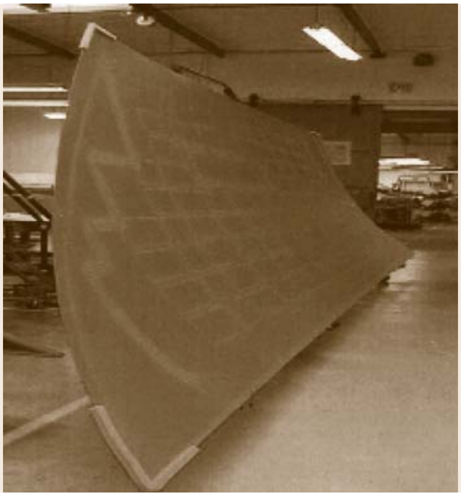

Fig. 51.5 Skin with scribed mask

sides of the skin, moving a spray nozzle along optimized patterns to achieve homogeneous mask coverage thickness and to minimize overspray. After the mask is sufficiently dry, skins are positioned onto the flexible pogo table, stabilized with suction cups to pogos. The skin surface pointing to the outside of the aircraft is positioned onto pogos and does not require any chemical milling. A gantry robot moves the head with a carbon-dioxide laser in five DOFs across the inner surface of the skin, scribing (cutting) mask along certain patterns to facilitate peeling off of the mask. After all patterns are cut (Fig. 51.5) skins are processed using computer-controlled cranes to move skins through the chemical milling tanks. First, the mask is removed in areas which will lead to the thinnest skin cross-sections. Skin is dipped into the chemical milling tank, allowing NaOH chemical (kept at elevated temperatures) to etch exposed aluminum surface long enough to achieve the desired remaining cross section. Etching velocity depends on the NaOH concentration (which is controlled daily). The etching velocity is used as an input parameter to the crane controller, which pulls the skin out of the tank at a predetermined time automatically. If measurement of the desired aluminum skin thickness is verified, the next mask area is peeled off, and the next chemical milling process is repeated, until all required skin areas are processed. The last skin processing step involves trimming of boundaries and drilling of tooling and determinant assembly holes. These tasks are accomplished on the five-axis trimming and drilling machine (Fig. 51.6). Pogos of the flexible machine table are driven in three linear DOFs to positions dictated by the skin configuration, and swiveling suction cups on top of pogos stabilize the skin during the trimming and drilling operations. Mechanical cutters and chip extraction nozzles surrounding the cutter are used. Net trimmed skins with tooling and determinant assembly holes are now ready for assembly.

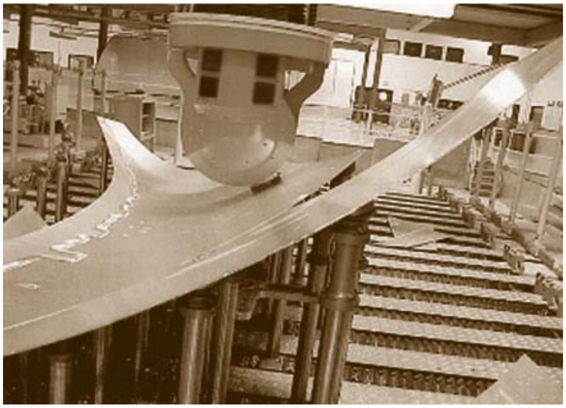

Fig. 51.6 CNC trimming and drilling system

All crane movements in the galvanic process line and the robotic chemical mask application process are controlled by a simple program. For mask scribing, the laser gantry robot, and the trimming/drilling robotic system, computer-aided design (CAD) skin geometry data is imported into the process simulation and a semi-automated program creation system generates processing programs.

51.2.4 Superplastic Forming (SPF) and Superplastic Forming/ Diffusion Bonding (SPF/DB)

Process Description

The SPF process is an elevated-temperature process where fine-grain material, such as alpha-beta titanium (Ti-6Al-4V is most common) and certain aluminum alloys (7475, 2004, and 5083), can be formed into complex shapes using gas pressure. The process temperature depends on the material and alloy being formed: titanium (774–927 °C aluminum (454–510 °C). SPF parts, such as those shown in Fig. 51.7, are produced with typical elongations up to 300% [51.4–8].

The basic principles of the superplastic forming process are illustrated in Fig. 51.8, typically using heat and gas pressure to fully form aluminum or titanium part blanks to match the tool's contour.

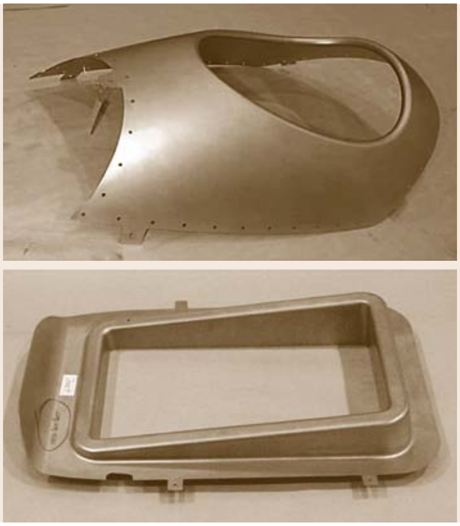

Fig. 51.7 Parts fabricated using super plastic forming (SPF)

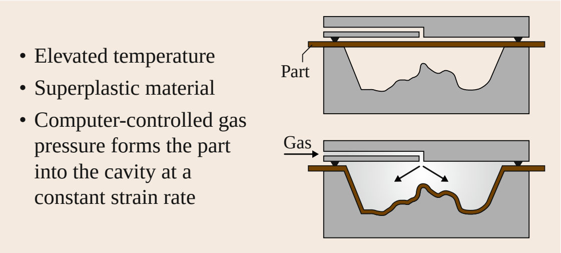

- Elevated temperature
- Superplastic material
- Computer-controlled gas pressure forms the part into the cavity at a constant strain rate

Fig. 51.8 SPF process principles

The SPF/DB process combines an SPF operation with a diffusion bonding (DB) process, whereby two or more sheets of titanium are used to create an integrally stiffened panel structure. For DB to occur, the titanium sheets must contact each other in an inert atmosphere at controlled temperatures and pressures for a specified time. Several methods can be used to achieve these conditions. The one shown in Fig. 51.9 uses a heated press and tool pressure to bring the sheets together. Another method uses gas pressure inside the welded titanium pack to force the sheets into contact with each other. Diffusion bonding is a solid-state process and no melting occurs at the bond line. Once the individual grains on the surface touch each other, they start growing across the interface of the two sheets. This process continues until the sheets are completely diffusion bonded to each other and there is no evidence microscopically of there having been two, or more, pieces of material.

The typical hot (up to 982 °C) shuttle table press, shown in Fig. 51.9, produces SPF and SPF/DB aluminum and titanium parts and has computer-controlled heating, pressure, and gas systems.

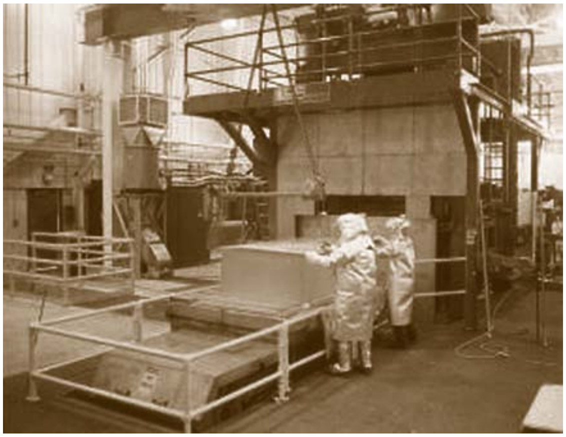

Fig. 51.9 Hot press, tool, and SPF part

SPF Benefits. The benefits of the SPF process are that:

- It replaces multipiece assemblies with one monolithic component, saving cost, weight, and tooling.
- It can produce complex geometry and sharp radii.
- Components contain very little, if any, residual stress (no spring-back).
- Less assembly is required (lower cost, lighter weight, and better dimensional accuracy).
- Titanium parts are corrosion resistant.

SPF/DB Benefit. The benefit of the SPF/DB process is that:

- It reduces assembly, producing an integral structure, with no fasteners needed to attach inner structure to outer skin.

51.2.5 Automated Composite Cutting Systems

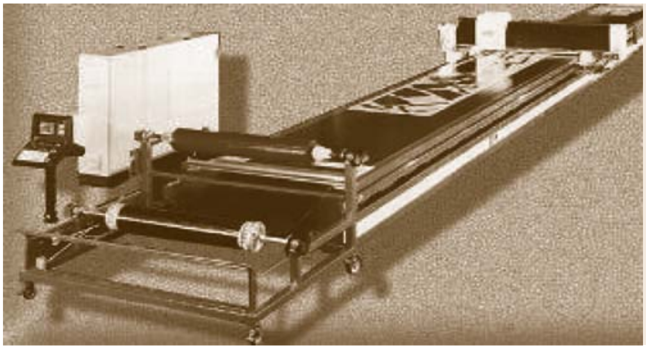
Ultrasonic Cutting Machine

Uncured unidirectional and fabric carbon fiber, glass fiber, Kevlar, prepreg, and honeycomb materials can be cut into various shapes or forms (preforms) prior to hand placement. Automated computer-controlled ultrasonic cutting machines precisely perform this task with minimal waste of these expensive materials due to advanced computer nesting programs. Up to ten plies of prepreg can be cut at the same time by a carbide ultrasonic knife, which translates up and down at 30 000 strokes per second to provide a clean cut.

The prepreg material, which includes a backing film, is pulled off a roll at the end of the cutting machine bed (Fig. 51.10) and is laid down on a rubber table. A disposable bag is then placed over the prepreg material and any wrinkles are smoothed out. Vacuum is turned on in the table, which pulls the bag down on top of the prepreg material and stabilizes it during the cutting operation. The two-axis N/C machine accurately positions the ultrasonic knife along a preprogrammed path to achieve the desired shape. Once the cutting operation is complete, the vacuum is released and the vacuum bag is removed. Then the preforms and scrap material are manually removed from the machine bed [51.9–15].

Abrasive Water Jet

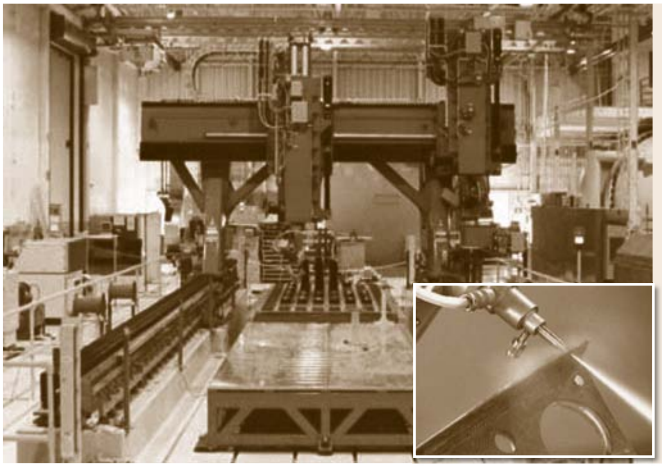
Cured graphite–epoxy composite structure has very strong fibers in a softer matrix, so trimming them with



Technical data

- Typical configuration: flat bed two-axis gantry
- Work zone: up to 10 ft × 100 ft
- Cutting speed: up to 1000 in/min
- Rapid traverse speed: 2000 in/min
- Positioning accuracy: 0.002 in/ft–0.015 in overall
- Knife: 20 000–30 000 strokes/s

Fig. 51.10 Two-dimensional ultrasonic cutting machine



Technical data

- Precision multiaxis overhead gantry, 5 up to 11 axes
- Work zone: up to 20 ft × 50 ft × 5 ft
- Cutting speed: up to 250 in/min
- Rapid traverse speed: 1200 in/min
- Positioning accuracy: 0.002 in/ft–0.015 in overall
- Thin stream: 0.020 to 0.050 in dia.

← Insert shows a 60 000 psi waterjet stream cutting a part

Fig. 51.11 Gantry abrasive water jet with *pogostick* tooling

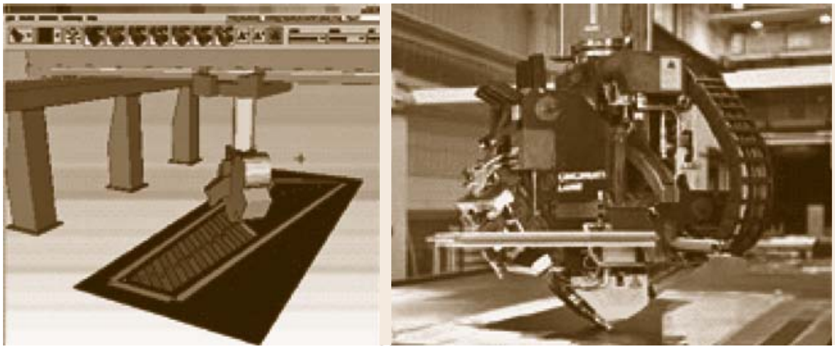
conventional machining techniques does not work very well, since heat and the abrasive nature of composites tend to wear out cutters rapidly and delaminate or pull fibers out of the adhesive matrix. Abrasive water jets are being used extensively to trim, and in some cases drill, holes in these materials due to the clean cut, low fiber pull out, and little or no delamination. The majority of water-jet systems used in aerospace are high-pressure (60 000–87 000 psi) garnet or aluminum-oxide grain abrasive water-jet units (Fig. 51.11).

An N/C machine positions a high-pressure abrasive water jet near the periphery of a composite part that is held in the correct contour by a series of headers or pogos (Fig. 51.11). The computer program drives the N/C machine in a very accurate path at various speeds to cut off the excess material and provide the finished edge of the part.

51.2.6 Automated Tape Layup Machine

Automated tape layup (ATL) is an additive process used to construct large structures from composite prepreg tape material. It is primarily used in the aerospace industry. Machines typically have a five-axis precision overhead gantry and an application head that is suspended from a cross rail. The machine motion and head functions are controlled by a computer with specialized programming. Prepreg tape is typically more than 3 in wide, which is suited to flat or mild contours (Fig. 51.12).

The highly specialized head can precisely lay any number of plies of composite filament tape, in any desired orientation, assuring consistent part shape, thickness, and quality. A typical machine draws from supply reels, then deposits 3, 6 or 12 in tape on flat or mild-contour layup tools. The layup heads can heat the



Technical data

- Precision five-axis overhead gantry with multifunction head
- Work zone: up to 20 ft × 100 ft
- Feed rate: up to 1200 in/min
- Traverse speed: 2200 in/min
- Positioning accuracy: 0.002 in/ft−0.015 in/overall
- Layup rate: up to 50 unknown unit lbs/h

Tailstock

Technical data

- Precision multiaxis platform with horizontal ram with multifunction head
- Work zone: up to 20 ft dia./times 75 ft
- Working feed rate: 1200 in/min
- Traverse speed: = 2200 in/min
- Positioning accuracy: 0.002 in/ft−0.015 in/overall
- Layup rate: up to 30 unknown unit lbs/h

Fig. 51.13 Automated fiber placement machine

tape prior to laying it down, then compact or compress the tape after it is placed on the layup tool. Each layer or ply of tape can be oriented in a direction that optimizes the specific desired part characteristics [51.9–15].

51.2.7 Automated Fiber Placement Machine

Automated fiber placement (AFP) machines, such as that shown in Fig. 51.13, combine two technologies widely used in industry: automated tape layup (ATL) and filament winding (FW). The AFP process is used by the aerospace industry to construct large-circumference and complex structures such as fuselage barrels, ducts, and pressure vessels from composite prepreg materials. The Boeing 787 fuselage barrel in Fig. 51.14 is a primary example [51.9–15].

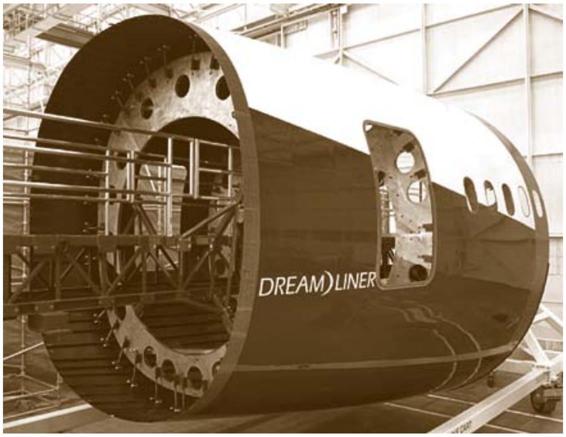

Fig. 51.14 Boeing 787 fuselage barrel

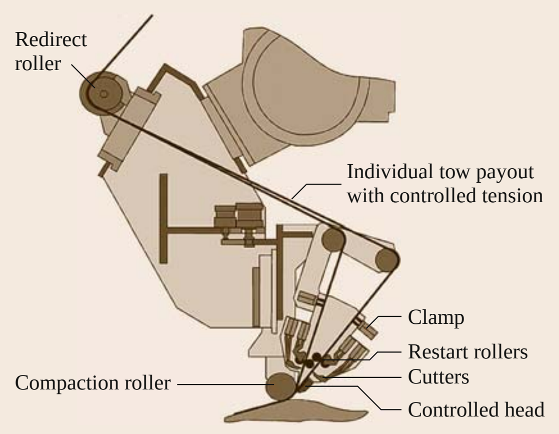

Fig. 51.15 Automated tape layup process head

This additive process utilizes relatively narrow strips of unidirectional composite prepreg tape, commonly called tow, which have unidirectional fibers preimpregnated with a thermoset resin that is later cured. Central to the process is the fiber placement machine, basically a seven-axis manipulator with a head (Fig. 51.15) that arrays a group of tows side-by-side into a continuous band and compacts them against the surface of a concave, convex, contoured combined layup mandrel. The mandrel is mounted on a trunion system similar to a lathe, so that it can rotate as the manipulator is placing the tow. AFP combines the advantages of both filament winding and automated tape layup. The raw materials used are tow-preg or slit-tape rolls of aramid, fibreglass or carbon fiber, preimpregnated, typically with epoxy resin. The width of tow or slit-tape ranges from 3.2 mm to 6.4 mm with thicknesses ranging from 0.13 mm to 0.35 mm. Typical systems permit the use of 12, 24, or 32 tows simultaneously and can lay up on the top of a honeycomb core without degrading it.

51.3 Automated Part Inspection Systems: Examples

The nondestructive inspection (NDI) of aircraft systems is performed at the very highest level of sensitivity because of the criticality of the components. X-ray radiography is the primary method for the inspection of metallic components, particularly welds in tubes and ducts of titanium and inconel as well as other aerospace welded joints [51.1, 2]. Ultrasonic inspection is the primary method for carbon-fiber polymer composites [51.3,4]. Both x-ray and ultrasonics benefit in terms of quality and value by the implementation of highly automated systems. Ultrasonic systems have required major developments in robotics for inspection rate and sensitivity requirements for both production [51.5–7] and for field in-service inspection operations [51.8, 9]. Automated x-ray systems have been slower to be implemented, but progress is being made. The future direction in aircraft part inspection will be automated interpretation of the NDI data that is currently being implemented in higher-production-rate industries.

51.3.1 X-ray Inspection Systems

Figure 51.16 shows a diagram and photograph of a seven-axis CNC system for digital radiography (DR) of welds at Boeing Commercial Airplanes Fabrication Division in Auburn, WA, USA. The CNC manipulator, source, and detector are located in a radiation vault. A complex welded duct is positioned by the CNC manipulator at a series of preprogrammed locations between the x-ray source and digital detector, as shown in the right-hand image. The insert in the lower right of the figure shows the DR image from the operator's console display. The system consists of five major components: the Siemens controller-based CNC manipulator, the x-ray source, the digital x-ray detector, the control computer for the CNC manipulator, and the image display and analysis system. The system requirement is for x-ray image quality indicator sensitivity of 1-1T (1% part thickness with visible hole of 1% part thickness diameter) in the radiographic image for 100% coverage of the part. To achieve this image quality an x-ray spot size of 20 μm nominal and a magnification of 4.5× is used to create images with greater than ten line-pairs per millimeter resolution and better than 1% contrast sensitivity. Position of the weld to be inspected is critical to achieving the required image quality and this is accomplished by automated control of the CNC manipulator. Table 51.1 lists the critical characteristics of the CNC manipulator system. The CNC manipulator is programmed to begin a testing session by positioning and imaging a test standard at the same geometric factors, exposure parameters, and image display settings as will be used for the part to be inspected. Once the operator approves the quality of the inspection for the

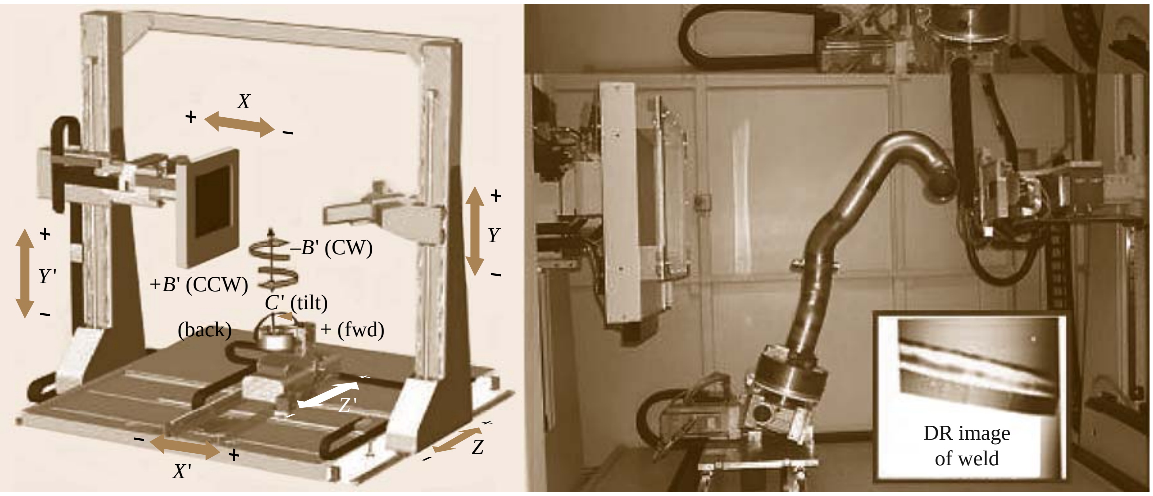

Fig. 51.16 Diagram and photograph of robotic digital radiography system (courtesy of Boeing)

standard, inspection of the part begins. Each part configuration is programmed in the CNC manipulator to allow the weld to be 100% inspected by a series of radiographic views. The CNC manipulator positions the part according to the program for an exposure at the first location. Following operator review of the resulting radiographic image, the CNC manipulator advances to the next position in the sequence and the process repeats until the entire part is inspected. Typical inspection sequences for the CNC manipulator include 20–50 views, taking approximately 10–20 min. Images are reviewed by automated sequence of viewing parameters followed by preset adjustments of the image display for enhancement of areas of interest for detail review. Enhancement and measurement features include different window/level parameters, digital magnification, and contrast enhancement [51.16–28].

51.3.2 Ultrasonic Inspection Systems

For carbon-fiber polymer composite materials including laminate, sandwich structure, and bonds, ultrasound is the principle inspection method and requires highly automated scanners to keep up with the production rate. Sophisticated automation is also needed to handle the complex contoured geometry of the large composite assemblies. Ultrasonic scanning systems can be constructed in a variety of forms from small portable units to large gantry systems. Ultrasonic inspection is most commonly performed with some type of water coupling of the ultrasonic energy between the piezoelectric transducer and the test part. Methods include: immersion where the part is submerged in a water bath with the transducer; bubbler systems, where the transducer rides on the surface in a shoe that also has a flow of water;

Table 51.1 Boeing commercial airplane robotic x-ray system characteristics

Characteristic		Values
Robot	Type	Siemens Simotion seven axis
	Range of motion	Magnification axis: ≈1.5 m, loading axis: 0.3 m, rotation axis: 360°, tilting table axis: ±60°
	Positional accuracy	0.5 mm, angular axis < 1°
	Load-carrying ability	70 kg
X-ray source	Model	FEINFOCUS, Model: FXE-225, 320 W (225 kV at 1400 mA)
	Spot size	Less than 20 μm
Detector	Model	Perkin Elmer 1620
	Pixel size/bit depth	200 μm/16 bit
Weld radiography quality	Image quality	1-1T, with > 10 line pairs/mm at 4.5×
	Inspection time	10 s per view, 30 s to 1 min per weld

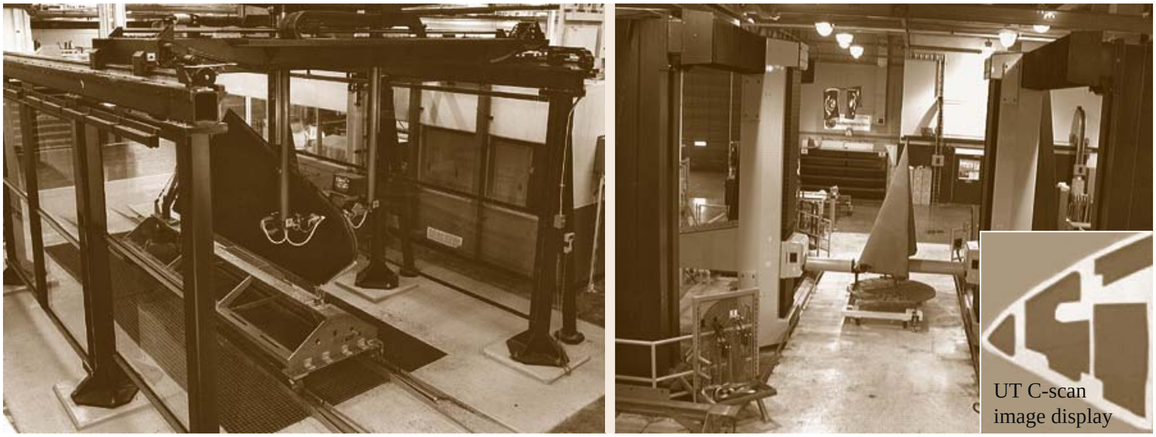

Fig. 51.17 Two types of automated ultrasonic inspection systems: independent tower system (*right*) and gantry system (*left*) (courtesy of Boeing)

and squirter systems, where the transducer is located in a nozzle that shoots water at a part from a short distance. The ultrasonic inspection can use one or more transducers in a variety of combinations. The typical inspection uses either one transducer in pulse echo (PE) mode, or two transducers, each aligned on opposite sides of the part, for through transmission ultrasound (TTU). Pitch-catch mode uses two transducers on the same side of the part. For high throughputs using automated systems, the scanning robotics may handle arrays of transducers that provide coverage of large areas of material [51.16–27].

As aerospace structures become larger and more complicated, overhead gantry systems or tower gantry systems such as that illustrated in Fig. 51.17 are used. The overhead bridge scanning system can be used with transducer manipulators with up to five axes of motion: X, Y, and Z translations, rotation, and tilt. Using motion control software, the transducer can be oriented normal to complex curved part surface during scanning. Two transducer manipulators are employed for through transmission imaging. The computer software can keep the squirter transducers aligned and normal to the part surface for complex geometric configurations. The part geometries are taught by manual selection of a few data points along a scan or using CAD surface data. In some cases the systems will take pulse echo data from each transducer on each side of the part and through transmission data simultaneously. The tower scanner uses independent machines on each side of the part to be tested. The advantages of this configuration include the independent surface following from each side, the improved *reach in* capability stiffness, and reduced ceiling height. The ultrasonic testing (UT) data from a quality surface following scanner includes 1-to-1 flaw sizing on complex curvature objects. The test part shown in the tower system in Fig. 51.17 is a landing gear pod fairing. The UT C-scan image data shown in the lower-right side of the figure is the two-dimensional (2-D) ultrasonic C-scan representation of the three-dimensional (3-D) object, in which light areas indicate laminate and darker areas indicate honeycomb core. Laminate inspections are usually performed at 5 MHz, while honeycomb is commonly inspected with 1 or 2.25 MHz ultrasound.

Inspection speeds depend on the data acquisition rates. The data acquisition rate in X and the step size in Y are determined by the minimum defect size that is to be detected. Three data points are required for the minimum defect size, such that 0.08 in data space is used for 0.25 in defect sensitivity. Many scanners and the associated acquisition electronics can scan at up to 40 in/s while maintaining 0.04 in data spacing in the scan direction. Coverage of 25–50 ft^2/h is possible on many parts.

51.4 Automated Assembly Systems/Examples

Conversion to digitally defined parts is a key factor that has enabled the widespread use of automation. Aircraft assembly machines are custom-designed to meet specific requirements, where the combination of tight engineering tolerances, the need to reduce part variation, and large machine envelope drives large and expensive machines. Despite the high initial cost, the use of automation has been very successful in addressing the needs to improve quality, reduce costs, and improve ergonomics of aircraft fabrication and assembly. Assembly systems are designed around the type of structures to be assembled. For single and very large panels, C-frame riveting/fastening machines are commonly used. The most suitable system to assemble half-shells (fuselage barrels) is a ring riveter, and final aircraft assembly is performed manually using advanced hand tools and, more recently, newly developed, flexible, adaptable, portable assembly systems.

51.4.1 C-Frame Fastening Machine

Automated wing panel fastening machines are used to build stringer stiffened wing panels by riveting stringer-to-wing skins and fastening adjacent wing panels together. Structurally, they are large C-frames mounted on rails that travel the length of the wing. Floor-mounted header tooling supports the temporarily tacked together wing panel to ensure proper panel positioning for permanent fastener installation. The C-frame wraps around the wing skin and applies drilling and fastener installation tools to both sides of the panel. For accurate positioning, wing riveters obtain positional accuracy from the stringers mounted on the underside of the wing panel. A typical rivet installation cycle involves positioning the machine to the proper location, clamping the skin and stringer together, drilling a hole, inserting a rivet, hydraulically squeezing a rivet, and shaving the formed head. Then, an electronic vision system verifies if the shaved rivet meets the flushness requirement. Bolts are applied in a similar sequence, with sealant being applied prior to bolt insertion, and then the nuts are installed and torqued.

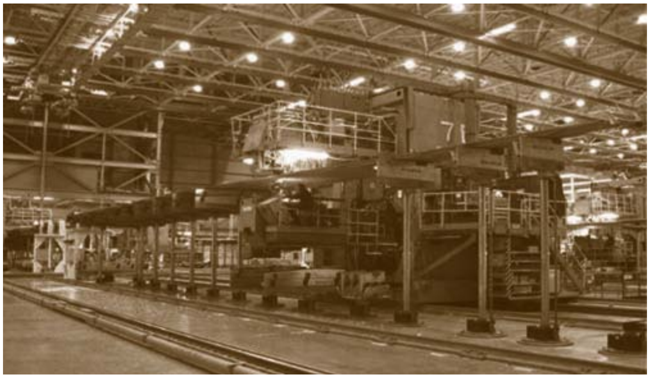

Fig. 51.18 Gemcor automated wing fastening system

A Boeing wing panel fastening system is shown in production in Fig. 51.18. Typical production wing lines have multiple wing assembly machines capable of operating on multiple parallel rail systems with turntables and interconnecting tracks allowing a machine to move to work stations within the track network [51.4–8].

Machine Features

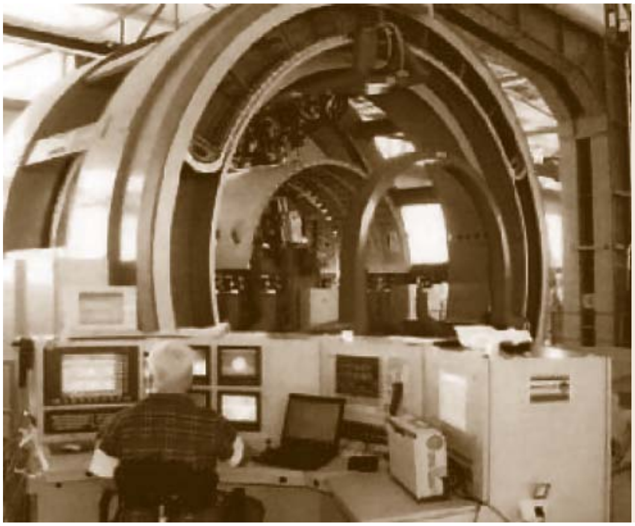
- 50 000 lbs rivet upset capability to accommodate 7/16 in-diameter 7050 rivets
- Full servo programmable control including:
  - High-speed upper head transfer
  - High-speed drill and shave spindles
  - High-speed servo buck
  - High-speed servo lower head
  - Servo clamp
- Up to six upper head positions
- Statistical process control (SPC) of fastener installation processes
- Automatic fastener selection
- Fastest machine cycle time in the industry
- Standard slug squeeze process
- Squeeze/squeeze III slug installation process
- Vibratory insertion process for two-piece fasteners in high interference fit conditions
- Torque-controlled nut runner
- Lockbolt swage collar tooling

51.4.2 Ring Riveter for Fuselage Half-Shell Assembly

System Description

This computer-controlled riveting/fastening machine is being used to automatically join fuselage half-shells made from single panels along longitudinal and radial joints as shown in Fig. 51.19. It consists of:

1. Outer ring, moving on longitudinal rails, carrying a multifunction end-effector, which moves radially on the inside of the machine ring structure
2. A robotic arm, moving on the floor inside the ring on rails longitudinally, carrying a second multifunction end-effector
3. A flexible fixture to support the half-shell during the assembly operations
4. Machine controller, executing assembly sequence programs generated using an offline programming system [51.1–3].



Technical data

- Assembly of 180° half shells
- Machine size: $L = 10–80\,\mathrm{m}$; $W = 6–12\,\mathrm{m}$; $H = 6–10\,\mathrm{m}$
- Fully automated process, CNC control
- Automatic work piece transfer
- Precision rivet/fastener head position
- Solid work piece clamping during run time
- Number of rivet/fastener cassettes = 16 or more
- Drill spindle rpm = 0 to 20 000
- Spindle feed = 0 to 0.006 ipr
- Pneumatic hammer for interference fastener insertion
- Rivet installation rate = 4 to 10 rivets/min
- Fastener installation rate = 2 to 6 fasteners/min
- Off-line or teach-in programming

Fig. 51.19 Ring riveter assembly system (courtesy of Broetje)

Assembly Process

Single panels and all parts building the half-shell are tacked together and half-shell stabilized on the flexible fixture is moved into the ring's working envelope. The multifunction end-effector moving on the outside of the half-shell, and the internal multifunction end-effector, perform synchronous riveting/fastening operations through the skin. The outside multifunction end-effector uses a drilling module, a rivet fastener feeding module, and a rivet upsetting tool; and the internal multifunction end-effector uses a clamping tool and rivet upsetting or sleeve installation tool module, if two-piece fasteners are being installed. Process parameters such as the clamping force generated by internal and external end-effector bushings at the drilling location are adjusted for structural material (aluminum, titanium, composite) and stiffness. The drill unit's RPM and feed force are selected as a function of hole diameter, required hole tolerance (e.g., 0.001 in) and cutter material (e.g., carbide, PCD). The position of all machine components (ring, robot, end-effectors) is CNC controlled and a vision system built into the outside multifunction end-effector provides the operator with visual control and enables precision position adjustments if required. The internal multifunction end-effector can be quickly decoupled from the robotic arm and replaced with the C-frame type of multifunction end-effector for shear tie-to-frame riveting operations. This multifunction end-effector locates a feature (hole or rivet) on the frame, using a vision system, and communicates information to the robot controller, which then positions the end-effector to the proper location for clamping, drilling, and rivet insertion/upsetting tasks. All process parameters are monitored and saved to a quality-assurance data bank to verify and document process and part quality.

51.4.3 Airplane Moving Line Assembly

System Description

In 1913 Henry Ford put the first moving assembly line ever used for large-scale manufacturing into use.

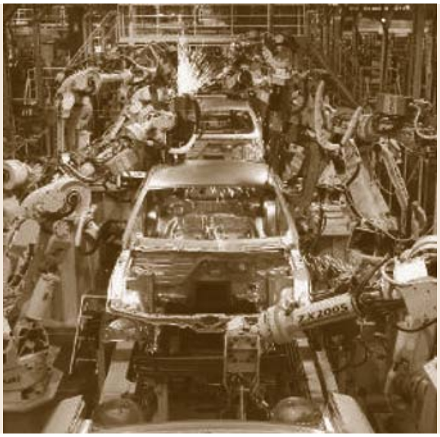


Fig. 51.20 Ford Motor Company moving assembly line

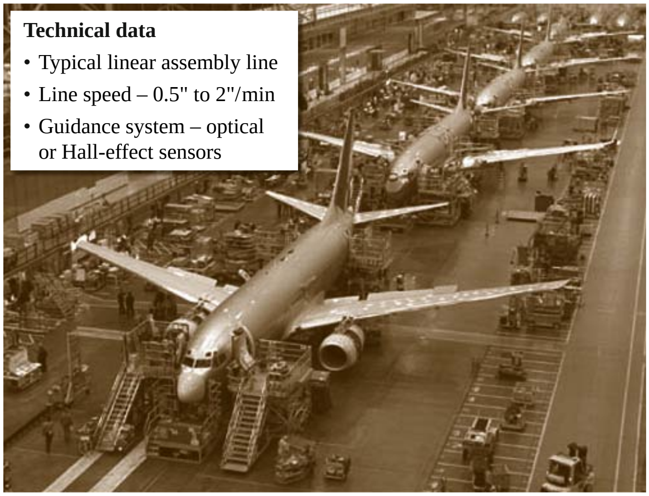

Technical data
- Typical linear assembly line
- Line speed – 0.5" to 2"/min
- Guidance system – optical or Hall-effect sensors

Fig. 51.21 Boeing 737 final assembly line

Ford lowered the price of a car by producing them at record-breaking rates with this new assembly process. Today almost all automobile manufacturers use moving lines to assemble their products for cost, quality, and flow time reasons. In the past 5 years some aerospace companies have moved away from traditional stationary dock assembly systems in favor of the more efficient moving assembly lines similar to those used in the automobile industry. State-of-the-art examples are the Ford production line at Flatrock, MI, USA, shown in Fig. 51.20 and the Boeing 737 final assembly line in Renton, WA, USA, shown in Fig. 51.21.

Assembly Process

Major sections of commercial aircraft are assembled in stationary fixtures until they are structurally stable and need little or no support from external tools. At this point the aircraft is placed on a barge or carrier and begins its final assembly as it is towed by a motorized automated tug. The tug attaches to the front of the barge and pulls it forward under the power of a motor that is computer controlled. Steering is accomplished by an optical sensor that follows a white line along the floor.

Major subassemblies and components such as the landing gear, interior systems, and passenger seats are installed by mechanics as the airplane moves down the assembly line. In addition, functional testing is performed on the various systems in the airplane and the engines are attached. The use of moving assembly line can typically reduce the final assembly time by 50% and significantly reduce the number of days for this task. The assembly time reduction is due to the application of lean manufacturing techniques, which were introduced into the aerospace industry in late 1999. Moving lines help companies achieve higher efficiencies because they create a sense of urgency as well as streamlining and standardizing assembly processes to eliminate waste and nonvalue operations. Computer-controlled tugs set the pace or *takt time* (the manufacturing time needed to accomplish certain predetermined tasks). As the airplane moves past visible marks on the floor, teams of mechanics install prekitted parts and tools using standard processes within the allotted time so that the next team can continue adding value to the airplane as assembly progresses [51.9–15].

51.5 Concluding Remarks and Emerging Trends

Aircraft fabrication and assembly technologies are undergoing significant changes driven by the need to achieve performance and economic targets and only a few predominant trends are discussed here. There is a never-ending search for higher aircraft performance, coupled with the desire to reduce the production labor content, processing time, and cost. This requires progressiveness and innovative use of exotic materials with improved specific mechanical properties (such as carbon-fiber composites), and development of more efficient fabrication and assembly technologies for metallic and nonmetallic structures. The move to more composite aircraft mitigates some typical problems with metallic parts (i. e., the shorter fatigue life and galvanic corrosion inherent to aluminum alloys compared with equivalent composite parts).

A majority of today's manual high-level assembly operations, such as joining fuselage barrels and wing boxes, could be replaced in the future with flexible, adaptable, and affordable, semi-automated assembly systems to perform clamping of parts using electromagnets, drilling, and countersinking, and fastener installation tasks.

One example offering potentially significant improvements in assembly efficiency, is the friction stir welding (FSW) process, developed for space launch vehicle fabrication (for joining Delta II and IV aluminum panels to fuel tanks). This technology, once thoroughly tested and approved, can be introduced into commercial aircraft structural assembly, replacing today's time-consuming mechanical joining techniques.

The potential capability to produce high-level assemblies with composite structures helps to eliminate several lower-level assembly tasks. This has been achieved, as evidenced by the redesign of multipanel aluminum fuselage barrels into a one-piece composite barrel. Such moves call for development of innovative structural configurations, and require mastering engineering challenges associated with tooling, equipment, processes, and inspection.

The emergence and growth of rapid prototyping/fabrication technology could revolutionize the fabrication/manufacturing of parts and assemblies. Parts will be *grown* in a system that requires only the electronic part geometry information and raw material in powder form as inputs. Parts are currently created (grown) by layered material deposition and particle fusion using lasers. These plastic net-shape, or near-net-shape, metallic parts eliminate the need for a majority of the material removal processes and reduce the material buy-to-fly ratios and manufacturing cost. This trend could evolve into *growing substructures* or even complete aircraft segments, eliminating all part fabrication and assembly tasks.

The trend toward monolithic metallic and large-scale integral composite structures will probably continue in the future, and will require the development of advanced automated fabrication and assembly systems to meet demands for improved aircraft performance at minimal cost. The current trend is to machine or fabricate components accurately with automated machines and then use accurately machined features in the detail parts as references to build larger assemblies. At some point, as the structure increases in size, it becomes cost prohibitive to use conventional automation to assemble large parts, so the fall-back position has been to join or splice larger assemblies manually. To capture the benefits of automation with larger assemblies in the future, a new generation of flexible portable automation is being developed. These lightweight portable systems use the aircraft structure as their foundation and will produce quality parts at an affordable cost.

52. Semiconductor Manufacturing Automation

Tae-Eog Lee

We review automation requirements and technologies for semiconductor manufacturing. We first discuss equipment integration architectures and control to meet automation requirements for modern fabs. We explain tool architectures and operational issues for modern integrated tools such as cluster tools, which combine several processing modules with wafer-handling robots. We then review recent progress in tool science for scheduling and control of integrated tools and discuss control software architecture, design, and development for integrated tools. Next, we discuss requirements and technologies in fab integration architectures and operation such as modern fab architectures and automated material-handling systems, communication architecture and networking, fab control application integration, and fab control and management.

52.1 Historical Background

The world semiconductor market has been growing fast and amounted to US$ 270 billion in 2007. The semiconductor manufacturing industry has kept making innovations in circuit design and manufacturing technology. Some key innovations include circuit width reductions from 1.0 μm in 1985 to 60 nm in 2005, 40 nm in 2007, and even down to 14 nm by 2020, and wafer size increase from 200 mm to 300 mm wafers, and even to 450 mm or larger in the near future. Some fabs are producing 1 Gb random-access memory (RAM) by using 50 nm technology, which reduces the cost by about 50% compared with 60 nm technology. Such technology innovations have led to higher circuit density, increased circuit speed, and remarkable price reduction, which also have created new demand and expanded the market.

In 2007, 35 new wafer fabs began to ramp up world monthly fab capacity by two million 200 mm wafers, that is, a 17% increase. A modern fab construction costs about US$ 2 billion. On the other hand, the semiconductor manufacturing industry has suffered strong competition due to excessive capacity. Therefore, the industry has tried to reduce costs, improve quality, and shorten the manufacturing cycle time. Automation has been the key for such manufacturing improvement and business success. Consequently, there have been many aggressive technology innovations and standardizations for fab automation. We therefore need to review those efforts, the state of art, and the future challenges for fab automation.

In this chapter, we briefly introduce semiconductor manufacturing systems and automation requirements, architecture and control for processing equipment and material-handling systems, communication architecture and networking, and software architecture for process control, equipment control, and fab-wide control. We explain academic research works as well as industrial technologies and practices.

52.2 Semiconductor Manufacturing Systems and Automation Requirements

52.2.1 Wafer Fabrication and Assembly Processes

The semiconductor manufacturing process consists of wafer fabrication and assembly. In the wafer fabrication process, multiple circuit layers (up to 30 or more) are laid out on a wafer surface through the repetition of identical sequences of process steps. Most fabrication process steps are chemical processes that oxidize a wafer surface, coat photosensitive chemicals onto the surface, expose it to a circuit image from a light source, develop and etch the circuit pattern, deposit other chemicals onto it, diffuse and implant additional chemicals on the etched pattern, and so on. Once a circuit layer is formed, the wafer reenters the fabrication line to form the next circuit layer. The total number of process steps may amount to 480 or more. A wafer has several hundreds of formed circuit devices. For strict quality control, the formed circuits are measured by metrology equipment frequently after some key process steps. Based on the metrology results, some devices in a wafer may be repaired, reworked or scrapped. Wafter yield may be rather low, especially during the ramp-up stage for the initial 3–6 months. Wafers are transported and loaded into processing tools using a carrier called a *cassette* or *pod* that loads 25 wafers. A typical fab produces 40 000 wafers each month. The fabrication cycle time is several weeks or even a few months, depending on the fab management performance. About 20 000–100 000 wafers may be in progress at any given time.

Once a wafer completes the fabrication processes, devices on a wafer undergo intensive circuit tests called electronic die sorting (EDS). Depending on the test results, the devices are classified into different final products with specifications on clock speed, number of effective transistors, and so on. A device that fails to satisfy the specification of a high-grade product is classified into a lower-grade product. Such a sorting process is also called *binning*. Some devices may be defective. Due to the yield problem and binning, it is difficult to predict the number of final products of each grade or type.

Wafers that complete EDS are sent to an assembly or packaging plant. The fabrication processes leading to EDS and the assembly processes after EDS are called *front-end* and *back-end processes*, respectively. In the back-end processes, a wafer is sliced into individual devices. The sliced devices undergo packaging processes that include tape mounting, wire bonding, molding, and laser marking. The packaged devices take final tests, where additional binning is carried out. The back-end processes have been regarded as relatively low technology with low value added and tend to be subcontracted. However, multichip packages (MCP) that combine several chips together into a single package are becoming increasingly popular due to growing demand from the mobile-device industry. MCP or other advanced packaging technologies such as wafer-scale packaging and flip chips increase the value and importance of the back-end processes. Hence, a number of back-end processes still involve manual material handling while the front-end processes have become highly automated. Figure 52.1 summarizes the overall semiconductor manufacturing processes.

A process step is performed by a number of similar or identical wafer processing tools. Due to strict quality requirements, some wafer lots should be processed only with a restricted set of tools. Different types of wafer lots flow concurrently through the fab. Therefore, the fab can be viewed as a hybrid flow shop. Reentrant job

Part F | 52.2

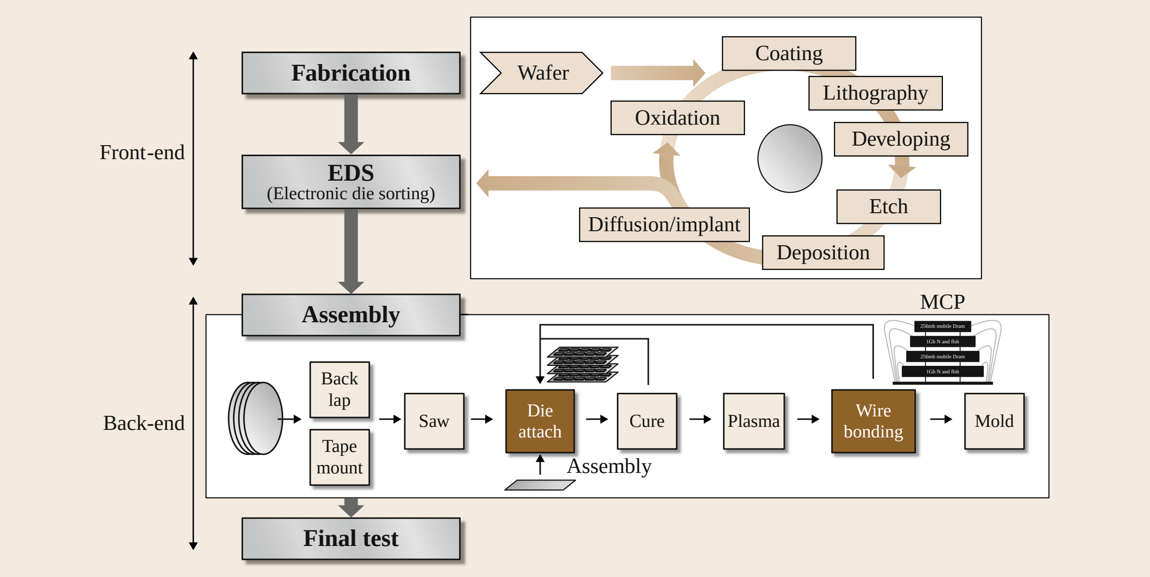

Fig. 52.1 Overall manufacturing processes

flows for processing multiple circuit layers and random yield make planning and scheduling complicated. A fab consists of several hundreds of processing and inspection tools. The tools are grouped into bays, where each bay consists of 10–20 processing tools. Each bay has a stocker, where wafer cassettes are waiting for processing or moving to the next bay.

52.2.2 Automation Requirements for Modern Fabs

There are several drivers for fab automation. The material-handling tasks in a fab are very large; for instance, a fab that processes 40 000 wafers a month requires 200 operators per shift just for moving wafer cassettes [52.1]. Therefore, automated material-handling systems (AMHSs) are used to reduce such high human operator requirements. Other drivers for material-handling automation include prevention of human's handling errors such as wafer dropping, and better tool utilization and reduced manufacturing cycle time by fast and reliable material transfer [52.1]. The key technological innovations in the front-end processes during the past decades are the continuing reduction of circuit features for higher density and functionality, and wafer size increase to 300 mm for higher throughput. These have led to significant fab automation. Extreme circuit shrinkage requires strict quality control and higher-class clean rooms to reduce increased risk of particle contamination. As human operators are a significant source of particle generation, the number of operators needs to be reduced. Wafer size increase leads to significantly heavier weight of a wafer cassette beyond human operator's adequate workload. Therefore, in recent 300 mm fabs, wafer-handling operations have been mostly automated. Control applications for equipment and AMHSs from many different vendors should be easily integrated. Design, scheduling, and control of fully automated fabs are highly complicated and require new concepts and ideas (Fig. 52.2).

Traditionally, wafers in a cassette have been processed in batch mode for most chemical processes such as etching, deposition, etc. However, as the wafer size increases and quality requirements become stricter due to circuit shrinkage, it becomes difficult to control gas or chemical diffusion on all wafer surfaces within a large processing chamber to be uniform enough for strict quality requirements. Therefore, single-wafer processing (SWP) technology that processes wafers one by one has been extensively introduced for most processes. In order to reduce excessive moving tasks between SWP chambers, several SWP chambers are integrated within a closed environment together with a wafer-handling robot. Such a system is called *cluster tools*. An integrated system of SWP chambers with multiple handling robots is often called a *track equipment* or *track system*. It can be considered as a combination of multiple cluster tools. Cluster tools or track equipment have been

increasingly used for most processes. Due to the internal complexity and restrictions, they pose scheduling and control challenges. First, their operations should be optimized to maximize throughput. Second, wafer delays within a processing chamber after processing should be controlled because residual gases and heat affect wafer quality significantly. Third, the tool controller should be reliable and easily adaptable for different tool configurations and changing wafer flow patterns or recipes. Scheduling and control, and tool application integration are not trivial.

Another important issue for fab automation is standardization for reducing integration effort and performance risk. Semiconductor Equipment and Material International (SEMI), an international organization, has developed extensive standards on architectural and interface standards of material-handling hardware, communication, and control software for fab automation. The standards themselves are based on state-of-the-art automation technologies; however, they should be continuously improved for higher operational goals and changing automation requirements.

52.3 Equipment Integration Architecture and Control

52.3.1 Tool Architectures and Operational Requirements

In a cluster tool, there is no intermediate buffer between the process modules (PMs). A wafer, once unloaded from a loadlock, can return to the loadlock only after it completes all required process steps and is often cooled down at a cooler module, if any. This is because a hot wafer returned to the wafer cassette at the loadlock may damage other wafers there and a hot wafer in progress should not be excessively cooled down before processing at the next PM. A wafer loaded into a PM immediately starts processing since the PM's chamber already has gases and heat. There are different cluster tool architectures, as illustrated in Fig. 52.3. Most tools have radial configurations of chambers, where robot move times between chambers are minimized. Linear configurations are also considered to add or remove chambers flexibly. The robot has a single arm or dual arms. The dual arms keep opposite positions. Dual-armed tools are known to have higher throughput than single-armed tools [52.2]. There are also tools with intermediate vacuuming buffers between chambers and loadlocks [52.3] in order to save vacuuming and venting times at the chambers. Some new cluster tools use multiple wafer slots in a chamber in order to improve throughput above that of SWP tools by processing several wafers together [52.4]. However, those new tool architectures tend to increase scheduling complexity significantly.

Track equipment or systems are also widely used for integrating several process steps. Photolithography processes use track systems that supply steppers with wafers coated with photosensitive chemicals and de-

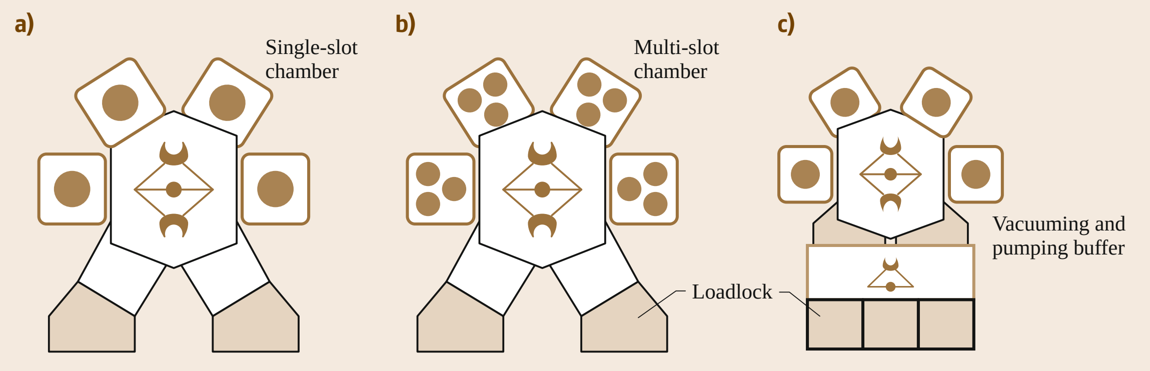

Fig. 52.3a–c Tool architectures: **(a)** single-slot cluster tool, **(b)** multi-slot cluster tool, **(c)** tool with intermediate buffers

velop the circuit patterns on the wafers that are formed by exposures to circuit pattern picture images at the steppers. Process modules for coating and developing, and accompanying baking and cooling modules are combined into a track tool with several robots, as illustrated in Fig. 52.4. Each process step has five to ten parallel modules [52.5, 6]. An automated wet station also has a series of chemical and rinsing baths for cleaning wafer surfaces, which are combined by several robots moving on a rail [52.7]. Recently, EDS processes for testing devices on wafers are automated to form a kind of track system. A number of testing tools for wafer burn-in (WBI) test, hot pretest, cold pretest, laser repair, and posttest are configured in series–parallel by several robots moving on a rail. EDS systems and wet stations can process several different wafers concurrently while most cluster tools or track tools for coating and developing repeatedly process identical wafers.

Wafers mostly go through a sequence of process steps in series. For some processes, wafers visit some process steps again; for instance, unlike conventional chemical vapor deposition, atomic-layer deposition process controls the deposition thickness by repeating extremely thin deposition multiple times. Therefore, a wafer reenters the chambers many times. In track systems, wafer reentrance can be achieved, depending on the chamber configuration and process recipe. In some processes, a chamber should be cleaned after a specified number of wafers have been processed or when sensors within the chamber detect significant contamination. If a wafer remains in a chamber after processing, this can lead to quality problems. This idle time, called *wafer delay*, must be bounded, reduced or regulated. Process times or tasks times are rather constant, but can be subject to random variation, mostly within a few percent. There can be exceptional delay, even if only rare, due to abnormal process conditions. A wafer alignment task, which correctly locates a wafer unloaded from a loadlock onto a robot arm by using a laser pointing system, sometimes fails and needs to be retried. Integrated tools mostly limit intermediate buffers. Therefore, blocking and waiting are common and even deadlocks can occur. Reentrance, wafer delays, cleaning cycles, and uncertainty all increase scheduling complexity significantly. Tool productivity by intelligent scheduling and control is critical for maximizing fab productivity and even affects wafer quality significantly.

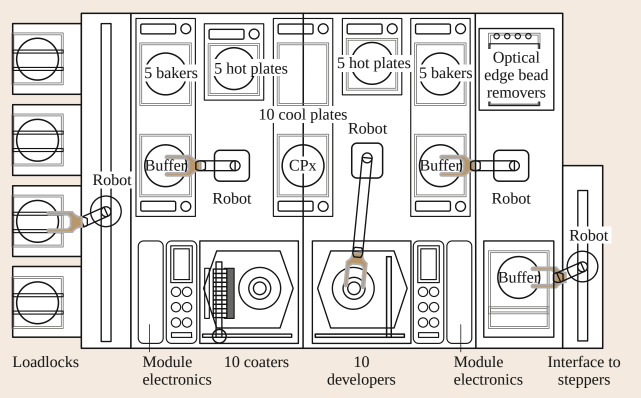

Fig. 52.4 A track system

52.3.2 Tool Science: Scheduling and Control

Scheduling Strategies

There can be alternative scheduling strategies for cluster tools. First, a dispatching rule determines the next robot task depending on the tool state. It can be considered dynamic and real time. However, it is hard to optimize the rule. We are only able to compare performances of heuristically designed dispatching rules by computer simulation. Second, a schedule can be determined in advance. This method can optimize performance if a proper scheduling model can be defined. When there is a significant change in the tool situation, rescheduling is done. *Cyclic scheduling* makes each robot and each processing chamber repeat identical work cycles [52.7, 8]. Once the robot task sequence is determined, all work cycles are determined. Most academic works on cluster tool scheduling consider cyclic scheduling. Cyclic scheduling has merits such as reduced scheduling complexity, predictable behavior, improved throughput, steady or periodical timing patterns, and regulated or bounded task delays or wafer delays and work in progress [52.7–10]. In cyclic scheduling, the timings of tasks can be controlled in real time while the sequence or work cycle is predetermined.

A cluster tool that repeats identical work cycles can be formally modeled and analyzed by a timed event graph (TEG), a class of Petri nets [52.12]. Transitions, places, arcs, and tokens usually represent activities or events, conditions or activities, precedence relations between transitions and places, and entities or conditions, respectively. They are represented graphically by rectangles, circles, arrows, and dots, respectively. Figure 52.5 is an example of a TEG model for cluster tools. Once a TEG model is made, the tool cycle time, the optimal robot task sequence, the wafer delays, and the optimal timing schedules can be systematically identified [52.7, 9, 10]; for instance, the tool cycle time is the maximum of the circuit ratios in the TEG model, where the *circuit ratio* of a circuit is the ratio of the sum of the total times in the circuit to the number of the tokens in the circuit. For instance, the cycle time of a dual-armed cluster tool can be derived from the ratio as

$$\max\left[\max_{i=1,\dots,n}\frac{p_i+2u+2l+3v}{m_i},\ (n+1)(u+l+2v)\right],$$

where p_i, m_i, u, l, v, and n are the process time of process step i, the number of parallel chambers for process step i, the unloading time, the loading time, the move time between the chambers, and the number of process steps, respectively [52.13].

Schedule Quality

For a cluster tool with a given cyclic sequence, there can be different classes of schedules, each of which corresponds to a firing schedule of the TEG model. A periodic schedule repeats an identical timing pattern for each d work cycles. When $d = 1$, the schedule is called *steady*. In a steady schedule, task delays such as wafer delays are all constant. In a d-periodic schedule, the wafer delays have d different values, while the average is the same as that of a steady schedule. The period d is determined from the TEG model. A schedule that starts each task as soon as the pre-

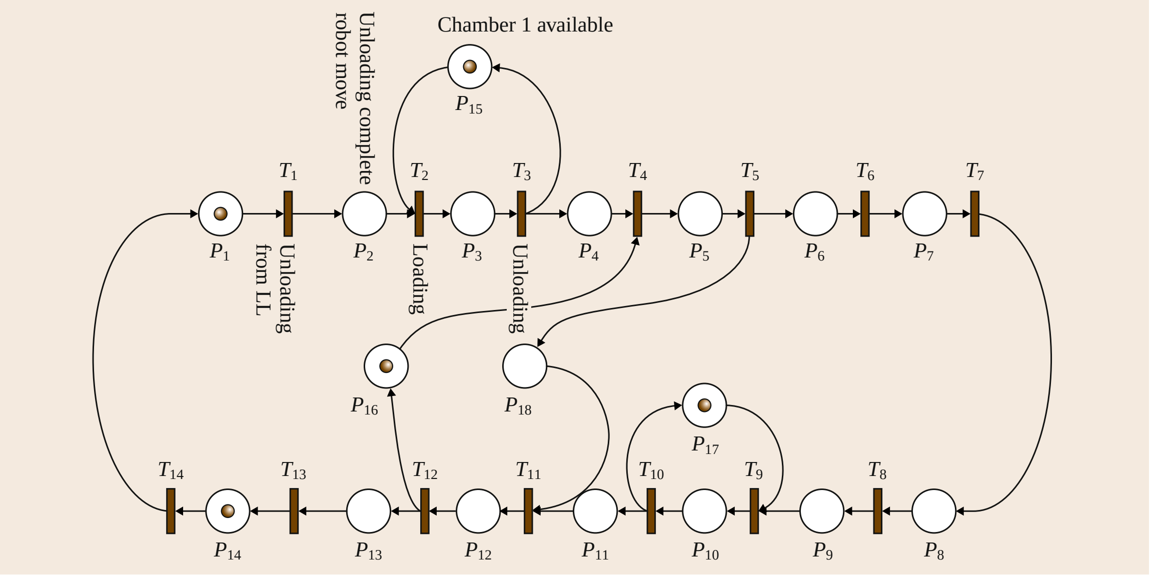

Fig. 52.5 A timed event graph model for a dual-armed cluster tool [52.11]

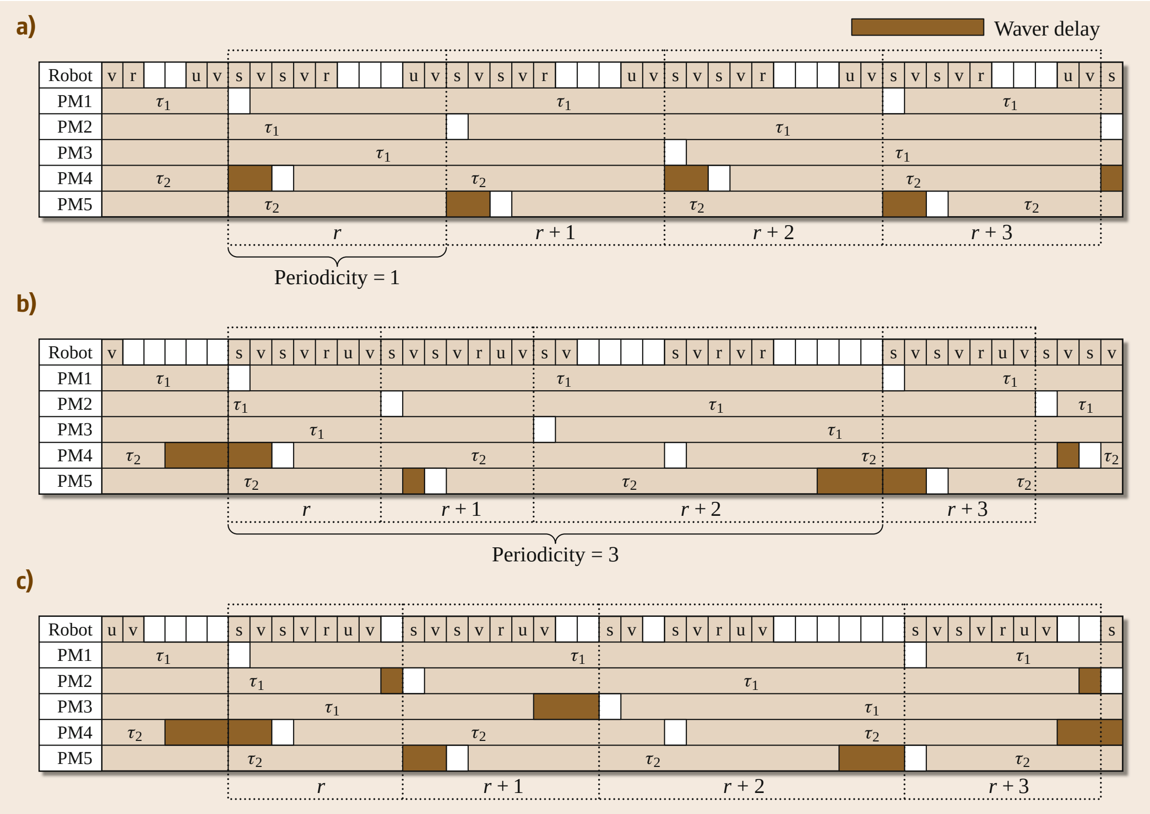

Fig. 52.6a–c Examples of schedules. **(a)** Steady schedule: a SESS, **(b)** 3-periodic schedule, **(c)** irregular schedule

ceding ones complete is called *earliest*. An earliest schedule can be generated by the earliest firing rule of the TEG model that fires each transition as soon as it is enabled. In other words, an earliest starting schedule need not be generated and stored in advance. The TEG model with the earliest firing rule can be used as a real-time scheduler or controller for the tool. Therefore, an earliest schedule can be implemented by an event-based control, which initiates a task when an appropriate event, for instance, a task completion, occurs. Therefore, an earliest starting schedule based on such event-based control has merits. First, potential logical errors due to message sequence changes can be prevented. When a tool is controlled by a predetermined timing schedule, communication or computing delays may cause a change in a message sequence and a critical logical error; for instance, a robot may try to unload a wafer at a chamber before processing at the chamber has been completed and hence when the wafer slot is still closed. Second, the earliest schedule minimizes the average tool cycle time, which is the same as the maximum circuit ratio of the TEG model. Therefore, the most desirable schedule is a *steady and earliest starting schedule* (SESS). For a cluster tool with cyclic operation, there always exists a SESS. Figure 52.6a is an example of SESS for the TEG model. A SESS can be computed in advance using the max-plus algebra or a kind of longest-path algorithm [52.9] and implemented by an event-based controller based on the TEG model [52.10, 13].

Controlling Wafer Delays

When a tool has a strict constraint on the maximum wafer delay, as in low-pressure chemical vapor deposition, coating processes or chemical cleaning processes, it is important to know whether there exists a feasible schedule that satisfies the constraint. There have been works on the schedulability of a cluster tool, that is, the existence of a feasible SESS [52.11, 14]. *Lee* and *Park* [52.14] propose a necessary and sufficient condition for schedulability, that is, the existence of a feasible SESS, based on circuits in an extended version of TEG called negative event graph, which models the time-window constraints on wafer delays by negative places and tokens. In fact, schedulability can also be verified by the existence of a feasible solution in an associated linear program. However, the necessary sufficient condition identifies why the time constraints are violated, and often gives a closed-form schedulability condition based on the scheduling parameters such as the process times, the robot task times, and the number of parallel chambers for each process step.

Most schedulability analyses assume deterministic process and task times. When a cluster tool is operated by a SESS, the wafer delays are kept constant. However, in reality, there can be sporadic random disruptions such as wafer alignment failures and retrials or exceptional process times. In this case, the schedule is disturbed to a non-SESS, in which the wafer delays fluctuate and may exceed the specified limits. However, there are regulating methods that quickly restore a disrupted schedule. *Kim* and *Lee* [52.15] propose a *schedule stability* condition for which a disrupted earliest firing schedule of a TEG or a cluster tool converges to the original SESS regardless of the disruptions, and a simple way of enforcing such stability by adding an appropriate delay to some selected tasks. Therefore, we can regulate wafer delays to be constant. Such a stability control method has been proven to be effective even when there are persistent time variations of a few percent [52.15]. Even when the process times or the robot task times vary significantly, but only if they are within a bounded range, schedulability against wafer delay constraints can be verified by an efficient algorithm on an associated graph [52.15]. When the initial timings are not appropriately controlled or a SESS is disrupted, the earliest schedule converges to a periodic schedule whose period is determined from the TEG. Therefore, the wafer delays can be much larger than the constant value for a SESS. For a given wafer delay constraint, even if the schedulability condition is satisfied, that is, a feasible SESS exists, a periodic schedule may have wafer delays that exceed the limit. Therefore, we are concerned with whether such a periodic schedule with fluctuating wafer delays can satisfy the wafer delay constraint. *Lee* et al. [52.10] proposed a systematic method for identifying exact values of task delays of a TEG or wafer delays of a cluster tool for each type of schedule: steady or periodic, earliest or not. From the method, the schedulability of periodic schedules, which occurs when timings are not well controlled, can be verified.

Workload Balancing for Tools

In a traditional flow line or shop, the workload of a process step is the sum of the process times of all jobs for the step. The bottleneck is the process step with the maximum workload. Imbalance in the workloads of the process steps causes waiting of jobs or work in progress before the bottleneck. However, in automated manufacturing systems such as cluster tools, the workload is not easy to define because the material-handling system interferes with the job processing cycle. To generalize the workload definition, we can define the generalized workload for a resource as the circuit ratio for the circuit in the TEG that corresponds to the work cycle of the resource [52.10, 16]; for instance, the workload for a chamber at process step i with m_i parallel chambers in a single-armed tool is $(p_i + 2l + 2u + 3v)/m_i$, because each work cycle of a chamber requires a wafer processing (p_i), two loading tasks ($2l$), two unloading tasks ($2u$), and three robot moves ($3v$). A robot has workload $(n+1)(u+l+2v)$, the sum of all robot task times. Therefore, the overall tool cycle time is determined by the bottleneck resource as

$$\max\left[\max_{k=1,2,\dots,n}\frac{p_k+2l+2u+3v}{m_k},\right.\\ \left.(n+1)(u+l+2v)\right].$$

Imbalance between the workloads or circuit ratios causes task delays such as wafer delays. In a single-armed tool, the workload imbalance between process step i's cycle and the whole tool cycle is

$$\max\left[\max_{k=1,2,\dots,n}\frac{p_k+2l+2u+3v}{m_k},\right.\\ \left.(n+1)(u+l+2v)\right]-\frac{(p_i+2l+2u+3v)}{m_i}.$$

Notice that each chamber at process step i has cycle time $(p_i + 2l + 2u + 3v)$, while the overall cycle time at the process step is $(p_i + 2l + 2u + 3v)/m_i$. Therefore, the delay in each cycle of a chamber at process step i is m_i times as long as the workload imbalance at the process step. Consequently, the average wafer delay at a chamber at process step i is [52.10]

$$m_i\max\left[\max_{k=1,2,\dots,n}\frac{p_k+2l+2u+3v}{m_k},\right.\\ \left.(n+1)(u+l+2v)\right]-(p_i+2l+2u+3v).$$

We note from the well-known queueing formula, Little's law, that the average delay is proportional to the average work in progress. In a cluster tool, wafer delays are more important than the number of waiting wafers because of extreme limitation on the wafer waiting space. Wafer delays can be reduced or eliminated by balancing the circuit ratios. Such *generalized workload balancing* can be done by adding parallel chambers to a bottleneck process step, accommodating the process times within technologically feasible ranges or intentionally delaying some robot tasks [52.10, 16]. *Lee* et al. [52.10, 16] proposed a linear programming model that optimizes such workload balancing decisions under given restrictions. Workload balancing is essential for cluster tool engineering.

Additional Works

Cluster tools with cleaning cycles, multi-slots, and reentrance present more challenging scheduling problems. There are some works on using cyclic scheduling for these problems [52.4, 17, 18]. For a tool controlled by a dispatching rule, we cannot optimize the rule and identify or control wafer delays. Wafer delays are unexpected and can be excessively long. Nonetheless, dispatching rules are inevitable when the scheduling problem is too complex or involves uncontrollable significant uncertainty. Reentrance, cleaning cycles, and multi-slots contribute significantly to scheduling complexity. In general, process times and robot task times in cluster tools and track equipment are relatively well regulated and have variations within a few percent, because most processes are designed to terminate within a specified time. However, modern adaptive process control that adapts process control parameters based on real-time sensor information may cause significant time variation. Cleaning based on chamber conditions may occur randomly and hence increase uncertainty significantly. There are some works on dispatching rules for cluster tools with cleaning and multi-slots [52.19].

52.3.3 Control Software Architecture, Design, and Development

In a cluster tool, each processing module or chamber is controlled by a process module controller (PMC). The robot, loadlocks, and slot valves at the chamber are controlled by a transport module controller (TMC). A module controller receives data from the sensors in a chamber, and issues control commands to the actuators such as gas valves, pumps, and heaters. The module controllers use bus-type control networks called *fieldbuses* such as process field bus–decentralized peripherals (PROFIBUS-DP) and control area networks (CANs) for communication and control with sensors and actuators. The module controllers are also coordinated by a system controller, called the *cluster tool controller* (CTC). A CTC has a module manager and a real-time scheduler. A module manager receives essential event messages from the PMCs, manages the states of the process modules, and sends the PMCs detailed control commands to perform a scheduling command from the scheduler. Communication between the PMCs, TMC, and the CTC usually uses transmission control protocol/Internet protocol (TCP/IP) based on Ethernet because they are well-known and accepted universal standards.

A real-time scheduler monitors the key events from each PMC and the TMC through the module manager. The events include starts and completions of wafer processing or robot tasks, which are essential for scheduling. Then, the scheduler determines the states of the modules and scheduling decisions as specified by the scheduling logic or rules, and issues the scheduling commands to the module manager. Since the wafer flow pattern can change, the scheduling logic should be easily changed without much programming work. The modules are often configured by a tool vendor to fulfill a specific cluster tool order. For large liquid-crystal display (LCD) fabrication, the modules are often integrated at a fab to assemble a large-scale cluster tool. Therefore, the scheduler should implement the scheduling logic in a modular way for flexibility when changing logic. To do this, the scheduling logic can be implemented by an extended finite state machine (EFSM) [52.13]. An EFSM models state change of each module and embeds a short programming code for the scheduling logic or procedure. The scheduling logic also includes procedures for handling exceptions such as wafer alignment failures, processing chamber failures, robot arm failures, etc. Figure 52.7 illustrates a typical architecture for communication and control in a cluster tool. A track system has a similar communication and control architecture.

A SEMI standard, cluster tool module communication (CTMC), specifies a model of distributed application objects for module controllers and a CTC, and a messaging standard between the objects [52.20]. *Lee* et al. [52.21] also propose an object-oriented application integration framework based on a high-level fieldbus communication protocol and service standard, PROFIBUS-field message specification (FMS), which defines a messaging standard between manufacturing equipment based on their object models. They sug-

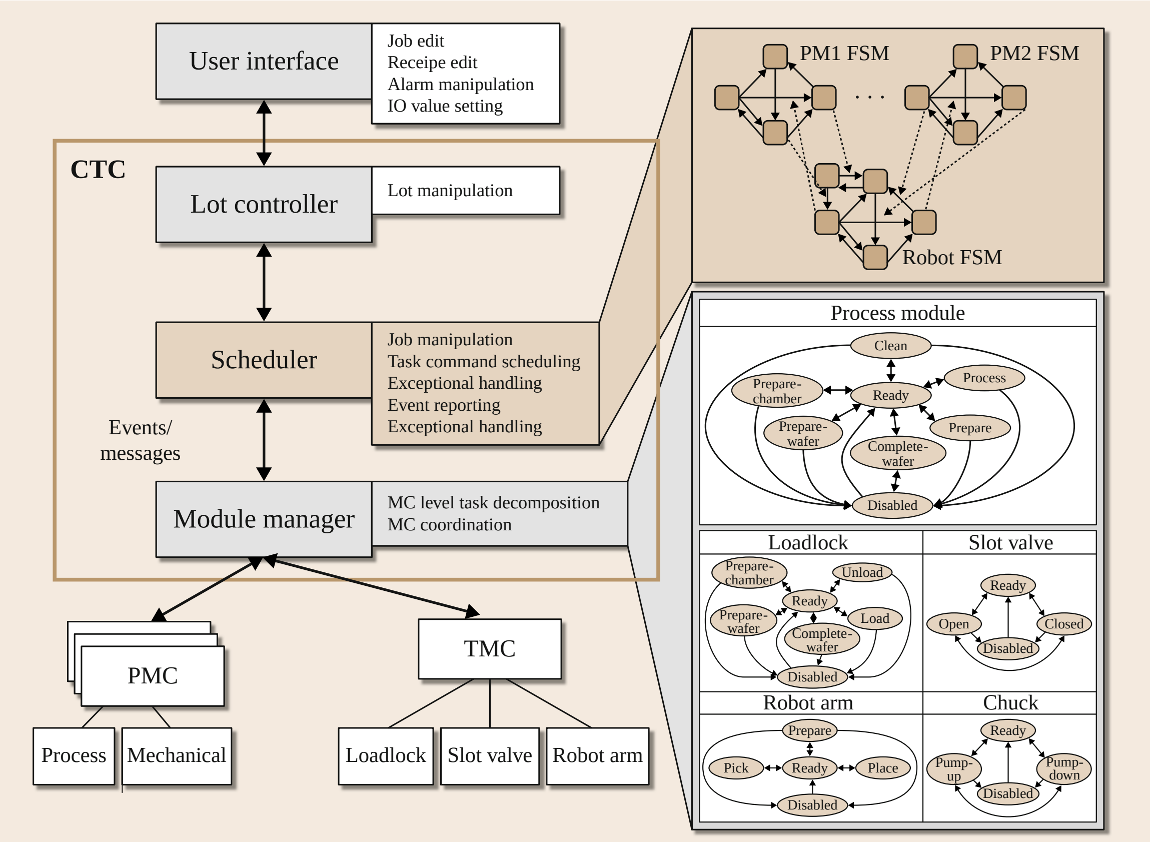

Fig. 52.7 A cluster tool controller architecture [52.22]

gest that some object models in CTMC, which were defined based on a traditional object model for material-handling systems, need to be modified to handle the robot tasks in a cluster tool.

Each time a new cluster tool is developed, the scheduling logic and a CTC application should be integrated and extensively tested. However, tool testing and verification involve difficulties. First, a real tool is expensive and hence cannot be tied up for extensive testing. Second, testing with a real tool can be hazardous due to mechanical or space restrictions. Third, since the dynamics of a real cluster tool is slow, it takes significant time to test the system. Finally, it is often difficult to recognize subtle logical errors by observing operational behavior of a real tool. Therefore, the CTC and scheduler need to be tested in a virtual environment such as a *virtual cluster tool* (VCT), in which the process modules and the transport modules are replaced by their emulators [52.22]. The emulators receive control commands from the scheduler through the module manager and/or the module controllers, and create messages for events such as process completions or robot task completions at appropriate times. The process times can be accelerated for initial rough-cut testing. Tool engineers examine the sequence of the events generated at the CTC or module controllers, and detect an anomaly. Such verification takes several days or weeks and is tedious. Some errors are hard to recognize and are often missed. *Joo* and *Lee* [52.22] propose the use of event sequence finite state machines for automatic error detection, which is basically identical to a finite state machine except that, when an event other than allowed ones at a state occurs, an error is assumed. They detected several unexpected logical errors, including logical errors caused by message sequence changes due to communication delay. Most tool simulators, such as ToolSim by Brooks Automation, focus on performance evaluation of a configured tool rather than high-fidelity modeling and verification of tool operation and messaging between a CTC and module controllers.

52.4 Fab Integration Architectures and Operation

52.4.1 Fab Architecture and Automated Material-Handling Systems

In modern 300 mm fabs, wafer cassette-handling tasks for interbay moves as well as intrabay ones are automated. In order to save the footprint and secure human operator access for equipment maintenance or exception handling, overhead transport (OHT) systems are mostly used. Traditional automated guided vehicle (AGV) or rail-guided vehicle (RGV) systems have been replaced by OHTs. In order to reduce particle contamination risk, tasks of loading and unloading wafer at tools are automated by using a new wafer carrier, the front open unified pod (FOUP), and a standard mechanical interface (SMIF). Processing tools are often enclosed in a minienvironment with extreme cleanness. Design and operation of the architecture and AMHSs of such fully automated fabs should be optimized to maximize throughput and reduce the cycle time while minimizing capital investment. An AMHS itself can be a bottleneck due to a limited number of vehicles and congestion on transport rails. Transport routes are not so flexible and should be considered as a limited resource. Therefore, in some 300 mm fabs, even critical metrology steps are skipped in order to reduce excessive vehicle traffic and the cycle time. Scheduling and dispatching systems are not yet well designed to handle such fully automated fabs. Control software such as manufacturing execution systems (MESs), material control systems (MCSs), equipment controllers, and schedulers as well as the AMHS architecture are not yet as intelligent and flexible as human operators, who make adaptive and intelligent decisions depending on the situation. There still remain many challenges to smart and efficient fully automated fabs. Figure 52.8 illustrates a typical OHT system layout, which consists of intrabay and interbay loops. There are works on optimal design of OHT networks, optimal number of OHTs, and performance analysis [52.23, 24].

Automated material-handling systems mostly have limited handling capacity and flexibility due to restricted paths and limited number of vehicles. Therefore, stockers or waiting places have been mandatory solutions for such problems. Stocking wafer cassettes at a bay involves significant delay due to prior waiting cassettes and handling operations. Therefore, in some 300 mm fabs, a desire to minimize the delivery cycle time led to attempts to combine several bays into a larger cell by eliminating bay-stockers in order to enforce direct delivery. However, this may cause significant OHT congestion and blocking, and hence throughput degradation. Nonetheless, direct delivery is one of the key technological challenges for next-generation 450 mm fabs [52.25]. To achieve the goal of direct delivery, we need quite different architectures of fabs and material-transfer systems. A solution might be to mimic a transfer line or a conveyor system, where wafer cassettes go through a significant number of process tools without intermediate stocking. Such a system is called an *inline* system. One of the most serious disadvantages of inline systems is lack of flexibility. In future fabs, lot sizes will continue to shrink. Therefore, con-

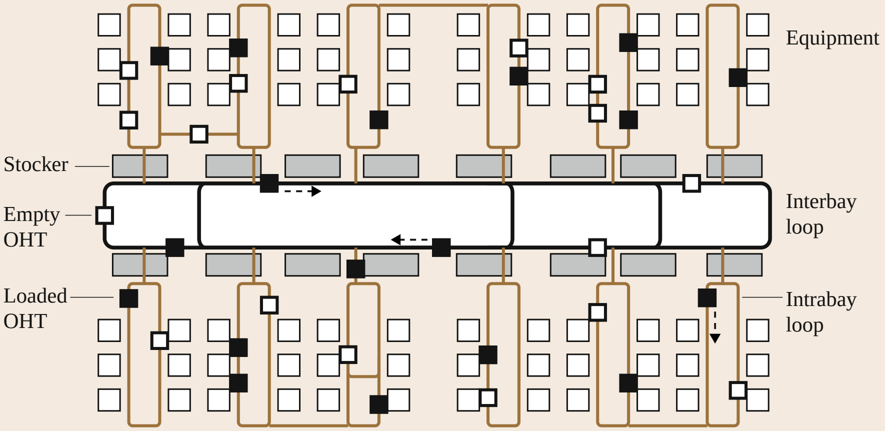

Fig. 52.8 An overhead transport system

flicting goals of flexibility and direct delivery should be resolved. LCD fabs, for which material transfer has been fully automated from the early stage due to manual handling difficulties, tend to introduce inline systems for more process steps as the panel size increases continually. A future 450 mm fab may also resemble an LCD line [52.25]. Stocker racks may be extensively located in parallel to the inline system [52.25]. Several alternatives for future fab and material-handling system architectures are now being discussed [52.26].

Traditionally, AMHSs have been scheduled and controlled separately from job scheduling. That is, wafer processing jobs are scheduled disregarding the limited capacity of the AMHS, and then material-transfer tasks, which are requested from the job schedule executor such as a real-time dispatcher, are separately planned and controlled by a material control system (MCS), that is, the AMHS controller. However, such decoupling is not so effective for modern integrated systems where job scheduling is significantly restricted by the AMHS, and vice versa. Interaction between job schedules and material transfer control should be considered, or they should be simultaneously scheduled as in cluster tools. MCSs have been engineered by AMHS vendors and are managed by automation engineers in fabs. However, job scheduling has been done by production management or control staffs. In the future, the two staff groups should better collaborate to tightly couple job scheduling and AMHS control. As fab technologies evolve, material-handling requirements become more challenging. SEMI has updated a roadmap for AMHSs for future fabs [52.27].

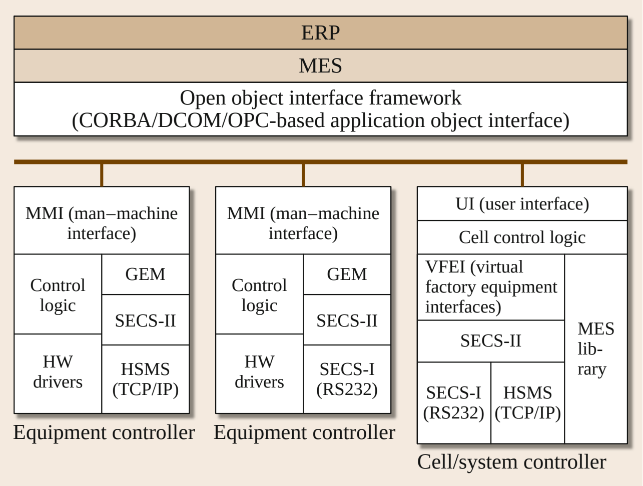

Fig. 52.9 Communication architecture for fab automation

52.4.2 Communication Architecture and Networking

SEMI communication standards have been widely used in fabs to reduce system integration efforts [52.28]. While old tools are connected only by RS-232 ports, modern tools have Ethernet connections. The semiconductor equipment communication standard I (SECS-I) and high-speed message standard (HSMS) define data standards on RS-232-based serial communication and TCP/IP communication over Ethernet connection, respectively. SECS-II defines messaging standards. The generic equipment model (GEM) and virtual factory equipment interfaces (VFEI) are object-based application interface standards for equipments and factory control applications, respectively. The overall communication architecture is summarized in Fig. 52.9. AMHSs use fieldbus or control networks, either open or proprietary.

As advanced process control (APC) technology for real-time process sensing and real-time adaptive control becomes widespread, there is increasing demand on high-speed real-time communication technology, beyond the current communication architecture, in order to process massive process sensing data in real time.

52.4.3 Fab Control Application Integration

The most critical application for factory integration is a manufacturing execution system (MES). Its basic functions are to monitor equipment, send recipes, and keep track of wafers or other auxiliary materials such as photomasks. Quality monitoring and scheduling functions tend to be performed by separate applications from specialized vendors. MES applications should be easily and reliably integrated with equipment control applications. Traditionally, MESs used middleware based on message queueing to reliably process massive event messages from many equipments. No messages should be lost and the response time should be controlled. Therefore, such messages from many different tools are queued and the message queues are served by reasonable queueing or service policies for load balancing and response time control. Such message-based communication and integration require significant application work to integrate MES applications with equipment control applications. An application designer should understand all low-level messages and their required sequence for logical interaction between the MES and equipment controllers. Debugging, verification, and modification are not easy. An alternative approach is object-based application integration. Each equipment and an MES application have a model of constituent objects, which specify the functions and informational states. Then, interactions between an MES and equipment are implemented by method calls or service requests between their corresponding objects. The common object request broker architecture (CORBA) is a middleware solution for facilitating application integration and interaction between such distributed objects and managing objects and services. MES application designers can conveniently make use of the high-level services of the objects in equipment control applications as well as common MES application objects. Detailed messaging sequences are handled by the methods of the objects that provide the relevant services. SEMI proposed an object-based MES application design standard, called the computer-integrated manufacturing (CIM) framework. SEMI also developed a standard object model for control applications of process equipment, called the object-based equipment model (OBEM). There have been concerns about whether CORBA can work reliably and fast enough for modern fab environments that generate massive amounts of real-time data. However, MES vendors have successfully implemented CORBA-based MES solutions, for example, IBM's SiView and AIM System's NanoMES. Figure 52.10 illustrates object-based interaction.

Recently, the service-oriented architecture (SOA) has been increasingly popular for business and enterprise applications [52.29]. Business processes tend to change frequently to cope with business requirement changes, and to be distributed over the Internet. Therefore, more flexibly composable *services* are defined and called as needed to form a new business process. Objects are considered to have too small granularity to be used for business processes [52.29]. Further, distributed objects technology such as CORBA and the distributed component object model (DCOM) are not easy standards to work with, because it is difficult to integrate object applications that were developed by different people at different places on different platforms at different times. Furthermore, CORBA and DCOM are not widely understood by software engineers and control and automation engineers. Web services have been open standards for easily integrating applications distributed on the Internet by using extensible markup language (XML)-based open standards such as simple object access protocol (SOAP), web services description languages (WSDLs), and universal description, discovery, and integration (UDDI), and standard web protocols such as XML, hypertext transfer protocol (HTTP), and transmission control protocol/Internet

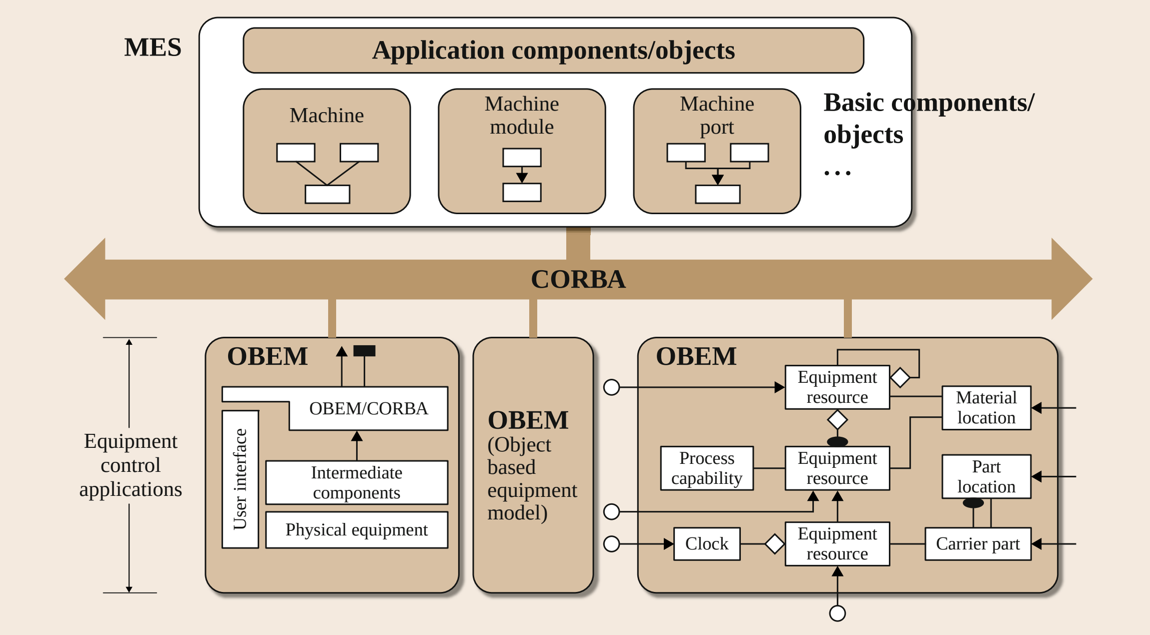

Fig. 52.10 Object-based interaction for MES and equipment control applications

protocol (TCP/IP). Therefore, SOA based on web services can provide open standards for easily integrating distributed factory applications with proper granularity. Therefore, some fabs or vendors for MESs or fab management applications are also now considering SOA-based design. However, it should be studied more whether SOA really makes sense for factory applications in terms of reliability and real-time performance.

52.4.4 Fab Control and Management

Fab operation is highly complicated due to the complex process steps and the massive number of lots in progress. One of the most crucial fab control applications is a real-time dispatcher that keeps track of the lots and equipment states, and determines which lots will be processed at which tools. It uses dispatching or scheduling rules that are proven to be effective for fab operation. The rules may be developed and tested for each fab through extensive simulation in advance. The essential function of a dispatcher is to process massive amounts of job and equipment data reliably and quickly, and compute a dispatch list quickly. A dispatcher sends a scheduling command to the MCS and the process equipment directly in an automated fab, whereas in a manual fab human operators perform the job of loading tasks as specified in the dispatch list.

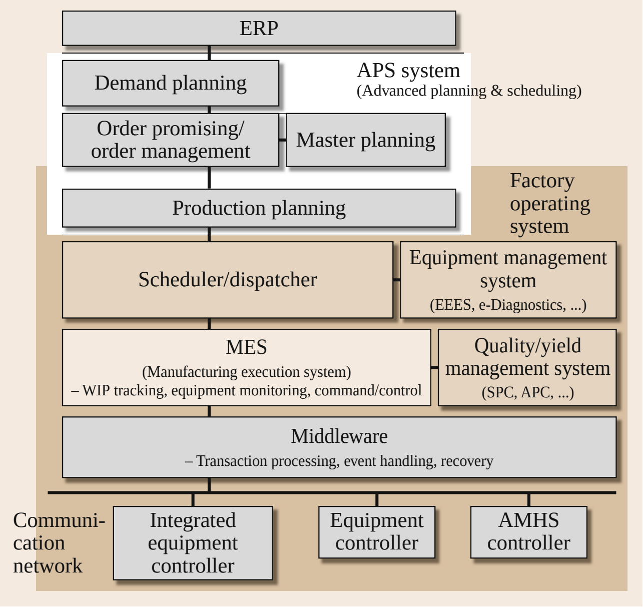

Fig. 52.11 A fab control system architecture (EEES – engineering equity extension service, SPC – statistical process control)

An alternative scheduling approach to the dispatching rules is to have a separate scheduler that determines an appropriate work-in-progress level for each process step by using a dynamic lot flow model and then determines an optimal schedule for each process step separately under the restriction of the ready times and the due dates that are imposed by the schedule of other process steps. Frequent rescheduling is needed to cope with changes in fabs. Even in this case, the dispatcher retains the basic functions except for the scheduling function, and may change the schedule from the scheduler by local rules depending on the fab state. This approach has potential for further improving fab performance. However, there should be more experimental studies on which approach is more effective for different fab management environments.

A production planning system or supply-chain planning system determines daily production requirements for key process stages to meet order due dates or demand forecasts while minimizing inventory level. The system also considers binning due to random yields and capacity constraints. Other important fab control applications include yield management systems and advanced planning and scheduling (APS) systems. An overall fab control application architecture is summarized in Fig. 52.11.

In spite of extensive literature on fab scheduling, control, and management, there still remain many issues, including how the dispatching and scheduling systems, and scheduling rules should be developed to fulfill complex scheduling requirements for fully automated 300 mm fabs or future 450 mm fabs, in which AMHSs will be more strongly coupled with job scheduling for direct delivery, and lot definition and job flows will change significantly.

52.4.5 Other Fab Automation Technologies

Fab automation aims at an autonomous factory that reliably and intelligently produces high-quality wafers. As quality requirements have become stricter and the cost of attaining this quality has increased, fabs have developed *quality-sensitive automation* technologies. Advanced process control (APC) technology includes fault detection and classification (FDC) and run-to-run (R2R) control [52.30]. FDC makes use of statistical methods such as multivariate analysis, or intelligent computing or data-mining technologies such as neural networks or rules, in order to detect early any anomaly in process control that will cause significant quality problems, classify the problems, and report them to the quality engineers. R2R control intelligently adapts process control parameters based on in situ measurements from process sensors. The response models between the measurement and control parameters are dynamic, nonlinear, multiple-input multiple-output (MIMO), and uncertain [52.30]. Therefore, advanced stochastic or statistical functional models and algorithms, or neural networks are used. An equipment engineering system (EES) is for tool vendors to remotely monitor process control of tools at fabs and tune process parameters. It is intended to reduce the initial ramp-up period and cost. Tool vendors cannot keep high-class engineers at customer sites for long periods, for instance, even more than 6 months. Another automation technology for quality is e-Diagnostics, which enables tool vendors in remote locations to detect an anomaly in tools in production at fabs quickly. It can prevent or reduce production of defective wafers and reduce the lead time to dispatch tool engineers to customer sites. Tool vendors and SEMI have developed EES and e-Diagnostics technologies and standards, including data standards, security control, remote control or manipulation, etc. [52.31].

52.5 Conclusion

Semiconductor manufacturing fabs have extensively developed and implemented state-of-the-art industrial automation technologies. We have briefly reviewed them in this Chapter. There remain many challenges for the future, such as for 450 mm fabs. Future fabs for manufacturing nanodevices may require quite new concepts of equipment and material handling, and hence new automation technologies. Concepts, technologies, and practices of semiconductor manufacturing automation can give insights into automation of other manufacturing industries or service systems.

53. Nanomanufacturing Automation

Ning Xi, King Wai Chiu Lai, Heping Chen

This chapter reports the key developments for nanomanufacturing automation. Automated CAD guided nanoassembly can be performed by an improved atomic force microscopy (AFM). Although CAD guided automated manufacturing has been widely studied in the macro-world, nanomanufacturing is challenging. In nanoenvironments, the nanoobjects are usually distributed on a substrate randomly, so the nanoenvironment and the available nanoobjects have to be modeled in order to design a feasible nanostructure. Because of the positioning errors due to the random drift, the actual position of each nanoobject has to be identified by our local scanning method. The advancement of AFM increases the efficiency and accuracy to manipulate and assemble nanoobjects. Besides, the manufacturing process of carbon nanotube (CNT) based nanodevices is discussed. A novel automated manufacturing system has been especially designed for manufacturing nanodevices. The system integrates a new dielectrophoretic (DEP) microchamber into a robotic based deposition workstation and increases the yield to form semi-conducting CNTs for manufacturing nanodevices. Therefore, by using the proposed CNT separation and deposition system, CNT based nanodevices with specific and consistent electronic properties can be manufactured automatically and effectively.

53.1 Overview

Nanoscale materials with unique mechanical, electronic, optical, and chemical properties have a variety of potential applications such as nanoelectromechanical systems (NEMS) and nanosensors. The development of nanoassembly technologies will potentially lead to breakthroughs in manufacturing new revolutionary industrial products. The techniques for nanoassembly can be generally classified into *bottom-up* and *top-down* methods. Self-assembly in nanoscale is reported as the most promising *bottom-up* technique, which is applied to make regular, symmetric patterns of nanoentities. However, many potential nanostructures and nanodevices are asymmetric, which cannot be manufactured using self-assembly only. A *top-down* method would be desirable to fabricate complex nanostructures.

The semiconductor fabrication technique is a matured *top-down* method, which has been used in the fabrication of microelectromechanical systems (MEMS). However, it is difficult to build nanostructures using this method due to limitations of the traditional lithography. Although smaller features can be made by electron beam nanolithography, it is practically very difficult to position the feature precisely using e-Beam nanolithography. The high cost of the scanning electron microscopy (SEM), ultrahigh vacuum condition, and space limitation inside the SEM vacuum capsule also impede its wide application.

Atomic force microscopy (AFM) [53.1] has proven to be a powerful technique to study sample surfaces down to the nanoscale. It can work with both conductive and insulating materials and in many conditions, such as air and liquid. Not only can it characterize sample surfaces, it can also modify them through nanolithography [53.2, 3] and nanomanipulation [53.3, 4], which is a promising nanofabrication technique that combines *top-down* and *bottom-up* advantages. In recent years, many kinds of AFM-based nanolithographies have been implemented on a variety of surfaces such as semiconductors, metals, and soft materials [53.5–8]. A variety of AFM-based nanomanipulation schemes have been developed to position and manipulate nanoobjects [53.9–13]. However, nanolithography itself can hardly be considered as sufficient for fabrication of a complete device. Thus, manipulation of nanoobjects has to be involved in order to manufacture nanostructures and nanodevices. The AFM-based nanomanipulation is much more complicated and difficult than the AFM-based nanolithography because nanoobjects have to be manipulated from one place to another by the AFM tip, and sometimes it is necessary to relocate the nanoobjects during nanomanipulation while nanolithography can only draw patterns. Since the AFM tip as the manipulation end-effector can only apply a point force on a nanoobject, the pushing point on the nanoobject has to be precisely controlled in order to manipulate the nanoobjects to their desired positions. In the most recently available AFM-based manipulation methods, the manipulation paths are obtained either manually using haptic devices [53.9, 10] or in an interactive way between the users and the atomic force microscope (AFM) images [53.11, 12]. The main problem of these schemes is their lack of real-time visual feedback, so an augmented reality interface has been developed [53.14, 15]. But positioning errors due to deformation of the cantilever and random drift such as thermal drift cause the nanoobjects to be easily lost or manipulated to wrong places during manipulation; the result of each operation has to be verified by a new image scan before the next operation starts. This scan-design-manipulation-scan cycle is usually time consuming and inefficient.

In order to increase the efficiency and accuracy of AFM-based nanoassembly, automated CAD guided nanoassembly is desirable [53.16]. In the macroworld, CAD guided automated manufacturing has been widely studied [53.17]. However, it is not a trivial extension from the macroworld to the nanoworld. In the nanoenvironments, the nanoobjects, which include nanoparticles, nanowires, nanotubes, etc., are usually distributed on a substrate randomly. Therefore, the nanoenvironment and the available nanoobjects have to be modeled in order to design a feasible nanostructure. Because manipulation of nanoparticles only requires translation, while manipulation of other nanoobjects such as nanowires involve both translation and rotation, manipulation of nanowires is more challenging than that of nanoparticles. To generate a feasible path to manipulate nanoobjects, obstacle avoidance must also be considered. Turns around obstacles should also be avoided since they may cause the failure of the manipulation. Because of the positioning errors due to the random drift, the actual position of each nanoobject must be identified before each operation.

Beside, the deformation of the cantilever caused by manipulation force is one of the most major nonlinearities and uncertainties. It causes difficulties in accurately controlling the tip position, and results in missing the position of the object. The softness of the conventional cantilevers also causes the failure of manipulation of sticky nanoobjects because the tip can easily slip over the nanoobjects. An active atomic force microscopy probe is used as an adaptable end effector to solve these problems by actively controlling the cantilever's flexibility or rigidity during nanomanipulation. Thus, the adaptable end effector is controlled to maintain straight shape during manipulation [53.18].

Apart from nanoassembly, manufacturing process of nanodevices is important. Carbon nanotube (CNT) has been investigated as one of the most promising candidates to be used for making different nanodevices. CNTs have been shown to exhibit remarkable electronic properties, such as ballistic transport and semiconducting behavior, which depend on their diameters and chiralities. Recently, it was demonstrated that CNTs can be used to build various types of devices such as nanotransistors [53.19], logic devices [53.20], infrared detectors [53.21, 22], light emitting devices [53.23], chemical sensors [53.24, 25], etc. The general manufacturing processes of CNT-based devices is shown in Fig. 53.1. The most challenging parts include CNT selection, deposition, and assembly. Basically, CNT assembly can be done by our AFM-based nanomanipulation system [53.26]. With the advancement of our automated local scanning method for AFM systems [53.27], automated assembly for CNT-based devices can be done effectively. However, electronic properties of CNTs vary and CNTs can be classified into two types: semiconducting CNTs and metallic CNTs. Therefore, an automatic method for the selection and deposition of a single CNT with a specific electronic property should be established [53.28, 29].

Selection of a CNT with the desired electronic property is crucial to its application. Basically, several approaches have been pursued to separate different electronic types of CNTs. *Arnold* et al. demonstrated that semiconducting CNTs and metallic CNTs were separated by using some encapsulating agents or surfactants [53.30]. Besides, *Avouris* et al. demonstrated turning a metallic CNT into a semiconducting CNT after removal of metallic carbon shells by an electrical breakdown process [53.31]. *Krupke* et al. reported a technique to enrich metallic CNT thin film. They demonstrated that metallic CNTs were concentrated on a substrate by using dielectrophoresis [53.32, 33]. Based on the review of these CNT separation techniques, we develop a microchamber to filter different types of CNTs effectively.

Various methods have been proposed to move and deposit a CNT to the metal microelectrodes; this advances the manufacturing process of the CNT-based nanodevices. A nanorobotic technique uses nanomanipulators inside a scanning electron microscopy (SEM) to perform the nanomanipulation. Since a sample chamber of an SEM is spacious, it is possible to put some custom-design nanomanipulators inside the chamber. *Yu* et al. put a custom piezoelectric vacuum manipulator inside the chamber of an SEM, and they visually observed the manipulation process of CNTs [53.34]. *Dong* et al. also developed a 16-degree-of-freedom nanorobotic manipulator to characterize CNTs inside an SEM system [53.35]. The idea of nanoassembly inside SEM is promising, but it needs a vacuum environment for proper operation. Alternatively, electric field assisted methods have been proposed to manipulate and deposit CNTs directly. *Green* et al. introduced AC electrokinetics forces to manipulate sub-micrometer particles on microelectrode structures [53.36]. Bundled CNTs have also been manipulated by dielectrophoretic (DEP) force [53.37, 38]. Moreover, *Dong* and *Nelson* reported the batch fabrication of CNT bearings and transistors by assembling CNTs on a silicon chip using DEP force [53.39, 40]. A fabricated chip was immersed in a reservoir that contained CNT suspension, and CNTs were deposited on the microchip by applying a composite AC/DC electric field. This electric field manipulation technique is an effective and feasible method to batch manipulate CNTs manually. However, an automated robotic system for mass production of consistent CNT-based devices has not been archived.

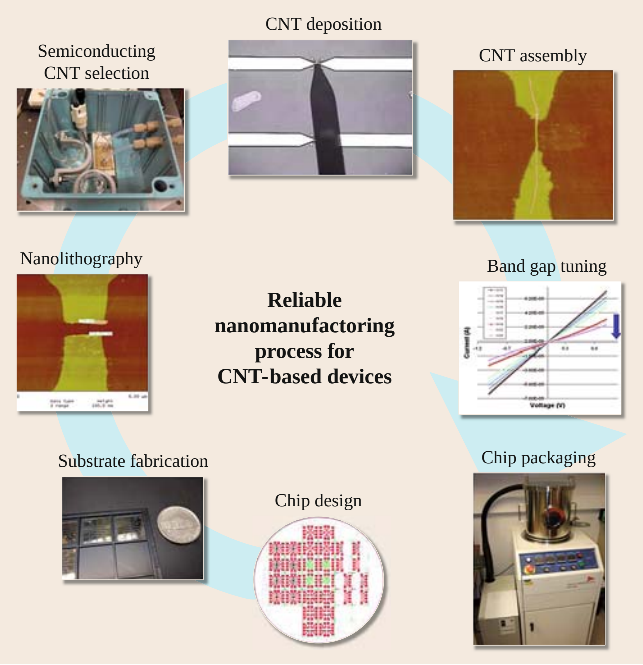

Fig. 53.1 Flow chart of nanomanufacturing of CNT-based devices

An automated nanomanipulation system is discussed in Sect. 53.2. The collision-free paths are generated based on the CAD model, the environment model, and the model of the nanoobjects. A local scanning method is developed to obtain the actual position of each nanoobject to compensate for the random drift. Moveover, automatic nanoassembly of nanostructures using the designed CAD models is presented. The nanomanufacturing process of CNT-based device is discussed in Sect. 53.3. The process includes the development of a novel CNT separation system and an automated deposition processes for both single-walled carbon nanotubes (SWCNTs) and multi-walled carbon nanotubes (MWCNTs).

53.2 AFM-Based Nanomanufacturing

In recent years, many kinds of nanomanipulation schemes have been developed to manipulate nanoobjects. A nanorobotic technique uses nanomanipulators inside an SEM to perform the nanomanipulation [53.34, 35]. The idea of nanoassembly inside SEM is promising, but it needs a vacuum environment for proper operation. AFM is a promising tool for nanomanufacturing [53.12, 41]. Nanoobjects were manipulated by an AFM tip to build nanostructures and devices effectively because of its high resolution. Besides, it does not need to work in a vacuum environment, which allows more freedom in the nanomanufacturing process. In order to use AFM for nanomanufacturing, further studies and improvements have been done. Since nanoobjects are usually distributed on a substrate randomly in the nanoworld, the nanoenvironment and the nanoobjects must be modeled in order to design a feasible nanostructure. In order to manipulate nanoobjects automatically, obstacle avoidance must be considered to generate a feasible path to manipulate nanoobjects. Because of positioning errors due to the random drift, the actual position of each nanoobject must be identified before each operation; this correction can be done by our local scanning method. In order to increase the efficiency and accuracy of AFM-based nanoassembly, automated CAD guided nanoassembly is desirable.

53.2.1 Modeling of the Nanoenvironments

Because the nanoobjects are randomly distributed on a surface, the position of each nanoobject must be determined in order to perform automatic manipulation. Also the nanoobjects have different shapes, such as nanoparticles and nanowires, as shown in Fig. 53.2. They must be categorized before manipulation because the manipulation algorithms for these nanoobjects are different.

After an AFM image is obtained, the nanoobjects can be identified and categorized. The X, Y coordinates and the height information of each pixel can be obtained from the AFM scanning data. Because the height, shape, and size of nanoobjects are known, they are used as criteria to identify nanoobjects and obstacles based on a fuzzy method as follows. Firstly, all pixels higher than a threshold height are identified. The shapes of clustered pixels are categorized and compared with the ideal shapes of nanoobjects. If the shape of clustered pixels is close to the ideal shape, the pixels are assigned a higher probability (p_1). Secondly, if the height of a pixel is close to the ideal height of nanoobjects, a higher probability (p_2) is assigned to it. Thirdly, the neighboring pixels with higher probability ($p_1 p_2$) are counted and the area of the pixels is identified. If the area is close to the size of nanoobjects, the pixels are assigned a higher probability (p_3). If the probability ($p_1 p_2 p_3$) of a pixel is higher than a threshold, it is in a nanoobject. Using the neighboring relationship of pixels, objects can then be identified. The length of a nanoobject can be calculated by finding the long and short axes using a least squares fitting algorithm. If the length/width ratio is larger than a set value, it is considered as a nanowire, otherwise, as a nanoparticle.

53.2.2 Methods of Nanomanipulation Automation

Since the AFM tip can only apply force to a point on a nanoobject in AFM-based nanomanipulation, it is very challenging to generate manipulation paths to manipulate nanoobjects to a desired location, especially for nanowires, because manipulation of nanoparticles only requires translation, while that of nanowires involves translation as well as rotation. Turns around obstacles should be avoided since they may cause manipulation failure. In the following sections, automated manipulation of nanoparticles and nanowires, respectively, will be discussed.

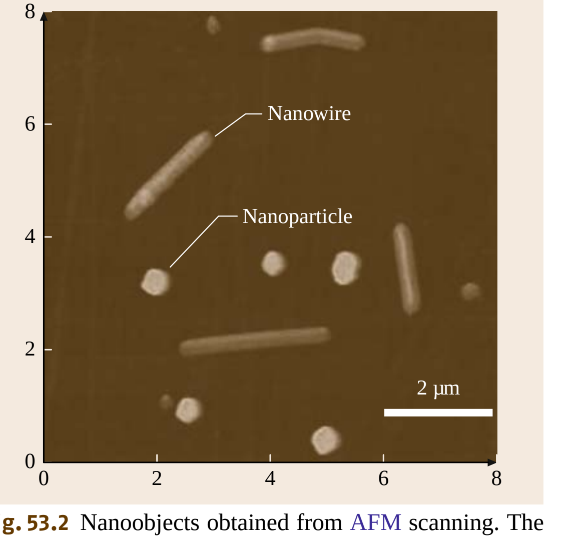

Fig. 53.2 Nanoobjects obtained from AFM scanning. The scanning area is 8 µm × 8 µm

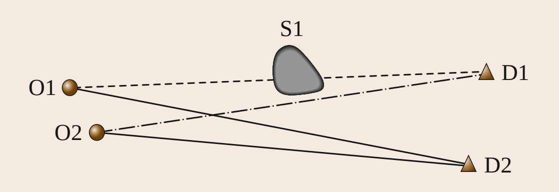

Fig. 53.3 The straight line connection between an object and a destination. O1 and O2 are objects, D1 and D2 are destinations, S1 is an obstacle

Automated Manipulation of Nanoparticles

Once the destinations, objects, and obstacles are determined, a collision-free path can be generated by the tip path planner.

A direct path (straight path) is a connection from an object to a destination using a straight line without any obstacles or potential obstacles in between. Figure 53.3 shows the connections between objects and destinations. The paths from O2 to D2 and from O1 to D2 are direct paths, and the path between O1 and D1 is not a direct path due to collision.

Due to the van der Waals force between an object and an obstacle, the object may be attracted to the obstacle if the distance between them is too small. Therefore, the minimum distance has to be determined first to avoid the attraction. Figure 53.4a shows a particle object and a particle obstacle, and Fig. 53.4b a particle object and a nanowire obstacle, respectively.

In the first case, all objects and obstacles are assumed to be spheres; the van der Waals force can be expressed as [53.42]

$$\boldsymbol{F}_{\mathrm{w}} = \frac{-A}{6D}\frac{R_1 R_2}{R_1+R_2}\,, \tag{53.1}$$

where $\boldsymbol{F}_{\mathrm{w}}$ is the van der Waals force, A is the Hamaker constant, D is the distance between the two spheres, and R_1 and R_2 are the radii of the two spheres. For the second case that the obstacle is a nanowire, the nanowire can be considered as separated nanoparticles, so the van der Waals force between a nanoparticle and each separated nanoparticles can be calculated using (53.1).

Different materials have different Hamaker constants. Nevertheless, the Hamaker constants are found to lie in the range $(0.4-4)\times 10^{-19}$ J [53.42]. If an object is not attracted to an obstacle, the van der Waals force between an object and a destination has to be balanced by the friction force between the object and the surface. The friction force between the object and the surface can be formulated as [53.43]

$$\boldsymbol{F}_{\mathrm{c}} = \mu_{\mathrm{os}}\boldsymbol{F}^{\mathrm{r}}_{\mathrm{os}} + \nu\boldsymbol{F}^{\mathrm{a}}_{\mathrm{os}}\,, \tag{53.2}$$

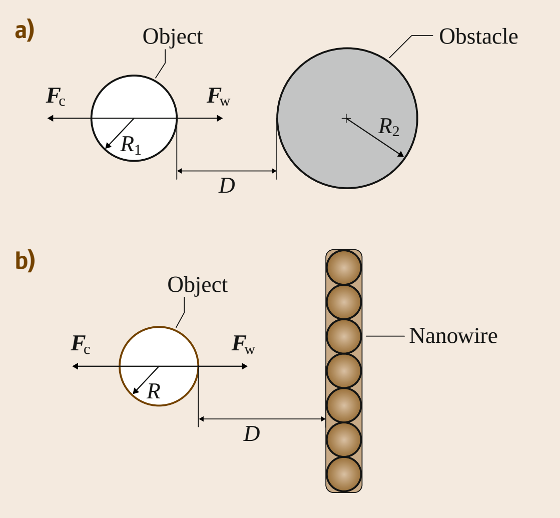

Fig. 53.4a,b The van der Waals force between objects and obstacles. The objects are nanoparticles. **(a)** The obstacle is a nanoparticle. R_1 and R_2 are the radius of the two spheres respectively, D is the distance between the two spheres, $\boldsymbol{F}_{\mathrm{w}}$ is the van der Waals force, and $\boldsymbol{F}_{\mathrm{c}}$ the friction force. **(b)** The obstacle is a nanowire. The nanowire can be considered as a line of nanoparticles. R is the radius of the sphere

where $\boldsymbol{F}_{\mathrm{c}}$ is the friction force, μ_{os} is the sliding friction coefficient between an object and the substrate surface, ν is the shear coefficient, $\boldsymbol{F}^{\mathrm{r}}_{\mathrm{os}}$ is the repulsive force, and $\boldsymbol{F}^{\mathrm{a}}_{\mathrm{os}}$ is the adhesive force. When pushing an object, the minimum repulsive force equals the adhesive force. Then (53.2) becomes

$$\boldsymbol{F}_{\mathrm{c}} = (\mu_{\mathrm{os}}+\nu)\boldsymbol{F}^{\mathrm{a}}_{\mathrm{os}}\,. \tag{53.3}$$

The adhesive force $\boldsymbol{F}^{\mathrm{a}}_{\mathrm{os}}$ can be estimated by [53.43]

$$\boldsymbol{F}^{\mathrm{a}}_{\mathrm{os}} = \frac{A_{\mathrm{os}}}{A_{\mathrm{ts}}}\boldsymbol{F}^{\mathrm{a}}_{\mathrm{ts}}\,, \tag{53.4}$$

where A_{os} is the nominal contact area between an object and a substrate surface, A_{ts} is the nominal contact area between the AFM tip and the substrate surface, and $\boldsymbol{F}^{\mathrm{a}}_{\mathrm{ts}}$ is the measured adhesive force between the AFM tip and the surface.

Since the van der Waals force must be balanced by the friction force during manipulation, the minimum distance D_{min} can be calculated using (53.1), (53.3) and (53.4)

$$D_{\mathrm{min}} = \frac{A}{6}\frac{R_1 R_2}{R_1+R_2}\frac{A_{\mathrm{ts}}}{(\mu_{\mathrm{os}}+\nu)A_{\mathrm{os}}F^{\mathrm{a}}_{\mathrm{ts}}}\,. \tag{53.5}$$

The distance between an object and a nanowire must be larger than D_{min} during manipulation. If there is an

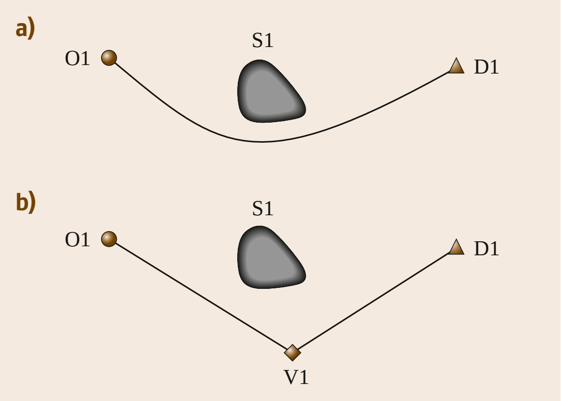

Fig. 53.5 **(a)** A path with turns. An object may be lost during turns. **(b)** A virtual object and destination (VOD) connects an object and a destination. O1 is an object, D1 is a destination, S1 is an obstacle, and V1 is a VOD

obstacle that is close or on the straight line, the path formed by the straight line is not considered as a direct path. For example, the path between O2 and D1 in Fig. 53.3 is not a direct path due to the attraction.

After the direct paths are generated, objects are assigned to the destinations one to one. There are some destinations that may not have any objects assigned to them. This is because there are no direct paths to some destinations. Therefore, indirect paths (curved paths) to avoid the obstacles must be generated. In general, it is possible to lose particles during nanomanipulation in both direct paths or curved paths, but a curved path as shown in Fig. 53.5 has a much higher risk of losing objects than a direct path. The AFM-based manipulation system can use force feedback to detect the lost particle during the manipulation. A surface must be scanned again if an object is lost during manipulation. Because the scanning time is much longer than the manipulation time, turns should be avoided during nanomanipulation. To solve the problem, a virtual-object-destination algorithm has been developed. Figure 53.6 shows a virtual-object-destination (VOD).

An object and a destination are connected using direct paths through a VOD. Since there are many possible VODs to connect an object and a destination, a minimum distance criterion is applied to find a VOD. The total distance to connect an object and a destination through a VOD is

$$\begin{aligned} d &= \sqrt{(x_2 - x_0)^2 + (y_2 - y_0)^2} \\ &\quad + \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2} \,, \end{aligned} \tag{53.6}$$

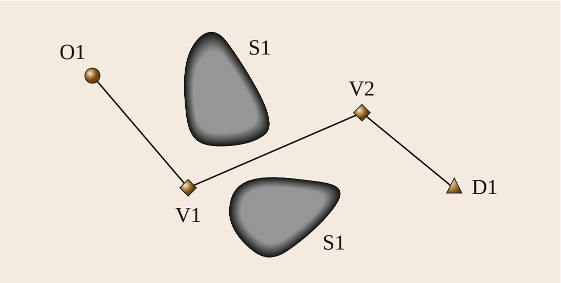

Fig. 53.6 Two VODs connect an object with a destination. O1 is an object, D1 is the destination, and S1 and S2 are obstacles

where x_2, y_2 are the coordinates of the center of a VOD, x_0, y_0 are the coordinates of the center of an object, and x_1, y_1 are the coordinates of the center of a destination.

The connections between the VOD, object and destination have to avoid the obstacles, i. e.,

$$\sqrt{(x - x_s)^2 + (y - y_s)^2} \geq D_{\min} + R' \,, \tag{53.7}$$

where x, y are the coordinates of the object center along the path and x_s, y_s are the coordinates of the center of the obstacle. R' is defined as

$$R' = R_1 + R_2 \,. \tag{53.8}$$

Then a constrained optimization problem is formulated

$$\begin{aligned} \min_{x_2, y_2} d &= \sqrt{(x_2 - x_0)^2 + (y_2 - y_0)^2} \\ &\quad + \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2} \,, \\ \text{subject to: } &\sqrt{(x - x_s)^2 + (y - y_s)^2} \geq D_{\min} + R' \,. \end{aligned} \tag{53.9}$$

This is a single objective constrained optimization problem. A quadratic loss penalty function method [53.44] is adopted to deal with the constrained optimization problem by formulating a new function $G(x)$

$$\min_{x_2, y_2} G(x) = \min_{x_2, y_2} d + \beta(\min[0, g])^2 \,, \tag{53.10}$$

where β is a big scalar and g is formulated using the given constraint, i. e.

$$g = \sqrt{(x - x_s)^2 + (y - y_s)^2} - (D_{\min} + R') \,. \tag{53.11}$$

Then the constrained optimization problem is transferred into an unconstrained one using the quadratic loss penalty function method. The pattern search method [53.45] is adopted here to optimize the unconstrained optimization problem to obtain the VOD.

If one virtual object and destination cannot reach an unassigned destination, two or more VODs must be found to connect an object and a destination. Figure 53.6 illustrates the process. Similarly, the total distance to connect the object and destination can be calculated. The constraint is the same as (53.9). Then, a single objective constrained optimization problem can be formulated to obtain the VODs.

Automated Manipulation of Nanowires

The manipulation of a nanowire is much more complicated than that of a nanoparticle because there is only translation during manipulation of a nanoparticle, while there are both translation and rotation during manipulation of a nanowire. A nanowire can only be manipulated to a desired position by applying force alternatively close to its ends. From an AFM image, nanowires can be identified and represented by their radius and two end points. Each end point on a nanowire must be assigned to the corresponding point on the destination. The starting pushing point is important since it determines the direction along which the object moves. By choosing a suitable step size, an AFM tip path can be generated. Therefore, the steps of automated manipulation of nanowire are: find the initial position and destination of a nanowire, find the corresponding points, find starting pushing point, and calculate the pushing step and plan the tip trajectory. The details of the steps are given below.

To automatically manipulate a nanowire, its behavior under a pushing force has to be modeled. When a pushing force is applied to a nanowire, the nanowire starts to rotate around a pivot if the pushing force is larger than the friction force. Figure 53.7 shows the applied pushing force and the pivot. The nanowire rotates around point D when it is pushed at point C by the AFM tip. The nanowire under pushing may have different kinds of behavior, which depend on its own geometry property. If the aspect ratio of a nanowire is defined as

$$\sigma = d/L \,. \tag{53.12}$$

A nanowire with the aspect ratio of $\sigma > 25$ usually behaves like a wire, which will deform or bend under pressure. The rotation behavior was observed for nanowires with aspect ratio of $\sigma < 15$. In this case, the pushing force $\boldsymbol{F}$ from the tip causes the friction and shear force $\boldsymbol{F}' = \mu_{\text{ot}}\boldsymbol{F} + \nu\boldsymbol{F}^{\text{a}}_{\text{ot}}$ along the rod axis direction when the pushing direction is not perpendicular to the rod axis, where μ_{ot} and ν are the friction and shear coefficients between the tip and the nanowire, which depend on the material properties and the environment, $\boldsymbol{F}^{\text{a}}_{\text{ot}}$ is the adhesion force between the tip and the nanowire.

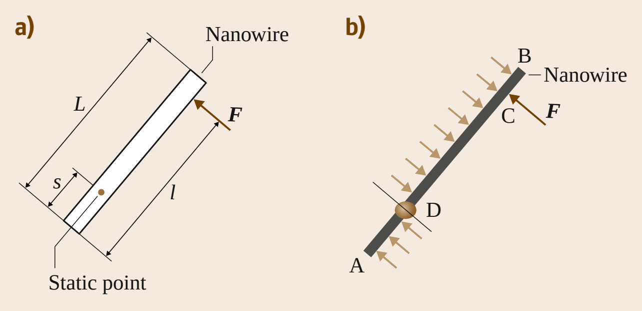

Fig. 53.7a,b The behavior of a nanowire under a pushing force: **(a)** F is the applied external force, L is the length of the nanowire **(b)** the detailed force model. D is the pivot where the nanowire rotates, C is the pushing point

Fortunately, it is easy to prove that the force $\boldsymbol{F}'$ hardly causes the rod to move along the rod axis direction. Assuming that the shear forces between rod and surface are equal along all directions during moving,

$$fL = f'_{\max} d \,. \tag{53.13}$$

Because the shear force is usually proportional to the contact area, and the contact area between a nanowire and surface is much greater than that between the tip and the nanowire,

$$\nu\boldsymbol{F}^{\text{a}}_{\text{ot}} \ll f'd \,. \tag{53.14}$$

Also note that

$$\boldsymbol{F} \le fL = f'_{\max} d \,, \tag{53.15}$$

and because μ is usually very small, finally it is reasonable to assume that

$$f'd = \boldsymbol{F}'\mu\boldsymbol{F} + \nu\boldsymbol{F}^{\text{a}}_{\text{ot}} < f'_{\max} d \,. \tag{53.16}$$

This means that the rod will have no motion along the axis direction and, therefore, the static point D must be on the axis of the nanowire. Considering the above analysis, the nanowire can be simplified as a rigid line segment. The external forces applied on the nanowire in surface plane can be modeled as shown in Fig. 53.7. The pivot D can be either inside the nanowire or outside the nanowire. First assume that D is inside the nanowire. In this case, all the torques around D are self-balanced during smooth motion.

$$\boldsymbol{F}(l-s) = \frac{1}{2} f(L-s)^2 + \frac{1}{2} fs^2 \,, \tag{53.17}$$

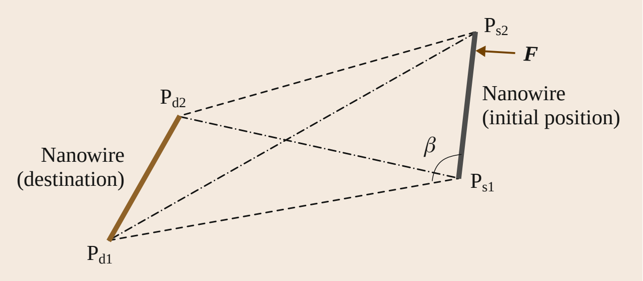

Fig. 53.8 The initial position of the nanowire and the destination where it is manipulated

where $\boldsymbol{F}$ is the applied external force, f is the evenly distributed friction and shear force density on the nanowire, L is the length of the nanowire, s is the distance from one end of the nanowire (point A in Fig. 53.7) to the pivot D, and l is the distance from A to C, where the external force is applied. Equation (53.17) can be written as

$$\boldsymbol{F} = \frac{f(L-s)^2 + fs^2}{2(l-s)} \,. \tag{53.18}$$

The pivot can be found by minimizing $\boldsymbol{F}$ with respect to s, i. e.

$$\frac{\mathrm{d}\boldsymbol{F}}{\mathrm{d}s} = 0 \quad \Rightarrow \quad s^2 - 2ls + lL - L^2/2 = 0 \,. \tag{53.19}$$

Since we have assumed that $0 < s < L$, a unique solution of the pivot for any $0 < l < L$ except $l = L/2$ can be determined by

$$s = \begin{cases} l + \sqrt{l^2 - lL + L^2/2} & l < L/2 \\ l - \sqrt{l^2 - lL + L^2/2} & l > L/2 \end{cases} \,. \tag{53.20}$$

When $l = L/2$, there is no unique solution. A detailed analysis will show that s can be any value when the force $\boldsymbol{F}$ is applied in the exact middle of the rod, the point T becomes a bifurcation point. Now, assume the static point D is outside of rod and on the left side. Noting that $s < 0$ now, the self-balanced torque equation becomes

$$f(l-s) = fL(L/2-s) \,, \tag{53.21}$$

namely

$$\boldsymbol{F} = \frac{fL(L/2-s)}{2(l-s)} \,. \tag{53.22}$$

It can be seen that $\boldsymbol{F}$ can only be minimized at $l = L/2$

$$\frac{\mathrm{d}\boldsymbol{F}}{\mathrm{d}s} = 0, \qquad \text{for} \quad l = L/2 \,. \tag{53.23}$$

Similarly, if static point D is on the right side ($s > 0$), the analysis results should be the same. Practically, it is hard to keep T at this bifurcation point ($l = L/2$). Therefore, during manipulation, it is better to avoid pushing the exact middle of the rod because it is hard to predict the behavior of the rod in this case.

The corresponding points between a nanowire and its destination have to be matched in order to plan a manipulation path. Figure 53.8 shows the initial position and the destination of a nanowire. P$_{s1}$ and P$_{s2}$ are the initial positions, and P$_{d1}$ and P$_{d2}$ are the destinations.

The nanowire rotates anti-clockwise and moves downward if the starting pushing point is close to P$_{s2}$. Similarly, the nanowire rotates clockwise and moves upward if the starting pushing point is close to P$_{s1}$. The starting pushing point can be determined by the angle β as shown in Fig. 53.8. If $\beta > 90°$, the starting pushing point should be close to P$_{s2}$. Otherwise, P$_{s1}$. Figure 53.9 shows the process to manipulate a nanowire from its initial position to its destination. The manipulation scheme of a nanowire has to go through a zigzag strategy in order to position the nanowire with specified orientation.

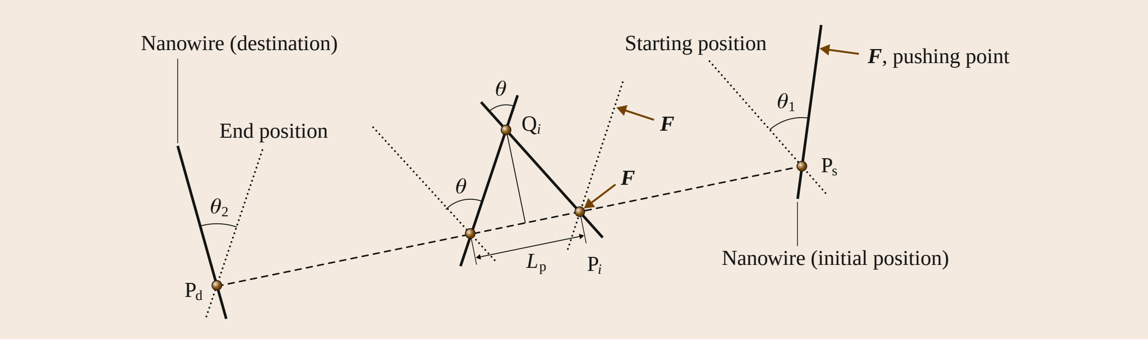

Fig. 53.9 The manipulation of a nanowire from an initial position to its destination

When the alternating pushing forces at two points on the nanowire are applied, a nanowire rotates around two pivots P_i and Q_i. The distance L_1 between P_i and Q_i can be calculated if the pushing points are determined. The two pivots P_s and P_d are connected to form a straight line, and the distance d between the two points is calculated. d is then divided into N small segments (the number of manipulations). Then L_p in Fig. 53.9 can be obtained

$$L_\mathrm{p} = \frac{d}{N}, \qquad 0 < L_\mathrm{p} < 2L_1 . \tag{53.24}$$

During manipulation, the pivot P_i is always on the line generated by the two points P_s and P_d. Then the rotation angle for each step can be obtained

$$\theta = 2a\cos\left(\frac{L_\mathrm{p}}{2L_1}\right) . \tag{53.25}$$

The rotation angle θ stays the same during manipulation. The initial pushing angle θ_1 and the final pushing angle θ_2 in Fig. 53.9 can be calculated by finding the starting position and the ending position. After θ is determined, the pivots P_i and Q_i $(i = 1, \ldots, N)$ can be calculated. The pushing points can then be determined. Here we show how to determine the pushing points when a nanowire rotates around the pivot P_i as an example. Figure 53.10 shows the frames used to determine the tip position.

The following transformation matrix can be easily calculated. The transformation matrix of the frame originated at P_s relative to the original frame is $\mathbf{T}_s$. The transformation matrix of the frame originated at P_i relative to the frame originated at P_s is $\mathbf{T}_i$. Supposing the rotation angle is $\beta(0 < \beta \le \theta)$, the transformation matrix relative to the frame originated at P_i is $\mathbf{T}_{\beta i}$. β can be obtained by setting a manipulation step size. The coordinates of the pushing point can then be calculated

$$\begin{pmatrix} X_F \\ Y_F \\ 1 \end{pmatrix} = \mathbf{T}_s \mathbf{T}_i \mathbf{T}_{\beta i} \begin{pmatrix} 0 \\ L - 2s \\ 1 \end{pmatrix} . \tag{53.26}$$

Similar steps can be followed to determine the pushing position for a nanowire rotating around the pivot Q_i, $i \in [1, N]$. After the coordinates of the pushing point are obtained, the manipulation path for a nanowire can be generated.

53.2.3 Automated Local Scanning Method for Nanomanipulation Automation

The random drift due to thermal extension or contraction causes a major problem during nanomanipulation, because the object may be easily lost or manipulated to wrong destinations. Before the manipulation, the objects on the surface are identified and their positions are labeled. However, the labeled positions of the nanoobjects have errors due to random drift. To compensate for the random drift, the actual position of each nanoobject must be identified before each operation. Because the time to scan a big area is quite long, a quick local scanning mechanism is developed to obtain the actual position of each nanoobject in a short time. Nanomanipulation is then performed immediately after the local scan. Figure 53.11 shows the local scanning method.

From the path data, the original position of a nanoobject is obtained. Also, the nanoobject is categorized into two groups: the nanoparticle and nanowire. A scanning pattern is generated for the nanoobject according to its group. The scanning pattern is fed to the imaging interface to scan the surface. If the nanoob-

P$_1$ and P$_2$ are the interactions between the particle edge and a horizontal scan line, Q$_1$ and Q$_2$ are the intersections between the particle edge and the vertical scan line

ject is not found, a new scanning pattern is generated. The process continues until the nanoobject is discovered. The actual position of the nanoobject can then be computed. The manipulation path is then adjusted based on the actual position. For nanoparticles and nanoobjects, different scanning patterns must be used in order to obtain their actual position.

For example, the location of a nanoparticle can be represented by its center and radius. The radius of each particle R has been identified before the manipulation starts. The actual center of a nanoparticle can be relocated by two lines, a lateral and a cross line as shown in Fig. 53.12. First, the nanoparticle is scanned using line L_0, which passes the original center of the particle in the image. If the particle is not found, then the scanning line moves up and down alternatively by a distance of $3/2R$. Once the particle has been found, two intersection points, P$_1$ and P$_2$ between the particle edge and the lateral line are located. A cross line scan V, which goes through the middle point between P$_1$ and P$_2$, is used to locate the center of the particle. The cross scan line has two intersection points, Q$_1$ and Q$_2$, with the particle edge. The middle point between Q$_1$ and Q$_2$ is the actual center of the nanoparticle. The local scanning range (the length of the scanning line) l can be determine by the maximum random drift such that $l > R+r_{\max}$, where $r_{\max}$ is the estimated maximum random drift distance.

After the center of a nanoobject has been identified, the drifts in the XY directions are calculated. The drifts in the XY directions are then used to update the destination position as shown in Fig. 53.13a. Finally a new path is generated to manipulate the nanoparticle.

After the local scan of the first nanoparticle, the direction and size of the drift can be estimated. The information can be used to generate the scanning pattern for the next nanoobject as shown in Fig. 53.13b.

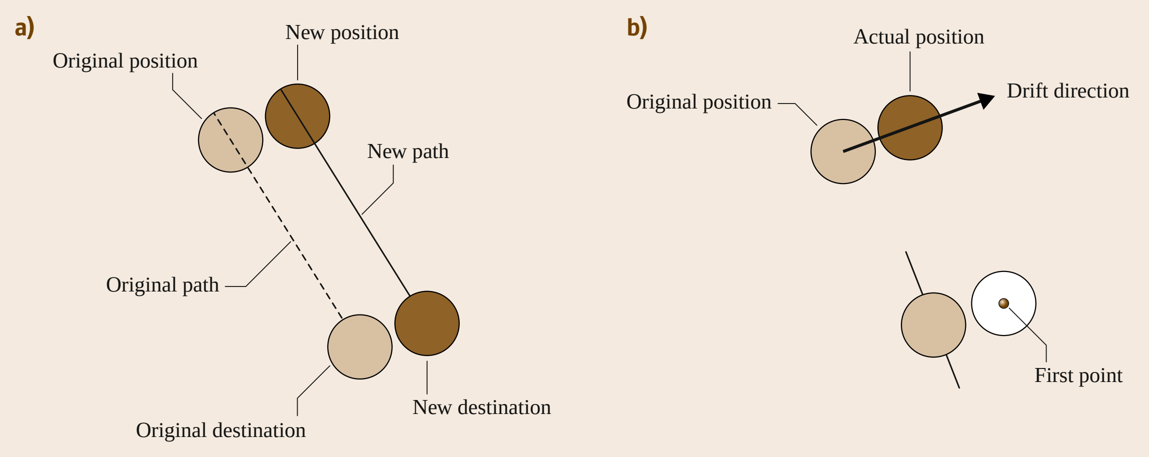

Fig. 53.13 **(a)** The updated path after drift compensation. **(b)** The local scan after the drift direction and size are determined from the previous local scan

53.2.4 CAD Guided Automated Nanoassembly

In order to increase the efficiency and accuracy of AFM-based nanoassembly, automated CAD guided nanoassembly is desirable. A general framework for automated nanoassembly is developed to manufacture nanostructures and nanodevices, as illustrated in Fig. 53.14. Based on the CAD model of a nanostructure and the distribution of nanoobjects on a surface from an AFM image, the tip path planner generates manipulation paths to manipulate the nanoobjects. The paths are fed to a user interface to simulate the manufacturing process and then to the AFM system to perform the nanoassembly process.

The AFM tip path planner is the core of the general framework. Figure 53.15 shows the architecture of the tip path planner. Nanoobjects on a surface are first identified based on the AFM image. A nanostructure is then designed using the available nanoobjects. Initial collision-free manipulation paths are then generated based on the CAD model of a designed nanostructure. In order to overcome the random drift, a local scanning method is applied to identify the actual position of a nanoobject before its manipulation. Each manipulation path of the nanoobject is adjusted accordingly based on its actual position. The regenerated path is then sent to the AFM system to manipulate the nanoobject. The process continues until all nanoobjects are processed. A nanostructure is finally fabricated.

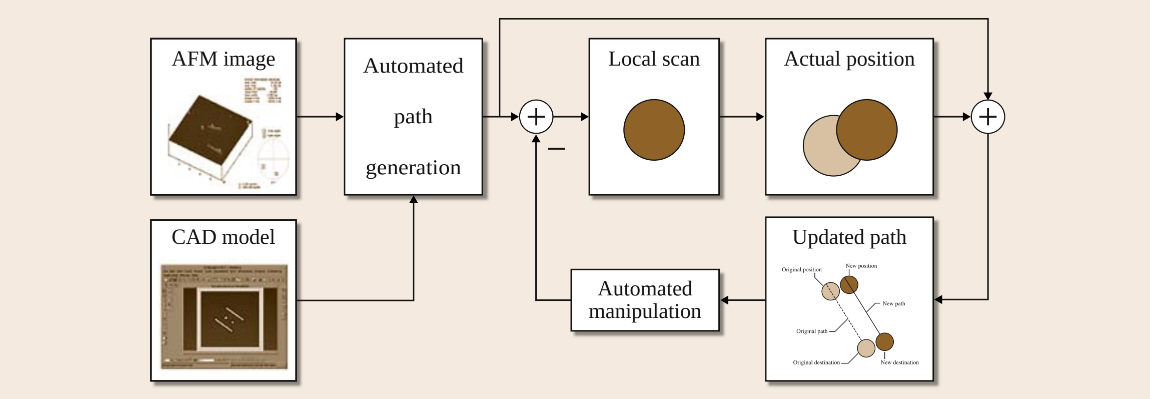

Fig. 53.15 Automated tip path planner. Initial paths are generated based on the CAD model of a designed nanostructure and the randomly distributed nanoobjects on a surface. The manipulation path of each nanoobject is adjusted accordingly based on the local scanning result

53.3 Nanomanufacturing Processes

The nanomanufacturing process for nanodevices is not straightforward, especially in nanomaterial preparation, selection, and deposition processes. To prepare the nanomaterial, nanoobjects are usually dissolved into solution, then the nanoobject suspension is put in an ultrasonicator or a centrifuge for dispersing the nanoobjects. Afterwards, specific properties of the nanoobjects should be selected. Finally, they are delivered to assemble the nanodevices. However, the nanoobjects are too small to be manipulated by traditional robotic systems, novel devices and systems must be developed for this. Since the nanoobjects are dissolved into fluids, dielectrophoresis and microfluidic technology can be considered to perform the tasks. The material preparation can be done by micromixers; the selection process can be done by microfilters; and the deposition process can be done by integrating the microchannel and microactive nozzle to deposit the nanoobject suspension. CNT is one of the most common nanoobjects and it has some promising properties that are useful for generation nanodevices. In this chapter, the development of a novel automated CNT separation system to classify the electronic types of CNTs will be described, which involves the analysis for DEP force on CNTs and fabrication of a DEP microchamber. Moreover, this DEP microchamber was successfully integrated into an automated deposition workstation to manipulate a single CNT to multiple pairs of microelectrodes repeatedly. The automated deposition processes for both SWCNTs and MWCNTs will be presented. As a result, CNT-based nanodevices with specific and consistent electronic properties can be manufactured automatically. The resulting devices can potentially be used in commercial applications.

53.3.1 Dielectrophoretic Force on Nanoobjects

Dielectrophoresis has been used to manipulate and separate different types of biological cells. DEP forces can be combined with field-flow fractionation for simultaneous separation and measurement [53.46]. DEP force induces movement of a particle or a nanoobject under non-uniform electric fields in liquid medium as shown in Fig. 53.16. The nanoobject is polarized when it is subjected to an electric field. The movement of the nanoobject depends on its polarization with respect to the surrounding medium [53.47]. When the nanoobject is more polarizable than the medium, a net dipole is induced parallel to the electric field in the nanoobject and, therefore, the nanoobject is attracted to the high electric field region. On the contrary, an opposite net dipole is induced when the nanoobject is less polarizable than the medium, and the nanoobject is repelled by the high electric field region. The direction of the DEP force on the particle is given by the Clausius–Mossotti factor (CM factor, K). It is defined as a complex factor, describing a relaxation in the effective permittivity of the particle with a relaxation time described by [53.47, 48]

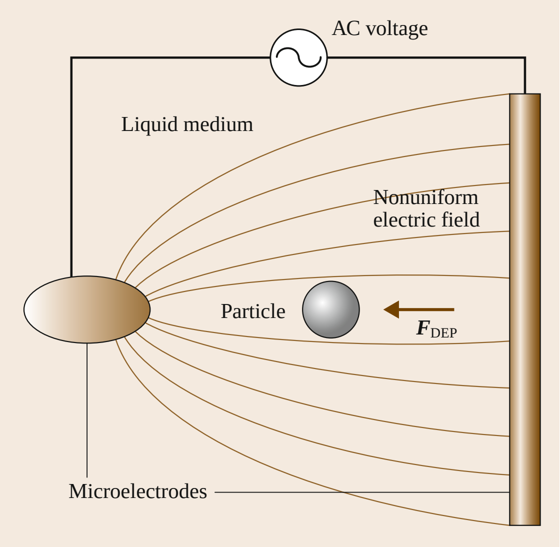

Fig. 53.16 Illustration of the dielectrophoretic manipulation

$$K(\varepsilon_p^*, \varepsilon_m^*) = \frac{\varepsilon_p^* - \varepsilon_m^*}{\varepsilon_p^* + 2\varepsilon_m^*} \,. \tag{53.27}$$

Complex permittivities of the nanoobject (ε_p^*) and medium (ε_m^*) are defined and given by [53.47, 48]

$$\varepsilon_p^* = \varepsilon_p - i\frac{\sigma_p}{\omega} \,, \tag{53.28}$$

$$\varepsilon_m^* = \varepsilon_m - i\frac{\sigma_m}{\omega} \,, \tag{53.29}$$

where ε_p and ε_m are the real permittivities of the nanoobject and the medium, respectively, σ_p and σ_m are the conductivities of the nanoobject and the medium, respectively, and ω is the angular frequency of the applied electric field; the CM factor is frequency-dependent. The time-averaged DEP force acting on the particle is given by [53.47, 48]

$$F_{\text{DEP}} = \frac{1}{2} V \varepsilon_m \text{Re}(K) \nabla \mid E \mid^2 \,, \tag{53.30}$$

where V is the volume of the nanoobject and $\nabla \mid E \mid^2$ is the root-mean-square of the applied electric field. Based on this equation, the direction of the DEP force is determined by the real part of the CM factor K. When $\text{Re}[K] > 0$, the DEP force is positive, and therefore the CNT is moved toward the microelectrode in the high electric field region. When $\text{Re}[K] < 0$, the DEP force is negative, the particle is repelled away from the microelectrode. Moreover, we know that the magnitude and direction of DEP forces depends on the size and material properties of the nanoobjects, so separation of nanoobjects can be done.

53.3.2 Separating CNTs by an Electronic Property Using the Dielectrophoretic Effect

A theoretical analysis of DEP manipulation on a CNT was performed, and CM factors were calculated for a metallic SWCNT (m-SWCNT) and a semiconducting MWCNTs (s-SWCNT), respectively. In the analysis, semiconducting and metallic CNT mixtures are dispersed in the alcohol medium assuming the permittivities of a s-SWCNT and a m-SWCNT are $5\varepsilon_0$ [53.32] and $10^4\varepsilon_0$ [53.37], respectively, where ε_0 is the permittivity of free space ($\varepsilon_0 = 8.854188 \times 10^{-12}$ F/m). The conductivities of a s-SWCNT and a m-SWCNT are 10^5 S/m and 10^8 S/m [53.37], respectively. The permittivity and conductivity of the alcohol are $20\varepsilon_0$ and $0.13\,\mu$S/m, respectively. Based on these parameters and (53.27), plots of Re[K] for different CNTs are obtained and shown in Fig. 53.17. The result indicated that s-SWCNTs undergo a positive DEP force at low frequencies (<1 MHz) while the DEP force is negative when the applied frequency is larger than 10 MHz. However, m-SWCNTs always undergo a positive DEP force at the applied frequency from 10 to 10^9 Hz. The result also matched the experimental result from [53.33], which showed that the positive DEP effect on SWCNTs reduced as the frequency of applied electric field increased. In addition, the theoretical result provides a better understanding of DEP manipulation on different types of CNTs. DEP force can be used to separate and identify different electronic types of CNTs (metallic and semiconducting). Based on the result shown in Fig. 53.17, metallic CNTs can be selectively attracted to the microelectrodes by applying AC voltage in the high frequency range (>10 MHz). However, semiconducting CNTs cannot be attracted by using the same frequency range; this makes the selection of semiconducting CNTs difficult. In order to select semiconducting CNTs to make nanodevices, we fabricated a microchamber (DEP chamber) with arrays of microelectrodes to filter metallic CNTs in the medium. Design and fabrication of the DEP chamber will be discussed in the next section.

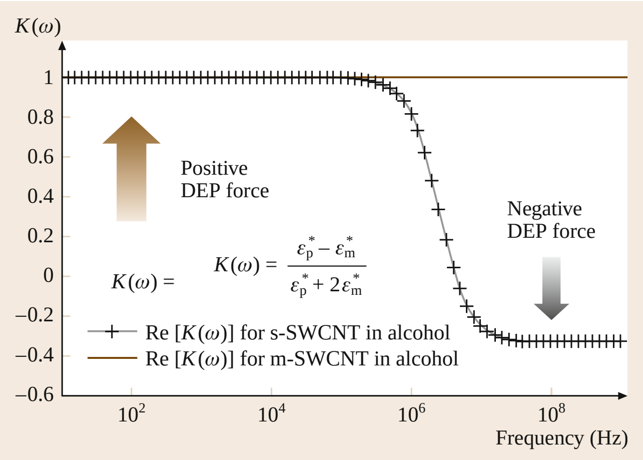

Fig. 53.17 Plots of Re[$K(\omega)$] that indicated positive and negative DEP forces on different CNTs

53.3.3 DEP Microchamber for Separating CNTs

A DEP microchamber was designed and fabricated to filter metallic CNTs in CNT suspension as shown in Fig. 53.18. Many finger-like gold microelectrodes were first fabricated inside the chamber. The performance of the filtering process was affected by the design of these finger-like microelectrodes; the microelectrode

Fig. 53.18a,b DEP microchamber to filter metallic CNT. Metallic CNTs are attracted on microelectrodes. Only semiconducting CNTs flow to the outlet. **(a)** Side view; **(b)** top view structure with higher density induced a stronger DEP force such that more CNTs could be attracted to the microelectrodes. The gap distance between these microelectrodes is 5–10 μm. The micropump pumped the CNT suspension to the DEP chamber; a high frequency AC voltage was applied to the finger-like microelectrodes so that metallic CNTs were attracted to them and stayed in the DEP chamber. Semiconducting CNTs remained in the suspension and flowed out of the chamber. Finally, the filtered suspension (with semiconducting CNTs only) was transferred to an active nozzle for the CNT deposition process. This will be described in the next section.

The fabrication process of the DEP microchamber is shown in Fig. 53.19. It was composed of two different substrates. Polymethylmethacrylate (PMMA) was used as the top substrate because it is electrically and thermally insulating, optically transparent, and biocompatible. By using a hot embossing technique, the PMMA substrate was patterned with a microchannel (5 mm L × 1 mm W × 500 μm H) and a microchamber (1 cm L × 5 mm W × 500 μm H) by replicating from a fabricated metal mold. In order to protect the PMMA substrate from the CNTs-alcohol suspension, a parylene C thin film layer was coated on the substrate, because parylene resists chemical attack and is insoluble in all organic solvents. Alternatively, quartz was used as the bottom substrate, and arrays of the gold microelectrodes were fabricated on the substrate by using a standard photolithography process. A layer of AZ5214E photoresist with thickness of 1.5 μm was first spun onto the 2″ × 1″ quartz substrate. It was then patterned by AB-M mask aligner and developed in an AZ300 developer. A layer of titanium with a thickness of 3 nm was deposited by thermal evaporator followed by depositing a layer of gold with thickness of 30 nm. The titanium provided a better adhesion between gold and quartz. Afterwards, photoresist was removed in acetone solution, and arrays of microelectrodes were formed on the substrate. Finally, PMMA and quartz substrate were bonded together by UV-glue to form a close chamber. The fittings were connected at the ends of the channel to form an inlet and an outlet for the DEP chamber.

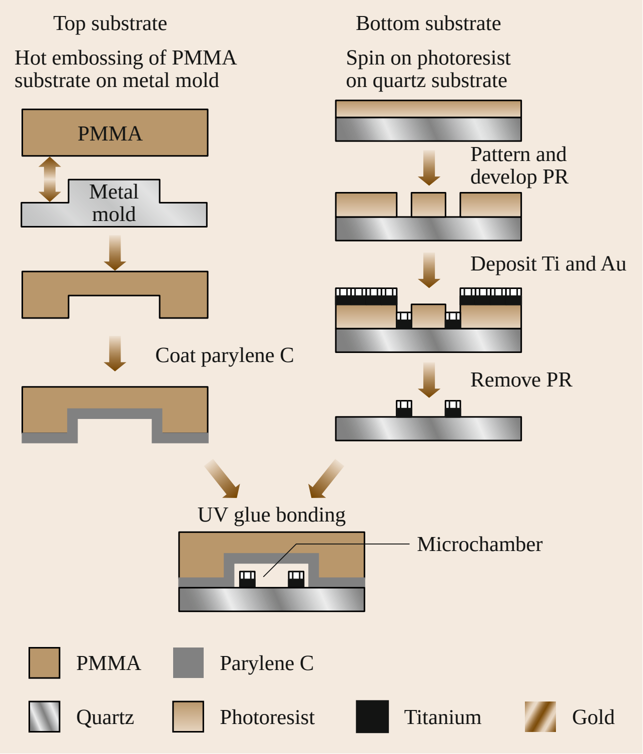

Fig. 53.19 The fabrication process of a DEP microchamber

The separation performance of the DEP chamber should be optimized for different nanoobjects. Several parameters should be considered in the process: the concentration of nanoobjects in the suspension, the strength of the DEP force, the flow rate of the suspension in the DEP chamber, the structure of the channel, and the microelectrodes of the DEP chamber.

53.3.4 Automated Robotic CNT Deposition Workstation

In order to manipulate a specific type of CNTs precisely and fabricate the CNT-based nanodevices effectively, a new CNT deposition workstation has been developed as shown in Fig. 53.20. The system consists of a microactive nozzle, a DEP microchamber, a DC microdiaphragm pump, and three micromanipulators. By integrating these components into the deposition workstation, a specific type of CNT can be deposited to the desired position of the microelectrodes precisely and automatically. The micron-sized active nozzle with a diameter of 10 μm was fabricated from a micropipette using a mechanical puller and is shown in Fig. 53.21. It transferred the CNT suspension to the microelectrodes on a microchip, and a small droplet of the CNT suspension (about 400 μm) was deposited on the microchip due to the small diameter of the active nozzle. The volume of the droplet is critical because excessive CNT suspension easily causes the formation of multiple CNTs. The microactive nozzle was then con-

nected to the DEP chamber, which was designed to filter metallic CNTs and select semiconducting CNTs in the CNT suspension. The raw CNT suspension was firstly pumped to the DEP chamber through a DC microdiaphragm pump (NF10, KNF Neuberger, Inc.). After the filtering process, the CNT suspension from the DEP chamber was delivered to the active nozzle for CNT deposition. By mounting the active nozzle to one of the computer controllable micromanipulators (CAP945, Signatone Corp.), the active nozzle could be moved to the desired position of the microelectrodes automatically. In order to apply the electric field to the microelectrodes during the deposition process, the other pair of micromanipulators was connected to an electrical circuit and moved to the desired location of the microelectrodes; therefore, AC voltage with different magnitudes and frequencies could be applied.

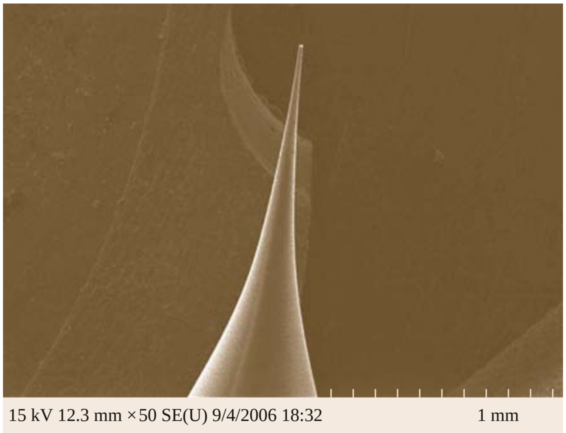

Fig. 53.21 SEM image of the micro active nozzle with 10 µm tip diameter

The micromanipulators, DC microdiaphragm pump, and electrical circuit were connected to the computer and controlled simultaneously during the deposition process. By controlling the position of the micromanipulators, the magnitude and frequency of the applied AC voltage, and the flow rate of the micropump, the CNT suspension can be handled automatically and deposited to the desired position.

In the deposition process, AC voltage of 1.5 V peak-to-peak with frequency of 1 kHz was applied; a positive DEP force was induced to attract CNTs to the microelectrodes. CNT deposition on multiple pairs of microelectrodes was implemented by controlling the movement of the micromanipulator, which was connected with the active nozzle. Since the position of each pair of the microelectrodes was known from the design CAD file, distances (along *x* and *y* axes) between each pair of microelectrodes were then calculated and recorded in the deposition system. At the start, the active nozzle was aligned to the first pair of the microelectrodes as shown in Fig. 53.22a. The position of the active nozzle tip was 2 mm above the microchip. When the deposition process started, the active nozzle moved down 2 mm and a droplet of CNT suspension was deposited on the first pair of microelectrodes as shown in Fig. 53.22b. Afterwards, the active nozzle moved up 2 mm and traveled to the next pair of microelectrodes as shown in Fig. 53.22c. The micromanipulator moved down again to deposit the CNT suspension on the second pair of microelectrodes as shown in Fig. 53.22d. This process repeated continuously until CNT suspension was deposited on each pair of microelectrodes on the microchip. By activating the AC voltage simultaneously, a CNT was attracted and connected between each pair of microelectrodes. The activation time was short

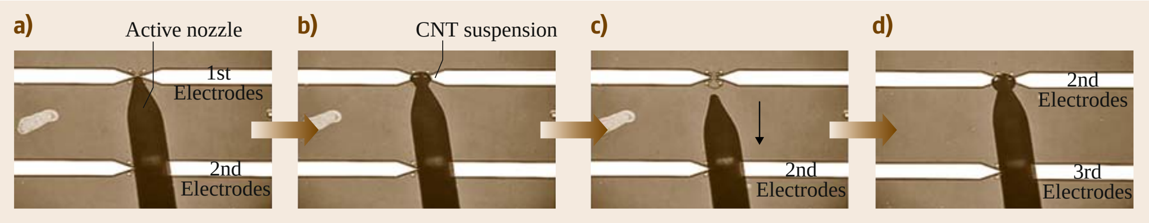

Fig. 53.22a–d CNT deposition process flow observed under the optical microscope. **(a)** The active nozzle tip aligned to the initial electrodes, **(b)** CNT suspension deposited, **(c)** the nozzle was moving to next electrodes, and **(d)** CNT suspension deposited on the second electrodes

(≈ 2 s) to avoid the formation of bundled CNTs on the microelectrodes.

After the deposition process, AFM was used to check the CNT formation as shown in Fig. 53.23. Sometimes, there are some impurities or more than one CNT trapped between the microelectrodes as shown in Fig. 53.23f. Therefore, it is necessary to take another step to clean up the microelectrodes gap area and adjust the position of the CNT to make the connection. This final step is very critical and is termed CNT assembly; it can be done by our AFM-based nanomanipulation system. I–V characteristics of the CNT-based devices were also obtained as shown in the inset images of Fig. 53.23. Based on the results, this indicates that both SWCNTs and MWCNTs could be repeatedly and automatically manipulated between the microelectrodes by using the deposition system. This CNT deposition workstation integrates all essential components to manipulate the specific type of CNTs to desired positions precisely by DEP force. The development of this system produces benefits to the assembling and manufacturing of CNT-based devices. The yield of depositing CNTs on the microelectrodes is very high after optimizing the following factors: the concentration of the CNT suspension, the volume of the CNT suspension droplet, and the activation time, magnitude and frequency of the applied electric field.

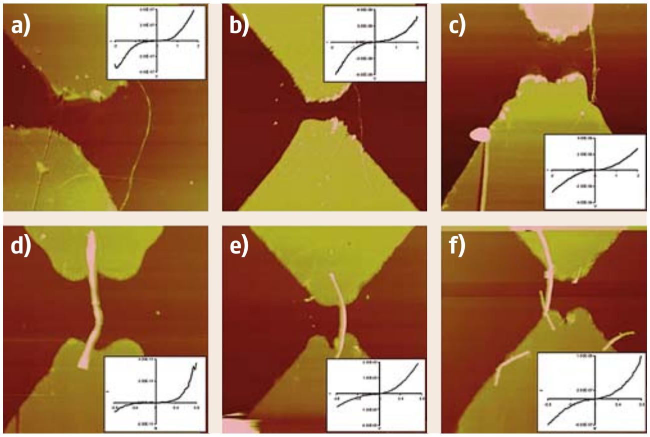

Fig. 53.23a–f AFM images showing the individual CNTs was deposited on the microelectrodes. Panels **(a–c)** are SWCNTs, panels **(d–f)** are MWCNTs. The *inset images* are the corresponding I–V curves of each CNT

In order to validate the separation performance of different CNTs by the DEP chamber, experiments for both raw CNT suspension (before passing through the DEP chamber) and filtered CNT suspension were conducted, respectively. The procedure for preparing the CNT suspension was the same as the process presented in the previous section. SWCNT powder (BU-203, Bucky USA, Nanotex Corp.) was dispersed in an alcohol liquid medium, and the CNT suspension was put in the ultrasonicator for 15 min. The length of the SWCNT is 0.5–4 μm. Finally, the raw SWCNT suspension was prepared and the concentration was about 1.1 μg/ml. Afterwards, the separation process was performed on the raw SWCNT suspension as illustrated in Fig. 53.24. During the process, the raw SWCNT suspension was pumped to the DEP chamber through the micropump. The flow rate was about 0.03 l/min. A high frequency AC voltage (1.5 Vpp, 40 MHz) was applied to the microelectrodes in the DEP chamber; it induced a positive DEP force on metallic SWCNTs in the suspension but a negative DEP force on semiconducting SWCNTs. Since the metallic SWCNTs were attracted to the microelectrodes and stayed in the DEP chamber, it was predicted that only semiconducting SWCNTs remained in the filtered SWCNT suspension. The filtered SWCNT suspension was then collected at the outlet of the chamber for later CNT disposition process.

After preparing the raw and filtered SWCNT suspension, the deposition process was performed by using our CNT deposition workstation, which was intro-

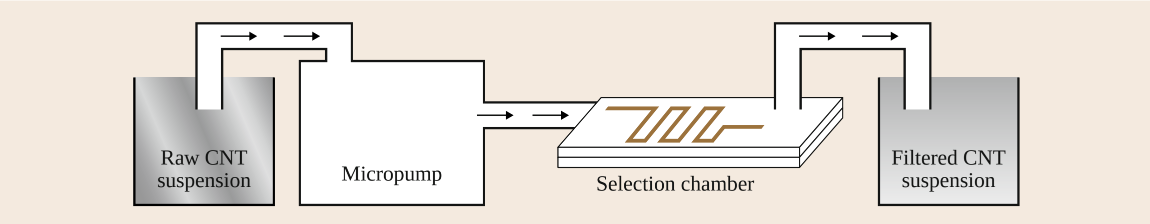

Fig. 53.24 The CNT filtering process

duced in the previous section. In the experiment, the raw SWCNT suspension and the filtered SWCNT suspension were deposited on the microchip 20 times, respectively. The electronic properties of CNTs in both suspensions were then studied by measuring the *I*–*V* curves. The yields to obtain semiconducting CNTs from the raw CNT suspension and filtered CNT suspension were also compared. Based on the preliminary results, the yield of depositing semiconducting SWCNTs (from the raw SWCNT suspension) was about 33% as shown in Fig. 53.25; the yield of depositing semiconducting SWCNTs (from the filtered SWCNT suspension) was about 65% as shown in Fig. 53.25. The yield to form semiconducting CNTs is very important because many devices require materials with semiconducting properties. The results indicated that there was significant improvement in forming semiconducting CNTs on the microelectrodes by using our DEP chamber. The yield in forming semiconducting CNTs changed from 33% (before the filtering process) to 65% (after the filtering process). The yield should be improved by optimizing the concentration of CNT suspension, the strength of the DEP force, the flow rate of the suspension in the DEP chamber, the structure of the channel, and the microelectrodes of the DEP chamber.

The yield to form semiconducting CNTs is very important because it affects the successful rate to fabricate nanodevices. The yield to form semiconducting CNTs was increased by using our system. Although there is a synthesis that produces nearly 90% of semiconducting CNTs by PECVD [53.49], both CNT synthesis methods and post-processing separation methods are important and can be combined for different applications. Our separation system is a post-processing method, which can be used together with different CNT synthesis methods. Since our system used electrical signal to control the

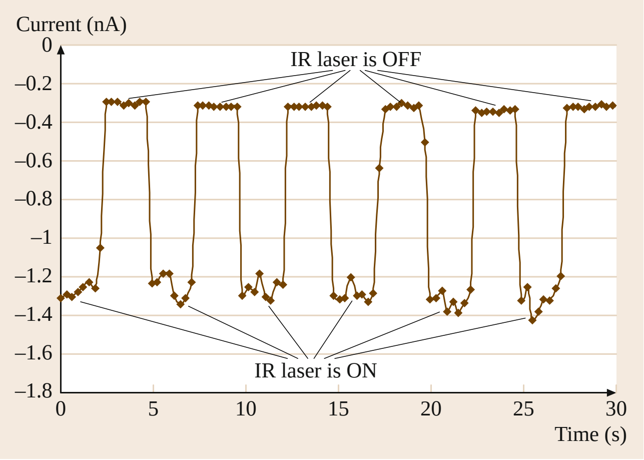

Fig. 53.26 Temporal photoresponses of a CNT-based IR detector

DEP manipulation and separation, it can be integrated with current robotic manufacturing systems easily, and eventually the process can be operated automatically and precisely. As a result, batch nanomanufacturing of nanodevices can be achieved by this system.

53.3.5 CNT-Based Infrared Detector

When semiconducting CNTs are deposited on the microelectrodes, the photonic effects of the CNT-based nanodevice can be studied. For example, a CNT device was put under the infrared (IR) laser source (UH5-30G-830-PV, World Star Tech, optical power: 30 mW; wavelength: 830 nm), and the photocurrent from the CNT-based nanodevice was measured. The laser source was configured to switch on and off in several cycles; the temporal photoresponses of the device are shown in Fig. 53.26. The experimental result showed the CNT-based device was sensitive to the IR laser, so CNTs can be used to make novel IR detectors. More detail design and fabrication of CNT-based IR detectors are given in [53.50–52]

53.4 Conclusions

Automated nanomanipulation is desirable to increase the efficiency and accuracy of nanoassembly. Automated nanoassembly of nanostructures is very challenging because of the manipulation path generation for different nanoobjects, position errors due to random drift, and cantilever deformation during nanomanipulation. This chapter discussed automated nanomanipulation technology for nanoassembly. Automated nanomanipulation methods of nanoobjects were developed, and an automated local scanning method was presented to compensate for the random drift. A CAD guided automated nanoassembly method was developed. CAD guided automated nanoassembly was able to open a door to assembly of complex nanostructures and nanodevices. The effectiveness of the system has also been verified by inscribing nano features on soft surface, manipulating nanoparticles DNA molecules and characterization of biological samples [53.53–56]. Moreover, CNT separation by a DEP chamber and the development of an automated CNT deposition workstation that applies DEP manipulation on CNTs were presented. The system assembles semiconducting CNTs to the microelectrodes effectively and, therefore, it is possible to improve the success rate to fabricate nanodevices. The separation method developed in this paper is a post-processing method, which can be used together with different CNT synthesis methods. Since our system used electrical signals to control CNT separation and DEP manipulation, it can be integrated into current robotic manufacturing systems easily, and eventually it will be possible to operate the process automatically and precisely. It opens the possibility of batch fabricating CNT-based devices. Furthermore, the nanomanufacturing process is not limited to CNTs, but it can be used on other nano materials such as ZnO and InSb nanowires etc. The development of the nanomanufacturing process will achieve different novel nano devices effectively.

54. Production, Supply, Logistics and Distribution

Rodrigo J. Cruz Di Palma, Manuel Scavarda Basaldúa

To effectively manage a supply chain it is necessary to coordinate the flow of materials and information both within and among companies. This flow goes from suppliers to consumers, as it passes through manufacturers, wholesalers, and retailers. While materials and information move through the supply chain, automation is used in a variety of forms and levels as a way to raise productivity, enhance product quality, decrease labor costs, improve safety, and even to perform tasks that go beyond the precision and reliability of humans. A rapid development in information technology has transformed not only the way people work and interact with each other; electronic media enable enterprises to collaborate on their work and missions within each organization and with other independent enterprises, including suppliers and customers.

Within this chapter, the focus is on the main benefits of automation in production, supply, logistics, and distribution environments. The first Section centers on machines and equipment automation for production. The second section focuses on computing/communication automation for planning and operations decisions. Finally, the last section highlights some considerations regarding economics, productivity, and flexibility important to bear in mind while designing an automation strategy.

54.1 Historical Background

Automation is any technique, method or system of operating or controlling a process without continuous input from an operator, thereby reducing human intervention to a minimum. Many believe that automation of supply chain networks began with the use of personal computers in the late 1970s, while others date it back to the use of electricity in the early 1900s. The fact is that, regardless of when we place the beginning of automation, it has changed the way we work, think, and live our lives. Children are now in contact with automation from the day they are born, such as automated machines that monitor the vital signs of premature infants. As people grow older, they continually have contact with automation via automatic teller machines (ATMs),

Table 54.1 Supply chain evolution at a food-products production and service company

	Before supply chain	After supply chain design	Advantages
Forecasting/ ordering	The company determines the amount of nuts that a customer will expect in its food products.	The company and its customer share sales forecasts based on current point-of-sale data, past demand patterns, and upcoming promotions, and agree on an amount and schedule to supply.	Forecasting accuracy, collaborative replenishment planning
Procurement	The company phones its Brazilian office and employees deliver the orders in person to local farmers, who load the raw nuts on trucks and deliver them to the port.	The company contacts its Brazilian office by email, but employees still must contact local farmers personally.	Enhanced communication
Transportation	The shipping company notifies the company when the nuts have sailed. When the nuts arrive in a US port, a freight-forwarder processes the paperwork to clear the shipment through customs, locates a truck to deliver them to the company plants, and delivers the nuts to the company's manufacturing plant, although it may be only half-full and return empty, costing the company extra money.	Shippers and truckers share up-to-date data online via a collaborative global logistics system that connects multiple manufacturers and transportation companies and handles the customs' process. The system matches orders with carriers to assure that trucks travel with full loads.	Online tracking, transportation cost minimization
Manufacturing	The nuts are cleaned, roasted, and integrated with various food products manufactured by the company according to original production forecast.	Production forecast is updated based on the current demand for product mix, and products are manufactured under lean manufacturing and just-in-time principles.	Capacity utilization, production efficiency
Distribution	The products are packed, and trucks take them to the company's multiple warehouses across the country, from where they are ready to be shipped to stores. However, they may not be near the store where the customer needs them because local demand has not been considered.	After food products are inspected and packed at the plant, the company sends the products to a third-party distributor, which relieves the company of a supply chain activity not among its core competencies. The distributor consolidates the products on trucks with other products, resulting in full loads and better service.	Enhanced distribution planning, inventory management and control.
Customer	If the company ordered too many nuts, they will turn soft in the warehouses, and if they ordered too few, the customer will buy food products with nuts elsewhere.	The company correctly knows the customer's needs so there is neither a shortage nor an oversupply of the products. Transportation, distribution, warehousing, and inventory costs drop, and product and service quality improve.	Increased customer satisfaction. Cost minimization, profit maximization

self-operated airplanes, and self-parking cars. In the industrial realm, automation now can be seen from such simple tasks as milking a cow to complex repetitive task such as building a new car. Computing and communications have also transformed production and service organizations over the past 50 years. While working in parallel, error recovery, and conflict resolution have been addressed by human workers since early days of industry, they have recently been transformed by computer into integrated functions [54.1].

Automation is the foundation of many of society's advances. Through productivity advances and reductions in costs, automation allows more complex and sophisticated products and services to be available to larger portions of the world's population. The evolution of supply chain management at a company as an automation example of the production, supply, logistics, and distribution is described in Table 54.1. An example of such evolution for a specific company is discussed in [54.2].

54.2 Machines and Equipment Automation for Production

54.2.1 Production Equipment and Machinery

Automation has been used for many years in manufacturing as a way to increase speed of production, enhance product quality, decrease labor costs, reduce routine labor-intensive work, improve safety, and even to perform tasks that go beyond the precision and reliability of normal human abilities [54.3, 4]. Examples of automation range from the employment of robots to install a windshield on a car, machine tools that process parts to build a computer processor, to inspection and testing systems for quality control to make certain the precise amount of cereal is in each box of cornflakes. An example of industrial robots for car production is shown in Fig. 54.1.

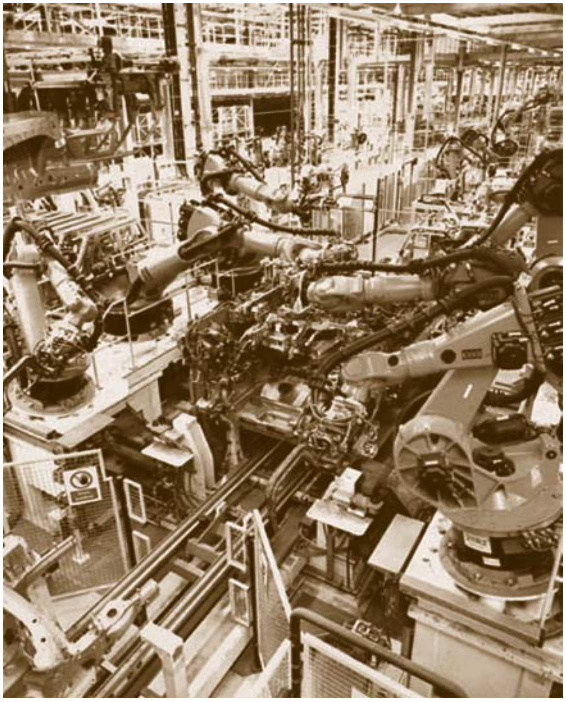

Fig. 54.1 Industrial robotics in car production (courtesy of KUKA Robotics)

There are many reasons that explain why automation has become increasingly important in today's production systems. The main justifications arise from the relative strengths that automation provide in comparison with humans within a production environment. Automated machines are able to perform systematic and repetitive tasks, requiring precision, storing large amounts of information, executing commands fast and accurately, handling multiple tasks simultaneously, and conducting dangerous/hazardous work [54.5, 6].

However, in spite of the numerous benefits and advantages automation may offer, it is not always the best solution and in some cases it is not even a feasible one. In situations with elevated levels of variation, short product lifecycles, or highly customized production, a solution involving automation can be unnecessarily complex and expensive when compared with a traditional manual process. Under these circumstances, the benefits of a manual process, such as the flexibility and lower capital requirements, begin to gain relative advantage when compared with an automated process.

54.2.2 Material Handling and Storage for Production and Distribution

Material handling equipment plays an important role in the automation of production, storage, and distribution systems, by interconnecting the fixed or flexible work-

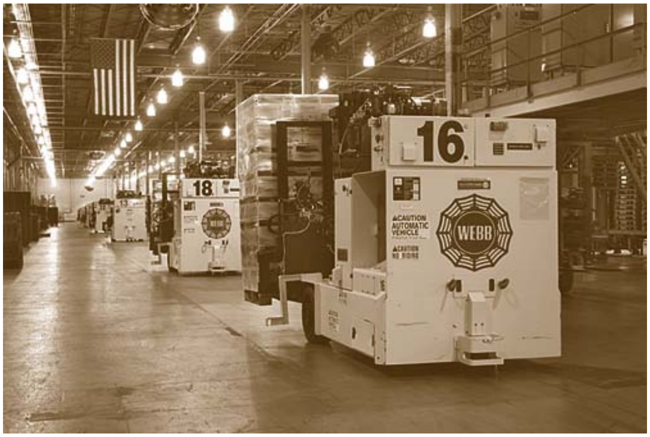

Fig. 54.2 Inertial guidance automatic guided vehicle (courtesy of the Jervis B. Webb Company)

stations that compose them. Typical automated material handling systems include conveyors for moving product in a general direction inside a facility, sorters and carousels for distributing products to specific locations, and automated storage and retrieval systems (ASRS) for storage and automated guided vehicles (AGVs) for transporting materials between work stations [54.7]. For instance, AGVs play an important role in the paper industry, where moving roles quickly and efficiently is critical. The key is not to damage rolls during this handling process. An example of an AGV in the paper industry is shown in Fig. 54.2.

Conveyors are believed to be the most common material handling system used in production and distribution processes. These systems are used when materials must be transferred in relatively large quantities between specific machines or workstations following a predetermined path or route. Most of these systems use belts or wheels to transfer materials horizontally or gravity to move materials between points at different heights. Frequently within production or distribution systems several types of conveyors are utilized in a combined manner, constituting conveyor networks or integrated systems.

In more sophisticated conveyor networks, sorters are utilized. A sorter consists of an array of closely coupled, high-density diverters used to sort units (materials, products, parts, etc.) to specific lanes for further consolidation. Consequently, in addition to the transfer functionality supported by regular conveyor systems, sorter mechanisms provide, by means of sensors, a classification capability that makes them especially attractive for highly variable, small-size shipments. Examples of operations that utilize sorters for their shipments are Federal Express, United Parcel Services, and Amazon.

Kimberly-Clark claims that a sorter mechanism implemented at one of its distribution facilities in Latin America has improved the truck loading operation time from 1–3 h to 20 min. With capacity of 200 cases per minute and fully customizable logic (i. e., it can be programmed to follow a balanced sorting sequence per dock or a sorting sequence by customer orders), this sorter has significantly increased truck rotation at the Kimberly-Clark distribution center versus the previous manual system.

54.2.3 Process Control Systems in Production

Production systems can be designed with different levels of automation. However in all automated production systems, even at the lowest levels of sophistication constituted by automated devices such as valves and actuators, a control system of some kind is required.

At the individual machine level, the automatic control is executed by computer systems. An example is computer numerical control (CNC), which reads instructions from an operator in order to drive a machine tool. At the automatic process level there are two main types of control systems, the programmable logic controller (PLC) and the distributed control system (DCS). These systems were initially developed to support distinctive process control functions. PLCs began replacing conventional relay/solid-state logic in machine control while DCSs were merely a digital replacement of analog controllers and panel-board displays. However, the technology of both types of process control systems has evolved over the years and the differences in their functionalities have become less straightforward. Further up in the hierarchy, at the production cell level, cell controllers provide coordination among individual workstations by interacting with multiple PLCs, DCSs, and other automated devices. At the highest production automation level, control systems such as manufacturing control systems and/or integrated plant systems initiate, coordinate, and provide visibility of the manufacturing operation of all other lower control levels [54.6, 8].

54.3 Computing and Communication Automation for Planning and Operations Decisions

54.3.1 Supply Chain Planning

To manage the supply chain effectively it is necessary to coordinate the flow of materials and information both within and between companies (e.g., [54.9]). The focus of the supply chain planning process is to synchronize activities from raw materials to the final customer. Supply chain planning processes strive to find an integrated solution for the strategic, tactical, and operational activities in order to allow companies to balance supply and demand for the movement of goods and services.

Information and communication technology (ICT) plays a vital role in supply chain planning by facilitating the flow of information and enhancing the cooperation between customers, suppliers and third party partners. As show in Fig. 54.3, intranets can be used to integrate information from isolated business processes within the firm to help them manage their internal supply chains. Access to these private intranets can also be extended to authorized supplies, distributors, logistics services, and to retail customers to improve coordination of external supply chain processes [54.10].

Electronic data interchange (EDI) and other similar technologies not only save money by reducing or eliminating human intervention and data entry, but also pave the way for collaboration initiatives between organizations. An example would be vendor-managed inventory (VMI) where customers send inventory and consumption information to suppliers, who schedule deliveries to keep customer inventory within agreed upon ranges. VMI not only provides benefits for the customer but also increases demand visibility for the supplier and leads to cost savings and reduced inventory investment for the supplier. As shown in Fig. 54.4, EDI can significantly improve productivity. A typical illustration is the case of Warner-Lambert that increased its prod-

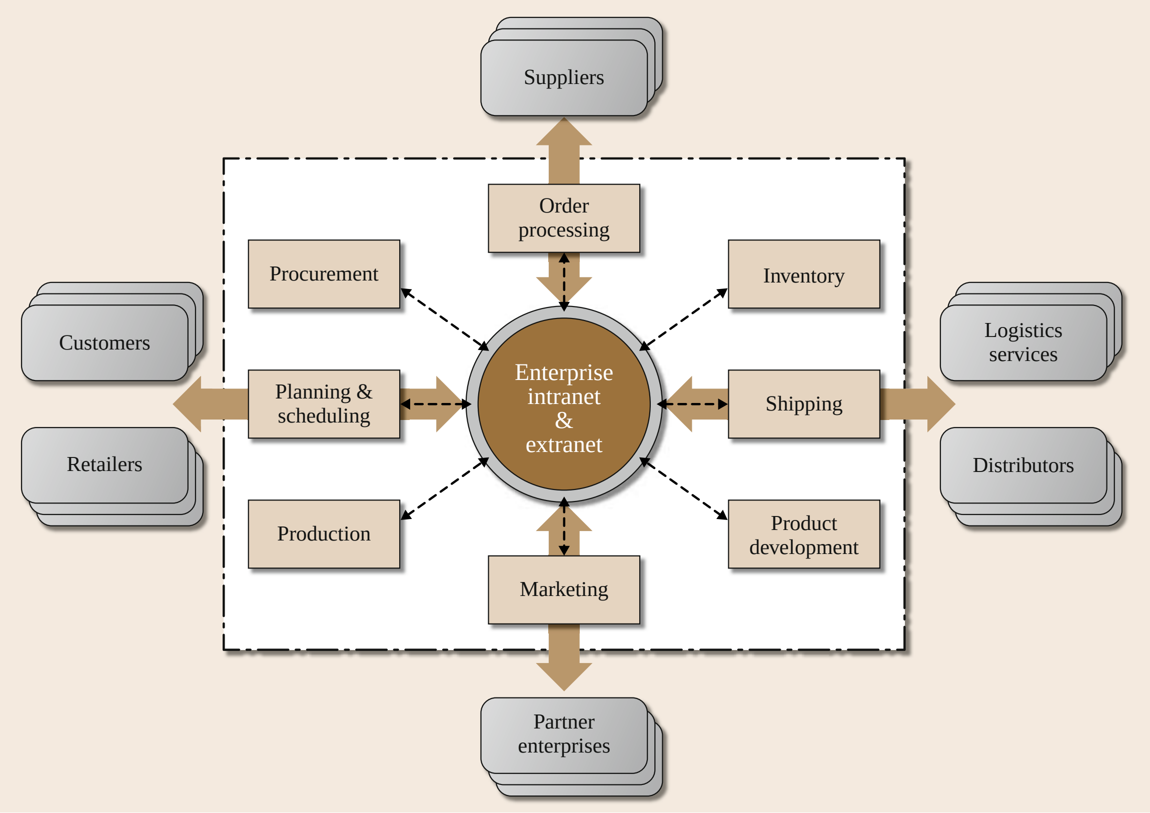

Fig. 54.3 Intranet and extranet for supply chain planning

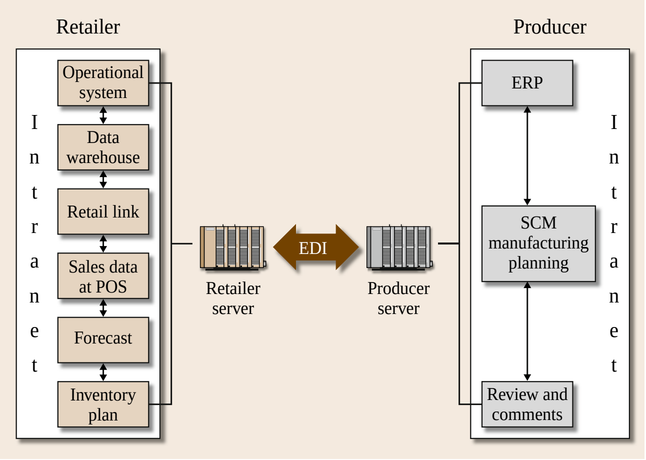

Fig. 54.4 Producer and retailer EDI application

ucts' shelf-fill rate at its retailer Wal-Mart from 87% to 98% by EDI application, earning the company about US $ 8 million a year in additional sales [54.11].

ICT is key to the strategic, tactical, and operational analysis required for supply chain planning. Transactional ICT helps to automate the acquisition, processing, and communication of raw data related to historic and current supply chain operations. This data is utilized by ICT systems for evaluating and disseminating decisions based on rules; for example, when inventory reaches a certain level, a purchase order for replenishment is automatically generated [54.12]. The data from ICT systems can also be used for simulating and optimizing a system. An example could be where ICT data is used to simulate the impact on a process with different levels of work in process on total productivity.

54.3.2 Production Planning and Programming

As the rate of technological innovation increases, maintaining a competitive cost structure may rely heavily on production efficiency generated by an effective production planning and programming process. For large-scale, global enterprises where traditional MRPI (material resource planning (1st generation)) and MRPII (material resource planning (2nd generation)) approaches may not be sufficient, new enterprise resource planning (ERP) solutions are being deployed that not only link all aspects from the bill of materials to suppliers to customer orders, but also utilize different algorithms in order to efficiently solve the scheduling conundrum. A general framework of ERP implementation is shown in Fig. 54.5.

Off-the-shelf solutions such as those provided by software supplier SAP advance planner and optimizer (APO) provide automatic data classification and retrieval, allowing key measures to be retrieved for strategic, tactical, and operational planning. However, typical ERP systems are rigid and have a difficult time adjusting to the complexity in demand requirements and constant innovation of the product portfolio

mix. Global companies that compete in diverse marketplaces may choose to address these issues by building their own large-scale optimization models. With a solid database structure, these models are able to adapt to continuous changes in portfolios and can incorporate external influences on demand, such as market trends in promotions and advertisement. Over the past decade, there has been a shift in focus from business functions to business processes and further into value chains. Nowadays, enterprises focus on the effectiveness of the operation that requires functions to be combined to achieve end-to-end business processes [54.13].

54.3.3 Logistic Execution Systems

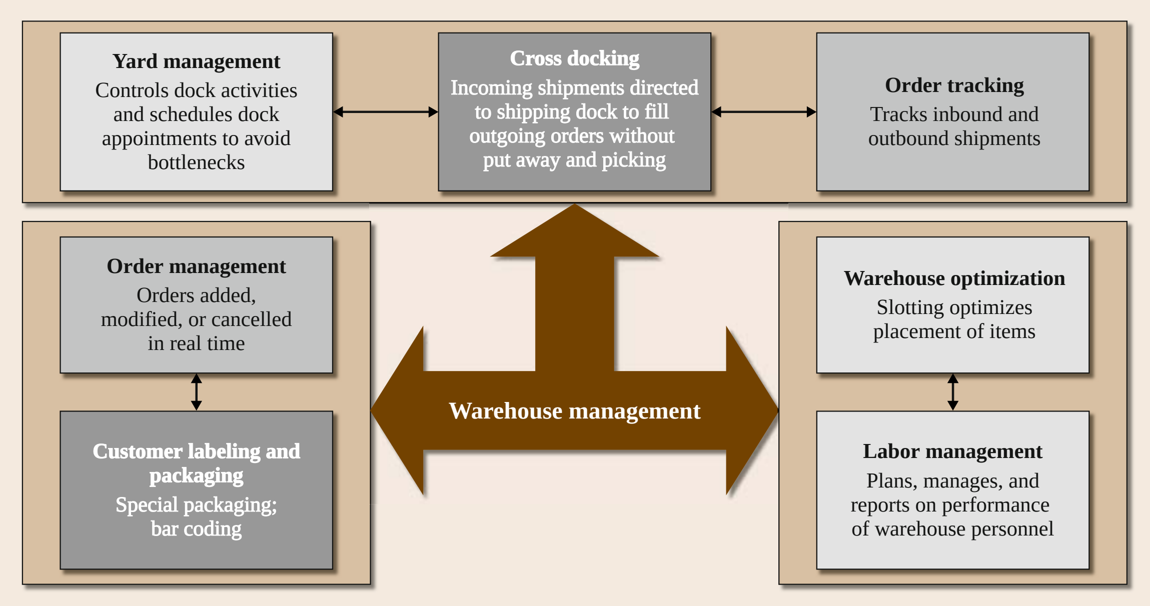
Logistic execution systems (LES), seek to consolidate all logistic functions, such as receiving, storage, inventory management, order processing, order preparation, yard management and shipping into an integrated process. The LES can be designed to communicate with the firms enterprise network and external entities such as customers and suppliers.

The LES might be part of the ERP system or otherwise should communicate with it through interfaces in order to interact with other modules such as finance, purchasing, administration, and production planning. Usually it also communicates with customers, suppliers, and carriers via EDI or web-based systems with the purpose of sharing logistic information relevant to all parties such as order status, trucks availability, confirmation of order reception, etc.

A LES is usually composed of a warehouse management system (WMS) complemented with a labor management system (LMS) and a transportation management system (TMS). Essentially WMS issues, manages, and monitors tasks related to warehouse operation performance. A WMS improves efficiency and productivity of warehousing operations usually supported by (1) barcode and (2) radiofrequency data communications technologies. Both of these technologies provide a WMS with instantaneous visibility of warehouse operations, facilitating precise inventory control as well as accurate knowledge of labor and equipment resources availability. The addition of labor and transportation management in a LES has expanded the span of WMS functionality to the point of practically embracing every logistic function from receiving to the actual shipping of goods. An example of a WMS is shown in Fig. 54.6.

54.3.4 Customer-Oriented Systems

Many times, automation is thought to only apply to the production environment. However, there are a myriad of examples where other critical non-production-related processes have been automated, such as order entry,



Yard management
Controls dock activities and schedules dock appointments to avoid bottlenecks
Cross docking
Incoming shipments directed to shipping dock to fill outgoing orders without put away and picking
Order tracking
Tracks inbound and outbound shipments
Order management
Orders added, modified, or cancelled in real time
Customer labeling and packaging
Special packaging; bar coding
Warehouse management
Warehouse optimization
Slotting optimizes placement of items
Labor management
Plans, manages, and reports on performance of warehouse personnel

Fig. 54.6 A warehouse management system with decision support systems

inventory management, customer service, and product portfolio management. The goal of these applications is to improve upon the customers' experience with suppliers.

For many companies, the customer experience is a very tangible and measurable effect that should be *viewed through the eyes of the customer*. The goal for the supplier is to be *easy to do business with*. For this reason, many companies have decided to automate how the customer exchanges information related to sales and logistics functions. One example of this automation is the use of cellular phone messaging technology to coordinate in real time to the customer the status of their order throughout the delivery process.

54.4 Automation Design Strategy

54.4.1 Labor Costs and Automation Economics

Competitive dynamics and consumer needs in today's marketplace demonstrate the need for manufacturer flexibility in response to the speed of change. Modern facilities must be aligned with the frequent creation of new products and processes and be prepared to manage these changes and resulting technological shifts. Therefore, one of the most difficult issues now facing companies is identifying a manufacturing strategy that includes the optimal degree of automation for a given competitive environment.

As shown in Fig. 54.7, increased production costs, including the mitigation of possible labor shortages, is one of the initial reasons companies look towards automation. However, production costs alone are usually not sufficient to justify the cost of investment. Productivity, customer response time, and speed to market are many times key factors to the success of automating a production process and must be measured in order to effectively determine the impact on costs and expected revenues in the future.

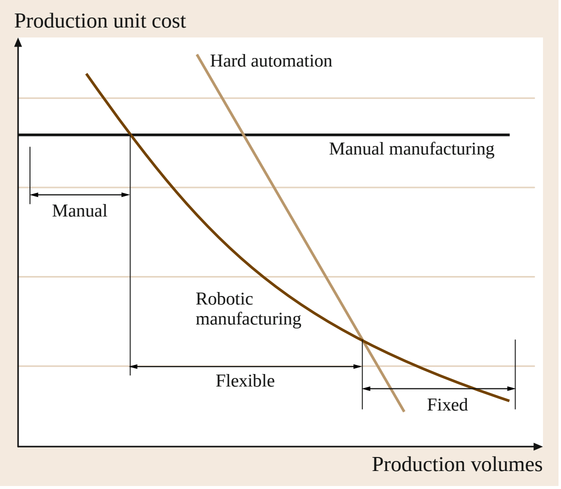


Fig. 54.7 Automation tradeoffs based on production volumes

54.4.2 The Role of Simulation Software

Determining the benefits of automation may prove to be a challenge, especially when there are complex relationships among processes. Will there be improvement in throughput and will this be sufficient to justify the required investment? With the availability of software such as ARENA by Rockwell Automation, simulation can be used as a tool to test different possible scenarios without having to make any physical changes to an existing system. This tool can be especially useful in cases where the required investment for automation is high and the expected benefits are not easily measured. In addition, the visual simulation capabilities related to this type of software facilitates the analysis of the process as well as obtaining top management support.

54.4.3 Balancing Agility, Flexibility, and Productivity

Typical business concerns such as increasing sales and operating profit are always considered key performance drivers that lead the investment strategy within an organization. However, with the complexity that can be found within certain marketplaces, a local niche or a well-developed global market, the need for sustainable growth has increasingly become one of the most important aspects when determining a competitive strategy.

A major competitive concern in the global market is agility in order to react to a dynamic market. To maintain agility between autonomous and geographically distributed functions significant investment in automated error detection is required to facilitate recovery and conflict resolution [54.1].

This complexity has adjusted the traditional return-on-investment (ROI) approach to automation investment justification by determining success on how well the solution is able to create value for customers through services or products. What are customers looking for? Is it on-shelf availability at a slightly higher price? A highly computerized ASRS (automated storage and retrieval system) may provide increased throughput, less errors, and speed in distribution. What if the customers change how and where products are required? An AS/RS may not be flexible enough to adjust quickly to changes in demand patterns or shifts in the demand network nodes. The correct solution should address customers' expectations regarding product quality, order response times, and service costs, seeking to obtain and sustain customer loyalty.

54.5 Emerging Trends and Challenges

The use of automation in production and supply chain processes has expanded dramatically in recent years. As globalization advances along with product and process innovation, it would seem that the importance of automation will continue to intensify into the future.

The landscape of global manufacturing is changing. More and more production plants are being built in India, Brazil, China, Indonesia, Mexico, and other developing countries. The playing field is rapidly being leveled. However, by crossing borders, companies also increase the complexity of operations and supply chains. Virtually seamless horizontal and vertical integration of information, communication, and automation technology throughout the organization is needed by companies such as Wal-Mart, Kimberly-Clark, Procter and Gamble, Clorox, and Nestle, in order to address the dynamics of today's manufacturing environment. Collaborative design, manufacturing, planning, commerce, plant-to-business connectivity, and digital manufacturing are just some of the many models that seem to be on the horizon for leading manufacturing companies in order to induce further integration of processes. Several technologies and systems are reaching the required level of maturity to support these models, and thereby accelerate the adoption of automation in production and supply chains. Examples of these technologies would be:

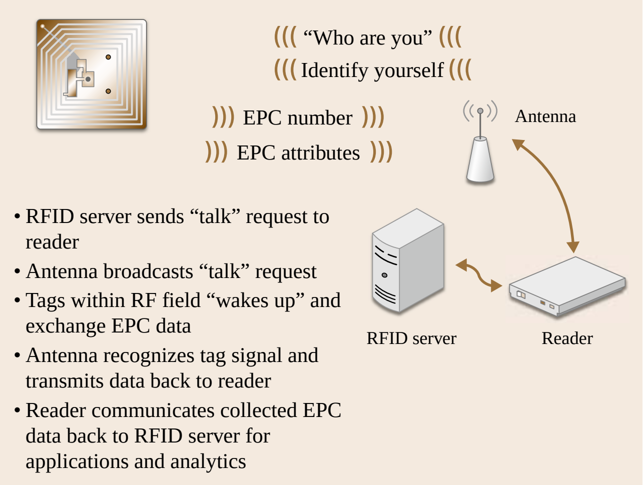
- Supply chain planning systems
- Supply chain security
- Manufacturing operations management solutions
- Active radiofrequency identification (RFID)
- Sensor-based supply functions
- Industrial process automation.

Furthermore other technologies such as manufacturing process management frameworks, supplier relationship management suites, supply chain execution systems, passive RFID technology, Six-Sigma IT (information technology), and lean manufacturing systems are more on an emerging or adolescence level of maturity [54.3, 4].

In addition, collaborative e-Work theory and techniques are emerging as powerful automation support for production, supply, logistics, and distribution [54.14, 15] (see also Chap. 88).

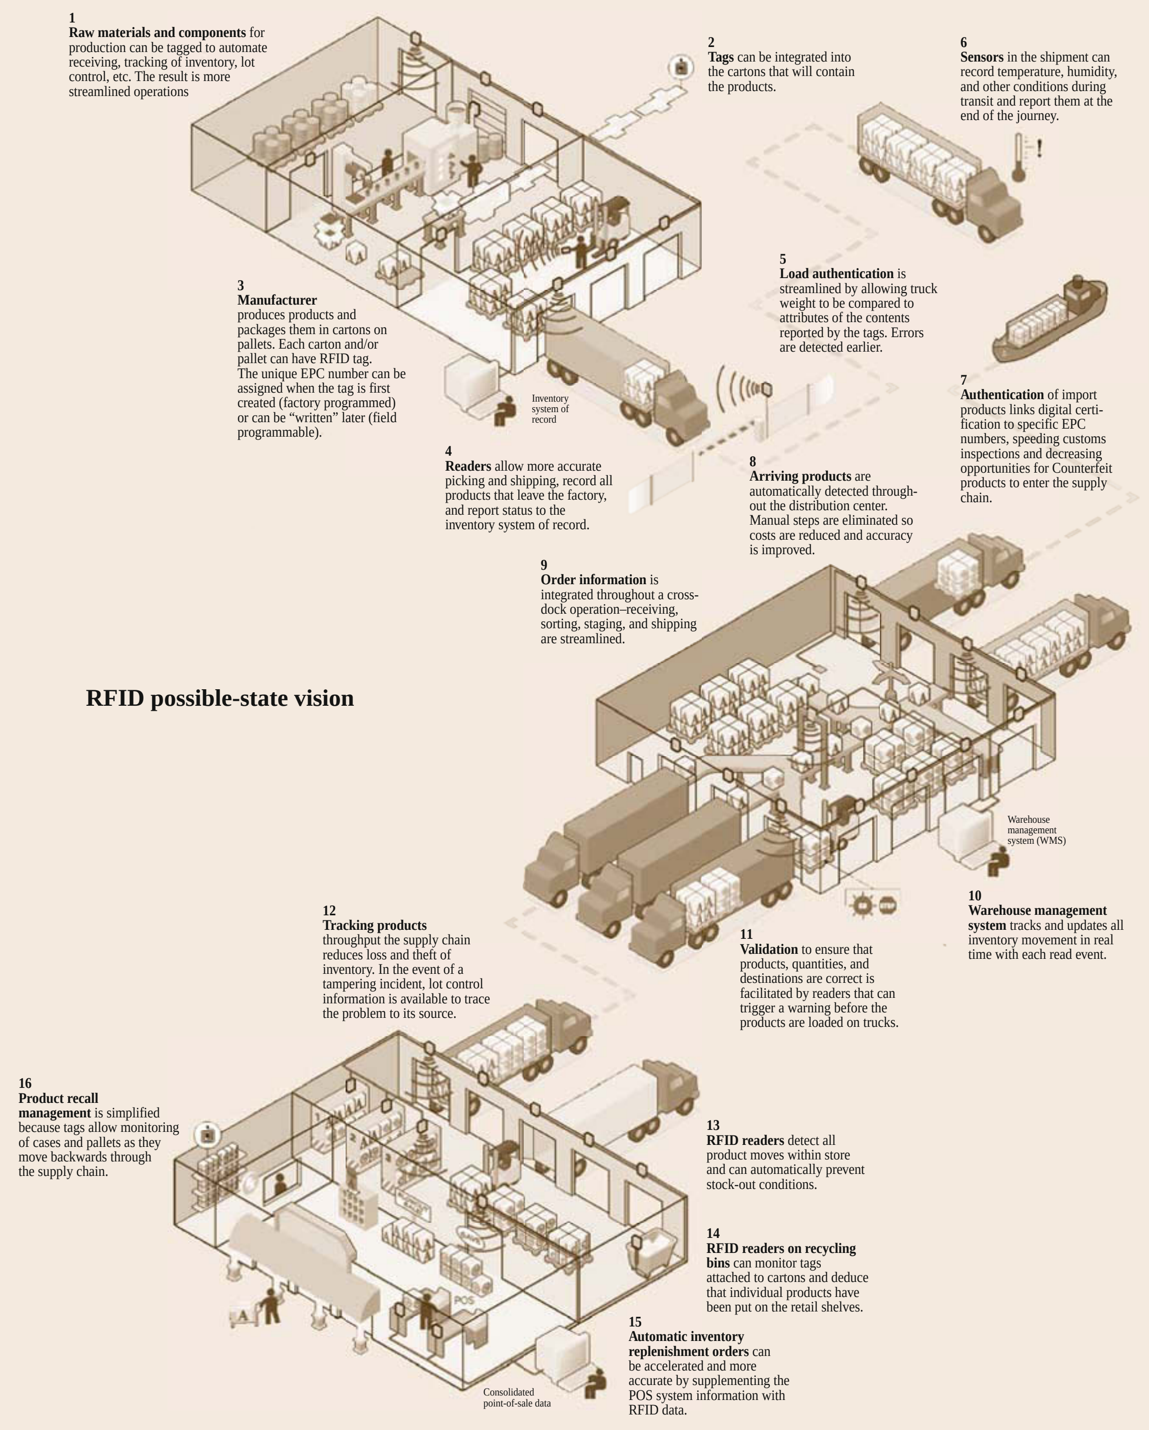
54.5.1 RFID Technology in Supply Chain and Networks

An emerging technology with great promise is the use of radiofrequency identification (RFID) to automate the collection of data. A RFID tag is a small computer chip that can send via radiofrequency a small amount of information a short distance. The signal is captured by a RFID antenna and then transferred to a computer network for data processing (Fig. 54.8). The general RFID system architecture, applications, frequencies, and standards are shown in Fig. 54.9 and Table 54.2.



• RFID server sends "talk" request to reader
• Antenna broadcasts "talk" request
• Tags within RF field "wakes up" and exchange EPC data
• Antenna recognizes tag signal and transmits data back to reader
• Reader communicates collected EPC data back to RFID server for applications and analytics

Fig. 54.8 How RFID works



Inventory system of record
Warehouse management system (WMS)
POS
Consolidated point-of-sale data

RFID possible-state vision

1
Raw materials and components for production can be tagged to automate receiving, tracking of inventory, lot control, etc. The result is more streamlined operations

2
Tags can be integrated into the cartons that will contain the products.

3
Manufacturer produces products and packages them in cartons on pallets. Each carton and/or pallet can have RFID tag. The unique EPC number can be assigned when the tag is first created (factory programmed) or can be "written" later (field programmable).

4
Readers allow more accurate picking and shipping, record all products that leave the factory, and report status to the inventory system of record.

5
Load authentication is streamlined by allowing truck weight to be compared to attributes of the contents reported by the tags. Errors are detected earlier.

6
Sensors in the shipment can record temperature, humidity, and other conditions during transit and report them at the end of the journey.

7
Authentication of import products links digital certification to specific EPC numbers, speeding customs inspections and decreasing opportunities for Counterfeit products to enter the supply chain.

8
Arriving products are automatically detected throughout the distribution center. Manual steps are eliminated so costs are reduced and accuracy is improved.

9
Order information is integrated throughout a cross-dock operation–receiving, sorting, staging, and shipping are streamlined.

10
Warehouse management system tracks and updates all inventory movement in real time with each read event.

11
Validation to ensure that products, quantities, and destinations are correct is facilitated by readers that can trigger a warning before the products are loaded on trucks.

12
Tracking products throughput the supply chain reduces loss and theft of inventory. In the event of a tampering incident, lot control information is available to trace the problem to its source.

13
RFID readers detect all product moves within store and can automatically prevent stock-out conditions.

14
RFID readers on recycling bins can monitor tags attached to cartons and deduce that individual products have been put on the retail shelves.

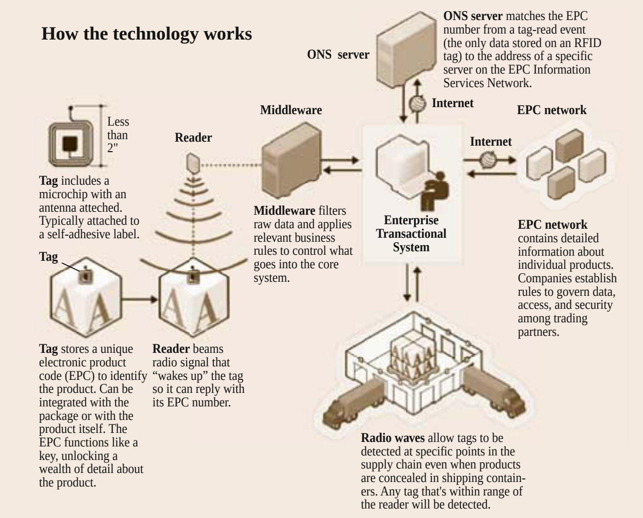
15
Automatic inventory replenishment orders can be accelerated and more accurate by supplementing the POS system information with RFID data.

16
Product recall management is simplified because tags allow monitoring of cases and pallets as they move backwards through the supply chain.

Fig. 54.9a,b RFID in the supply chain (courtesy of BearingPoint's RFID solution)

Table 54.2 RFID functions, frequencies, and standards [54.16]

Applications	Frequencies	Standards
Animal, identification dogs, cats, cattle	< 135 kHz	ISO 18000–2 ISO 11784 ISO 11785 ISO 14223
Smart cards, passport, books at library	13.553–13.567 MHz	ISO 18000–3 ISO 7618 ISO 14443 ISO 15693 13.56 MHz ISM band class 1
Supply chain for retail	868–928 MHz	EPC global class 1 Gen-2 ISO 18000–6



How the technology works
ONS server
ONS server matches the EPC number from a tag-read event (the only data stored on an RFID tag) to the address of a specific server on the EPC Information Services Network.
Internet
Middleware
EPC network
Less than 2"
Reader
Internet
Tag includes a microchip with an antenna atteched. Typically attached to a self-adhesive label.
Middleware filters raw data and applies relevant business rules to control what goes into the core system.
Enterprise Transactional System
EPC network contains detailed information about individual products. Companies establish rules to govern data, access, and security among trading partners.
Tag
Tag stores a unique electronic product code (EPC) to identify the product. Can be integrated with the package or with the product itself. The EPC functions like a key, unlocking a wealth of detail about the product.
Reader beams radio signal that "wakes up" the tag so it can reply with its EPC number.
Radio waves allow tags to be detected at specific points in the supply chain even when products are concealed in shipping containers. Any tag that's within range of the reader will be detected.

Fig. 54.9 (b)

RFID is becoming increasingly prevalent as the price of the technology decreases. Some RFID applications are summarized in Table 54.3. In supply chain applications, current uses of RFID technology are focused on location identification of products. These are as varied as identifying trailers and ocean freight trailers in a trailer yard, stopping of shoplifting of small but higher-priced fast-moving consumer goods such as razor blades, as well as an alternative to a WMS. In broader uses Wal-Mart is discovering RFID technology can help it increase sales by making sure inventory at the store's loading dock is actually placed on the shelf.

The barriers to implementing RFID technology are cost, effectiveness, and fears of a loss of personal privacy. The cost of a RFID tag has declined 90% in the past few years, but is still expensive and their use is usually limited to pallets and not on individual cases, products or boxes. It is believed that the uses of RFID

Table 54.3 RFID applications and examples

Application	Examples
Documents (e.g., passports)	Year 2000: Malaysia, Year 2005: New Zealand, The Netherlands, Norway, Year 2006: Ireland, Japan, Pakistan, Germany, Portugal, Poland, Year 2007: UK, Australia, and USA

Product tracking	Cattle tracking Jewelry tracking Library book or bookstore tracking Truck and trailer tracking
Supply chain network	Wal-Mart inventory system Boeing 787 Dreamliner maintenance and inventory system Promotion tracking

tags on individual packages is many years away. The other cost barrier is the investment in antennas. For a company such as Wal-Mart to utilize RFID technology, they need to install antennas in all of their distribution centers as well as all of their stores. Also RFID technology has problems sending signals through certain dense materials such as liquids, which limits their use. Finally, some people feel that, if RFID technology improves in terms of the distance a signal can be sent, then people will be able to determine which products are in people's homes, and thoughts of *Big Brother* come to mind. Currently the technology is not capable of fulfilling these privacy concerns, but the concern will continue to slow the acceptance of the technology. 55. Material Handling Automation in Production and Warehouse Systems

Jaewoo Chung, Jose M.A. Tanchoco

This chapter presents material handling automation for production and warehouse management systems that process: receipt of parts from vendors, handling of parts in production lines, and storing and shipping in warehouses or distribution centers. With recent advancements in information interface technology, innovative system design technology, and intelligent system control technology, more sophisticated systems are being adopted to enhance the productivity of material handling systems. Information interface technology utilizing wireless devices such as radiofrequency identification (RFID) tags and mobile personal computers significantly simplifies information tracking, and provides more accurate data, which enables the development of more reliable systems for material handling automation. Highly flexible and efficient automated material handling systems have been newly designed for various applications in many industries. Recently these systems have been connected into large-scale integrated automated material handling systems (IAMHS) that create synergy with material handling automation by proving speedy and robust infrastructures. As a benefit of high-level material handling automation, the modern supply chain management (SCM) successfully synchronizes sales, procurement, and production in enterprises.

In today's competitive environment, suppliers must be equipped with more cost-effective and faster supply chain systems to remain in the market. Companies are investing in material handling automation (MHA) not only to reduce labor cost, delivery time, and product damage, but also to increase throughput, transparency, and integratability in production and warehouse management systems. The material handling industry has grown consistently over many years. The Material Handling Industry of America (MHIA) estimates that, in 2006, new orders of material handling equipment machines (MHEM) grew 10% compared with 2005 and set a new record high at US$ 26.3 billion in the USA [55.1].

In the past, labor cost was the most important element for estimating the return on investment (ROI) of a stand-alone automated material handling system (AMHS), and the system was a relatively small part of the production or warehouse facility. Nowadays, the impact of the system throughout the supply chain is becoming larger and more complicated; for example, a radiofrequency identification (RFID) system enhances customer satisfaction by providing convenience in data tracking as well as reducing order picking times and shipping errors in warehouse. AMHSs are not alternatives selected after prudent economic analysis, but are rather major components in a production and warehouse facility. Also, the sizes of systems and the complexities of their operations are increasing. Multiple AMHSs consisting of RFID systems, automated guided vehicles (AGVs) systems, and au-

tomated storage and retrieval systems (AS/RSs) are typically installed in a production and warehouse facility as a connected system. As its complexity has increased, optimization of the design and operation of these systems has become of interest to both AMHS vendor companies and their customers. Many examples of these integrated systems can be observed in the semiconductor [55.2], automotive [55.3], and freight industries [55.4, 5].

This chapter introduces practical applications of MHA for production and warehouse systems. It starts by introducing a concept of the IAMHS that uses several types of the AMHS in a single integrated system (Figs. 55.1 and 55.2). The focus is particularly on what an IAMHS consists of and how it collaborates with other systems in SCM. Based on this introduction, components of the IAMHS and their recent technology advancement in the MHA will be reviewed.

55.1 Material Handling Integration

55.1.1 Basic Concept and Configuration

An IAMHS integrates different types of automated material handling equipment in a single control environment. A simple type of IAMHS was used for seaport or airport cargo terminals, which are served by stacker cranes and AGV systems [55.5]. The main issue of the simple IAMHS is how to reduce wait-

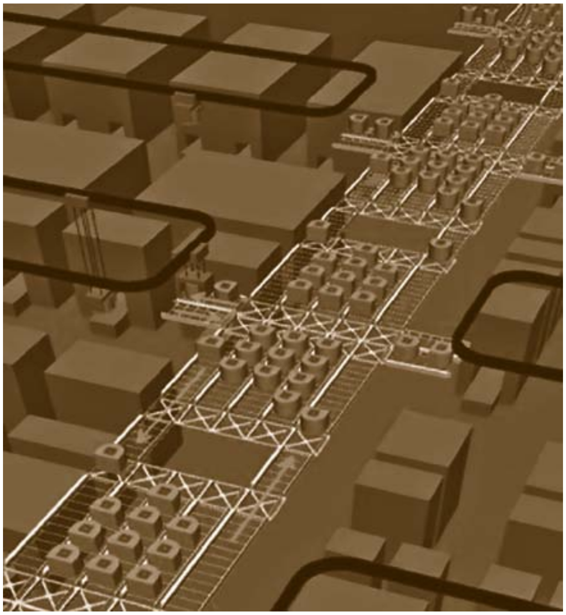

Fig. 55.2 New IAMHS design for next-generation semiconductor fab (courtesy of Middlesex)

ing time during job transition between two different AMHSs to increase throughput; for instance, an AGV has to wait after arriving at the load position if the crane is not ready to unload a container to the AGV. If their jobs are poorly synchronized, the waiting time will be longer, and as a consequence throughput will drop.

Recently IAMHSs with more complicated component systems have been implemented for many companies in different industries. Figure 55.1 shows an example IAMHS used in a warehouse system in the pharmaceutical industry [55.6]. In this configuration, there are five different types of the AMHS. First, a pallet AS/RS is installed and the temperatures of each shelf in the AS/RS can be controlled according to the characteristics of the products stored to maintain product quality. Second, a free-size AS/RS is used for storage of individual orders and items that are frequently replenished. It can store items regardless of their size, shape, or weight since it uses a hoisting carriage that can handle a wide range of products. Third, an automated overhead traveling vehicle is installed to replenish items with minimum labor cost and waiting time. It uses overhead space to increase space efficiency. Another AMHS used is a digital picking system, providing convenience for picking tasks by displaying directions on a digital panel installed on the shelves. Finally, the IAMHS is operated by handheld terminals providing many applications in the warehouse. It is equipped with an RFID or barcode reader that allows flexible adaptation to changes in distribution quantity.

The semiconductor industry is equipped with one of the most complex IAMHSs for wafer fabrication (fab) lines (Fig. 55.3). A fab line may consist of more than 300 steps and 500 process tools. Material transportation between tools in a wafer fab line is fully automated by the overhead hoist transporter (OHT) system, which is a type of rail-guided vehicle (RGV) system, an AS/RS called the *stocker*, a lifting system that transfers wafer carriers between different floors, and a mini-environment that is used for a standard interface of machines with the AMHS. For the next generation of IAMHS in a fab line, Middlesex has proposed a new concept using conveyor systems (Fig. 55.2) instead of OHT systems and stockers, which guarantees larger-capacity transfers and quick response times for deliveries. Middlesex has focused on high-end conveyor systems for many years. More reviews of the IAMHS in the semiconductor industry are provided by *Montoya-Torres* [55.2].

These IAMHSs are generally highly flexible in design for customized usage, and some of them are even unique and revolutionary. *Kempfer* [55.7] introduced an order picking system utilizing a voice recognition system and RFID system in a large-scale automated distribution center. The article reports that the average order picking performance was improved from 150 cases per man-hour to 220 cases per man-hour by reducing operators' information handling time. A few companies also achieved similar

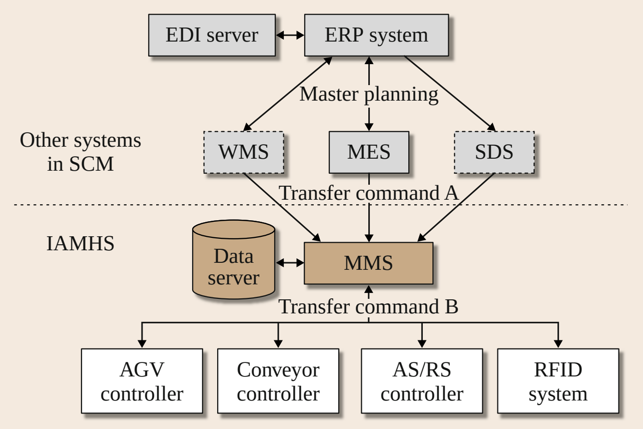

Fig. 55.3 IAMHS in hierarchical system architecture

improvements by adopting an integrated RFID and voice recognition system [55.8, 9]. *Chang* et al. [55.9] proposed an integrated multilevel conveying device for an automated order picking system that transfers articles between two different levels of a multistorey building to improve the operational and spatial efficiency of the warehouse system. The system employs a specially designed device comprised of a stacker crane, a vehicle-based transporter, and conveyor system.

55.2 System Architecture

In the design of a large-scale IAMHS, a well-structured system reduces the redundancies of functions in different modules, unnecessary transactions between modules, and system errors caused by large and complex individual functions of these modules. An algorithm ignoring the system architecture sometimes tends to create many problems during implementation, mainly because of the lack of necessary information and difficulty in interacting with existing systems [55.10]. Examples of this limitation can be found in the literature. An AGV scheduling algorithm under an FMS environment determines a sequence of the AGV route within a certain time horizon, considering the information from both the work centers and AGV systems on a shop floor. However, under this system architecture, it is very difficult for an AGV controller to take into consideration complex constraints of work centers such as machine status, processing times, and setup times because of the long calculation time. Therefore, generally, job sequencing and scheduling are performed independently by the scheduling and dispatching system, which is then connected to the AGV controller using a sequence of protocols. An AGV controller only takes care of requested transfer commands, which specify source and destination locations, priorities, and command trigger times. There is already too much load on the AGV controller in its original tasks, which include path planning for a vehicle, job dispatch for a newly idle vehicle, vehicle dispatch for a new job requested, error recovery, etc. [55.11]. Therefore, the developed AGV scheduling algorithm should be modified based on the structure of the system architecture. One way to carry out this modification is to break up the algorithm for different modules in the system structure. During this break-up process, it is unavoidable to change the algorithm depending on the availability of information to the module, which sometimes causes significant performance degradation compared with the original algorithm. As the number of subsystems being used in production and warehouse systems continues to increase, a well-structured system will be beneficial for facilitating collaborations between different departments as well as these systems. However, it is an open challenge to construct a well-designed system structure that accommodates all the different types of AMHS regardless of the size of the system and the type of business on which the IAMHS is centered.

Various types of system architecture can be used to design an IAMHS with other application systems, depending on the manufacturing type of the shop floor, the size of the total system, the number of transactions per second, etc. Figure 55.3 illustrates a design example of the system architecture for the IAMHS presented in Fig. 55.1. The focus of this figure is on software modularity. Each AMHS has its own controller (the four controllers at the bottom of Fig. 55.3), which is responsible for its own tasks and communication with the material management system (MMS), which is a high-level integrating system that will be explained later in more detail; for example, an AGV controller addresses job allocation, path planning, and collision avoidance, receives a transfer command from the MMS (transfer command B in Fig. 55.3), and reports necessary activities such as vehicle allocation and job completion to the MMS so that data are kept for tracking in the future. Each controller also has to process error-recovery routines for robustness of the system control. The MMS manages multiple controllers of different AMHSs, and has a database server to store all transactions of the subsystems in the IAMHS. It receives transfer commands or short-term scheduling results of processing machines from the scheduling module in a higher-level system in the SCM (transfer command A in Fig. 55.3). In this structure, long-term optimization of processing machines is responsible for the higher-level system, and the MMS focuses on efficiencies during the transportation of unit loads within production and warehouse facilities. Details of the MMS are explained in the next section. As shown in Fig. 55.3, the higher-level systems of the MMS can be a manufacturing execution system (MES), warehouse management system (WMS), and enterprise resource planning (ERP) system. The WMS can be substituted by the MMS if the warehouse is composed of relatively simple systems.

Understanding high-level decision-support systems in SCM helps to understand the scope of control tasks performed by the IAMHS. The advanced planning and scheduling (APS) system generally consists of planning and scheduling modules. Sometimes the scheduling module is again broken down into scheduling and dispatching modules (SDS in Fig. 55.3). The ERP system generally includes the planning module; however, the scheduling and dispatching modules can be included in any other systems such as the MES and WMS. In Fig. 55.3, it is assumed that the modules are running in a stand-alone system called the SDS that communicates with the ERP system, MES, and MMS. The planning module makes a long-term production or procurement plan based on customer orders, demand forecasting results, and capacity constraints. Its time horizon varies from weeks to months. Practically, it hardly optimizes complex factors of resources on the shop floor because of the long computation time, but constructs highly aggregated planning. Its results include production quantities for each product type and time bucket, or production due dates for each product type or product group. Detailed resource requirement plans are not specified by the planning module due to the uncertainties and complexities of operations. The scheduling module is responsible for delineating more concrete plans for the shop floor to meet the target production plan from the planning module. It typically tries to optimize various resource constraints with several objectives such as due-date satisfaction and throughput maximization. Detailed resource requirement plans over time buckets within a time horizon are created by the scheduling module. It sometimes takes into account constraints in the AMHS for more robust scheduling. The time horizon of the scheduling module varies from a few hours to days. The dispatching module determines the best unit load for a machine in real time following a trigger event from the machine or unit load. It tries to follow up closely the scheduling results, which are globally optimized. The MMS in the IAMHS receives transfer commands from either the scheduling module or dispatching module based on its system architecture. These transfer commands are the result of the scheduling, machine assignment or job sequencing on processing machines. The MMS manages the process of the given transfer command by creating more detailed transfer commands to the AMSHs in the IAMHS. The dispatching module is sometimes included in the MMS, and creates the transfer commands based on the scheduling results and its own dispatching rules for the real-time status of the shop floor. The IAMHS takes charge of the final execution of the SCM in an enterprise and also provides useful information as described above.

The higher-level systems of the IAMHS automate information processing throughout an enterprise. The MES in Fig. 55.3 is a tracking system that collects important data from processing machines and stores them in well-structured database tables for analysis of quality and process controls; however, it has expanded its role into many other areas based on a powerful open architecture. It has been popularly used in the electronic industry such as in semiconductor fabs and surface-mounting technology (SMT) lines, and has recently spread into other industries. The warehouse management system (WMS) is generally used in mid- or large-size warehouse facilities, similar to MES for a production shop floor; it tracks every movement of materials and support operations for material handling in the warehouse. Its focus is on information processing automation. The objective of implementing an ERP system in a company is information sharing for rapid and correct decision-making, and implementation throughout the enterprise by using an integrated database system [55.12]. Chapter 90 provides a more thorough discussion of ERP and related concepts. The whole procedures of order entry, production planning, material procurement, order delivery, and corresponding cash flow are managed by the system. All the data from different applications in an enterprise or between different enterprises are exchanged by an electronic data interchange (EDI) server, which allows automated exchange of data between applications. Based on the EDI technology, applications freely exchange purchase orders, invoices, advance ship notices, and other business documents directly from one business system to the other without human support. Figure 55.4 illustrates the connectivity of IAMHS to other systems in SCM, which is used in an actual industry.

55.2.1 Material Management System

The role of the MMS is very important in a complex IAMHS for high-level automation. The main functions of the MMS are summarized below, in increasing order of importance. This summary does not discuss the dispatching module that assigns unit loads to process-

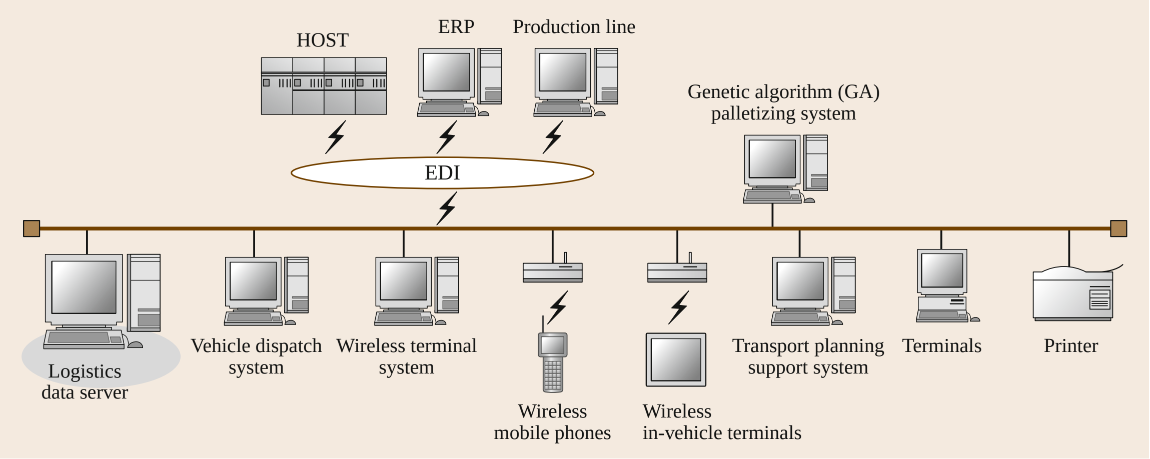

Fig. 55.4 Connectivity of IAMHS to other systems in SCM (courtesy of Murata Machinery)

ing machines because this involves so many topics; however, the dispatching functions bounded to AMHSs (i. e., dispatching unit loads while not considering process machines) will be discussed here.

The roles of the MMS in a complex IAMHS are:

1. Determining the best destination among several possible AMHS alternatives
2. Determining the best route to get to the destination from a source location via several AMHSs
3. Determining a proper priority for the transfer command
4. Storing and reporting various data using a database server
5. Transfer command management between different AMHSs
6. Error detection and recovery for the transfer command
7. Providing a user interface for control, monitoring, and reporting.

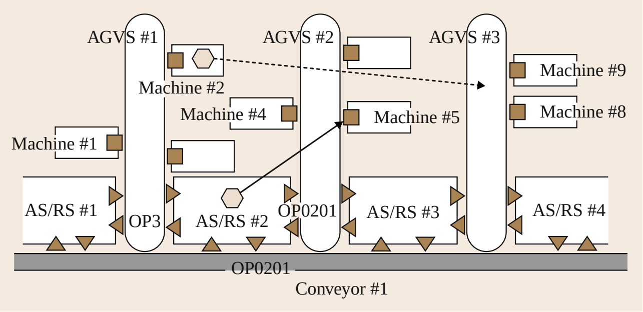

Fig. 55.5 Example of IAMHS

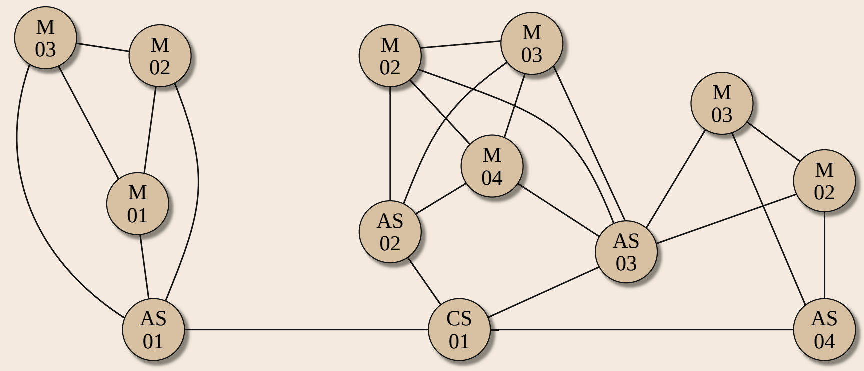
For a unit load to be transferred, its source and destination locations are mainly determined by the dispatching or scheduling module; however, when the candidate destinations are AMHSs, it is sometimes more efficient for the MMS to determine the final destination than for the scheduling or dispatching module to do so. Consequently, the dispatching and scheduling system provides a destination group to the MMS. Figure 55.5 illustrates the execution process of a transfer command. In the figure, if a unit load from Machine #2 has just finished its processing and has to be transferred to an AS/RS to be processed next, on one of the machines connected to AGVS #3 (dashed arrow in the figure), there are two candidate AS/RSs connected to AGVS #3: AS/RS #3 and AS/RS #4. The AS/RS group connected to AGVS #3 is named AS_Group #3. The MMS will receive a transfer command from the dispatching module, specifying the source location as Machine #2 and the final destination as AS_Group #3. Since there are two alternative destinations, the MMS may consider the product type of the unit load, the full rate of each AS/RS, the load port status of each AS/RS, the shortest distances from the unit load to the AS/RSs considering current active jobs in each system, and so on. It will determine the best AS/RS amongst the two alternatives and trigger a transfer command to AGVS #1, which will first move the load to AS/RS #1 from Machine #2.

The MMS is also responsible for determining the destination subsystem in an AMHS, such as the load/unload port (or pickup/drop-off port) in an AS/RS, because there are generally multiple load/unload ports with different types and numbers of buffers. The ports may differ, being load only, unload only or of unified type. Assume that a unit load in AS/RS #2 in Fig. 55.5 has to be moved to Machine #5, connected to AGVS #2 (solid arrow in Fig. 55.5). First, the unit load has to be moved to one of the output ports in the AS/RS. The AS/RS controller may not know which output port will be the best among the three possible ones in the figure because it does not know the next destination of the unit load. The MMS may determine a load port connected to AGVS #2, OP0201 in Fig. 55.5. In practical application, the problems are generally much more complicated than this illustration due to the increased instances in the system. Few studies have addressed this type of problem. *Sun* et al. [55.13] and *Jimenez* et al. [55.14] stress the importance of this problem in the literature and introduce a few ideas being used in practical applications; however, their methods leave much room for improvement in that they use static approaches and consider limited factors.

Obtaining the best route to get to the destination is another important task of the MMS. In a complex IAMHS, there are many possible routes consisting of different AMHS types. The IAMHS in Fig. 55.5 is represented by the graph in Fig. 55.6. A graph can be encoded in database tables by using an adjacency matrix or incidence matrix for use by a computer program. The adjacency matrix is a simple from–to chart between a pair of vertices, in which the value of an edge is the distance between the vertex pair, being zero if the pair are not connected. The incidence matrix represents the connectivity of vertices by edges. Using a graphical representation of the IAMHS, many predefined properties and algorithms of graph theory can be applied to develop algorithms for the MMS; for example, Dijkstra's algorithm can be used to determine the shortest path from a source to destination location.

The time intervals between the arrivals of transfer commands are sometimes completely random in that there are significant fluctuations in the number of arrivals during different time periods. When the queue size increases on AMHSs, use of different priorities for transfer commands often provides a very useful solution to improve overall system performance. It is reported that a good priority algorithm can improve the throughput of a production facility [55.15].

There are two types of tables in the database of the MMS. One type of table stores parameters for control algorithms and status user interfaces (UIs). These need a minimum number of entities to achieve a shorter transaction time when they are queried. The other type of table stores data for movement histories based on communication messages between component systems of the IAMHS. The accuracy of these historical data have been significantly improved by material handling automation with advanced information interface technology (IIT) by using RFID technology or barcode systems. A large amount of information can be extracted from the historical data, including the standard operating time of a machine, the processing routes of



Naming convention of vertices in the graph:
Two-digit number in a vertex followed by alphabets represents the index number of machines or AMHS. For example, M01 is the machine #1 connected to AGVS #1 and CS 01 is the conveyor #1. Acronyms are as follows. M: Machine, AS: AS/RS, CS: Conveyor System

Fig. 55.6 Graphical representation of the IAMHS in Fig. 55.5

a unit load over machines in different process stages, the lead time of the unit load from start to finish, etc.

These data provide useful information for various purposes. Most of all, without accurate data from production and warehouse systems, it is hard to achieve successful realization of the enterprise-level decision support systems explained above. Good planning strongly depends on accurate data. In practice, many companies have invested in expensive ERP systems capable of automated production planning for their shop floors; however, many of them do not use the module because of poor planning and scheduling quality from the system. One of the main reasons for this poor quality is sometimes due to the lack of good data from the material handling system, which relies on manual jobs and operator paperwork. Accurate data from AMHSs also helps to achieve lean manufacturing on the shop floor by providing precise measures. For a complicated shop floor, it is often difficult to define a bottleneck stage or performance measures of the bottleneck machines. Lean manufacturing starts from well-defined and accurate performance measures. Many details of the machines can be analyzed by data relating to material movements from machine to machine, examples of which include machine throughput, product lead time, and the work-in-process (WIP) for each processing stage. Sometimes they also provide benefits for engineering analysis for the improvement of quality control. The performance of the IAMHS can also be measured and improved by using these historical data. A new algorithm under test can be easily tracked to assess how it performs in an actual application. Since there are many data transactions, summarized tables are sometimes used for long-term analysis. Data-mining approaches are helpful in designing these tables.

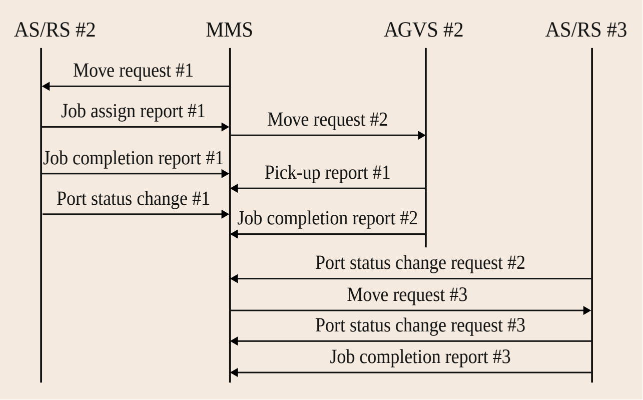


Fig. 55.7 Message sequence for a simple transfer command

Another important task of the MMS is the path management function, which controls a sequence of transportation jobs. Let us consider the following simple transfer request as an example. A transfer request is sent to the MMS from the dispatching module to move a unit load from a rack in AS/RS #2 to AS/RS #3 through AGVS #2 in Fig. 55.5. Figure 55.7 shows a message sequence illustrating communication between the MMS and AS/RS controllers involved in this transfer, and between the MMS and AGV controller. A few more messages might be used in actual systems. As seen in the figure, although this is a relatively simple transferring task, more than 13 messages are used to complete the task. First, transfer request #1 is triggered by the MMS (it can be triggered by either the dispatching module or a procedure of the MMS itself). This request message transmits the source location as AS/RS #2, the destination as the unload port of the AS/RS, and the unit load identity to the AS/RS controller #2. If there are other high-level systems such as a WMS or MES, the MMS will send additional messages to these systems. In this case, the status of the unit load possibly needs to be updated from *Waiting* to *Busy* or *Transferring* for the WMS and MES. To send this message to AS/RS controller #2, the MMS has to make at least two major decisions: it has to select an unload port among several idle ports, and to determine to which among the many other AMHSs this message should be sent. For the former decision, the closest idle port to the next destination (i. e., AGVS #2) is selected based on the MMS algorithm. After receiving the transfer request from the MMS, AS/RS controller #2 will put the job into its queue, if it is performing other tasks. If it is its turn, the controller will send the job assign report to the MMS so that it triggers another transfer request command to AGV controller #2. This transfer command could be sent later after the job completion message from the AS/RS controller #2 has been received; however, by sending before the completion message, it can synchronize the transfer activities of two systems and thereby reduce the waiting time of the unit load for the vehicle at the unload port of AS/RS #2. The explanation of the rest of the messages in the figure is omitted.

The MMS integrates not only systems but also human operators in the system environment. A user interface (UI) plays a major role in this integration. Operators can monitor the number of AMHSs using the UI. Also, parameters to control an individual AMHS and IAMHS are changed through the UI. Another important function provided is reporting. Various reports can be queried directly from the database of the MMS.

55.3 Advanced Technologies

This section surveys advanced technologies enabling the IAMHS to achieve the high-level MHA. First, the IIT utilizing wireless devices will be reviewed, then the focus will move onto design and control issues of the MHA. A wide range of methodologies across artificial intelligence (AI) and operations research (OR) techniques have been adopted to solve challenging problems in design and control of MHA. The design and control issues with AMHS types will be briefly described including different points of interest. The review focuses on the technical issues of the MMS, which is the most important element of the IAMHS. Finally, AI and OR techniques are compared according to several criteria in MHA.

55.3.1 Information Interface Technology (IIT) with Wireless Technology

Benefits of wireless communication systems include mobility, installation flexibility, and scalability. Applications of the wireless communication used for MHA are radiofrequency identification (RFID), wireless local-area network (LAN) (i. e., Ethernet), and wireless input/output (I/O). The wireless sensor network has also great potential for many applications of the MHA to collect data or form a closed-loop control system.

Radiofrequency Identification (RFID)

RFID enhances information tracking with a wide variety of applications for material handling [55.16]; for example, it prevents loss of boxes and incorrect shipping in a distribution center and reduces time for reading tags in boxes or carriers on a manufacturing shop floor. Its greatest advantages over barcode systems are its long read range, flexibility of locating tags in boxes, multitasking for reading many tags at the same time, and robustness against damage. Finally, RFID systems increase the accuracy of data from material handling systems and reduce time for data collection. With more reliable and faster information tracking, more sequential operations can be automated and integrated without affecting system performance or requiring human interventions. It also enables the development of higher-level MHA in production and warehouse systems.

An RFID system consists of tags and readers. An RFID tag has two components, a semiconductor chip and antenna, and there are basically two types of RFID tags, *passive and active tags*, based on the source of the power. A passive tag does not have a battery and is powered by the backscattered RF signal from the reader, while an active tag has a battery and is therefore more reliable. Although the read range of a tag depends strongly on its power level, antenna, and frequency, and the environment in which it is used, an active tag can have a range of up to 30 m or more while a passive tag can be read reliably over a few meters. In between these two types, there is a semiactive tag that is powered by RF from the reader and consumes power from a battery while communicating with the reader. The lifetime of the battery is about 7 years or more. Another classification of RFID tags is based on the ability to write information to tags. Some tags are classified as *read-only* and can be written only once but read many times; these are generally passive tags. Information can be written by both users and producers. There are also rewritable passive tags in which the program can be rewritten by users. Most active tags are rewritable. RFID readers send RF signals to tags, receive signals from tags, and communicate with a central system. Their functions varies from a simple on/off check for data collection to control of a large system. Popularly used tags are as large as an electronic card, being installed in a larger computer system with network capability; however, they can be as small as $0.05 \times 0.05\,\mathrm{mm}^2$, as shown in Fig. 55.10. On the right-hand side of Fig. 55.8, powder-type RFID chips developed by Hitachi are compared with a human hair.

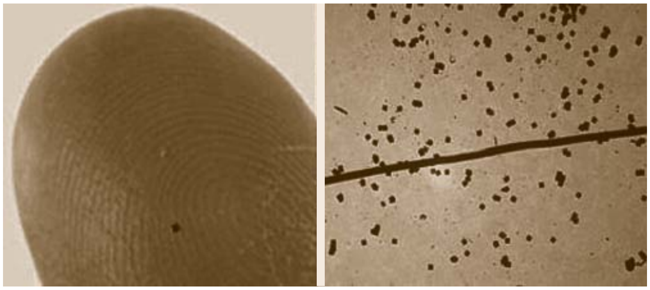

Fig. 55.8 Mu-chips and powder type RFID chips (courtesy of Hitachi)

These powder-type RFID tags are 64 times smaller than those in current use ($0.4 \times 0.4\,\mathrm{mm}^2$ mu-chips, on the left, produced by the same company), which can already be embedded into paper currency, gift certificates, and identification documents. For more information in RFID see Chap. 49.

Wireless LAN

A wireless LAN establishes a network environment by using wireless devices instead of wired ones within a limited space. One popular application that adopts wireless LAN in MHA is AGV systems, which use it for communication between vehicles and controllers. Each vehicle has a network interface card (NIC) that is connected to the wireless LAN. An access point is a gateway to connect to a wired LAN and similar to a LAN hub, connecting 25–50 vehicles within a range of 20–150 m. The infrastructure network is always connected to an access point, which connects the wired LAN with the wireless LAN. In the infrastructure network, the basic service set (BSS) is formed and acts as a base station connecting all vehicles in the cell to the LAN. BSSs that use nonoverlapping channels can be part of an extended service set (ESS). The vehicles within the ESS but in different BSSs are connected through roaming. *Lee* and *Lee* [55.17] develop an integrated communication system that connects Profibus and IEEE 802.11, which are wired and wireless LAN communication protocols, for a container terminal automated by an AGV system. Using this protocol converter, the wireless LAN can be connected to the existing wired fieldbus for soft real-time data exchange that loses some of its usefulness after a time limit.

Wireless I/O

A wireless I/O device is a small circuit card with an antenna installed in a material handling system or its controller; it can be used for both data-acquisition and closed-loop control applications. It receives microwave radio data from I/O points, and sends those data to a central processing device such as a programmable logic controller (PLC), data loggers, supervisory control, and data-acquisition system (SCADA), or a general PC [55.18]. Since it does not use wireless LAN or a fieldbus, implementation is much easier than afor wireless LAN. It can be simply regarded as removing the necessity for wires; however, by itself, it offers many advantages such as broader connectivity, increased mobility and flexibility, reduced installation time, and reduced points of failures. One of the disadvantages of wireless I/O is that, since it uses a relatively narrow range of wireless signals, a smaller number of wireless I/Os can be used in a certain area. Therefore, as the number of points in an area grows, a wireless or wired LAN will become more appropriate.

Wireless Sensor Networks

Sensor networks [55.19] are currently limited to novel systems. Many sensors, distributed in a system or area, can be used to build a network for monitoring a space shuttle, military equipment unit or nuclear power plant. Wireless sensor networks conceptually use small, smart, cheap sensors that consist of a sensing module, a data-processing module, and communication components; however, conventional sensors can also be used. The network is mainly used for monitoring systems that requires highly autonomous and intelligent decision-making in a dynamic and uncertain environment. They have a great deal of potential to be adopted in MHA even though few researchers have studied these applications. There are two areas of wireless sensor network applications for the MHA.

First, reliability is often very important for the MHA because, in a highly automated system, the failure of an AMHS causes the breakdown of multiple machines or a whole area operated by the system. This may be more critical than the failure of an individual processing tool in production systems. Therefore, monitoring and diagnosing the AMHS lead to some important issues; for instance, vibration sensors and optical sensors attached to the crane of an AS/RS collaborate to detect a potential problem that might cause positioning or more critical errors. By detecting the problem before the AS/RS actually breaks down, engineers can recognize the problem more precisely and prepare required parts and tools in advance; hence, repair time can be significantly reduced.

Second, most AMHSs use a closed feedback system that controls the system based on feedback from component systems or sensors. *Walker* et al. [55.20] studied a method to control an industrial robot that handles flexible materials such as wires and rubber hoses. It utilizes feedback from sensor network cameras to predict the motion of the robot with the better vision. Since the feedback can be created from many different points such as grasps, paths, and goal points, it reduces blind spots of unpredictable motions and greatly enhances control precision. Chapter 20 provides additional information on sensor networks.

Table 55.1 Design issues and related studies on MHA

Reference	AMHS type	Design issue	Criteria	Solution approach
Cho and *Egbelu* [55.21]	IAMHS	MHS equipment selection problem	Qualitative factors, equipment variety (minimizing)	Fuzzy logic and knowledge-based rule
Nadoli and *Rangaswami* [55.22]	IAMHS	Design and modeling for a new semiconductor fab	Design lead time	Expert system, computer simulation
Jimenez et al. [55.23]	IAMHS	Performance evaluation of AMHS	Delivery time, transport time, throughput	Computer simulation
Huang et al. [55.24]	General MHS	Location of MHS	Total distance, fixed cost of MHS	Lagrangian relaxation and heuristic method
Jang et al. [55.25]	AS/RS	Estimation of AS/RS performance	Delivery rate, in-process inventory	Queuing network model
Lee et al. [55.26]	AS/RS	Optimal design of rack structure with various sized cells	Space utilization (lost space)	Modular cells, heuristic
Ting and *Tanchoco* [55.27]	AGV	Location of the central path	Total rectilinear distance	MIP
Gaskins and *Tanchoco* [55.28]	AGV	Guide path design: direction of path segments	Total flow distance	Integer programming, heuristic
Tanchoco and *Sinriech* [55.29]	AGV	Guide path design: optimal design of a single-loop	Total flow distance	Integer programming
Bozer and *Srinivasan* [55.30]	AGV	Guide path design: tandem guide path	Balanced workload	Integer programming, set partition
Caricato and *Grieco* [55.31]	AGV	Guide path design	Flow distance, computation time	Simulated annealing
Nazzal and *McGinnis* [55.32]	AGV	Estimation of performance measures	Vehicle utilization, blocking time, empty vehicle interarrival time	Queuing network model
Vis et al. [55.33]	AGV	Estimation of the number of vehicles	Service level (waiting time)	Network flow

55.3.2 Design Methodologies for MHA

MHA design studies largely deal with strategic decision-making, which includes optimal selection of automated material handling equipment, locating storage and vehicle paths for new facility planning, rack design for AS/RSs, flow path design for AGV systems, and capacity estimation of the system. Table 55.1 briefly summarizes studies related to design issues. The MHA design problem is sometimes closely related to the layout design problem in that both consider issues at a very early stage of system implementation. Also, they share performance measures in many areas. *Peters* and *Yang* [55.34] integrate these two methods into a single procedure using the space-filling curve (SFC) method. *Ting* and *Tanchoco* [55.27] propose a new layout design method for a semiconductor fab. They use an integer programming model to determine the optimal location of the AGV track. *Chung* and *Jang* [55.35] also suggest a new layout alternative called *integrated room layout* for better material handling in a semiconductor fab and scrutinize the benefits of the layout compared with existing layout alternatives in the industry using qualitative and quantitative analysis.

One of the difficulties in design of large-scale IAMHSs is estimation of system capacity. Although computer simulation has been used, its feedback cycle from modeling to results analysis is very slow for a large problem, which is an issue as timing of the solution is sometimes very important. Also, a simple deterministic analysis using from–to charts of material flows cannot provide a precise estimation of variances in the system. As an alternative approach studied for capacity analysis, the queuing network approach shows good performance [55.32]. *Rembold* and *Tanchoco* [55.36] explore a framework that evaluates and improves a sequence of modeling tasks for material flow systems. They aim to develop a more fundamental solution to the problems while encountered while designing an IAMHS. The framework addresses the following questions of designers: selection of the software application for solving a problem, organizing the data sets required for the design, incorporation of the design into parts that cannot be automated, and diagnosing problems in material flow systems. Those authors use an open architecture for the framework, since advance identification of all factors and cases for evaluation and redesign of the material flow processes are limited. With the open architecture for the framework, users can easily find their own methods by incorporating ad hoc situations into the framework.

55.3.3 Control Methodologies for MHA

Extensive research has been performed on the control of the AMHS. Especially, AGV control problems have benefited from strong research streams in academia and the MHA industry, since AGVs have been popular for use in many industries. Figure 55.9 shows an interesting AGV design with many storage racks that is used in a hospital. Recently, two well-organized literature surveys on the AGV system were published by *Vis* [55.37], and by *Le-Anh* and *De Koster* [55.38]. One of the characteristics of control algorithms of MHA is that minimizing flow distance in time is a dominant criterion, among others. Other criteria such as resource utilization, throughput, and load balance have frequently been subgoals to achieve the minimum flow time. Necessity for a very short response time is another characteristic of control algorithms for the MHA; for example, a vehicle dispatch algorithm for the AGV controller should respond within a few seconds or less, otherwise the vehicle will have to wait for a job command on the path. For a short response time, the time horizon of the control algorithms is zero or very short, because a longer time horizon often causes an explosion of the search space. The minimum control horizon also helps to yield a reliable solution because uncertain parameters will be used less. If a control algorithm malfunctions, the result will be more serious than just a performance drop. It sometimes causes a detrimental failure in the shop floor. Hence, a conservative approach tends to be used in real applications.

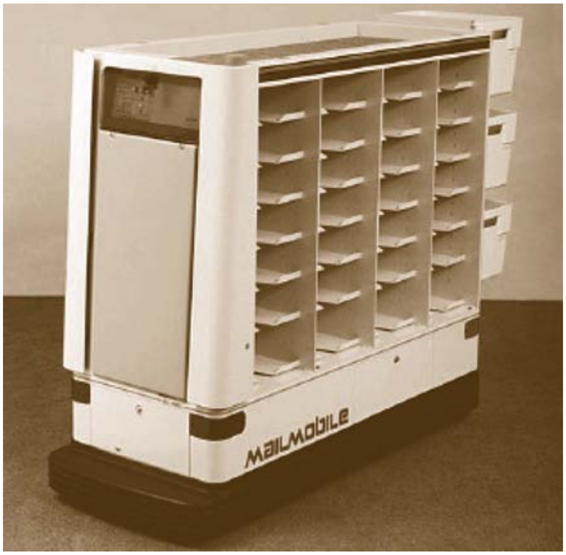

Fig. 55.9 AGV used in a hospital (courtesy of Egemin)

A big challenge in AGV control problems is that users want to use a larger loop with many vehicles in order to reduce transportation time and investment. AGV systems implemented earlier generally used a modular structure to avoid heavy load on one AGV loop and had many loops, with a maximum of about five vehicles in a loop; however, these days, a large loop with a maximum about 40 vehicles is used. Therefore, the vehicle dispatch, scheduling, routing, and deadlock avoidance problems are becoming more complicated and important. Table 55.2 summarizes control issues and their studies in the MHA.

Table 55.2 Control issues and related studies on MHA

Researchers	AMHS type	Control issue	Criteria	Solution approach
Dotoli and *Fanti* [55.39]	IAMHS	Integrated AS/RS and RGV control	Throughput, computation time	Colored Petri nets
Mahajan et al. [55.40]	AS/RS	Job sequencing	Throughput	Heuristic (nearest neighborhood)
Lin and *Tsao* [55.8]	AS/RS	Crane scheduling for batch job in CIM environment	Total fulfillment time of batch	Heuristic (dynamic availability oriented controller)
Lee et al. [55.41]	AS/RS	Rack assignment for cargo terminals stochastic demand	Expected travel time	Heuristic (storage reservation policy), stochastic
Chetty and *Reddy* [55.42]	AS/RS	Job sequencing	10 criteria (mean flow time, mean waiting time, min/max completion time, etc.)	Genetic algorithm
Sinriech and *Palni* [55.43]	AGV	Vehicle scheduling	Optimality of scheduling solution	MIP, heuristic (branch and bound)
Correa et al. [55.44]	AGV	Vehicle scheduling	Solution time, job processing time	MIP and CP hybrid method

IAMHS Research

Researchers recently started to study complicated issues of the IAMHS. A major concern is routing strategies from source to destination location in a complicated IAMHS, in which there are multiple routes from one location to the others. The routes consist of not only physical paths such as an AGV path or conveyor track but also AMHS themselves, such as AS/RSs, AGVSs, and buffer stations. Practical applications generally store predetermined static shortest routes in a database for all pairs of source locations and destinations; however, when the number of components increases, maintenance problems for the parameters involved become much more difficult since there are too many combinations of nodes. The shortest-distance algorithm using graph theory with an adjacency matrix might be a better approach.

A new concept called *flow diversion* is proposed to determine dynamic routing based on the load rate of the routes in automated shipment handling systems by *Cheung* et al. [55.51]. The authors utilize the multicommodity flow models using linear programming (LP) to solve this problem. In this model, the transfer time for a route is a function of the loads assigned to all pairs of unit loads in the system, which generates a nonlinear function in the objective function; those authors transform this nonlinear function to a piecewise-linear function to make the problem tractable. *Lau* and *Zhao* [55.4] study a joint job scheduling problem for the automated air cargo terminal at Hong Kong, which is mainly composed of AGV systems, AS/RSs, cargo hoists, and conveyors. In the model, activities between different AMHSs are triggered by communication between the systems. The scheduling algorithm constructs a cooperative sequential job served by different AMHSs, employing the maximum matching algorithm of the bipartite graph. A task for an AGV is assigned or matched to an stacker crane (SC) to reduce the SC delay time. A similar problem is solved by *Meersmans* and *Wagelmans* [55.5]. Their research focuses on the scheduling problem of the IAMHS in seaport terminals employing a local beam search algorithm. The nodes explored in the search algorithm are represented by a sequence of container IDs to be processed by different AMHSs, and the nodes in branches are cut based on the beam width determined by an evaluation function. Those authors prove that there exists an optimal sequence of tasks for one AMHS when the sequence is assigned to the other AMHS.

Sujono and *Lashkari* [55.52] study another integrating method allocating a part type to a processing machine and material handling (MH) equipment type simultaneously in a flexible manufacturing system (FMS). In that research, there are nine different types of the material handling systems in the experimental model. The method improves the algorithms proposed by *Paulo* et al. [55.53] and *Lashkari* et al. [55.54] and uses a 0/1 mixed integer programming model. Two objective functions are modeled: one minimizes operating costs related to machine operations, setup, and MH operations; the other maximizes the compatibility of the part types using MH equipment types. To measure compatibility, parameters are quantified from the subjective factors defined by *Ayres* [55.55]. Some of the constraints are: balance equations between parts and process plans, machines and process plan, processing machines, and MH equipment types. The other important constraint sets are capacity constraints: the total load of the allocated tasks for an MH equipment type cannot exceed its capacity, and a machine cannot be allocated more than its capacity. A test problem consisting of 1356 constraints and 3036 binary variables was solved in about 9.2 s by using LINGO in a Pentium 4 PC. Since this model considers many details of the practical factors in the FMS, and showed a successful calculation result, it can be used for many other practical applications.

In addition to the examples shown above, large-scale optimization problems such as the vehicle routing problem (VRP), vehicle scheduling problem (VSP), and integrated scheduling problem of IAMHS with consideration of processing machines have been modeled to increase MHA efficiency. However, to be used for actual applications and thereby achieve a higher-level MHA, shorter computation times are urgently required. In a complicated IAMHS, integrating software packages such as the MMS need sophisticated algorithms; however, it also needs high reliability in a dynamic environment. For most tasks, real-time decision-making that requires response times within a few seconds is a precondition for IAMHS algorithms.

MMS-related Issues

The MMS is a key component to integrate different AMHSs in an IAMHS. Destination allocation, routing algorithm, and prioritizing algorithm are essential roles of the MMS, among others. Graph theory is popularly used to represent components and relationships in the IAMHS. In Fig. 55.6, nodes represent the AMHSs and their subcomponents, such as load/unload ports. Edges represent the connection and distance between nodes. As mentioned above, this graph is stored in database tables using the adjacency and incidence matrices. The shortest-path algorithm is the most important and fundamental algorithm for an MMS since it is used for several purposes in the system such as destination assignment and best routing determination. Dijkstra's algorithm is popularly used [55.56]. The Bellman–Ford algorithm can be used if there are negative weights of the edges.

To determine the final destination of a unit load, the MMS has to evaluate various factors on the same scale. More specifically, to determine an AS/RS as the final destination among several alternatives, the shortest distance is generally the most important criterion; however, the full rates of the AS/RSs are sometimes also important to make the loads balanced between different AS/RSs. There are two applicable ways to standardize different scales of factors on the same scale. First, different weight values can be applied for each factor to find the best alternatives. Second, a priority and its threshold value can be given to each factor, and the most important alternative is selected if it is within the threshold, otherwise the next alternative will be considered.

Determining the best route from a source to destination location via several AMHSs is relatively simple when compared with the vehicle routing problem (VRP) or vehicle scheduling problem (VSP), because the graph generally has a smaller number of nodes than those of the general VRP or VSP. However, the problem can be complicated when the load level of systems has to be taken into account. A flow cost function determines the weight value of an edge based on the queue size and system processing time for one unit in an AMHS, i. e., the load level is measured by these factors. It converts the weight value to a distance value by using the speed factor of the system. In an actual problem, this task can be considerably more complicated.

Prioritizing for the unit load is sometimes very useful for vehicle-initiated dispatching rules [55.11] when the IAMHS becomes a bottleneck in an FMS for a certain period of time. The priority determined by the MMS can be used by an AGV controller to determine a job priority for a vehicle that has just become idle; for example, the first-come first-served rule picks up the job with the longest waiting time for all unit loads in the queue. If a priority is given to each job from 1 to 5, the priority unit can be treated as a certain time scale, e.g., 10 min, for each unit. Together with the actual waiting time, the controller can prioritize the unit loads; for instance, if a unit load waits for a vehicle assignment for 5 min and its priority given by the MMS is 3, then its final priority can be $10 \times 2 + 5$ min, which is equal to 25 min. The prioritizing methods used by the MMS generally address problems of how to avoid machine starvation. While various MMS prioritizing rules can be used based on the constraints of the shop floor, the importance of considering bottleneck machines to determine transfer priorities of unit loads is emphasized by *Koo* et al. [55.46] and *Li* et al. [55.15].

55.3.4 AI and OR Techniques for MHA

It is worthwhile to compare AI search and OR optimization techniques with respect to several different criteria of logical flexibility, computation time, and application areas in MHA. In general, AI search algorithms define problems with four instances: initial state, successor function, goal test, and path cost function [55.57]. The initial state is a state in which the given problem starts. The successor function receives a state as a parameter and returns a set of actions and successors. And the successors are new states reachable from the given new state. The definition of the state together with the successor function is very important to determine the overall search space of the given problem and information necessary for the solution. The goal test determines whether a given state satisfies all the conditions of the goal state. The path cost function calculates a numerical cost for each path explored by the successor function.

There are two types of AI search algorithms: uninformed and informed search. Uninformed search does not use prior information to explore a solution. Examples of uninformed search algorithms are the depth-first search, breadth-first search, and bidirectional search. Informed search utilizes given information for new states that will be opened during the search. Informed search is also called heuristic search, which includes greedy best-first search, A* search, memory-bounded, and local beam search, which again includes simulated annealing, tabu search, and genetic algorithm. Constraint programming (CP) is one of the AI search methods that uses a standard structured representation consisting of the *problem domain* and *constraint*. Figure 55.10 explains the main procedure used by the ILOG CP solver [55.58]. The domain is a set of possible values of the variable representing the problem, and the constraint is a rule that imposes a limitation on the variable. The most powerful aspect of this method is that it utilizes the concept of *constraint propagation*. It narrows down the search space by imposing a constraint on variables and the constraint imposed further reduces domains of other variables based on the constraints already posted on the variables. Among reduced domains of variables, the method uses a branching process with a backtracking algorithm to find the best solution. Because of high modeling flexibility, AI techniques have been popularly used for a wide variety of control applications such as robotics and automated planning.

The following studies illustrate the use of AI techniques for MHA. *Cho* and *Egbelu* [55.21] use

Table 55.3 Comparison of AI and OR techniques

Comparison items	AI approaches	OR approaches	Hybrid approaches
Modeling flexibility	High	Low	High
Time horizon	Short	Long	Long
Response time	Short	Long	Medium
Problem size	Small	Large	Large
Illustrations	IAMHS design: AMHS equipment type selection [55.21] AS/RS: Job sequencing [55.40], Stacker scheduling [55.8], Rack design [55.26] AGV: Deadlock avoidance [55.49]	IAMHS design: Performance evaluation [55.25, 32], AGV: Guide path design [55.28], AMHS location [55.24, 27]	AGV vehicle scheduling [55.44, 60] IAMHS: Integrated scheduling of AMHS and FMS [55.52]

knowledge-based rules, fuzzy logic, and decision algorithms to address AMHS equipment type selection problems. Their procedures consist of three phases: material handling equipment selections for each material flow connections, redundancy and excess capacity check, and budget constraint consideration. *Chan* et al. [55.59] also solve a similar problem using an expert system. An order picking sequence problem in an AS/RS is addressed by *Mahajan* et al. [55.40] by using an AI technique. In their procedure, the state is represented by a sequence of the orders, and a success function providing a selection criterion of the order sequence is developed by a nearest-neighborhood strategy.

Operations research techniques mainly focus on the optimization problems based on linear programming (LP) [55.61]. LP is extended to integer programming (IP) and mixed integer programming (MIP), that deal with integral variables, quadratic programming that uses a nonlinear objective function, and nonlinear programming that allows nonlinear functions in both the constraint and objective function. Stochastic programming, which incorporates uncertainties in its modeling, is also a variant of the LP. OR techniques use well-structured mathematical models of linear, integer, quadratic or nonlinear models. Simulation and queuing analysis form another important technical area of stochastic OR, mainly used for performance analysis.

OR techniques are also popular for solving problems in MHA. *Gaskins* and *Tanchoco* [55.28] and *Tanchoco* and *Sinreich* [55.29] formulate AGV guide path design problems using 0/1 MIP. *Nazzal* and *McGinnis* [55.32] estimate the system capacity requirement of the large-scale AMHS in a semiconductor fab by utilizing a queuing network model. *Ting* and *Tanchco* [55.27] and *Huang* et al. [55.24] address the location problems of the AMHSs in facility layouts using MIP formulations. Huang et al. further use a heuristic approach employing the Lagrangian relaxation method.

AI and OR have their backgrounds in computer science and industrial engineering, respectively. AI approaches utilize knowledge representation to solve a problem; however, OR techniques use mathematical modeling of the problem. Knowledge representation consists of symbols and mathematical equations with relationships. OR techniques generally use dedicated solvers such as CPLEX and LINDO to solve mathematical models of the problems, whereas AI techniques use their own languages such as list processing (LISP), and programming in logics (Prolog). Constraint programming (CP) uses a solver similarly to the OR solvers but has much greater flexibility in using procedures and algorithms. A widely known CP solver is the ILOG solver. One advantage of AI over OR techniques is their flexibility in expressing problems. Since the AI techniques listed above do not use strict mathematical formulations to represent problems, there is a great deal of flexibility to deal with instances and activities in the problems. On the other hand, OR techniques model problems with strict mathematical procedures that are generally used repeatedly in different problems. While OR techniques find optimal or near-optimal solutions, AI techniques find good solutions for the given problems. OR techniques have focused on large-scale optimization problems for decision support systems while AI techniques are rooted in control problems that have shorter horizons but need reliable solutions. However, it is also true that there has been some overlap between AI and OR techniques, especially for local beam search algorithms. Also, a group of researchers has tried to take advantage of the two techniques by integrating procedures in the techniques [55.44]. For more complete reviews on the history and state of the art comparing AI and OR techniques, refer to *Gomes* [55.61], *Kobbacy* et al. [55.62], and *Marcus* [55.63].

Table 55.3 compares AI, OR, and their hybrid approaches with several different characteristics. An application area that needs great logical flexibility, such as the selection problem of material handling systems, tends to use AI techniques more frequently. Problems with shorter time horizon use AI heuristic search approaches (second row in the table), and problems with a longer time horizon tend to use the OR approaches. Hybrid approaches focus on reducing computation times. OR techniques are frequently used for AMHS design problems because response time is less important for them and they consider a large number of instances in the system. The AGV dispatching and routing problems tend to use both heuristic and OR approaches to similar degrees. Approaches integrating AI and OR approaches pursue both flexibility and optimality and have been applied to very complicated problems for the MHA [55.44], which deal with AGV scheduling problems and integrated scheduling of IAMHS with FMS. Examples on application areas and their approaches used are listed in the last row of Table 55.3.

55.4 Conclusions and Emerging Trends

Material handling automation (MHA) in production and warehouse management systems provides speedy and reliable infrastructure for information systems in SCM such as ERP system, FMS, WMS, and MES. Most of all, it enhances accurate data tracking during material handling in shop floors and warehouses. Relying on these accurate data, high-level automation such as production and procurement planning, scheduling, and dispatching in the SCM systems can be made much more reliable; consequently, more intelligent functions in their decision-making procedures can be added. Another trend in MHA, the integrated and automated material handling system (IAMHS), has been increasingly implemented in various applications to help ever-complicated material handling operations in large-scale production and warehouse systems. The important issues of the IAMHS reviewed in this chapter can be largely broken down into design and control issues. The design issues cover material handling equipment selection, capacity estimation, innovative equipment design, and system design optimization. The control issues that have been hard constraints for the higher-level MHA tend to involve domain-specific problems for each component system in the IAMHS such as the AS/RS, AGVS, or MMS.

Several potential routes for further increasing the level of intelligence in the MHA are recognized in this chapter. While the number of components in the IAMHS continues to increase, long response time is regarded as a major limitation during implementations of new control algorithms. Continuous efforts to reduce the computation time of algorithms in the future are desired. It is also pointed out that newly developed algorithms should take into account system architecture for practical applications. As another possibility, a sensor network might be used for diagnosis of AMHSs since their reliability is becoming critical, and also its closed feedback mechanism can potentially be used for more precise controls, as seen in each context.

56. Industrial Communication Protocols

Carlos E. Pereira, Peter Neumann

This chapter discusses a very relevant aspect in modern automation systems: the presence of industrial communication networks and their protocols. The introduction of Fieldbus systems has been associated with a change of paradigm to deploy distributed industrial automation systems, emphasizing device autonomy and decentralized decision making and control loops. The chapter presents the main wired and wireless industrial protocols used in industrial automation, manufacturing, and process control applications. In order to help readers to better understand the differences between industrial communication protocols and protocols used in general computer networking, the chapter also discusses the specific requirements of industrial applications. As the trend of future automation systems is to incorporate complex heterogeneous networks, consisting of (partially homogeneous) local and wide area as well as wired and wireless communication systems, the concept of virtual automation networks is presented

56.1 Basic Information

56.1.1 History

Digital communication is now well established in distributed computer control systems both in discrete manufacturing as well as in the process control industries. Proprietary communication systems within SCADA (supervisory control and data acquisition) systems have been supplemented and partially displaced by Fieldbus and sensor bus systems. The introduction of Fieldbus systems has been associated with a change of paradigm to deploy distributed industrial automation systems, emphasizing device autonomy and decentralized decision making and control loops. Nowadays, (wired) Fieldbus systems are standardized and are the most important communication systems used in commercial control installations. At the same time, Ethernet won the battle as the most commonly used communication technology within the office domain, resulting in low component prices caused by mass production. This has led to an increasing interest in adapting Ethernet for industrial applications and several approaches have been proposed (Sect. 56.1.4). Ethernet-based solutions are dominating as a merging technology.

In parallel to advances on Ethernet-based industrial protocols, the use of wireless technologies in the industrial domain has also been increasingly researched. Following the trend to merge automation and office networks, heterogeneous networks (virtual automation networks (VAN)), consisting of local and wide area networks, as well as wired and wireless communication systems, are becoming important [56.1].

56.1.2 Classification

Industrial communication systems can be classified as follows regarding different capabilities:

- *Real-time behavior*: Within the automation domain, real-time requirements are of uttermost importance and are focused on the response time behavior of data packets. Three real-time classes can be identified based on the required temporal behavior:
  - Class 1: soft real-time. Scalable cycle time, used in factory floor and process automation in cases where no severe problems occur when deadlines are not met.
  - Class 2: hard real-time. Typical cycle times from 1 to 10 ms, used for time-critical closed loop control.
  - Class 3: isochronous real-time, cycle times from 250 µs to 1 ms, with tight restrictions on jitter (usually less than 1 µs), used for motion control applications.

  Additionally, there is a class *non real-time*, which means systems without real-time requirements; these are not considered here. It means (regarding industrial automation) exchange of engineering data maintenance, etc.
- *Distribution*: The most important achievement of industrial communication systems are local area communication systems, consisting of sensor/actuator networks (Chap. 20 and Sect. 56.3.2), Fieldbus systems, and Ethernet-based local area networks (LAN). Of increasing importance is the use of wide area networks (WAN) (telecommunication networks, Internet, etc.). Thus, it should be advantageous to consider WANs as part of an industrial communication system (Sect. 56.2), mostly within the upper layers of an enterprise hierarchy.
- *Homogeneity*: There are homogeneous parts (e.g. standardized Fieldbus systems) within an industrial communication system. But in real applications the use of heterogeneous networks is more common, especially when using WANs and when connected with services of network providers.
- *Installations types*: While most of the installed enterprise networks are currently wired, the number of wireless installations is increasing and this trend will continue.

56.1.3 Requirements in Industrial Automation Networks

The main requirements are:

- *Real-time behavior*: Diagnosis, maintenance, commissioning, and slow mobile applications are examples of non real-time applications. Process automation and data acquisition usually present soft real-time requirements. Examples of hard real-time applications are closed-loop control applications, such as in fast mobile applications and machine tools. Motion control is an example of an isochronous hard real-time application.
- *Functional safety*: Protection against hazards caused by incorrect functioning including communication via heterogeneous networks. There are several safety integrity levels (SIL) [56.2]. It includes the influence of noisy environments and the degree of reliability.
- *Security*: This means a common security concept for distributed automation using a heterogeneous network with different security integrity levels (not existent yet).
- *Location awareness*: The desired context awareness leads to the usage of location-based communication services and context-sensitive applications.

56.1.4 Chapter Overview

The remainder of the chapter is structured as follows. Section 56.2 discusses the concept of virtual automation networks (VANs), a key concept in future distributed automation systems, which will be composed of (partially homogeneous) local and wide area as well as wired and wireless communication systems leading to complex heterogenous communication networks.

In Sect. 56.3 the main wired industrial communication protocols are presented and compared, while Sect. 56.4 discusses wireless industrial communication systems. Section 56.5 deals with the use of wide area communications to execute remote automation operations.

56.2 Virtual Automation Networks

56.2.1 Definition, Characterization, Architectures

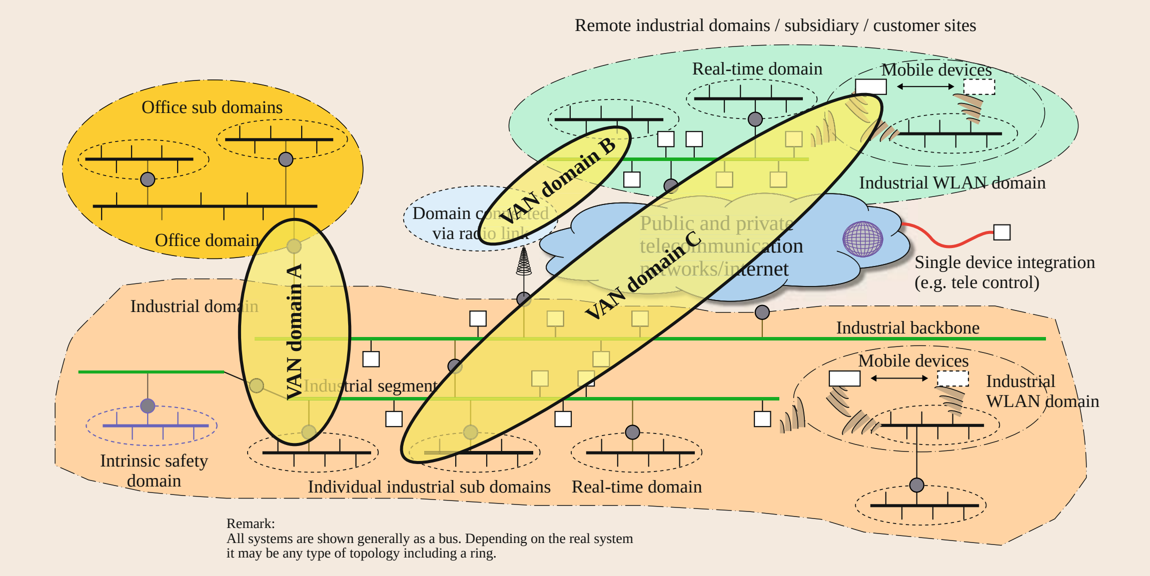
Future scenarios of distributed automation lead to desired mechanisms for geographically distributed automation functions for various reasons:

- *Centralized* supervision and control of (many) *decentralized* (small) technological plants
- Remote control, commissioning, parameterization, and maintenance of distributed automation systems
- Inclusion of remote experts or external machine-readable knowledge for plant operation and maintenance (for example, asset management, condition monitoring, etc.).

This means that heterogeneous networks, consisting of (partially homogeneous) local and wide areas, as well as wired and wireless communication systems, will play an increasing role. Figure 56.1 depicts the communication environment of a complex automation scenario. Following a unique design concept, regarding the objects to be transmitted between geographically distributed communication end points, the heterogeneous network becomes a *virtual automation network* (VAN) [56.3, 4]. VAN characteristics are defined for domains, where the expression *domain* is widely used to address areas and devices with common properties/behavior, common network technology, or common application purposes.

56.2.2 Domains

Within the overall automation and communication environment, a VAN domain covers all devices that are grouped together on a *logical or virtual* basis to represent a complex application such as an industrial application. Therefore, the encompassed networks may be heterogeneous and devices can be geographically



Remark:
All systems are shown generally as a bus. Depending on the real system it may be any type of topology including a ring.

Fig. 56.1 Different VAN domains related to different automation applications [56.3]

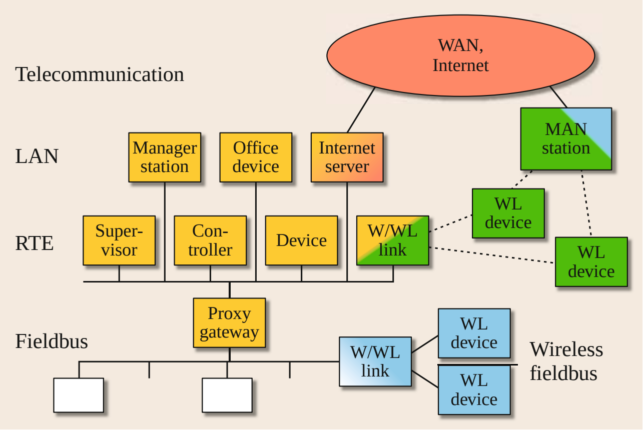


Fig. 56.2 Network transitions (local area networks (LAN), wireless LAN (WL), wired/wireless (W/WL), real-time Ethernet (RTE), metropolitan area network (MAN), wide area network (WAN))

distributed over a physical environment, which shall be covered by the overall application. But all devices that have to exchange information within the scope of the application (equal to a VAN domain) must be VAN aware or *VAN enabled* devices. Otherwise, they are VAN independent and are not a member of a VAN domain. Figure 56.1 depicts VAN domain examples representing three different distributed applications.

Devices related to a VAN domain may reside in a homogeneous network domain (e.g. the *industrial domain* shown in Fig. 56.1). But, depending on the application, additional VAN relevant devices may only be reached by crossing other network types (e.g., wide area network type communication) or they need to use proxy technology to be represented in the VAN domain view of a complex application.

56.2.3 Interfaces, Network Transitions, Transmission Technologies

A VAN network consists of several different communication paths and network transitions. Figure 56.2 depicts the required transitions in heterogeneous networks.

Depending on the network and communication technology of the single path there will be differences in the addressing concept of the connected network segments. Also the communication paths have different communication line properties and capabilities. Therefore, for the path of two connected devices within a VAN domain the following views are possible:

- The logical view: describing the properties/capabilities of the whole communication path
- The physical view: describing the detailed properties/capabilities of the passed technology-dependent communication paths
- The behavioral view: describing the different cyclic/acyclic temporal behavior of the passed segments.

There are different opportunities to achieve a communication path between network segments/devices (or their combinations). These are: Ethernet line (with/without transparent communication devices), wireless path, telecommunication network (1:1), public networks (n:m, provider-oriented), VPN tunnel, gateway (without application data mapping), proxy (with application data mapping), VAN access point, and IP mapping. All networks, which can not be connected via an IP-based communication stack, must be connected using a proxy. For connecting nonnested/cascaded VAN subdomains via public networks the last solution (VAN access point) should be preferred.

56.3 Wired Industrial Communications

56.3.1 Introduction

Wired digital communication has been an important driving force of computer control systems for the last 30 years. To allow the access to data in various layers of an enterprise information system by different users, there is a need to merge different digital communication systems within the plant, control, and device levels of an enterprise network. On these different levels, there are distinct requirements dictated by the nature and type of information being exchanged. Network physical size, number of supported devices, network bandwidth, response time, sampling frequency, and payload size are some of the performance characteristics used to classify and group specific network technologies. Real-time requirements depend on the type of messages to be exchanged: deadlines for end-to-end data transmission, maximum allowed jitter for audio and video stream transmission, etc. Additionally, available resources at the various network levels may vary significantly. At the device level, there are extremely limited resources (hardware, communications), but at the plant level powerful computers allow comfortable software and memory consumption.

Due to the different requirements described above, there are different types of industrial communication systems as part of a hierarchical automation system within an enterprise:

- Sensor/actuator networks: at the field (sensor/actuator) level
- Fieldbus systems: at the field level, collecting/distributing process data from/to sensors/actuators, communication medium between field devices and controllers/PLCs/management consoles
- Controller networks: at the controller level, transmitting data between powerful field devices and controllers as well as between controllers
- Wide area networks: at the enterprise level, connecting networked segments of an enterprise automation system.

Vendors of industrial communication systems offer a set of fitting solutions for these levels of the automation/communication hierarchy.

56.3.2 Sensor/Actuator Networks

At this level, several well established and widely adopted protocols are available:

- HART (HART Communication Foundation): highway addressable remote transducer, coupling analog process devices with engineering tools [56.5]
- ASi (ASi Club): actuator sensor interface, coupling binary sensors in factory automation with control devices [56.6].

Additionally, CAN-based solutions (CAN in automation (CIA)) are used for wide-spread application fields, coupling decentralized devices with centralized devices based on physical and MAC layers of the controller area network [56.7]. Recently, IO Link has been specified for bi-directional digital transmission of parameters between simple sensor/actuator devices in factory automation [56.8, 9].

HART

HART Communication [56.5] is a protocol specification, which performs a bi-directional digital transmission of parameters (used for configuration and parameterization of intelligent field instruments by a host system) over analog transmission lines. The host system may be a distributed control system (DCS), a programmable logic controller (PLC), an asset management system, a safety system, or a handheld device. HART technology is easy to use and very reliable. The HART protocol uses the Bell 202 Frequency Shift Keying (FSK) standard to superimpose digital communication signals at a low level on top of the 4–20 mA analog signal. The HART protocol communicates at 1200 bps without interrupting the 4–20 mA signal and allows a host application (master) to get two or more digital updates per second from a field device. As the digital FSK signal is phase continuous, there is no interference with the 4–20 mA signal. The HART protocol permits all digital communication with field devices in either point-to-point or multidrop network configurations. HART provides for up to two masters (primary and secondary). As depicted in Fig. 56.3, this allows secondary masters (such as handheld communicators) to be used without interfering with communications to/from the primary master (i. e. control/monitoring system).

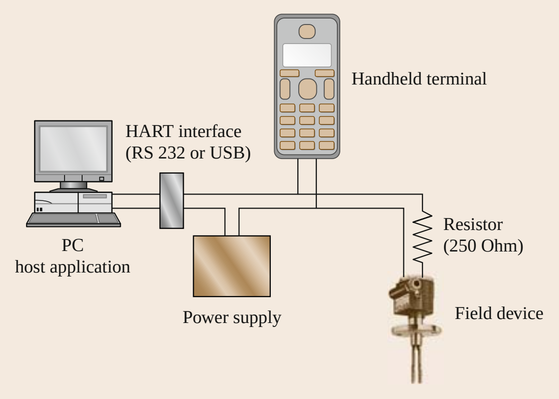

Fig. 56.3 A HART system with two masters (http://www.hartcomm.org)

ASi (IEC 62026-2)

ASi [56.6] is a network of actuators and sensors (optical, inductive, capacitive) with binary input/output signals. An unshielded twisted pair cable for data and power (max. 2 A; max. 100 m) enables the connection of 31 slaves (max. 124 binary signals of sensors and/or actuators). This enables a modular design using any network topology (i. e. bus, star, tree). Each slave can receive any available address and be connected to the cable at any location.

AS-Interface uses the APM method (alternating pulse modulation) for data transfer. The medium access is controlled by a master–slave principle with cyclic polling of all nodes. ASi masters are embedded (ASi) communication controllers of PLCs or PCs, as well as gateways to other Fieldbus systems. To connect legacy sensors and actuators to the transmission line, various coupling modules are used. AS-Interface messages can be classified as follows:

- Single transactions: maximum of 4 bit information transmitted from master to slave (output information) and from slave to master (input information)
- Combined transactions: more than 4 bits of coherent information are transmitted, composed of a series of master calls and slave replies in a defined context.

For more details see www.as-interface.com.

56.3.3 Fieldbus Systems

Nowadays, Fieldbus systems are standardized (though unfortunately not unified) and widely used in industrial automation. The IEC 61158 and 61784 standards [56.11, 12] contain ten different Fieldbus concepts. Seven of these concepts have their own complete protocol suite: PROFIBUS (Siemens, PROFIBUS International); Interbus (Phoenix Contact, Interbus Club); Foundation Fieldbus H1 (Emerson, Fieldbus Foundation); SwiftNet (B. Crowder); P-Net (Process Data); and WorldFIP (Schneider, WorldFIP). Three of them are based on Ethernet functionality: high speed Ethernet (HSE) (Emerson, Fieldbus Foundation); Ethernet/IP (Rockwell, ODVA); PROFINET/CBA: (Siemens, PROFIBUS International). The world-wide leading positions within the automation domain regarding the number of installed Fieldbus nodes hold PROFIBUS and Interbus followed by DeviceNet (Rockwell, ODVA), which has not been part of the IEC 61158 standard. For that reason, the basic concepts of PROFIBUS and DeviceNet will be explained very briefly. Readers interested in a more comprehensive description are referred to the related web sites.

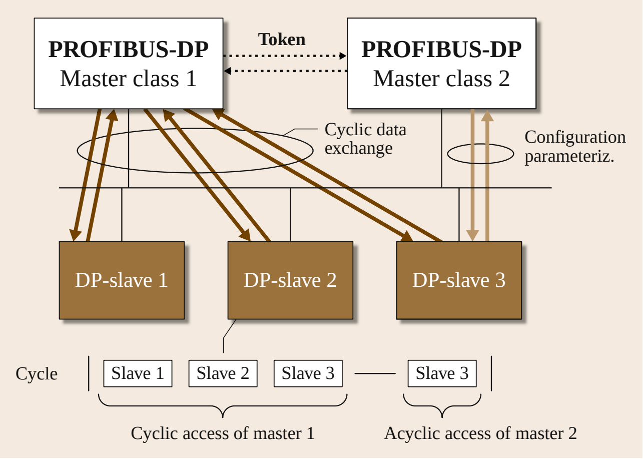

Fig. 56.4 Profibus medium access control (from [56.10])

PROFIBUS

PROFIBUS is a universal fieldbus for plantwide use across all sectors of the manufacturing and process industries based on the IEC 61158 and IEC 61784 standards. Different transmission technologies are supported [56.10]:

- RS 485: Type of medium attachment unit (MAU) corresponding to [56.13]. Suited mainly for factory automation. Technical details see [56.10, 13]. Number of stations: 32 (master stations, slave stations or repeaters); Data rates: 9.6/19.2/45.45/93.75/187.5/500/1500/3000/6000/12 000 kb/s.
- Manchester bus powered (MBP). Type of MAU suited for process automation: line, tree, and star topology with two wire transmission; 31.25 kBd (preferred), high speed variants w/o bus powering and intrinsic safety; synchronous transmission (Manchester encoding); optional: bus powered devices (≥ 10 mA per device; low power option); optional: intrinsic safety (Ex-i) via additional constraints according to the FISCO model. Intrinsic safety means a type of protection in which a portion of the electrical system contains only intrinsically safe equipment (apparatus, circuits, and wiring) that is incapable of causing ignition in the surrounding atmosphere. No single device or wiring is intrinsically safe by itself (except for battery-operated self-contained apparatus such as portable pagers, transceivers, gas detectors, etc., which are specifically designed as intrinsically safe self-contained devices) but is intrinsically safe only when employed in properly designed intrinsically safe system. There are couplers/link devices to couple MBP and RS485 transmission technologies.
- Fibre optics (not explained here, see [56.10]).

There are two medium access control (MAC) mechanisms (Fig. 56.4):

1. Master–master traffic using token passing
2. Master–slave traffic using polling.

PROFIBUS differentiates between two types of masters:

1. Master class 1, which is basically a central controller that cyclically exchanges information with the distributed stations (slaves) at a specified message cycle.
2. Master class 2, which are engineering, configuration, or operating devices. The slave-to-slave communication is based on the application model *publisher/subscriber* using the same MAC mechanisms.

The dominating PROFIBUS protocol is the application protocol DP (*decentralized periphery*), embedded into the protocol suite (Fig. 56.5).

Depending upon the functionality of the masters, there are different volumes of DP specifications. There are various profiles, which are grouped as follows:

1. Common application profiles (regarding functional safety, synchronization, redundancy etc.)
2. Application field specific profiles (e.g. process automation, semiconductor industries, motion control).

These profiles reflect the broad experience of the PROFIBUS International organization.

DeviceNet

DeviceNet is a digital, multi-drop network that connects and serves as a communication network between industrial controllers and I/O devices. Each device and/or controller is a node on the network. DeviceNet uses a trunk-line/drop-line topology that provides separate twisted pair busses for both signal and power distribution. The possible variants of this topology are shown in [56.14].

Thick or thin cables can be used for either trunklines or droplines. The maximum end-to-end network length varies with data rate and cable thickness. DeviceNet allows transmission of the necessary power on the network. This allows devices with limited power requirements to be powered directly from the network, reducing connection points and physical size. DeviceNet systems can be configured to operate in a master-slave or a distributed control architecture using peer-to-peer communication. At the application layer, DeviceNet uses a producer/consumer application model. DeviceNet systems offer a single point of connection for configuration and control by supporting both I/O and explicit messaging.

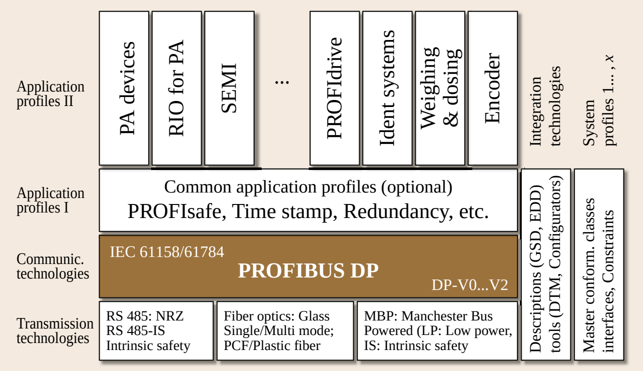

Fig. 56.5 PROFIBUS protocol suite (from [56.10])

DeviceNet uses CAN (controller area network [56.7]) for its data link layer, and CIP (common industrial protocol) for the upper network layers. As with all CIP networks, DeviceNet implements CIP at the session (i. e. data management services) layer and above, and adapts CIP to the specific DeviceNet technology at the network and transport layer, and below. Figure 56.6 depicts the DeviceNet protocol suite.

The data link layer is defined by the CAN specification and by the implementation of CAN controller chips. The CAN specification [56.7] defines two bus states called dominant (logic 0) and recessive (logic 1). Any transmitter can drive the bus to a dominant state. The bus can only be in the recessive state when no transmitter is in the dominant state. A connection with a device must first be established in order to exchange information with that device. To establish a connection, each DeviceNet node will implement either an unconnected message manager (UCMM)

or a Group 2 unconnected port. Both perform their function by reserving some of the available CAN identifiers. When either the UCMM or the Group 2 unconnected port is selected to establish an explicit messaging connection, that connection is then used to move information from one node to the other (using a publisher/subscriber application model), or to establish additional I/O connections. Once I/O connections have been established, I/O data may be moved among devices on the network.

At this point, all the protocol variants of the DeviceNet I/O message are contained within the 11 bit CAN identifier. CIP is strictly object oriented. Each object has attributes (data), services (commands), and behavior (reaction to events). Two different types of objects are defined in the CIP specification: communication objects and application-specific objects. Vendor-specific objects can also be defined by vendors for situations where a product requires functionality that is not in the specification. For a given device type, a minimum set of common objects will be implemented.

An important advantage of using CIP is that for other CIP-based networks the application data remains the same regardless of which network hosts the device. The application programmer does not even need to know to which network a device is connected.

CIP also defines device profiles, which identifies the minimum set of objects, configuration options, and the I/O data formats for different types of devices. Devices that follow one of the standard profiles will have the same I/O data and configuration options, will respond to all the same commands, and will have the same behavior as other devices that follow that same profile. For more information on DeviceNet readers are referred to www.odva.org.

56.3.4 Controller Networks

This network class requires powerful communication technology. Considering controller networks based on Ethernet technology, one can distinguish between (related to the real-time classes, see Sect. 56.1):

1. Local soft real-time approaches (real-time class 1)
2. Deterministic real-time approaches (real-time class 2)
3. Isochronous real-time approaches (real-time class 3).

The standardization process started in 2004. There were many candidates to become part of the extended Fieldbus standard IEC 61158 (edition 4): high speed Ethernet HSE (Emerson, Fieldbus Foundation); Ethernet/IP (Rockwell, ODVA); and PROFINET/CBA (Siemens, PROFIBUS International). Nine Ethernet-based solutions have been added. In this section a short survey of the previously mentioned real-time classes will be given, and two practical examples will be examined.

Local Soft Real-Time Approaches (Real-Time Class 1)

These approaches use TCP (UDP)/IP mechanisms over shared and/or switched Ethernet networks. They can be distinguished by different functionalities on top of TCP (UDP)/IP, as well as by their object models and application process mechanisms. Protocols based on Ethernet-TCP/IP offer response times in the lower millisecond range but are not deterministic, since data transmission is based on the best effort principle. Some examples are given below.

MODBUS TCP/IP (Schneider) [56.15]. MODBUS is an application layer messaging protocol for client/server communication between devices connected via different types of buses or networks. Using Ethernet as the transmission technology, the application layer protocol data unit (A-PDU) of MODBUS (function code and data) is encapsulated into an Ethernet frame. The connection management on top of TCP/IP controls the access to TCP.

Ethernet/IP (Rockwell, ControlNet International, Open DeviceNet Vendor Association) uses a common industrial protocol CIP [56.16]. In this context, IP stands for industrial protocol (not for Internet protocol). CIP represents a common application layer for all physical networks of Ethernet/IP, ControlNet and DeviceNet. Data packets are transmitted via a CIP router between the networks. For the real-time I/O data transfer, CIP works on top of UDP/IP. For the explicit messaging, CIP works on top of TCP/IP. The application process is based on a producer/consumer model.

High Speed Ethernet HSE (Fieldbus Foundation) [56.17]. A field device agent represents a specific Fieldbus Foundation application layer function (including Fieldbus message specification). Additionally, there are HSE communication profiles to support the different device categories: host device, linking device, I/O gateway, and field device. These devices share the tasks of the system using distributed function block applications.

PROFINET (PNO PROFIBUS User Organization, Siemens) [56.19]. uses object model CBA (component based architecture) and DCOM wire protocol with the remote procedure call mechanisms (DCE RPC) (OSF C 706) to transmit the soft real-time data. An open source code and various exemplary implementations/portations for different operating systems are available on the PNO web site.

P-Net on IP (Process Data) [56.20]. Based on P-Net Fieldbus standard IEC 61158 Type 4 [56.11], P-Net on IP contains the mechanism to use P-Net in an IP environment. Therefore, P-Net PDUs are wrapped into UDP/IP packages, which can be routed through IP networks. Nodes on the IP network are addressed with two P-Net route elements. P-Net clients (master) can access servers on an IP network without knowing anything about IP addresses.

All of the above mentioned approaches are able to support widely used office domain protocols, such as SMTP, SNMP, and HTTP. Some of the approaches support BOOTP and DHCP for web access and/or for engineering data exchange. But the object models of the approaches differ.

Deterministic Real-Time Approaches (Real-Time Class 2)

These approaches use a middleware on top of the MAC layer to implement scheduling and smoothing functions. The middleware is normally represented by a software implementation. Industrial examples include the following.

PROFINET (PROFIBUS International, Siemens) [56.19]. This variant of the Ethernet-based PROFINET IO system (using the main application model background of the Fieldbus PROFIBUS DP) uses the object model IO (input/output). Figure 56.7 roughly depicts the PROFINET protocol suite, containing the connection establishment for PROFINET/CBA via connection-oriented RPC on the left side, as well as for the PROFINET IO via connectionless RPC on the right side. The exchange of (mostly cyclic) productive data uses the real-time functions in the center.

The PROFINET IO service definition and protocol specification [56.21] covers the communication between programmable logical controllers (PLCs), supervisory systems, and field devices or remote input and output devices. The PROFINET IO specification complies with IEC 61158, Parts 5 and 6, specially the Fieldbus application layer (FAL). The PROFINET protocol is defined by a set of protocol machines. For more details see [56.22].

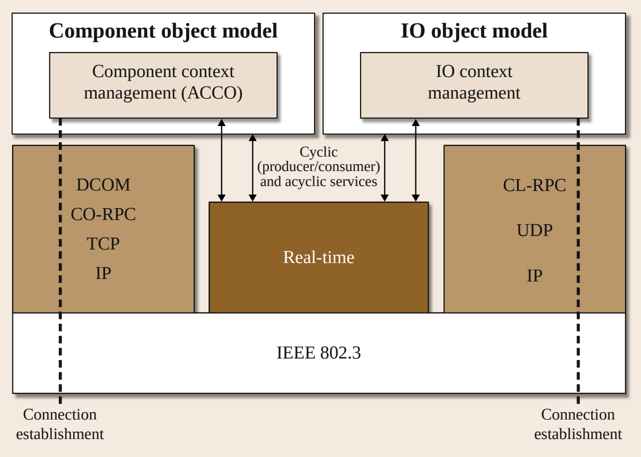

Fig. 56.7 PROFINET protocol suite of PROFINET (from [56.18]) (active control connection object (ACCO), connection-oriented (CO), connectionless (CL), remote procedure call (RPC))

Time-Critical Control Network (Tcnet, Toshiba) [56.23]. Tcnet specifies in the application layer a so-called *common memory* for time-critical applications, and uses the same mechanisms as mentioned for PROFINET IO for TCP(UDP)/IP-based non real-time applications. An extended data link layer contains the scheduling functionality. The common memory is a virtual memory globally shared by participating nodes as well as application processes running on each node. It provides a temporal and spatial coherence of data distribution. The common memory is divided into blocks with several memory lengths. Each block is transmitted to member nodes using multicast services, supported by a publisher node. A cyclic broadcast transmission mechanism is responsible for refreshing the data blocks. Therefore, the common memory consists of dedicated areas for the transmitting data to be refreshed in each node. Thus, the application program of a node has quick access to all (distributed) data.

The application layer protocol (FAL) consists of three protocol machines: the FAL service protocol machine (FSPM), the application relationship protocol machine (ARPM), and the data link mapping protocol machine (DMPM). The scheduling mechanism in the data link layer follows a token passing mechanism.

Vnet (Yokogawa) [56.24]. Vnet supports up to 254 subnetworks with up to 254 nodes each. In its application layer, three kinds of application data transfers are supported:

- A one-way communication path used by an endpoint for inputs or outputs (conveyance paths)
- A trigger policy
- Data transfer using a buffer model or a queue model (conveyance policy).

The application layer FAL contains three types of protocol machines: the FSPM FAL service protocol machine, ARPMs application relationship protocol machines, and the DMPM data link layer mapping protocol machine. For real-time data transfer, the data link layer offers three services:

1. Connection-less DL service
2. DL-SAP management service
3. DL management service.

Real-time and non real-time traffic scheduling is located on top of the MAC layer. Therefore, one or more time-slots can be used within a macro-cycle (depending on the service subtype). The data can be ordered by four priorities: urgent, high, normal, time-available. Each node has its own synchronized macro-cycle. The data link layer is responsible for clock synchronization.

Isochronous Real-Time Approaches (Real-Time Class 3)

The main examples are as follows.

Powerlink (Ethernet PowerLink Standardization Group (EPSG), Bernecker and Rainer), developed for motion control [56.25]. Powerlink offers two modes: protected mode and open mode. The protected mode uses a proprietary (B&R) real-time protocol on top of the shared Ethernet for protected subnetworks. These subnetworks can be connected to an open standard network via a router. Within the protected subnetwork the nodes cyclically exchange real-time data avoiding collisions. The scheduling mechanism is a time-division scheme. Every node uses its own time slot [slot communication network management (SCNM)] to send its data. The mechanism uses a manager node, which acts comparably with a bus master, and managed nodes act similar to a slave. This mechanism avoids Ethernet collisions. The Powerlink protocol transfers the real-time data isochronously. The open mode can be used for TCP(UDP)/IP based applications. The network normally uses switches. The traffic has to be transmitted within an asynchronous period of the cycle.

EtherCAT [EtherCAT Technology Group (ETG), Beckhoff] developed as a fast backplane communication system [56.26]. EtherCAT distinguishes two modes: direct mode and open mode. Using the *direct mode*, a master device uses a standard Ethernet port between the Ethernet master and an EtherCAT segment. EtherCAT uses a ring topology within the segment. The medium access control adopts the master/slave principle, where the master node (typically the control system) sends the Ethernet frame to the slave nodes (Ethernet device). One single Ethernet device is the head node of an EtherCAT segment consisting of a large number of EtherCAT slaves with their own transmission technology. The Ethernet MAC address of the first node of a segment is used for addressing the EtherCAT segment. For the segment, special hardware can be used. The Ethernet frame passes each node. Each node identifies its subframe and receives/sends the suitable information using that subframe. Within the EtherCAT segment, the EtherCAT slave devices extract data from and insert data into these frames. Using the *open mode*, one or several EtherCAT segments can be connected via switches with one or more master devices and Ethernet-based *basic slave* devices.

PROFINET IO/Isochronous Technology (PROFIBUS User Organization, Siemens) developed for any industrial application [56.27]. PROFINET IO/Isochronous Technology uses a middleware on top of the Ethernet MAC layer to enable high-performance transfers, cyclic data exchange and event-controlled signal transmission. The layer 7 functionality is directly linked to the middleware. The middleware itself contains the scheduling and smoothing functions. This means that TCP/IP does not influence the PDU structure. A special Ethertype is used to identify real-time PDUs (only one PDU type for real-time communication). This enables easy hardware support for the real-time PDUs. The technical background is a 100 Mbps full duplex Ethernet (switched Ethernet). PROFINET IO adds an isochronous real-time channel to the RT channels of real-time class 2 option channels. This channel enables a high-performance transfer of cyclic data in an isochronous mode [56.28]. Time synchronization and node scheduling mechanisms are located within and on top of the Ethernet MAC layer. The offered bandwidth is separated for cyclic hard real-time and soft/non real-time traffic. This means that within a cycle there are separate time domains for cyclic hard real-time, for soft/non real-time over TCP/IP traffic, and for the synchronization mechanism, see also Fig. 56.8.

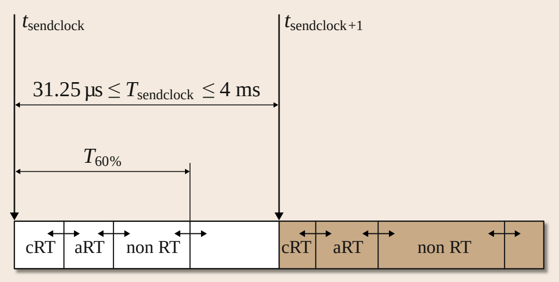

Fig. 56.8 LMPM MAC access used in PROFINET IO [56.22] (cyclic real-time (cRT), acyclic real-time (aRT), nonreal-time (non RT), medium access control (MAC), link layer mapping protocol machine (LMPM))

The cycle time should be in the range of 250 µs (35 nodes) up to 1 ms (150 nodes) when simultaneously TCP/IP traffic of about 6 Mbps is transmitted. The jitter will be less than 1 µs. PROFINET IO/IRT uses switched Ethernet (full duplex). Special four-port and two-port switch ASICs have been developed and allow the integration of the switches into the devices (nodes) substituting the legacy communication controllers of Fieldbus systems. Distances of 100 m per segment (electrical) and 3 km per segment (fiber-optical) can be bridged.

Ethernet/IP with Time Synchronization (ODVA, Rockwell Automation). Ethernet/IP with time synchronization [56.29], an extension of Ethernet/IP, uses the *CIP Synch protocol* to enable the isochronous data transfer. Since the CIP Synch protocol is fully compatible with standard Ethernet, additional devices without CIP Synch features can be used in the same Ethernet system. The CIP Synch protocol uses the *precision clock synchronization protocol* [56.30] to synchronize the node clocks using an additional hardware function. CIP Synch can deliver a time-synchronization accuracy of less than 500 ns between devices, which meets the requirements of the most demanding real-time applications. The jitter between master and slave clocks can be less than 200 ns.

SERCOS III, (IG SERCOS Interface e.V.). A SERCOS network [56.31], developed for motion control, consists of masters and slaves. Slaves contain integrated repeaters, which have a constant delay time T_{rep} (input/output). The nodes are connected via point-to-point transmission lines. Each node (participant) has two communication ports, which are interchangeable. The topology can be either a ring or a line structure. The ring structure consists of a primary and a secondary channel. All slaves work in forwarding mode. The redundancy provided by the ring structure prevents any downtime caused by a broken cable. The line structure consists of either a primary or a secondary channel. The last physical slave performs the loopback function. All other slaves work in forwarding mode. No redundancy against cable breakage is achieved. It is also possible to insert and remove slaves during operation (hot plug). This is restricted to the last physical slave.

56.4 Wireless Industrial Communications

56.4.1 Basic Standards

Wireless communication networks are increasingly penetrating the application area of wired communication systems. Therefore, they have been faced with the requirements of industrial automation. Wireless technology has been introduced in automation as wireless local area networks (WLAN) and wireless personal area networks (WPAN). Currently, the wireless sensor networks (WSN) are under discussion especially for process automation. For specific application aspects of wireless communications see Chap. 13 on *Communication in Automation, Including Networking and Wireless*, and Chap. 20 on *Sensors and Sensor Networks*. The basic standards are the following:

- Mobile communications standards: GSM, GPRS, and UMTS wireless telephones (DECT)
- Lower layer standards (IEEE 802.11: Wireless LAN [56.32], and 802.15 [56.33]: personal area networks) as a basis of radio-based local networks (WLANs, Pico networks and sensor/actuator networks)
- Higher layer standards (application layers on top of IEEE 802.11 and 802.15.4, e.g. WiFi, bluetooth [56.34], wireless HART, and ZigBee [56.35])
- Proprietary protocols for radio technologies (e.g. wireless interface for sensors and actuators (WISA) [56.36])
- Upcoming radio technologies such as *ultra wide band* (UWB) and WiMedia

For more detailed information and survey see [56.37–41].

56.4.2 Wireless Local Area Networks (WLAN)

The term WLAN refers to a wireless version of the Ethernet used to build computer networks for office and home applications. The original standard (IEEE802.11) specified an infrared, a direct sequence spread spectrum (DSSS) and a frequency hopping spread spectrum (FHSS) physical layer. There is an approval for WLAN to use special frequency bands, however it has to share the medium with other users. The WiFi Alliance was founded to assure interoperability between WLAN clients and access points of different vendors. Therefore, a certification procedure and a WiFi logo are provided. WLANs use a licence-free frequency band and no service provider is necessary.

WLAN is a mature technology and it is implemented in PCs, laptops, and PDAs. Modules for embedded systems development are also available. WLAN can be used almost world wide. Embedded WLAN devices need a powerful microcontroller. WLAN enables wireless access to Ethernet based LANs and is helpful for the vertical integration in an automated manufacturing environment. It offers high speed data transmission that can be used to transmit productive data and management data in parallel. The WLAN propagation characteristics fit into a number of possible automation applications. WLAN enables more flexibility and a cost effective installation in automation associated with mobility and localization. The transition to Ethernet is simple and other gateways are possible. The largest part of the implementation is achieved in hardware; however improvements can be made above the MAC layer.

56.4.3 Wireless Sensor/Actuator Networks

Various wireless sensor network (WSN) concepts are under discussion, especially in the area of industrial automation. Features such as time synchronized operation, frequency hopping, self-organization (with respect to star, tree, and mesh network topologies), redundant routing, and secure data transmission are desired. Interesting surveys on this topic are available in [56.41–44]. Process automation requirements can be generally fulfilled by two mesh network technologies:

- ZigBee (ZigBee Alliance) [56.35]
- Wireless HART [56.45, 46].

Both technologies use the standard IEEE 802.15.4 (2003) *low-rate wireless personal area network* (WPAN) [56.33], specifying the physical layer and parts of the data link layer (medium access control).

ZigBee

ZigBee distinguishes between three device types:

- Coordinator ZC: root of the network tree, storing the network information and security keys. It is responsible for connection the ZigBee network to other networks.
- Router ZR: transmits data of other devices.
- End device ZED: automation device (e.g. sensor), which can communicate with ZR and ZC, but is unable to transmit data of other devices.

An enhanced version allows one to group devices and to store data for neighboring devices. Additionally, to save energy, there are full-function devices and reduced-function devices. The ZigBee application layer (APL) consists of three sublayers: application support layer (APS) (containing the connection lists of the connected devices), an application framework (AF), and Zigbee device objects (ZDO) (definition of devices roles, handling of connection requests, and establishment of communication relations between devices).

For process automation, the ZigBee application model and the ZigBee profiles are very interesting. The application functions are represented by application objects (AO), and the generic device functions by device objects (DO). Each object of a ZigBee profile can contain one or more clusters and attributes, transferred to the target AO (in the target device) directly or to a coordinator, which transfers them to one or more target objects.

WirelessHART

Revision 7 of HART protocol includes the specification of WirelessHART [56.46]. The mesh type network allows the use of redundant communication paths between the radio-based nodes. The temporal behavior is determined by the time synchronized mesh protocol (TSMP) [56.47, 48]. TSMP enables a synchronous operation of the network nodes (called *motes*) based on a time slot mechanism. It uses various radio channels (supported by the MAC layer) for an end-to-end communication between distributed devices. It works comparably with a frequency hopping mechanism missed in the basic standard IEEE 802.15.4.

TSMP supports star, tree, as well as mesh topologies. All nodes have the complete routing function (contrary to ZigBee). A self-organization mechanism enables devices to acquire information of neighboring nodes and to establish connections between them. The messages have their own network identifier. Thus, different networks can work together in the same radio area. Each node has its own list of neighbors, which can be actualized when failures have been recognized.

To support security, TSMP uses mechanisms for encryption (128 bit symmetric key), authentification (32 bit MIC for source address), and integrity (32 bit MIC for message content). Additionally, the frequency hopping mechanism improves the security features. For detailed information see [56.46].

56.5 Wide Area Communications

With the application of remote automation mechanisms (remote supervisory, operation, service) using wide area networks, the stock of existing communication technology becomes broader and includes the following [56.18]:

- All appearances of the Internet (mostly supporting best effort quality of services)
- Public digital wired telecommunication systems: either line-switched [e.g. integrated services digital network (ISDN)] or packet-switched [such as asymmetric/symmetrical digital subscriber line (ADSL, SDSL)]
- Public digital wireless telecommunication systems (GSM-based, GPRS-based, UMTSbased)
- Private wireless telecommunication systems, e.g. trunk radio systems.

The transition between different network technologies can be made easier by using multiprotocol label switching (MPLS) and synchronous digital hierarchy (SDH). There are several private protocols (over leased lines, tunneling mechanisms, etc.) that have been used in the automation domain using these technologies. Most of the wireless radio networks can be used in non real-time applications, some of them in soft real-time applications; however industrial environments and industrial, scientific, and medical (ISM) band limit the applications. Figure 56.9 depicts the necessary remote channels.

The end-to-end connection behavior via these telecommunication systems depends on the recently offered quality of service (QoS). It strongly limits the use of these systems within the automation domains. Therefore, the following application areas have to be distinguished:

Non-Real-Time Communication in Automation

- Non real-time communication (Standard IT: upload/download, SNMP) with lower priority to real-time communication: for configuration, diagnostics, automation-specific up/download.
- Manufacturing-specific functions, context management, establishment of application relationships and connection relationships to configure IO devices, application monitoring to read status data (diagnostics, I&M), read/write services (HMI, application program), open loop control.

The automation domain has the following impact on non real-time WAN connections: addressing between multiple distributed address spaces, and redundant transmission for minimized downtime to ensure its availability for a running distributed application.

Real-Time Communication in Automation

- Cyclic real-time communications (i. e. PROFINET IO data) for closed loop control and acyclic alarms (i. e. PROFINET IO alarms) as major manufacturing-specific services
- Transfer (and addressing) methods for RT data across WAN can be distinguished as follows:

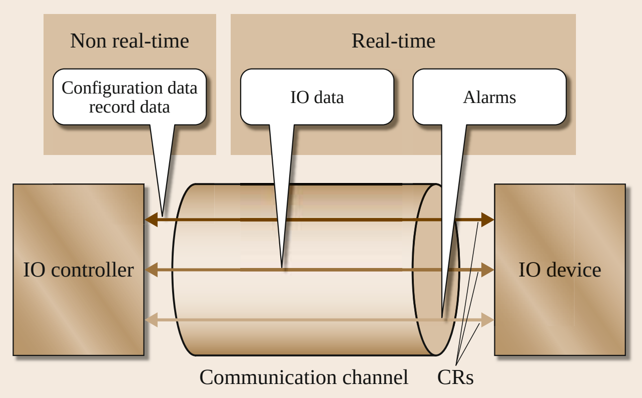

Fig. 56.9 Remote communication channels over WAN (input/output (IO); communication relation (CR))

  - *MAC based*: Tunnel (real-time class 1, partially real-time class 2 for longer send intervals, e.g. 512 ms), clock across WAN and reserved send phase for real-time transmission
  - *IP based*: Real-time over UDP (routed); web services based [56.49, 50].

The automation domain has the following impact on real-time WAN connections: a constant delay-sensitive and jitter-sensitive real-time base load (e.g. in LAN: up to 50% bandwidth reservation for real-time transmission).

To use a wide area network for geographically distributed automation functions, the following basic design decisions were made following the definitions in Sect. 56.2:

- A virtual automation network (VAN) is an infrastructure for standard LAN-based distributed industrial automation concepts (e.g. PROFINET or other) in an extended environment. The productive automation functions (applications) are described by their object models used in existing industrial communications. The application service elements (ASEs), as they are specified in the IEC 61158 standard, can additionally be used.
- The establishment of the end-to-end connections between distributed objects within a heterogeneous network is based on web services. Once this connection has been established, the runtime channel between these objects is equivalent to the runtime channel within the local area by using PROFINET (or other) runtime mechanisms.
- The VAN addressing scheme is *based on names* to avoid the use of IP and MAC addresses during establishment of the end-to-end path between logically connected applications within a VAN domain. Therefore, the IP and MAC addresses remain transparent to the connected application objects.
- Since there is no new Fieldbus or real-time Ethernet protocol, no new specified application layer is necessary. Thus, the well-tried models of industrial communications (as they are specified in the IEC 61158 standard) can be used. Only the additional requirements caused by the influence of wide area networks have to be considered and they lead to additional functionality following the above-mentioned design guidelines.

Most of the WAN systems that offer quality-of-service (QoS) support cannot provide real guarantees, and this strongly limits the use of these systems within the automation domain. To guarantee a defined QoS for data transmission between two application access points via a wide area network, written agreements between customer and service provider [service level agreements (SLA)] must be contracted. In cases where the provider cannot deliver the promised QoS, an alternative line must be established to hold the connection for the distributed automation function (this operation is fully transparent to the application function). This line should be available from another provider, independent from the currently used provider. The automation devices (so called VAN access points (VAN-APs)] should support functions to switch (either manually or automatically) to an alternative line [56.51].

There are different mechanisms to realize a connection between remote entities:

- *The VAN switching connection*: the *logical* connection between two VAN-APs over a WAN or a public network. One VAN switching connection owns one or more communication paths. VAN switching line is defined as one physical communication path between two VAN-APs over a WAN or a public network. The endpoints of a switching connection are VAN-APs.
- *The VAN switching line*: the *physical* communication path between two VAN-APs over a WAN or a public network. A VAN switching line has its provider and own QoS parameter. If a provider offers connections with different warranted QoS each of these shall be a new VAN switching line.
- *VAN switching endpoint access*: the physical communication path between one VAN-AP and a WAN or a public network. This is a newly introduced class for using the switching application service elements of virtual automation networks for communication via WAN or public networks.

These mechanisms are very important for the concept of VANs using heterogeneous networks for automation. Depending on the priority and importance of the data transmitted between distributed communications partners, the kind of transportation service and communication technology is selected based on economical aspects. The VAN provider switching considers the following alternatives:

- *Use case 1*: For packet-oriented data transmission via public networks a connection from a corresponding VAN-AP to the public network has to be established. The crossover from/to the public network is represented by the VAN switching endpoint access. The requirements made for this line have to be fulfilled by the service level agreements from the chosen provider. Within the public network it is not possible to influence the quality of service. The data package leaves the public network when the VAN switching endpoint access from the faced communication partner is achieved. The connection from the public network to the faced VAN-AP is also provided by the same or an alternative provider and guarantees defined requirements. The data exchange between two communication partners is independent of each other.

- *Use case 2*: For a connection-oriented data transmission (or data packages with high-level priority) the use of manageable data transport technology is needed. The VAN switching line represents a manageable connection. A direct *known* connection between two VAN-APs has to be established and a VAN switching endpoint access is not needed. The chosen provider guarantees the defined requirements for the complete line. When the current line loses the promised requirements it is possible to define the VAN-APs to build up an alternative line and hold on/disconnect the current line automatically.

56.6 Conclusions

As discussed in the above sections, the area of industrial communication protocols has been experiencing a tremendous evolution over the last ten years, being strongly influenced by advances in the area of information technology and hardware/software developments. Existing industrial communication protocols have impacted very positively both in the operation of industrial plants, due to enhanced diagnostic capabilities, which has improved maintenance operations, as well as in the development of complex automation systems.

The chapter has reviewed the main concepts of industrial communication networks and presented the most prominent wired and wireless protocols that are already incorporated in a large number of industrial devices (from thousands to millions).

Within this scope of a multitude of existing protocols and also motivated by the growth of the Internet and increasing possibilities of the World Wide Web network, and the increased demand for geographically distributed automation functions virtual automation networks (VAN), a very interesting approach would appear to be to allow integration via heterogeneous networks. The section presented the concepts of VAN domains and interfaces and the challenges on ensuring timely communication behavior, safety, and security across multiple VAN domains.

56.7 Emerging Trends

The number of commercially available industrial communication protocols has continued to increase, despite some trials to converge to a single and unified protocol, in particular during the definition of the IEC 61178 standard; the automation community has started to accept that no single protocol will be able to meet all different communication requirements from different application areas. This trend will be continued by the emerging wireless sensor networks as well as the integration of wireless communication technologies in all mentioned automation-related communication concepts. Therefore, increasing attention has been given to concepts and techniques to allow integration among heterogeneous networks, and within this context virtual automation networks are playing an increasing role.

With the proliferation of networked devices with increasing computing capabilities, the trend of decentralization in industrial automation systems will increase in the future (Figs. 56.10 and 56.11). This situation will lead to an increased interest in autonomic systems with self-X capabilities, where X stands for alternatives as configuration, organizing, optimizing, healing, etc. The idea is to develop automation systems and devices that are able to manage themselves given high level objectives. Those systems should have sufficient degrees of freedom to allow a self-organized behavior, which will adapt to dynamically changing requirements. The ability to deal with widely varying time and resources demands while still delivering dependable and adaptable services with guaranteed temporal qualities is a key aspect for future automation systems.

57. Automation and Robotics in Mining and Mineral Processing

Sirkka-Liisa Jämsä-Jounela, Greg Baiden

Mines and mineral processing plants need integrated process control systems capable of improving plant-wide efficiency and productivity. Mining automation systems today typically control fixed plant equipment such as pumps, fans, and phone systems. Much work is underway around the world in attempting to create the moveable equivalent of the manufacturing assembly line for mining. This technology has the goals of speeding production, improving safety, and reducing costs. Process automation systems in mineral processing plants provide important plant operational information such as metallurgical accounting, mass balances, production management, process control, and optimization. This chapter discusses robotics and automation for mining and process control in mineral processing. Teleoperation of mining equipment and control strategies for grinding and flotation serve as examples of current development of field.

57.1 Background

Mining is the act of extracting mineral determined to be ore from the earth to be processed in a mineral processing operation. All mining operations have a least some limited mineral processing available on site. Usually the sophistication of the complex is determined by unit process operations needed to make the product, or distribution and transportation costs (Fig. 57.1). The mineral extraction process can occur using many potential mining methods. Some of the methods include open pit, caving, bulk stoping, and/or selective mining techniques such as cut and fill, as well as *room* and *pillar* [57.1]. Each method and suite of mining equipment has the aim of extracting the mineral at a profit for processing.

The aim of a mineral processing operation is to concentrate a raw ore for the subsequent metal extraction stage. Usually, the valuable minerals are first liberated from the ore matrix by comminution and size separation processes (crushing, grinding, and size classification), and then separated from the gangue using processes capable of selecting the particles according to their physical or chemical properties, such as surface hydrophobicity, specific gravity, magnetic susceptibility, and color (flotation, magnetic or gravimetric separation, sorting, etc.) [57.2].

Process automation has always played a key role in the mineral process industries and is gaining momentum in mining extraction operations as mobile robotics techniques are being applied. The use of advanced technologies, including modeling, simulation, advanced control strategies, smart equipment, fieldbuses, wireless networks, remote maintenance, etc., is widespread in many sectors (Fig. 57.2). Information-based technologies are responsible for making mineral

processing more efficient and reliable, and help the industry to adapt to new competitive environments in a safe and environmentally sound manner. One critical step in achieving these objectives is to develop and apply improved control systems across the full range of applications from mining to processing and utilization.

While mineral processing has had extensive use of many advanced technologies, standard mining applications such as pumping, dewatering, hoist control, and power distribution remain the norm with some individual exceptions in ventilation systems and other mine wide systems. Overall, the complication and scale of mining operations has delayed the wide adoption of advanced technology. Several stand alone technologies have seen successful implementation in mining and pilot projects; full scale mine implementation have been attempted with extremely encouraging results. The Intelligent Mine Program in Scandinavia and the Mining Automation Program [57.3] in Canada were two main projects attempted in the 1990s and early 2000s. The main technology drivers were seen to be: telecommunications, positioning and navigation, integrated software systems, and mobile robotic equipment. The Intelligent Mine Program explored the issues from a rock and process characteristic point of view and the Mining Automation Program from an equipment point of view.

The optimization of the economics of the process operations is the key driver for the application of advanced control. Many successful control strategy implementations in mineral processing have been reported. The power of model-based control for industrial semi-autogenous grinding circuits was discussed by *Herbst* and *Pate* [57.4]. In the application, they used an expert system and online process models to find the optimum feed rate. A Kalman filter was used to estimate unmeasured variables such as mill filling and ore hardness that were required by the expert system. An 8% improvement in feed rate over manual control was achieved with the control system. In the multivariable control application on a two-stage milling circuit at the East Driefontein Gold Mine in South Africa, the average throughput t/h was increased from 73.1 to 79.2, and the average grain size $\% < 75\,\mu\text{m}$ from 76.5 to 78.5. The standard deviation of the grain size values was reported to decrease from 3 to the 0.9 [57.5]. Successful economic results and benefits from 13 years of computer control in flotation have been reported by *Miettunen* [57.6].

The economics of the application of intelligent robotics for mining was seen as having substantial benefits. These were discussed in *Baiden* [57.7]. This report showed that the fundamental definition of *ore* would be altered by the projected results of cost reduction and mining rate improvements. Further, robotic operation would improve the safety of miners as it would drop exposure levels. Subsequently, the Intelligent Mine Program and Mining Automation Program showed through field feasibility experimentation that these projections were realistic. Several projects around the world now are investigating the opportunity for robotic and teleoperated equipment in particular applications.

However, the control of mineral processes is faced with many challenges. At the present time it is not possible to measure, on a real-time basis, the important physical or chemical properties of the material processes. This is particularly true for the fresh ore feed characteristics (mineral grain size distribution, mineral composition, mineral association, grindability) and the ground material properties (liberation degree, particle composition distribution, particle hydrophobicity). An essential feature of control and optimization strategies is the availability of mathematical models that accurately describe the characteristics of the process. Satisfactory mathematical models are not, however, available for mineral processing unit processes due to the fact that the physics and chemistry of the sub-processes involved are poorly understood. Models for process analysis and optimization for comminution circuits are usually based on population balance models and the use of breakage and selection functions. Numerous empirical and phenomenological models based on various assumptions for flotation have been proposed in the literature. Among the many flotation models, the classical first-order kinetic model is widely used and can be utilized to optimize the design of the flotation circuit and its control strategy. Recently progress has been made in grinding circuit modeling using the discrete element method (DEM) [57.8–12], and efforts have been made in the CFD modeling of flotation [57.13].

57.2 Mining Methods and Application Examples

Mining in general has had little process control capability as mechanization of equipment was the only real opportunity that existed. For example, the absence of communication systems limited the types of process control that could be applied. In the last two decades work has been underway to change this. The portable size of computers and the availability of networks to connect them to spawned growth in the application of process control to mining. The basics of main distribution systems such as water and power are now the norm. Networks have further enabled the installation of rock mechanics systems such as microseismic systems. While these systems are important they do not get to the actual main production technologies because the machine systems for production are mobile.

Both the Intelligent Mine Program and the Mining Automation Program worked to change this and the concepts behind telemining started to gain momentum in the mid to late 1990s. Telemining (mobile process control for mining) is the application of remote sensing, remote control, and the limited automation of mining equipment and systems to mine mineral ores at a profit. The main technical elements are (Fig. 57.3):

- Advanced underground mobile computer networks
- Positioning and navigation systems
- Mining process monitoring and control software systems
- Mining methods designed specifically for telemining
- Advanced mining equipment.

Telemining has the capability to reduce cycle times, improve quality and increase the efficiency of equipment and personnel, resulting in increased revenue and lower costs.

Advanced high capacity mobile computer networks form the foundation of teleremote mining (Fig. 57.4). The mine may be connected via the telecommunication system so mines can be run from operation centers underground or on the surface. Several opportunities exist for communication, depending on the environment. Surface mines have trended towards network systems such as the 802.11 standard [57.14]. Whereas underground mines have focused on much higher bandwidth systems consisting of a high capacity backbone linked to 2.4 GHz capacity radio cells for communication. The high capacity allows the operation of not only data systems but mobile telephones, handheld computers, mobile computers on board machines, and multiple video channels to run multiple pieces of mining equipment from surface operation centers [57.15, 16].

To apply mobile robotics to mining, accurate positioning systems are an absolute necessity. Positioning systems that have sufficient accuracy to locate the mobile equipment in real-time at the tolerances necessary for mining have been developed [57.17, 18]. Practical uses of such systems include machine set-up, hole location, and remote topographic mapping. Surface systems use GPS for location and several of these systems have been developed. In underground mines, some of the most advanced positioning equipment consists of laser reference positioning, ring-laser-gyro (RLG), and accelerometers. Units are mounted on all types of drilling machines so that operators can position the equipment. These types of systems are just beginning to make their presence known over conventional surveying; several manufacturers offer this new product [57.19]. RLG systems track the location of mobile machinery in the

mine. Accurate positioning systems mounted on mobile equipment will enable the application of advanced manufacturing robotics to mining. Usually in advanced manufacturing, robotic equipment is fixed to the floor, allowing very accurate surveying and positioning of the equipment. The positioning systems being used for mining equipment allow accurate positioning of surface equipment using GPS, and inference techniques allow high accuracy positioning of mobile underground equipment.

Mine planning, simulation, and process control systems are growing using the foundations of telecommunications, positioning, and navigation. Linking geology and engineering directly to operations is important for the successful application of these systems. Several systems such as Datamine, Gemcom, Mine 24D, to name a few, are in use around the world today. Further, process control systems for the day-to-day operation of pumping, dewatering, and power distribution are the norm. New systems for ventilation control are starting to emerge as the cost of the overall system infrastructure is reduced.

57.3 Processing Methods and Application Examples

The overall objective of a grinding and flotation unit is to prepare a concentrate, which may be as simple as the net revenue of the plant. In practice, however, the links between the grinding and flotation circuits tuning and the economic objective are not obvious, and the objectives are always broken down into particle size reduction, mineral liberation, and mineral separation objectives. In the following, grinding and flotation areas are briefly discussed as application areas where automation has played an important role in mineral processing. These application areas serve as examples of current developments in the field of automation in mineral processing.

57.3.1 Grinding Control

Grinding ore to the optimum size for mineral extraction by flotation or leaching is an essential but high energy intensive part of most mineral processing operations. The benefits from improved grinding control are substantial, primarily in the areas of improved milling efficiency, more stable operation, higher throughput, and improved downstream processing. Grinding an ore finer than is necessary leads to increased energy costs, reduced throughput, increased mill liner consumption, and increased consumption of grinding media and reagents. Insufficient ore grinding, on the other hand, reduces the recovery rate of the valuable mineral.

Instrumentation

For grinding instrumentation both basic measurement and advanced indirect instruments are available. The most common measurements are: mass flow rate on a conveyor belt, volume flow rate, pipeline pressure, pulp density, sump level, mill motor power consumption, and mill rotation speed. Online particle size measurement is also a part of the well-instrumented grinding circuit. Indirect instruments are mostly used in mill or hydrocyclone operation monitoring. These measurements are based, for example, on acoustic measurements, vision-based monitoring, mill liner sensors, and mill power frequency analysis.

Mass flow rate measurement on a conveyor belt is mainly performed by nuclear weight gauges. In pipeline flow measurements magnetic instruments are the most typical. Pulp densities can be measured by a nuclear density meter, soft sensors, or alternatively by certain particle size analyzers.

Online particle size analysis can be performed using several techniques. The three most typical online particle size analysis methods in mineral processes are mechanical, ultrasonic, and laser diffraction-based devices. Outokumpu Technology's PSI-200 has been one of the most popular mechanical devices since the 1970s. The measurement is based on a reciprocating caliper with high precision position measurement. The measurement technique limits accurate size measurement to the coarser end of the distribution. The ultrasonic-based measurements were also developed in the 1970s, for example the Svedala Multipoint PSM-400. However, the method requires frequent calibration and is susceptible to air bubbles. The laser diffraction method represents the latest technology in online particle size analysis. The PSI-500 particle size analyzer, manufactured by Outokumpu, uses laser diffraction-based measurement, with automatic sample preparation. The system enables the development of new advanced control employing the full scale of the particle size distribution [57.20].

Some vision-based measurements have recently been developed. Mintek has a product CYCAM for hydrocyclone underflow monitoring. The equipment measures the angle of the discharge and therefore the conditions; for example, roping can be detected. For particle size on-belt monitoring of the grinding and crushing circuit Metso has a product called VisioRock.

Various methods are used for mill charge measurement. These include acoustic measurements [57.9], mill liner sensors and mill power frequency analysis [57.22–24]. The methods are mostly applied to specific processes, and there have been no significant commercial product breakthroughs.

To summarize, an example of a grinding circuit with typical instrumentation is given in Fig. 57.5.

Control Strategies

Control of the wet mineral grinding circuits might have different objectives depending on the application. The most common control objectives are:

- The particle size distribution of the circuit product is to be maintained constant at *constant feed rate*.
- The particle size distribution of the circuit product is to be maintained constant at *maximum feed rate*.
- Both the particle size distribution and solid contents circuit product are to remain *constant*.

The control strategy for the grinding circuit is based on a hierarchical structure. Basic controls mainly consist of traditional PI controllers and ratio controllers. The mill water feed typically has a ratio control with the ore feed. In many cases, sump levels are controlled by changing the pump speed. Furthermore, the pump speed is used to control the hydrocyclone feed pressure.

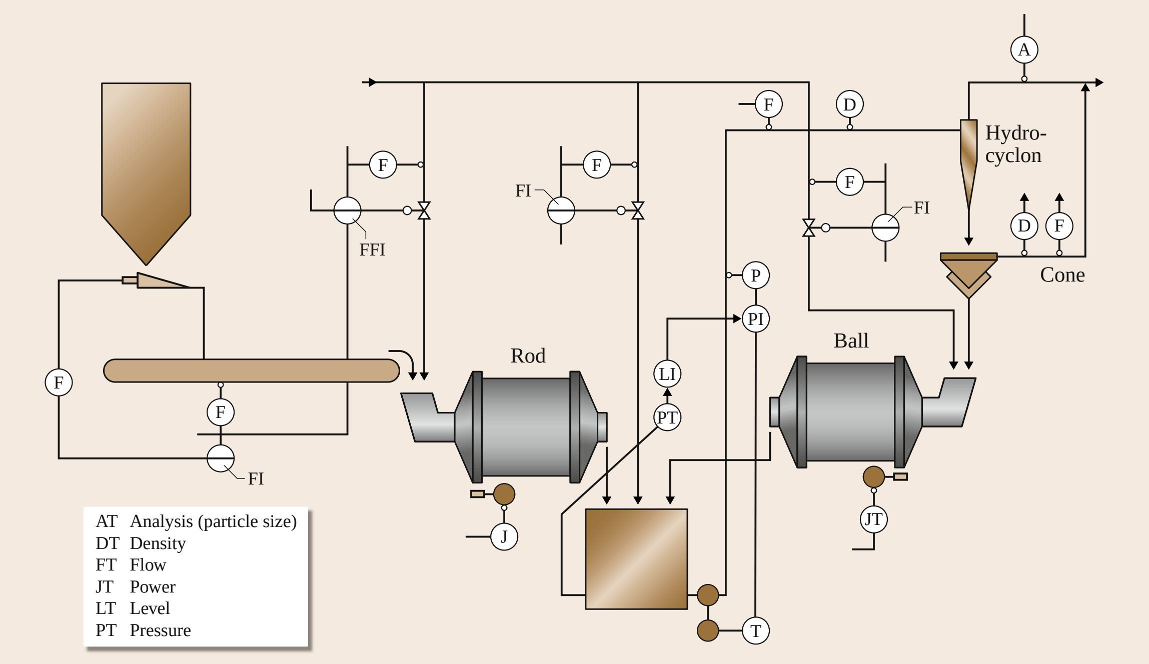

Fig. 57.5 Typical flowsheet of a grinding circuit (after [57.21])

The cyclone feed density is stabilized by manipulating an additional water feed rate to the sump. Particle size measurement is also currently applied in grinding circuit control. The product particle size measurement can, for example, be used to manipulate the ore feed rate to the primary mill. In addition, higher level optimization methods are typically applied to maximize the throughput with desired constraints.

57.3.2 Flotation

In flotation the aim of the control strategy is adjustment of the operating conditions as a function of the raw ore properties and feed rate, metal market prices, energy, and reagent costs [57.25]. Usually these objectives require a certain amount of trade-off between the concentrate and tonnage, the impurity contents and the operating costs.

Instrumentation

In flotation, instrumentation is available for measuring flow rates, density, cell levels, airflow rate, reagent feed rates, pH, and conductivity. Slurry flow measurement is mainly performed by a magnetic flow meter, and density by a nuclear density meter. The most typical instruments used for measuring the slurry level in a cell are a float with a target plate and ultrasonic level transmitter, a float with angle arms and capacitive angle transmitter, and reflex radar. The instrument for measuring flotation airflow rate contains a thermal gas mass flow sensor or a differential pressure transmitter with a venture tube, pitot tube, or Annubar element. A wide range of different instrumentation solutions for reagent dosing exist. The best choice is to use inductive flow meters and control valves. Electrochemical measurements give important information about the surface chemistry of valuable and gangue minerals in the process. pH is the most commonly measured electrochemical potential, and sometimes pH measurement can be replaced by conductivity measurement, which gives approximately the same information as pH measurement. Recently, other electrochemical potential measurements have also been under study. The use of minerals as working electrodes makes it possible to detect the oxidation state of different minerals and to control their floatability. Stability of the electrodes, however, has been a problem in online use, but some good results have been reported.

X-ray fluorescence is the universal method for online solid composition measurement in flotation. Equipment vendors now offer, however, more efficient, compact, flexible and reliable devices than were available in the 1970s.

To summarize, an example of a flotation circuit with typical basic instrumentation is given in Fig. 57.6. Conductivity and pH are measured in the conditioner. On-stream analyses are taken from the feed, tailings and concentrate, and also from several flows between the flotation sections. Flow rates, levels, and airflow rates are measured at several points. Most of the reagents are added in the grinding circuit, except for frother, which is added in the conditioner and additional sodium cyanide in the cleaner.

Recent developments in instrumentation have provided new instruments, such as image analysis-based devices for froth characteristics measurement. Three different image analysis products have been reported to be available commercially: FrothMaster from Outokumpu, JKFrothCam from JKTech, and VisioFroth from Metso Minerals. Research has been carried out on developing image processing algorithms and on analyzing the correlations between image analysis and process variables, more recently also on flotation control based on image analysis.

A comprehensive description of the flotation plant instrumentation has been reported by *Laurila* et al. [57.26].

Flotation Control

Flotation control designed according to the classical control hierarchy of base level controls, stabilizing control, and optimizing control has been widely accepted as a mature technology since 1970. Basic controls consist of traditional PI controllers for cell levels and airflow rates. A feedforward ratio controller is used for reagent flow rates. For cell levels in series a combination of feedforward and multivariable control strategy has been also widely applied in industrial use [57.27].

Developing flotation control strategies is still an active research topic since the benefits to be gained in terms of improved metallurgical performance are substantial. However, flotation control is becoming more and more difficult due to the emergence of low grade and complex ores. Machine vision technology provides a novel solution to several of the problems encountered in conventional flotation control systems, like the effects of various disturbances appearing in the froth phase. Structural characteristics such as bubble diameter and froth mobility give valuable information for following the trend in metal grade and recovery.

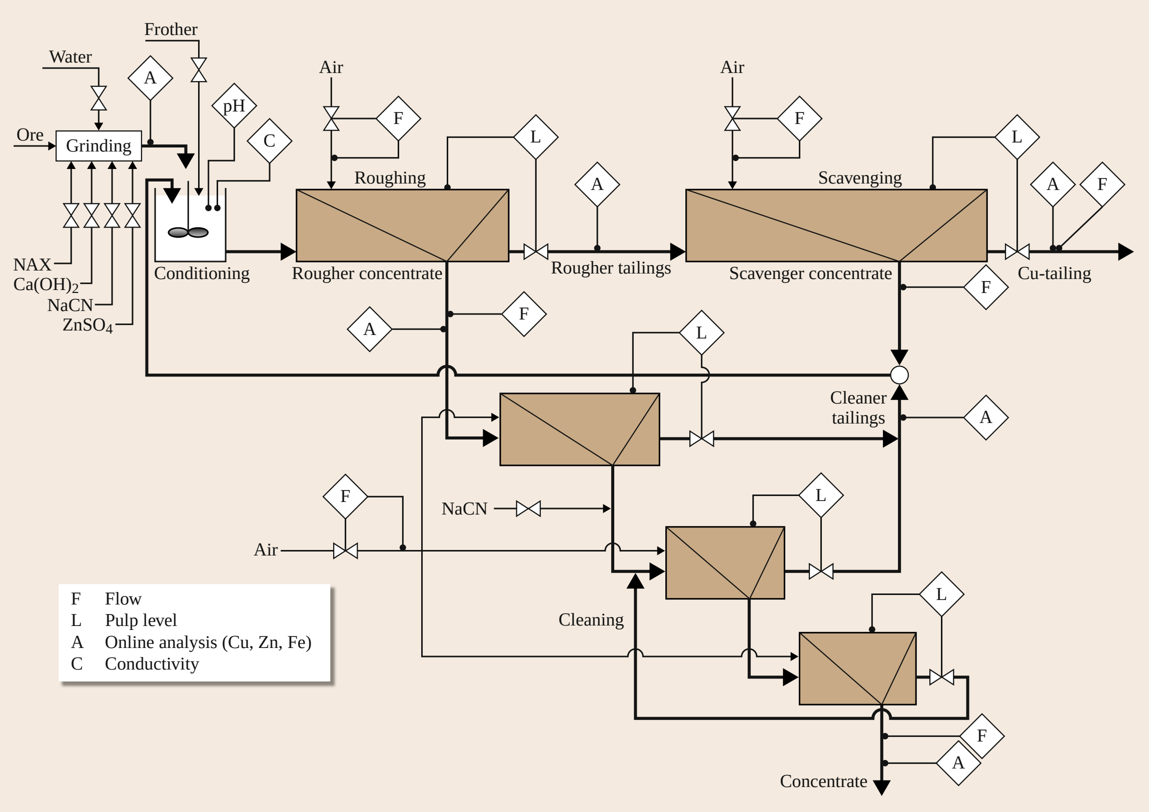

Fig. 57.6 Typical flowsheet of a flotation process (Cu circuit of Pyhäsalmi concentrator) (after [57.28])

In the FrothMaster-based control in the rougher flotation at Cadia Hills Gold Mine in New South Wales, Australia, three FrothMaster units measure froth speed, bubble size, and froth stability. The control strategy contains stabilizing and optimizing options. Stabilizing control strategy is logic based and manipulates the level, frother addition rate, and aeration rate to control the froth speed. Optimizing the control of the grade changes the setpoint values of the froth speed [57.29]. Many industrial implementations of the JKFrothCam system have been reported as well. The control system consists of PID controllers and/or an expert system. Measurements of bubble size, froth structure, and froth velocity are taken and reagent dosages, cell level, and aeration rates are used as manipulated variables [57.30]. VisioFroth is one module in the Metso Minerals CISA optimizing control system, by which froth velocity, bubble size distribution, and froth color can be measured. The largest VisioFroth installations are at Freeport, Indonesia, with 172 cameras and Minera escondida Phase IV, Chile, with 102 cameras. A combination of on-stream analysis and image analysis technology seems to be the most efficient way to control flotation today. Better concentrate grade consistency, and thus improved plant recovery, have been reported using this combination [57.31].

Flotation, being a time variant and nonlinear process that usually also undergoes large unknown disturbances is, however, difficult to manage optimally by classical linear control theory applications. Operator support systems are needed to overcome these problematic situations. The latest applications of the operator support systems are concentrating on solving the issue of feed type classification. At many mines, changes in the mineralogy of the concentrator feed cause problems in process control. After a change in the feed type a new process control method has to be found. This is usually done by experimentation because the new type is often unknown. These experiments take time and the resulting treatment method might not be optimal. The monitoring system developed by *Jämsä-Jounela* et al. [57.28] uses SOM for online identification of the feed ore type and a knowledge database that contains information about how to handle a specific ore type. A self-learning algorithm scans historical data in order to suggest the best control strategy. The key for successful implementations is the right selection of variables for the ore type determination.

57.4 Emerging Trends

Modern automation systems in plants that have to process ever more complex ore are faced with the challenge of incorporating the increasing capabilities of modern technology in order to be able to succeed in a very competitive and global market, in which product variety and complexity, as well as quality requirements, are increasing, and environmental issues are playing ever more important key roles.

Mines and processing plants need integrated process control systems that can improve plant-wide efficiency and productivity. Advances in information technology have provided the capabilities for sharing information across the globe and, as such, process automation and control have become more directly responsible for assisting in the financial decision making of companies. The future aim of the system approach is to cover the complete value-added chain from the mine to the end product, and to utilize the latest hardware and software technology advances in their systems (Fig. 57.12).

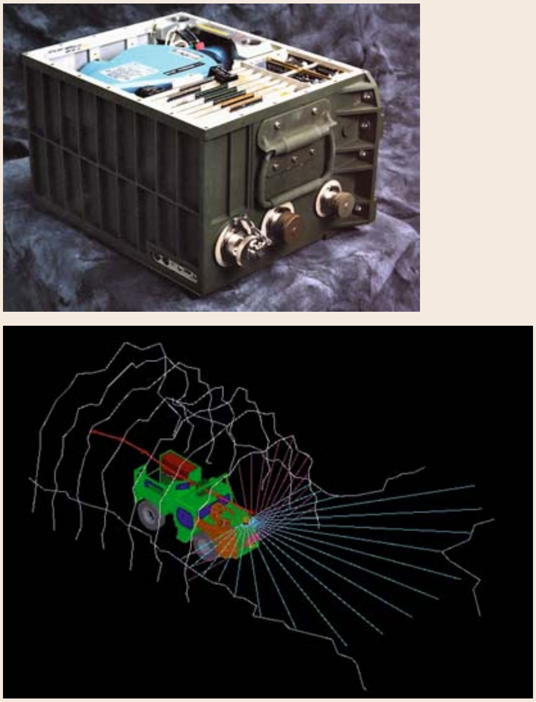

Fig. 57.7 RLG and test-bed (after [57.32])

Emerging trends in mining will likely take the form of moving towards advanced manufacturing techniques. Telecommunications systems on the surface and underground have opened the door to a completely new thinking in mining. The three biggest trends will be advances in positioning systems, telerobotic control of machinery, and the techniques that these systems will enable.

57.4.1 Teleremote Equipment

Work continues in the research field in building the equivalent to global positioning systems for underground. This technology development was recently reported at Massmin 2008 in Lulea, Sweden [57.33]. This new development combined with gyro technology will alter current practices in ways not yet comprehended. If this technology is combined with a RLG and a laser scanners mounted on a mobile machine such as shown in Fig. 57.7; the machines can have knowledge of positioning in real time on board the machine. Tasks

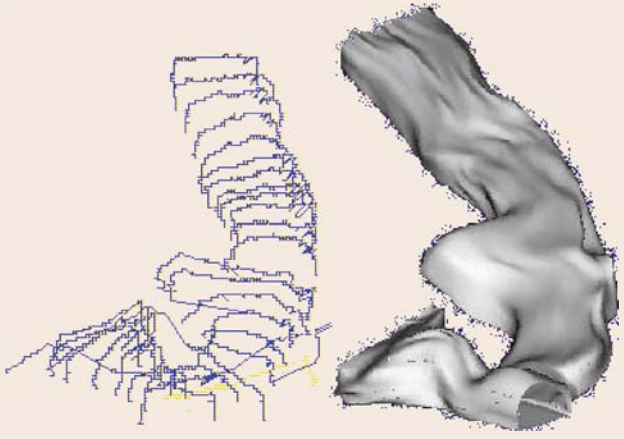

Fig. 57.8 Software generated drift from test-bed machine data (after [57.32])

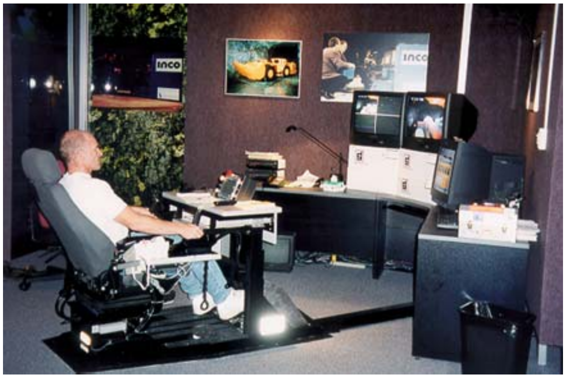

Fig. 57.9 Teleremote operation chair (after [57.32])

such as mapping, drill setup, and machine guidance systems will become simple to implement. Figure 57.7 shows a RLG and a concept of a machine for surveying. Figure 57.8 shows the actual mapping data collected by this surveying machine. At present, this unit is capable of surveying a 1 km drift (tunnel) in a few hours as opposed to several days using current work practices. The addition of an equivalent to GPS for underground will improve this technology and many more.

Another important trend is enabled by advances being made in communications capacity. The operation of teleremote equipment is possible for all processes and equipment. An operator station as shown in Fig. 57.9 is connected to the machine via the telecommunications system. This allows the operator to run several machines simultaneously, and together with positioning and navigation systems will allow the operator to instantaneously move from machine to machine across multiple mine environments. Several mines around the world are attempting this technology in operation. The list includes Inco, LKAB, Rio Tinto, and Codelco.

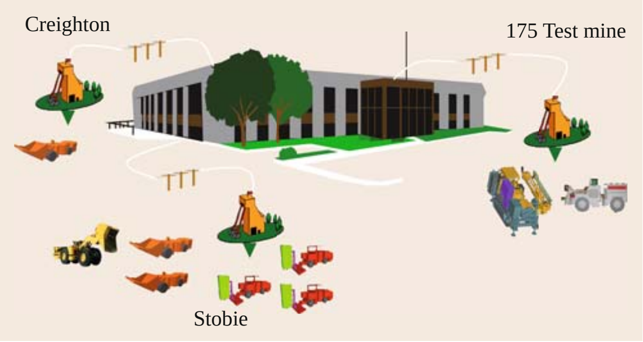

Fig. 57.10 Mines operation center

As the technology becomes more widespread, it will allow mining companies to consider the installation of mine operation centers such as the one shown in Fig. 57.10. Prototypes have been designed and installed around the world. The figure shows a mine operation center (MOC) that connects Stobie Mine, Creighton Mine, and the Research Mine at Inco. As seen in this picture, all are connected to the MOC. Three Tamrock Datasolo drills and five LHDs of various types are working or have worked from the MOC since its inception.

Benefits

Significant benefits of this teleremote style of operation lie in safety, productivity, and value-added time. Operators spend less time underground thus reducing exposure to underground hazards, and productivity is improved from the current one person per machine to one person per three machines. Initial tests indicate that 23 continuous LHD hours of operation in a 24 h period is possible, which is significantly better than the current 15 h. Clearly capital requirements in the latter situation are reduced.

The effectiveness of teleremote mining may be analyzed in the short term using computer-based simulation systems, which are powerful quantification and visualization tools of technology and operations. The following example shows the impact of the teleoperated mining technology on throughput, mine life, better resource utilization, and increased value generation for the organization.

57.4.2 Evaluation of Teleoperated Mining

A simulation model was used to evaluate the impact of teleremote operations on mine life and provide outputs required to make planning decisions. Teleremote operations have been shown in an operating mine to be capable of 7 to 7.5 h of operation per 8 h shift as compared to 5 h in a conventional mine. Other significant differences between conventional and telerobotic mining are increased flexibility and safety.

The comparative graphs shown in Fig. 57.11 show significant potential results from the application of robotics and automation. Mine life is reduced by 38% using teleremote mining versus conventional mining because of the higher mining rate from improved throughput and face utilization. Moreover, utilization of LHD equipment is increased by 80% in teleremote mining compared to conventional settings. With a total of two LHDs, high rates of production were achieved.

57.4.3 Future Trends in Grinding and Flotation Control

The optimization methods for grinding control are expected to be developed due to better particle distribution measurement systems, advanced mill condition measurements (e.g. frequency analysis), and the use of efficient grinding simulations based, for instance, on the discrete element method. Flotation is facing a new era in terms of process control and automation. Flotation cells have increased in size dramatically over the past years; flotation circuit design of multiple recycle streams will be replaced by simpler circuits, subsequently leading to a decreasing number of instruments with higher demands on reliability and accuracy. This will set new challenges for the control system design and implementation of these new plants. Process data driven monitoring methods, model predictive control (MPC), and fault tolerant control (FTC) will be among the most favorable methods to be applied together with the recently developed new measurement instruments.

58. Automation in the Wood and Paper Industry

Birgit Vogel-Heuser

Plant automation in the *timber (wood) industry* and *paper industry* has many analogies due to the similar process characteristics, i. e., hybrid process. From a plant automation point of view these industries are challenging because of their technical requirements. The USA is the largest producer of paper and paperboard. In a census by the America Census Bureau, the paper industry is placed 7 among 21 different industry groups, with 6% of the total value of product shipments for the years 2005 and 2006 [58.1]. China, as the second largest paper producer after the USA, is expecting a growth rate of 12.4% per annum (for the forecast from 1990 to 2010) [58.2]. The German woodworking machinery sector, with more than 26% of the world market share, had a € 3.4 billion turnover in 2006 and 72% export quota [58.3]. In 2006, the German print and paper industry grew by more than 7%, to € 8.5 billion and more than 84% export quota ([58.4], more details in [58.5]). This chapter will not only highlight the specific requirements from a technical point of view but also from the marketing point of view. Observations from these two points of view will lead to a heterogeneous automation system with proprietary devices for real-time and machinery-safety-related tasks, and standard devices for the rest. Both industries belong to plant manufacturing industries with their typical business characteristics. Automation in this field is technology driven and its importance is growing because more functionalities are being implemented using automation software to increase systems flexibility. The interface from automation level to enterprise resource planning (ERP) systems is being standardized in international manufacturing companies. Engineering is the key factor for improvement that needs to be considered in the coming years, and therefore also modularity and reusability where applicable.

58.1 Background Development and Theory

Both processes considered in this chapter are characterized by a large number of interrelated but independent processing steps as well as complex control parameters. Despite narrow limits and sophisticated process control, inhomogeneous properties of raw materials will cause variations in product quality. These variations cannot be measured directly at the time of production and can only be determined subsequently by destructive testing.

An overview of the requirements of process automation in plant manufacturing industry is provided in Table 58.1.

The criteria can be structured according to process requirements, automation system architecture, and project. A process automation system controls a *type of process*, e.g., *batch*, *continuous*, or *discrete*. Sometimes processes are composed of different process types and are then known as *hybrid* process. Both processes discussed in this chapter are hybrid process. Hybrid processes require different control strategies and therefore also different modeling notations, e.g., block diagrams (continuous) or state charts (batch). Both processes demand a *hybrid automation system* architecture.

Table 58.1 Overview of the requirements of process automation

Categories/criteria		Functionality/notation aspects
Process (hybrid)	Batch (continuous)	Transfer functions, block diagrams, differential equation
	Discrete	Status model, flow chart, continuous function chart, Petri net
	Real time	Hard real-time and event-controlled system, synchronized drive
	Reliability	Mapping of reliability aspects (failure mode and effects analysis: FMEA, fault tree analysis: FTA)
Automation system (heterogeneous)	Implementation	Programming language (C, IEC 61131-3, PEARL)
		Operation system [proprietary real-time operating system (RTOS proprietary)], Windows CE or XT
	Hardware platform	Programmable logic controller (PLC), distributed control system (DCS), personal computer (PC), microcontroller
	System architecture heterogeneous	Central, decentralized, distributed
	Human–machine interface (HMI)	PC-based standard HMI tools and proprietary tools for fast trending of process data

Specific requirements for both considered processes in terms of process automation are:

1. Wood, as the input material, fluctuates strongly due to the environment.
2. The required mechanical construction relies on heavy machinery.
3. They have hard and fast real-time requirements for the control of central machinery with a large number of control loops, which does not allow the use of one standard automation device, for example, a programmable logic controller (PLC) or a decentralized control system (DCS). As an example, during particle board manufacturing in a hydraulic press, up to 350 closed-loop controllers need to run within 10–20 ms cycle time.
4. Both timber and paper plants can consist of 3000–6000 analogue or digital inputs and outputs that are connected via a fieldbus. A paper plant needs to control up to 3500 control loops using 10–20 central processing units (CPUs) (PLCs or DCSs) that communicate via Ethernet-based bus systems.
5. The huge number of analogue control loops in a machine, in combination with requirements for fast real-time operation, results in the use of specific automation solutions. In the timber industry a versa module eurobus (VMEbus)-based control system is used, whereas in the paper(making) industry, decentralized control systems (DCS) with proprietary automation devices are used.
6. Worldwide environmental conditions lead to different automation architectures, i. e., decentralized and centralized design.
7. Consideration of both cross section and longitudinal section in control is required. The width of a pressed board is up to 2.9 m and in a paper machine up to 11 m, therefore the control and operation task has to deal with these two dimensions.
8. The need for precise synchronization between several drives in the machine, else the paper may be ripped, the timber mat may be ripped or compressed, or the steel belt of the hydraulic press may be damaged, thus causing damage to the surface of the panels. Speed of production depends strongly on product thickness, and ranges from 300 mm/s to 1.5 m/s in the timber industry and up to 25 m/s in the paper industry. Older solutions used vertical shafts to synchronize the drives accurately.
9. Continuous production around the clock, 365 days a year, demands high availability of plant automation system, i. e., about 90% in the timber industry and 99.9% in the paper industry.
10. Plant automation can automate almost 100% of tasks, but some important measurements such as moisture can still not be measured precisely, while other values such as internal bonding and bending strength are only available through laboratory experiments such as destructive testing.
11. Implementation of closed-loop controllers for mat weight or square weight, moisture, temperature, and thickness is required. Quality criteria for the sur-

Table 58.2 Languages of the IEC 61131-3 standard

Name/Functionality	Application
Ladder logic/circuit diagram	On/off, lamps
Instruction list/assembler type	Time-critical modules
Function block language/Boolean operations and functions	Interlocking, controller, reusable functions, communication
Sequential function chart/state diagram	Sequences
Structured text/higher programming language	Controller, technological functions

face structure include color and gloss in the paper industry and varnishing in the timber industry.

12. From the control-theoretic point of view, today both processes still lack a method that can model the whole process and the central machinery, i. e., the continuous hydraulic press in the timber industry and the paper machine in the paper industry. A first attempt to develop a model for the central machine has been made for the timber industry [58.6]. A method to model the process has not yet been developed due to lack of information concerning the process. Support from the operator and technologist is needed to bridge this gap, and to do this they would need, for example, a fast trending tool (sample time 10 ms for 450 analogue inputs) to analyze and optimize control loops in the entire machine or process.

After the discussion of technical requirements the typical market requirements should be mentioned. The company- and/or product-specific technological knowhow for both considered domains are of great value. The market is very competitive, which is why technological knowhow is kept within different production companies. Technological feedback to the machinery supplier is weak and therefore it is difficult to achieve technical control improvement. Suppliers are mostly situated in high-wage countries but the market is global, with growing competition from low-wage countries, therefore engineering efficiency and reduced engineering times are important for suppliers. Additionally, reduced start-up times and improved plant reliability are growing challenges in every part of the world. This means that engineering processes need to be optimized through modularity and reuse, as well as data integration along the engineering lifecycle. Modularity and reusability in modeling and simulation provide the opportunity to increase software quality while reducing start-up time.

During the design of each plant location, various requirements need to be taken into account, regarding: standards, type, and stability of power supply from power companies; ground connection; and the different qualifications of operator and service personnel.

Due to the availability requirement (see item 9 above) and the protection of technological knowhow while optimizing production, there is a need to provide maintainable and adaptable systems for the worldwide market. As far as possible standardized automation systems should be used, i. e., PLCs in the timber industry and DCSs in the paper industry.

The end customer usually specifies the brand of PLC, human–machine interface (HMI), or DCS, and sometimes also the drives used (if technologically possible). PLC and DCS systems are programmed according to the International Electrotechnical Commission (IEC) 61131-3 standards (Table 58.2). Customers in the USA prefer ladder logic as the programming language whenever possible. Technologically complex functions will be encapsulated in function blocks. However, standard PLCs and DCSs are not appropriate for fast real-time requirements and they can be manipulated by end customers; this should not be allowed as they are complex devices and there is the risk of machine hazards. This is why heterogeneous automation systems are standard in both industries. These heterogeneous systems consist of standard devices, standard HMIs, and fieldbus solutions, enriched with domain- or even company-specific solutions for fast real-time control. The important difference between the two industries is that the requirement for intrinsic safety is more relevant to the paper industry compared with the timber industry. The intrinsic safety requirement has a strong impact on the selection of appropriate equipment, especially sensors and actuators as well as fieldbus solutions.

Some green-field plants for the timber industry include glue production and/or paper machines that produce paper necessary for lamination.

Most machinery will be shipped in parts and is only commissioned on site, therefore machines or machine components will only be tested at the supplier's site. The final test is necessary after commissioning on site.

Training of maintenance personnel and operators takes place during commissioning and start-up. *Operator training systems* (OTS), which include simulation of the process, will be developed in the near future.

58.2 Application Example, Guidelines, and Techniques

As discussed, the requirements of the timber and paper industries are similar. This Chapter will first explain the continuous hydraulic press as an application example to show these requirements in more detail and appropriate automation solutions. After that, one solution for a paper machine will be introduced to highlight the similarities in terms of requirements and solutions.

58.2.1 Timber Industry

The production of fiber boards in the timber industry is a *hybrid production process* which generates a product (wooden panels) that has to meet many quality requirements. The thickness and density of the board or the consistency of the material are target values that need to be controlled within the tight intervals. The process consists of multiple steps where wood as the input material is prepared (Fig. 58.1). In the subsequent steps, the fiber mat is formed through continuous pressing process, heated, hardened, and sawn into discrete boards.

Wood is a natural material that is strongly influenced by temperature and humidity conditions. The input material's characteristics for the process varies widely.

The most costly piece of equipment to acquire and operate is the hydraulic press. It usually determines the maximum capacity of the production line [58.8]. The simplified press principle is described as follows. For the finished board, the material (already mixed with glue) has to be pressed with a specific pressure to obtain a certain thickness that is related to a set value. Wood is a natural material with underlying strong disturbing influences such as temperature or humidity

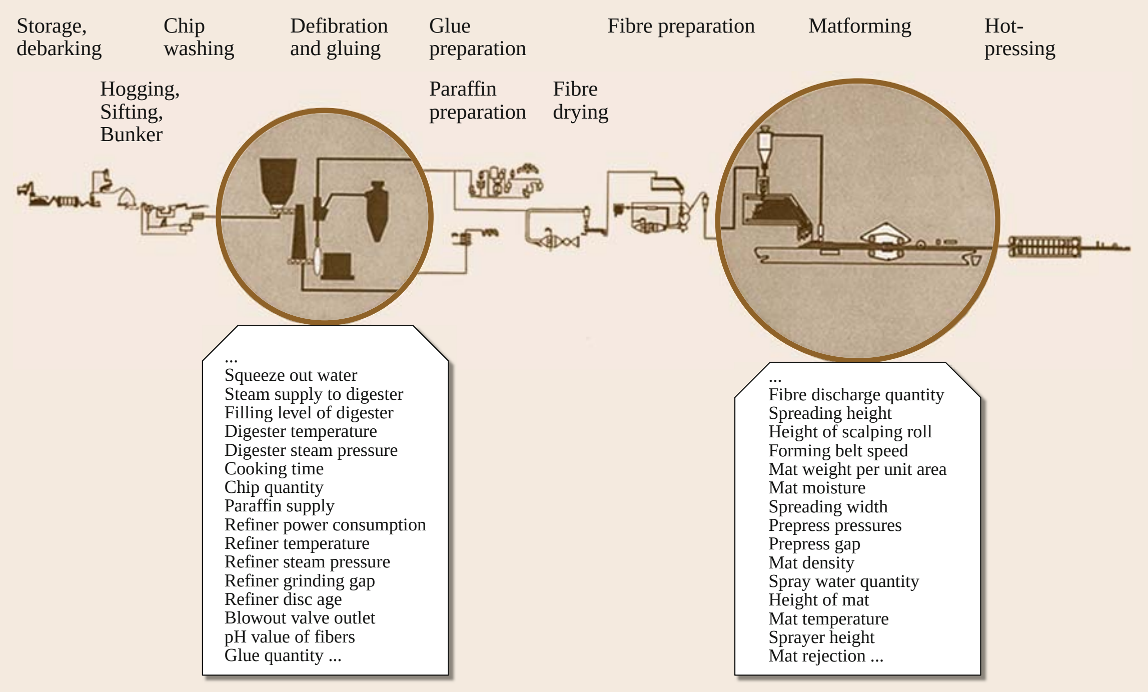

Fig. 58.1 Overview of the fiber board production process (after [58.7])

conditions. Thereby the characteristic of the input material to the press varies widely and cannot be measured with sufficient accuracy for automatic control. Hence the operator should be able to influence the automatic control strongly in order to compensate for such influences, based on his experience. The operator must be able to recognize that the situation is no longer in the range of the selected recipe and that he has to react by changing the distance or pressure parameters in a specific frame or group of frames (Fig. 58.2a). Therefore the operator needs a good overview of the real values of pressure and distance in cross-section and longitudinal directions (Fig. 58.2b).

Inclination of the press, which would produce an improper board, can be monitored on the distance profile (Fig. 58.2b right, section 6 slight inclination).

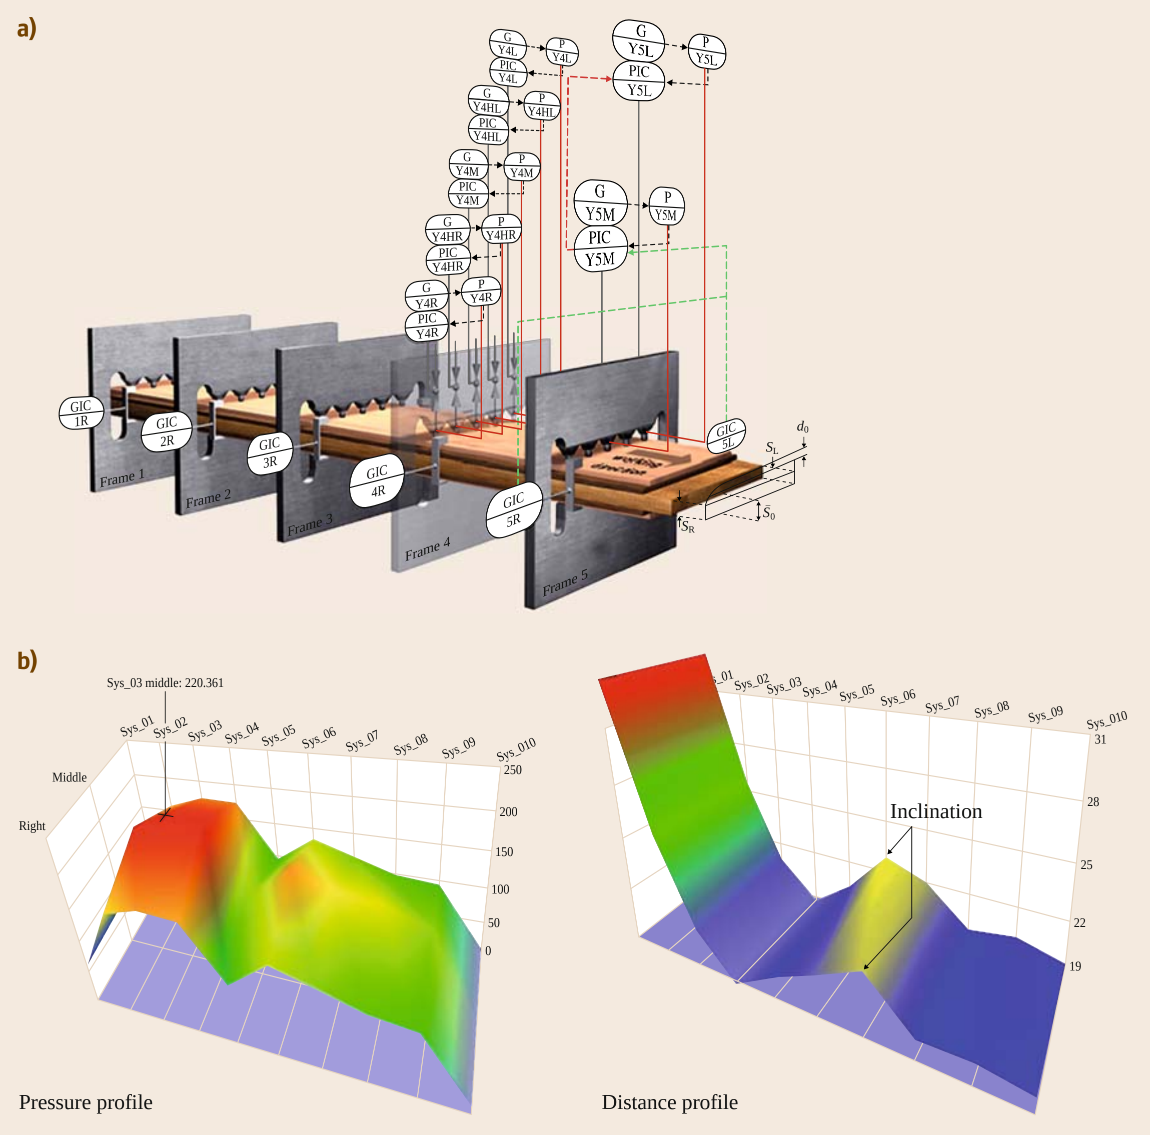

Fig. 58.2 (a) Process and instrumentation diagram of a continuous *thermohydraulic press* (only distance and pressure control, working direction from *left* to *right*). **(b)** Pressure and distance profile of a specific hydraulic press in 3-D; *x*-axis shows working direction from *left* to *right*, *y*-axis displays pressure profile (*left*) and distance profile (*right*) (after [58.9])

Torsion of the press table would be identified easily using this presentation. It is possible to identify if the pressure is too high along and/or across the press using the pressure profile (Fig. 58.2b left). The shape allows evaluation of whether the mat will be pressed regularly and symmetrically (across the cross section). Due to technical requirements a maximum pressure is set in order to achieve the thickness of the material. Distance control is realized by several hydraulic systems that consist of pressure transmitter and proportional valve with position sensor. One frame may consist of five hydraulic systems. The distance is measured on the left and right edge of the frame. A press may have up to 70 or more frames. Therefore, up to 350 pressure values and roughly 140 distance values, all with a spatial relation to each other, need to be controlled and displayed. The process and instrumentation diagram for five frames (Fig. 58.2a) shows the hydraulic cylinders, the pressure measurement, and the distance measurement. Real-time requirements for the entire loop need to be taken into account (Fig. 58.2a).

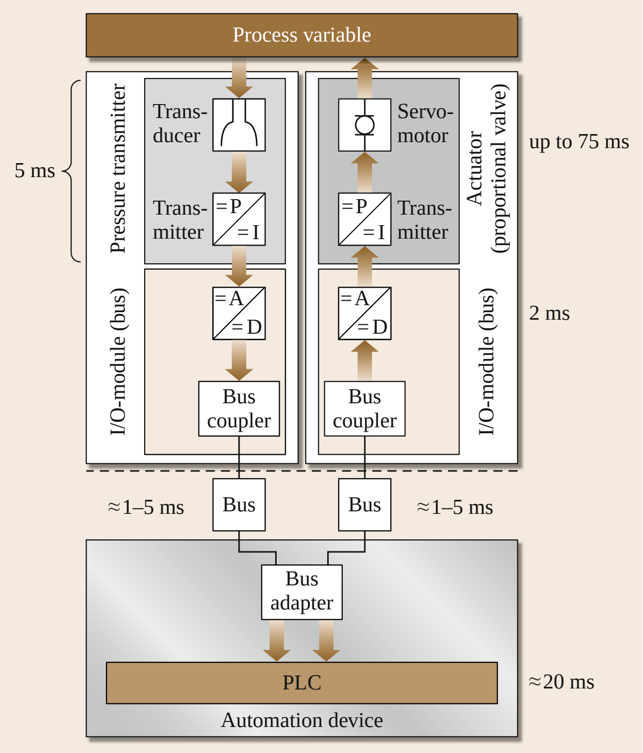

Fig. 58.3 System components of the control loop that needs to be considered for (hydraulic press) cycle time calculation. I/O – input/output

The controllers are more or less simple proportional–integral–differential (PID) controllers with filters or nested PID controllers. Complexity depends on their interdependency. Hydraulic systems are mechanically coupled to a thick steel plate to heat the mat so that the glue will harden. Besides the pressure control and distance control, temperature control and controllers to synchronize different drives at the inlet and the outlet of the press are also included. These drives need to be synchronized with the different forming line drives (mat forming and prepress) to avoid material problems in the press inlet.

Additionally the upper and lower steel belts need to be controlled depending on the position of the material in the press during first inlet or product changes. At the outlet of the press, synchronization between the cut-to-size saw and the cooling and stacking line is required. The endless board needs to be cut into pieces at high speed, e.g., 1.5 m/s. In the timber industry a cut-to-size saw is included for this task. Additional controllers in the forming line or press may be added depending on product requirements and the speed of the production process.

Figure 58.3 shows the usual time delays in the entire control cycle from data measurement to its effective influence on the process. It is necessary to reduce the cycle time for each distance controller in the controller itself to under 20 ms as hydraulic systems are highly dynamic, especially when the press is operated at top speed. In addition, synchronization between different frames is required if switch to another control mode is necessary.

Currently there is one supplier who provides a method to calculate the tension in the heating plate. The calculation is done by a machine-safety-related controller based on a finite-element calculation in the automation system.

Specific process control systems, which depends on the supplier's chosen solution, e.g., Motorola and VMEbus-based or personal computer (PC)-based systems with real-time operating system (RTOS), are needed to fulfill the strict time requirement. Only one supplier delivers a PLC solution, which needs less calculation power for a continuous press because it uses a different mechanical concept.

All distance control needs a data delay less than 10–20 ms in order to optimize the control loops for thin board. In order to optimize a controller, it is necessary to use a data sampling rate that is 5–10 times faster. This results in an optimized data gathering strategy and the development of proprietary trending systems [58.10].

Classically, HMI trending functionality is limited to the fastest sample time of 3 s or even slower because they focus on long-term trending. PLCs are connected with an Ethernet-based network (Fig. 58.4). Sensors and actuators are connected with a fieldbus system to ensure deterministic behavior. The cut-to-size saw is realized on PLCs with controllers for servo drives, or on more or less computer numerical control (CNC)-type devices to enable the required high speed.

Due to customer requirements in plant operation, such as long mean time between failures (MTBF), plant maintenance should be carried out by their plant service personnel. They should have the possibility to manipulate the PLC program within certain limits and to continue the optimization of processes. Therefore PLC is the preferred automation approach. The customer can specify the PLC supplier and bus systems supplier according to the market shares in his company and/or country, the service structure of the PLC supplier, and the skills of his maintenance personnel.

It is a marketing advantage to implement all control functionality on PLC. Due to the growth in system manipulation, a new challenge for PLC is emerging: the ability to track operator input and manipulations made on the PLC so that improper manipulations that may cause hazards can be detected and tracked. Password protection alone is not sufficient.

Regarding safety requirements, a strategy to overcome loss of power or press stoppage with material in the press is required because the material may start burning after a long time. Uninterruptible power supply (UPS) and emergency power supply are standard equipment.

The *cooling and stacking line* (sanding and trimming of particle boards) is needed to cool down the panel and prepare it for the finishing line with lamination or panel division, sorting, and packing. Intermediate and delivery storages in timber industry often follow a simple but chaotic storage strategy. However, tracking and tracing of boards is becoming increasingly important to the customer. For this reason, ERP and production management are becoming more important and a more precise storage system is needed. Board handling is often realized by using forklift trucks. The boards are chaotically stacked in a building until the truck from the customer arrives. They are identified only by a piece of paper with a printed barcode. Due to the manual handling strategy, tracking of faulty material is nearly impossible. Two strategies will be discussed and evaluated later (Sect. 58.2): radiofrequency identi-

Part F | 58.2

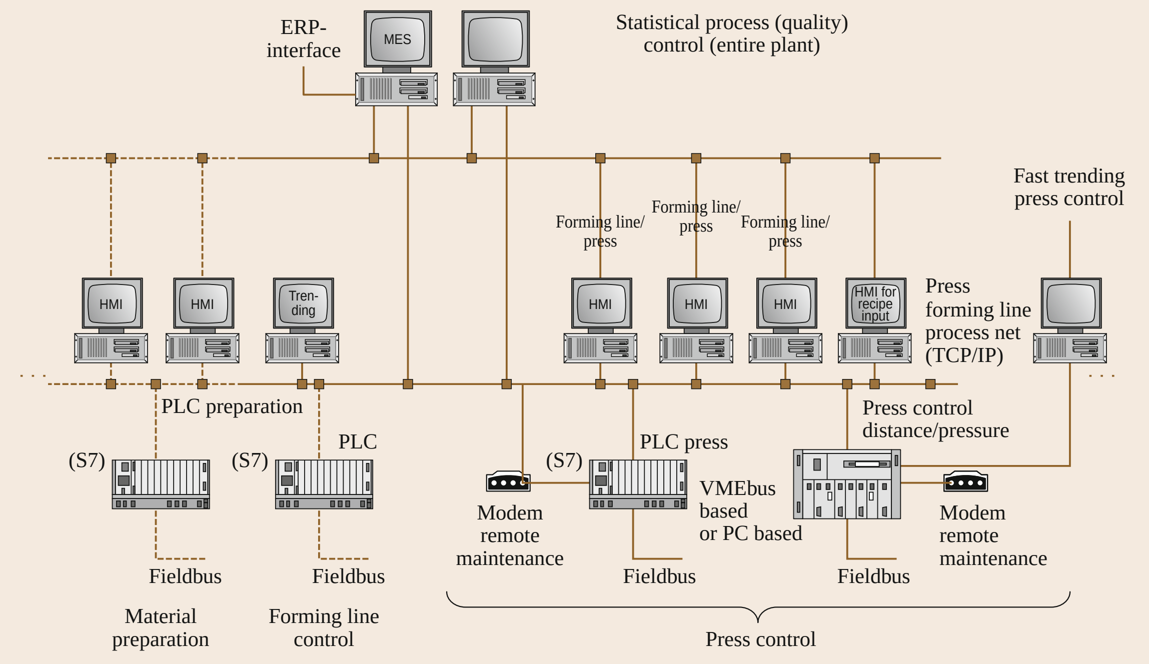

Fig. 58.4 Automation architecture (example from one supplier). TCP/IP – transmission control protocol/Internet protocol (MES – manufacturing execution system)

fication (RFID) of every board and global positioning system (GPS) detection of every stack.

There are also automated intermediate storage systems that allow handling of different board sizes on a mobile electrically powered rail-bound device using steel pallets [58.13]. The material flow is tracked and the product data are available. In production of thin medium-density fiber (MDF), board pallets need to be equipped with top and bottom protection panels to keep the product flat and protect its surface.

The quality of the board is not only influenced by the press but in all sections of the plant, particularly by the properties of the wood mixture and glue used [58.14]. The plant sections involved in the entire manufacturing process – starting with the hogged chip manufacturing, flaking or defibrating, drying, blending, straining, mat forming, up to prepressing and pressing sections – are all interdependent and, like the properties of the raw materials used, are subject to fluctuations. There are more than 100 parameters that have various intensities of effects on a plant's productivity and the quality of the product (Fig. 58.5). These parameters are input values for a process model based on a statistical algorithm [the three-stage least-squares (3SLS) algorithm [58.15, 16]].

Prerequisites for the analysis of data detailing the production history of the product, so-called material tracking and correspondingly time-correlated process data, need to be calculated. First implementations of a model-based quality-prediction and cost-optimization process control are running successfully [58.11, 12].

The quality of relevant process data and control parameters are taken into account to predict the resulting quality. Optimized process settings Y_{opt} for control parameters Y are calculated to ensure that nominal required quality in terms of costs is met

$$\text{cost}(Y) \to \text{Minimum}$$

under the condition

$$\begin{aligned}&Q_{\text{nom}}(t+1)\\&< Q_{\text{pred}}\big(X(t), Y_{\text{opt}}(t+1)\big) + S_{\text{pred}}\big(X(t), Y_{\text{opt}}(t+1)\big)\end{aligned}$$

and

$$\begin{aligned}&Q_{\text{nom}}(t+1)\\&> Q_{\text{pred}}\big(X(t), Y_{\text{opt}}(t+1)\big) - S_{\text{pred}}\big(X(t), Y_{\text{opt}}(t+1)\big)\,.\end{aligned}$$

To close the loop, these optimized process settings are entered as new nominal values for the control parameters.

58.2.2 Paper-Making Industry

Heterogeneous automation systems are implemented in the paper industry to control force, torque, temperature, moisture, and vibration. Required reliability is 0.9999 (24 h/365 days per year). An overview of process sections, controllers, and most importantly sensors is given in Fig. 58.6 (working direction: left to right, with the process divided into two figures). The paper machine is a device for continuously forming, dewatering, pressing, and drying a web of paper fibers [58.18].

The automation system is mainly realized using a DCS system. In the given example, the automation system was being realized using PCS 7 Siemens based on the 400 CPUs. The connection to the sensors and actuators is realized using the PROFIBUS DP fieldbus. Specific automation devices are implemented for cross-section control and transmission control. Most measuring devices, e.g., gloss, moisture, caliper and basis weight, and color, are equipped with their own automation device and will be connected with a controller area network bus (CANbus) to the cross-section control and over a measurement server (PC) to the HMI. Voith, for example, developed its own weight profile control system software named Profilmatic. Profilmatic cross-direction control software continuously and automatically aligns each actuator against its respective measurement position from the downstream scanner. An automapping algorithm monitors the movement of a normal profile control and aligns the cross-direction measurement data boxes against the actuator control zones. Each control output array compares the actual profile change against the expected profile change. A software model continuously updates the process-mapping model using the difference between measured and expected response.

Model-based soft sensors deliver high-quality data for superior longitudinal control of the paper machine. Similar to in the wood industry, a multivariate statistical approach is implemented to forecast, for example, the

weight profile at the end of the paper machine. Some basic constraints for the implementation of statistical process (quality) control in paper industry are given in [58.12], e.g.,

> *this assumes that all of the important variables are measured in a timely manner ... Another point to consider is the sampling frequency. Generally, the more variability in a material, the more often it should be sampled.*

Blatzheim gave an example of the benefit of such system: 15–16 km of waste material reduction was achieved after implementing this system, corresponding to an approximate increase of 200 000 of sellable paper per year.

Laukkanen mentioned OTS and appropriate workflow guidelines as being one of the keys to reduce commissioning and start-up, especially abroad [58.3].

Through the engineering life cycle, depending on the project phase, different tools and methods are used. In the worst case, the corresponding data have to be re-entered during the transition from one phase to the next because there are no appropriate interfaces between the individual tools. The ideal is to strive for a higher-level tool that consistently provides all system information in a model and enables the design to be realized both at an abstract level and in a conventional environment (e.g., electrical engineering computer aided engineering (E-CAE), IEC 61131-3).

58.3 Emerging Trends, Open Challenges

There are many open challenges in the timber and paper industries. Some will be discussed in this section, i. e., *engineering lifecycle* and *data integration*, *reduction of complexity* for operators, improvement of operator training, as well as evaluation of new technologies.

Open challenges are to increase engineering efficiency while reducing costs and start-up time by applying modularity and reuse. Communication is a major factor to consider when improving engineering quality because different disciplines such as sales, technology, mechanical engineering (including hydraulic), electrical engineering, and computer science are involved through different phases in the engineering process. Communication could be supported by a comprehensive model. Unfortunately modeling of hybrid systems in process automation is still a field for research and development, especially for reuse and modularity, and when the target group is engineers or technicians coming from different disciplines. One promising approach is to apply a comprehensive modeling notation such as the systems modeling language (SysML) [58.19] that is based on the unified modeling language (UML) and developed for systems engineering. This basically solves the deficiencies of UML for automation, i. e., modeling of hardware aspects, integration, and tracking of requirements. The advantage of UML in terms of supporting modularity through an object-oriented mechanism is fully available. The task is to evaluate SysML in terms of ease of application by engineers and technicians in automation depending on the availability of strong tools. One of the first steps to integrate modeling into IEC 61131-3 is already in progress in a research and development (R&D) project in Germany. Various UML diagrams are implemented in one of the market leading IEC 61131-3 tools [58.20]. Presenting the modules throughout the engineering life cycle from customers' requirements to operation is still not solved and will not only be a task for research but also for the development department of leading automation companies. Plant manufacturing companies need an easy way to evaluate whether a new plant concept could be realized by reusing existing modules or to determine the number of new modules that need to be developed. Data integration throughout the engineering life cycle is theoretically solved but still far away from realization in the applied tools. Coupling of computer-aided engineering (CAE) system on the basis of a tool-to-tool interface is not sufficient for the two considered industries.

There is also huge potential for cost saving during start-up by integrating engineering data into an ERP system, and offshoring in a global market. Additional elaboration on logistics, e.g., just-in-time machine or component to site, is needed. Today mainly mechanical construction has been subject to offshoring. This will change during the next few years. A lot of challenges for the engineering workflow will consequently be affected.

Operation and maintenance, which is challenging to improve, is also a very important phase in the engineering life cycle. Application of three-dimensional (3-D) visualization can successfully reduce complexity for operators and at the same time enhance their mental model of the process [58.9, 21]. An expert evaluation has proved the benefit of 3-D visualization. It would also be beneficial to implement a sliding mechanism to analyze data offline. Real process data presented in 3-D, e.g., a surface plot (Fig. 58.1b), may be analyzed in slow or fast motion. By selecting the time frame to be analyzed the technologist can view the data like a data player. This is integrated into standard HMI systems and allows analysis of critical situations as well as faulty situations in order to increase understanding of the process. Recent work focuses on application of this approach for operator training.

Regarding new technological trends, Ethernet-based fieldbus systems as well as identification technologies (RFID) need to be evaluated. A first implementation of Profinet in the cooling and stacking line has been realized. The upcoming question and design decision is whether Profinet should also be used for communication between PLC, sensors, and actuators, also in hazardous areas. Market shares outside Europe are hard to predict but this is a prerequisite before coming to a general decision for one bus system based on Ethernet standard.

The use of RFID to optimize material handling from the press outlet to customers is being discussed. There are some constraints that need to be evaluated before a test, e.g., placement of the RFID (how it can be fixed to the board before the press or after the cut-to-size saw); temperature resistance, as the boards are still at about 100 °C at the press outlet; and costs. The idea is to store all relevant data relating to the board during its production process on the RFID tag so that customers have access to the production data on request.

Board-handling satellite data to define the position of a panel stack in a chaotic storage system may also be helpful.

59. Welding Automation

Anatol Pashkevich

This Chapter focuses on automation of welding processes that are commonly used in industry for joining metals, thermoplastics, and composite materials. It includes a brief review of the most important welding techniques, welding equipment and power sources, sensors, manipulating devices, and controllers. Particular emphasis is given to monitoring and control strategies, seam-tracking methods, integration of welding equipment with robotic manipulators, computer-based control architectures, and offline programming of robotic welding systems. Application examples demonstrating state-of-the-art and recent advances in robot-based welding are also presented. Conclusions define next challenges and future trends in enhancing of welding technology and its automation potential, modeling and control of welding processes, development of welding equipment and dedicated robotic manipulators, automation of robot programming and process planning, human–machine interfaces, and integration of the automated robotic stations within the global production system.

59.1 Principal Definitions

Welding is a manufacturing process by which two pieces of materials (metals or thermoplastics) are joined together through coalescence. This is usually achieved by melting the workpieces and adding a filler material that causes the coalescence and, after cooling, forms a strong joint. Sometimes, pressure is applied in combination with heat, or alone. At present, heat welding is the most common welding process, which is widely used in automotive, airspace, shipbuilding, chemical and petroleum industries, power generating, manufacturing of machinery, and other areas [59.1–3].

For heat welding, many different energy sources can be used, including a gas flame, an electric arc, a laser or an electron beam, friction, etc. Depending on the *mode of energy transfer*, the American Welding Society (ASW) has grouped welding/joining processes and assigned them official letter designations, which are used for identification on drawings and in technological documentation. In particular, the ASW distinguishes *arc welding*, *gas welding*, *resistance welding*, *solid-state welding*, and *other welding processes*. Within each group, processes are distinguished depending on the *influence of capillary attraction* (which is the ability of a substance to draw another substance into it). For instance, the arc welding group includes gas metal arc (GMAW), gas tungsten arc (GTAW), flux cored arc welding (FCAW), and other types of welding. Detailed and complete classification of the welding processes is given in [59.4].

59.2 Welding Processes

59.2.1 Arc Welding

This group uses an electric arc between an electrode and the base material in order to melt metals at the welding point. The arc is created by direct or alternating current using consumable or nonconsumable electrodes. The welding region may also be protected from atmospheric oxidation and contamination by an inert or semi-inert gas (shielding gas). The oldest process of this type, *carbon arc welding* (CAW), uses a carbon electrode and has limited applications today. It has been replaced by *metal arc welding*. A typical example is *shielded metal arc welding* (SMAW), in which a flux-covered metal electrode produces both shielding (CO_2 from decomposition of the covering) and filler metal (from melting of the electrode core). This process is widely used in manual welding and is rather slow, since the consumable electrode rods (or *sticks*) must be frequently replaced.

Automatic arc welding is mainly based on the *gas metal arc welding* (GMAW) process, also known as metal inert gas (MIG) or metal active gas (MAG) welding [59.5]. The process uses a continuous wire feed as a consumable electrode and an inert or semi-inert gas mixture as shielding (Fig. 59.1a). The wire electrode is fed from a spool, through a welding torch. Since the electrode is continuous, this process is faster compared than SMAW. Besides, the smaller arc size allows making overhead joints. However, the GMAW equipment is more complex and expensive, and requires more complex setup. During operation, the process is controlled with respect to arc length and wire feeding speed. GMAW is the most common welding process in industry today; it is suitable for all thicknesses of steels,

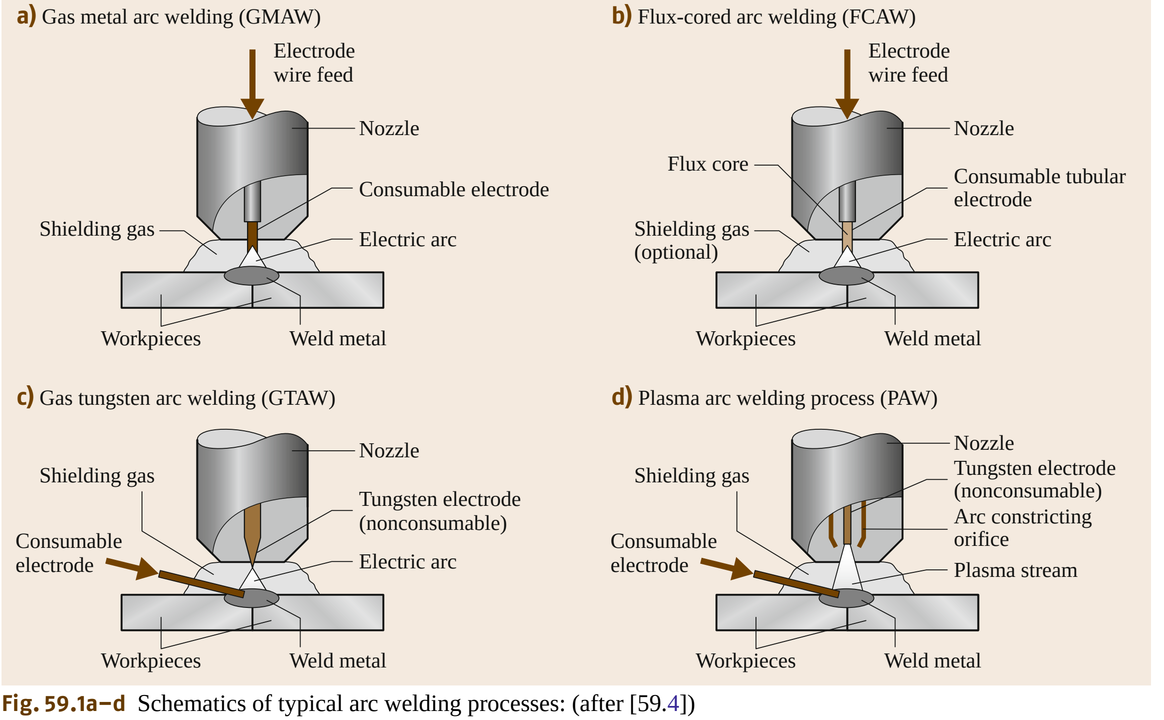

Fig. 59.1a–d Schematics of typical arc welding processes: (after [59.4])

aluminum, nickel, stainless steels, etc. This process has many variations depending on the type of welded metal and shielding gas, and also the metal transfer mode.

A related process, *flux-cored arc welding* (FCAW), uses similar equipment but is based on a continuously fed flux-filled electrode, which consists of a tubular steel wire containing *flux* (a substance which facilitates welding by chemically cleaning the metals to be joined [59.1]) at its core (Fig. 59.1b). The heat of the arc decomposes the electrode core producing gas for shielding and also deoxidizers, ionizers, and purifying agents. Additional shielding may be obtained from externally supplied gas. Obviously, this cored wire is more expensive than the standard solid one, but it enables higher welding speed and greater metal penetration.

Another variation is *submerged arc welding* (SAW) that is also based on the consumable continuously fed electrode (solid or flux cored), but the arc zone is protected by being *submerged* under a covering layer of granular fusible flux. When molten, the flux generates protective gases and provides a current path between the electrode and the base metal. Besides, the flux creates a glass-like slag, which is lighter than the deposited metal from the electrode, so the flax floats on the surface as a protective cover. This increases arc quality, since atmospheric contaminants are blocked by the flux. Also, working conditions are much better because the flux hides the arc, eliminating visible arc light, sparks, smoke, and spatters. However, prior to welding, a thin layer of flux powder must be placed on the welding surfaces.

For nonferrous materials (such as aluminum, magnesium, and copper alloys) and thin sections of stainless steel, welding is performed by the *gas tungsten arc welding* (GTAW) process, also referred to as *tungsten inert gas* (TIG) welding. The process uses a nonconsumable tungsten electrode with high melting temperature, so the arc heat causes melting of the workpiece and additional filling wire only (Fig. 59.1c). As an option, the filling metal may not be used (*autogenous* welding). The weld area is protected from air contamination by a stream of inert gas, usually helium or argon, which is fed through the torch. Because of the smaller heat zone and weld puddle, GTAW yields better quality compared with other arc welding techniques, but is usually slower. The process also allows a precise control, since heat input does not depend on the filler material rate. Another advantage is the wide range of materials that can be welded, so this process is widely used in the airspace, chemical, and nuclear power industries.

A related process, *plasma arc welding* (PAW), uses a slightly different welding torch to produce a more focused welding arc. In this technique, which is also based on a nonconsumable electrode, an electric arc transforms an inert gas into plasma (i. e., an electrically conductive ionized gas of extremely high temperature) that provides a current path between the electrode and the workpiece (Fig. 59.1d). Similar to the GTAW process, the workpiece is melted by the intense heat of the arc, but very high power concentration is achieved. To initiate the plasma arc, a tungsten electrode is located within a copper nozzle. First, a pilot arc is initiated between the electrode and nozzle tip, then it is transferred to the workpiece. Shielding is obtained from the hot ionized gas (normally argon) issuing from the orifice. In addition, a secondary gas is used (argon, argon/hydrogen or helium), which assists in shielding. PAW is characterized by extremely high temperatures (30 000 °F), which enables very high welding speeds and exceptionally high-quality welds; it can be used for welding of most commercial metals of various thicknesses. A variation of PAW is plasma cutting, an efficient steel cutting process.

59.2.2 Resistance Welding

Resistance welding is a group of welding processes in which the heat is generated by high electrical current passing through the contact between two or more metal surfaces under the pressure of copper electrodes. Small pools of molten metal are formed at the contact area, which possess the highest electrical resistance in this circuit. In general, these methods are efficient and produce little pollution, but their applications are limited to relatively thin materials. There are several processes of this type; two of them are briefly described below.

Resistance spot welding (RSW) is used to join overlapping thin metal sheets, typically, of 0.5–3.0 mm thickness. It employs two nonconsumable copper alloy electrodes to apply pressure and deliver current to the welding area (Fig. 59.2a). The electrodes clamp the metal sheets together, creating a temporary electrical circuit through them. This results in rapid heating of the contact area to the melting point, which is transformed into a nugget of welded metal after the current is removed. The amount of heat released in the spot is determined by the amplitude and duration of the current, which are adjusted to match the material and the sheet thickness. The size and shape of the spots also depend on the size and contour of the electrodes. The main advantages of this method are efficient energy use,

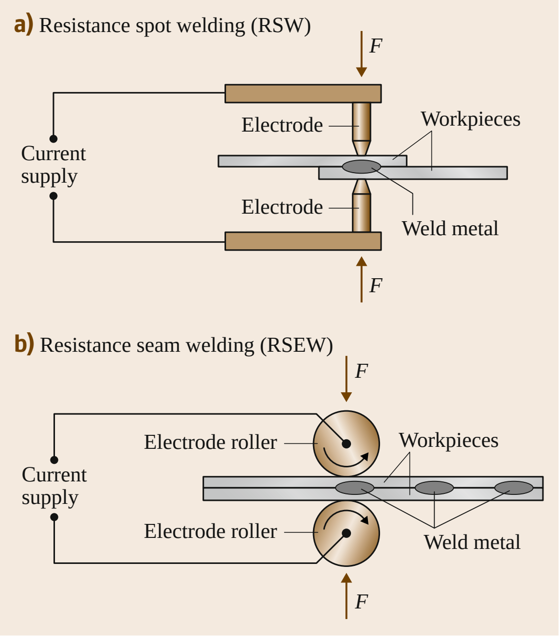

Fig. 59.2a,b Schematics of typical resistance welding processes (after [59.4])

low workpiece deformation, no filler materials, and no requirements for the welding position. Besides, this process allows high production rates and easy automation. However, the weld strength is significantly lower than for other methods, making RSW suitable for certain applications only (it is widely used in the automotive industry where cars can have up to several thousand spot welds).

Resistance seam welding (RSEW) is a modification of spot welding where the bar-shaped electrodes are replaced by rotating copper wheels. The rotating electrodes are moved along the weld line (or vice versa, the workpiece is moved between the electrodes), progressively applying pressure and creating an electrical circuit (Fig. 59.2b). This allows obtaining long continuous welds (for direct current) or series of overlapping spot welds (for alternative or pulsed current). In seam welding, more complicated control is required, involving coordination of the travel speed, applied pressure, and electrical current to provide the overlapping welds. This process may be automated and is quite common for making flange welds, watertight joints for tanks, and metal containers such as beverage cans. There are a number of process variants for specific applications, which include *wide wheel seam*, *narrow wheel seam*, *consumable wire seam welding*, and others.

59.2.3 High-Energy Beam Welding

Energy beam welding is a relatively new technology that has become popular in industry due to its high precision and quality [59.6]. It includes two main processes, laser beam welding and electron beam welding, differing mainly in the source of energy delivered to the welding area. Both processes are very fast, allow for automation, and are attractive for high-volume production.

Laser beam welding (LBW) uses a concentrated coherent light as the heat source to melt metals to be welded. Due to the extremely high energy concentration, it produces very narrow and deep-penetration welds with minimum heat-effective zones. Welds may be fabricated with or without filler metal; the molten pool is protected by an externally supplied shielding gas. It is a versatile process, capable of welding most commercially important metals, including steel, stainless steel, titanium, nickel, copper, and certain dissimilar metal combinations with a wide range of thickness. By using special optical lenses and mirrors, the laser beam can be directed, shaped, and focused on the workpiece surface with great accuracy. Since the light can be transmitted through the air, there is no need for vacuum, which simplifies equipment and lowers operating cost. The beam is usually generated using a gas-based CO_2 solid-state Nd:yttrium–aluminum–garnet (YAG) or semiconductor-based diode lasers, which can operate in pulsed or continuous mode. Furthermore, the beam is delivered to the weld area through fiber optics. For welding, the beam energy is maintained below the vaporization temperature of the workpiece material (higher energy is used for hole drilling or cutting where vaporization is required). Advantages of LBW include high welding speed, high mechanical properties, low distortion, and no slag or spatter. The process is commonly used in the automotive industry.

A derivative of LBW, *dual laser beam welding*, uses two equal power beams obtained by splitting the original one. This leads to a further increase in welding speed and improvement of cooling conditions. Another variation, laser hybrid welding, combines the laser with metal arc welding. This combination also offers advantages, since GMAW supplies molten metal to fill the joint, and a laser increases the welding speed. Weld quality is higher as well, as the potential for undercutting is reduced.

Electron beam welding (EBW) is a welding process in which the heat is obtained from high-velocity electrons bombarding the surfaces to be joined. The electrons are accelerated to a very high velocity (about

50% of the speed of light), so beam penetration is extremely high and the heat-affected zone is small, allowing joining of almost all metals and their combinations. To achieve such a high electron speed and to prevent dispersion, the beam is always generated in high vacuum and then delivered to the workpiece located in a chamber with medium vacuum or even out of vacuum. In the last case, specially designed orifices separate a series of chambers at various vacuum levels. Because of the vacuum, a shielding gas is not used, while a filler metal may be used for some materials (for deoxidizing the melted plain carbon steel that emits gases, to prevent weld porosity). The EBW process provides very narrow and high-quality welds; it is commonly used for joining stainless steels, superalloys, and reactive and refractory metals. The primary disadvantage of the EBW is high equipment cost and high operation price (due to the need for vacuum). Besides, location of the parts with respect to the beam must be very accurate.

59.3 Basic Equipment and Control Parameters

The described welding technologies utilize various types of equipment and control units. However, since arc and resistance spot welding are used in manufacturing most widely, they are expanded upon in more detail.

59.3.1 Arc Welding Equipment

Arc-welding processes employ the basic electrical circuit, where the currents typically vary from 100 to 1000 A, and voltage ranges from 10 to 50 V. The power supply can produce either direct current (DC) or alternating current (AC), and usually can maintain either constant current or constant voltage. Consumable-electrode processes (such as GMAW) generally use direct current, while nonconsumable-electrode processes (GTAW, etc.) can use either direct current (with negative electrode polarity) or alternating current (with square-wave AC pattern) [59.1, 3, 5].

For arc welding processes, the voltage is directly related to the arc length, and the current is related to the amount of heat produced. So, *constant-current* power supplies are most often used for manual welding, because they maintain a relatively constant heat output even if the voltage varies due to imperfect control of electrode position. *Constant-voltage* power supplies are usually utilized for automated welding, since the electrode spatial position (and arc length) is proper controlled and the current sensor can be used for adjusting the electrode position in the feedback loop.

Typical welding equipment for the GMAW process is shown in Fig. 59.3. It includes a power supply, welding cables, a welding gun, a water cooling unit, a shielding gas supplier, wire feed system, and a process control unit. Here, the cathode (negative) cable is connected to the workpiece, and the anode (positive) cable is connected to the welding gun. The consumable welding wire is continuously fed through the gun cable and the contact tube inside the gun, where an electrical connection is made to the power supply. In addition, the shielding gas and cooling water are also fed through the gun cable. The welding gun can be operated either man-

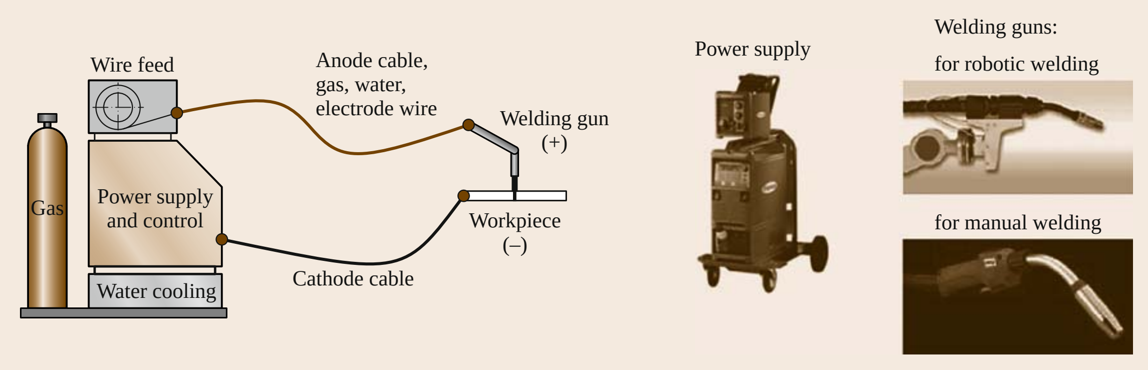

Fig. 59.3 Composition of a typical GMAW machine and its components (http://www.robot-welding.com/welding_torch.htm, http://www.binzel-abicor.com)

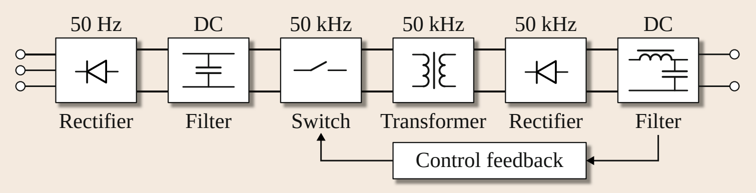

Fig. 59.4 General structure of the inverter-based welding power supply

ually or automatically, by a welding robot or some other automated setup. The gun shape is usually a swan-neck or straight. Guns with low current and light duty cycle are generally gas-cooled whereas those with higher current are water-cooled.

Formerly, welding machines were based on simple transformers with the operational frequency of the main energy source (i. e., 50 or 60 Hz). For DC welding, the transformer was equipped with a rectifier and an additional low-pass filter to suppress the ripples and produce a process-stabilizing effect. In modern *inverter-type* equipment (Fig. 59.4) the main conversion is performed at much higher frequency (approximately 20–50 kHz) allowing to decrease transformer weight, size, and magnetic losses (by about tenfold).

The output stage of the power supply may also include a controlled on/off switch circuit. By varying the on/off period (i. e., the pulse duty factor), the average voltage may be perfectly adjusted. For AC welding, the power source implements additional features such as pulsing the welding current, variable frequencies, variable ratio of positive/negative half-cycles, etc. This allows adjusting the square-wave shape to minimize the electrode thermal stress and the cleaning effect. In some cases, an AC sine wave is combined with high-frequency high voltage in the neighborhood of zero-crossing, to ensure noncontact arc reignition. Other variants use pulsed DC current of low-frequency (1–10 Hz) to reduce weld distortions and compensate cast-to-cast variations.

By relevant settings of welding parameters, it is possible to select three possible modes of operation (short arc mode, spray mode, and globular mode), which are distinguished by the way in which metal is transferred. The weld orientation relative to gravity, torch travel speed, and electrode orientation relative to the welding joint also have considerable influence on the weld formation. For most materials, electrode angles of 60–120° give welds with adequate penetration-depth-to-width ratio. In some cases, electrode cross-oscillation (weaving) is necessary. Other important control parameters are electrode feed speed, distance between the workpiece and contact nozzle, travel motion parameters (straight or weaving type), composition of shielding gas, and delivery of cooling gas/water.

59.3.2 Resistance Welding Equipment

The implementation of resistance spot welding involves coordinated application of force and current of the proper magnitude and time profile. Typically the current is in the range of 1–100 kA, and the electrode force is 1–20 kN. For the common combination “1.0 + 1.0 mm” sheet steel, the corresponding voltage between the electrodes is only 1.0–1.5 V, however the voltage from the power supply is much higher (5–10 V) because of the very large voltage drop in the electrodes [59.2–4].

The spot welding cycle is divided into four time segments: *squeeze*, *heat* (weld), *cool* (hold), and *off*, as shown in Fig. 59.5. The squeeze segment provides time to bring the electrodes into contact with the workpiece and develop full force. The heat segment is the interval during which the welding current flows through the circuit. The cool segment, during which the force is still held, allows the weld to be solidified, and the off segment is to retract the electrodes, and remove or reposition the workpiece. Typical values for the heat and hold times are 0.1–0.5 s and 0.02–0.10 s, respectively. In industry, the segment duration is often expressed in cycles of the main frequency (50 or 60 Hz).

Typical equipment for resistance welding includes the power supply with secondary lines, the electrode pressure system, and the control system. This structure applies to both spot and roller seam welding machines. Differences are in the type of electrode fittings and in the electrode shapes. For spot welding, the guns normally include a pneumatic or hydraulic cylinder and are designed to fit a particular assembly. The most common are C-type and X-type guns (Fig. 59.6), which differ in shape and force application mechanisms (in the first case, the cylinder is connected directly to the moving electrode; in the second case, it is connected via the lever arm). However, some new welding guns incorporate built-in electromechanical actuators for force generation.

Resistance welding may employ several power supply architectures that differ in the type of the current (AC/DC) and frequency of voltage conversion: *AC power source* based on a low-frequency (50 or 60 Hz) step-down transformer; *DC power source* with a low-frequency (50 or 60 Hz) transformer and rectifier; *impulse capacitive-discharge source*, where the rectified primary current is stored in capacitors and is transformed into high welding currents; *inverter-based power source*, where the primary supply voltage (50 or 60 Hz) is rectified and is converted to a mid-frequency (20–50 kHz) square wave. Similar to arc welding, the inverter-based method gives essential reduction of power supply size and weight. All methods may be used with single- or three-phase mains supply.

From a compositional point of view, there are two main types of resistance welding equipment. In the first type, an AC power unit with electric transformer is built directly into a welding gun. The second type uses a DC power unit with welding cables connected to the gun.

Modern computer-based control units allow programming of all essential process parameters, such as current magnitude, welding cycle times, and electrode force. Some sophisticated controllers also allow regulation of current during welding, control of pre/post-heat operations, or adjustment of the clamping force during the cycle. Particular values of the welding parameters depend on the physical properties and thickness of the joining materials, and also on the type of equipment used. Weld current shape is usually rectangular, but can also be trapezoid type with programmed rise/fall times. For some thick materials, several current pulses may be applied.

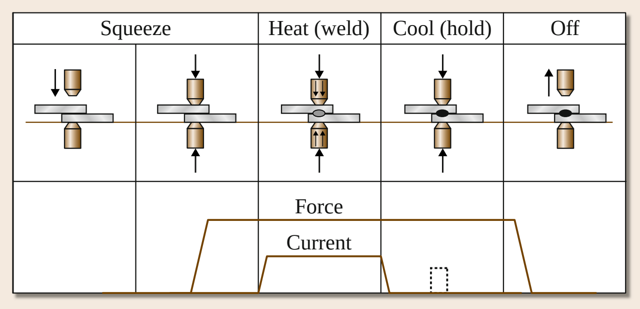

Fig. 59.5 Spot welding cycle

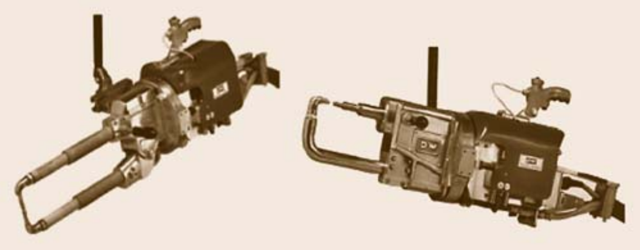

Fig. 59.6 Spot welding guns (X-type and C-type) (http://www.spotco.com)

59.4 Welding Process Sensing, Monitoring, and Control

Automated welding requires accomplishing a number of tasks (such as weld placement, weld joint tracking, weld size control, control of the weld pool, etc.) that are based on real-time monitoring and control of relevant parameters. These actions must be performed in the presence of disturbances caused by inaccurate joint geometry, misalignment of workpiece and welding tool, variations in material properties, etc. The main challenge is that the observable data is indirectly related to final weld quality, so sensing and feedback control relies on a variety of techniques. Basically, they are divided into groups (technological and geometrical), which provide correspondingly control/monitoring of the welding process and positioning of the workpiece relative to the energy source [59.7, 8].

59.4.1 Sensors for Welding Systems

For welding, technological parameters typically include voltage, current, and wire feed speed. The *arc voltage* is usually measured at the contact tube within the weld torch, but the voltage drop between the tube and the wire tip (where the arc starts) must be compensated. Another method is to measure the voltage on the wire inside the feeding system, which provides a more accurate result.

The *welding current* can be measured using two types of sensors, the Hall-effect sensor and current shunt. The former is a noncontact device that responds to the magnetic field induced by the current. The second sensor type employs a contact method where the current flows through a calibrated resistor (shunt) that converts the current into a measured voltage.

The *wire feed speed* is usually estimated by measuring the speed of the drive wheel of the feeder unit. However, this must be complemented with special features of the feeder mechanics, which ensures robustness with respect to wire diameter variations and bending/twisting of the wire conduit.

Sensors for geometrical parameters provide the data for seam tracking during welding and/or seam searching before welding. These capabilities ensure adaptation to the actual (i. e., nonnominal) weld joint geometry and the workpiece position/orientation relative to the torch. The most common geometrical sensors are based on *tactile*, *optical* or *through-arc* sensing principles.

Tactile sensors implement purely mechanical principles, where a spring-loaded guide wheel maintains a fixed relationship between the weld torch and the weld joint. In more sophisticated sensors the signals from the mechanical probe are converted into electrical signals to acquire the geometrical data.

Optical sensors usually use a laser beam, which scans the seam in linear or circular motions, and a charge-coupled device (CCD) array that captures features of the weld joint (Fig. 59.7a). By means of scanning, the sensor acquires a two-dimensional (2-D) image of the joint profile. When the welding torch and sensor are being moved, a full three-dimensional (3-D) description of the weld joint is created. By applying appropriate image processing techniques and the triangulation method, it is possible to compute the gap size and weld location with respect to the welding torch [59.9]. A laser-based optical sensor is typically mounted on the weld torch, ahead of the welding direction, and a one-degree-of-freedom mechanism is required to maintain this configuration during welding. A typical laser scanner provides a sweep frequency of 10–50 Hz and an accuracy of ±0.1 mm, which is sufficient for most of welding processes. However, high price often motivates the use of alternative sensing methods.

Through-arc sensing is based on the measurement of the arc current corresponding to weaving (i. e., scanning) torch motions (Fig. 59.7b). This is a popular and cost-effective method for seam tracking in GMAW and related processes [59.10]. This method employs the relation between variations of the arc current and the electrode/workpiece distance, which is negative proportional for constant arc voltage. Typically, triangular-, sinus- or trapezoid-type motions are used, with a few millimeters of weaving amplitude, to achieve accuracy of about ±0.25 mm. For this method, geometrical information can be retrieved using continuous current measurement or its measurements at the turning and/or center points of the weaving motion. Correspondingly, different control principles are applied based on difference computing or template matching.

In practice, the tracking capability is usually combined with a search function (i. e., preweld sensing of the joint location), where the torch gradually moves in a predefined direction until detecting the weld joint. There are two basic methods for this function, which differ in terms of sensors and search patterns:

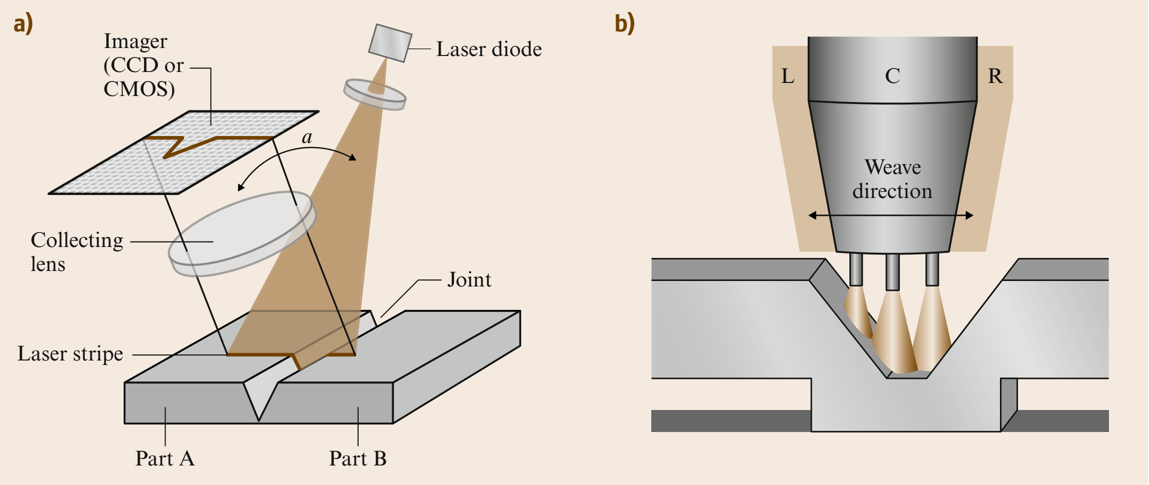

Fig. 59.7a,b Seam tracking using laser scanning **(a)** and through-arc sensing with weaving **(b)** (http://www.roboticsonline.com, http://www.thefabricator.com)

1. Approaching the workpiece without weaving, detecting electrical contact between the electrode and the weld plates, and calculating the starting position from this information
2. Approaching the workpiece with weaving, detecting the arc current, and tracking the seam in a normal way

For welding automation, other sensors can also be used, for example: inductive proximity sensors or eddy-current sensors, infrared sensors, ultrasonic sensors, and also sophisticated computer vision. However, they are not so common in this application, which is characterized by harsh environment with high temperatures, intense light, and high currents.

59.4.2 Monitoring and Control of Welding

Using data obtained from the sensors, it is possible to evaluate the weld quality and detect (or even classify) different weld defects, such as porosity, metal spatter, irregular bead shape, incomplete penetration, etc. These capabilities are implemented in monitoring systems, which usually use high-speed online analysis of welding voltage and/or current that are compared with preset nominal values or time patterns. Based on this analysis, an alarm is triggered if any difference from the preset values exceeds the given threshold. More sophisticated installations use computer-based image processing to evaluate the welding pool geometry and penetration depth [59.11].

To judge weld quality, the monitoring system relies on physical or statistical models, allowing the definition of alarm thresholds correlated with real weld defects or welding process specifications; for instance, for all GMAW processes, the voltage and current shape and mean values allows the detection of the metal transfer mode (short circuit, globular or spray transfer). In pulsed GMAW, the peak current is monitored and compared with preset values. For short-circuit GMAW, the monitoring features includes short-circuit time or frequency, as well as the average short-circuit current and the average arc current. In the general case, the features used for monitoring may be dependent on the specific algorithm and the welding condition.

For process feature analysis, various strategies are applied. The simplest ones employ deterministic decision making based on nominal values and tolerances, where any deviation from these is considered a potential cause of quality decrease. More sophisticated techniques employ template matching or treat the measured features as random variables and apply statistical methods such as control charts or spectrum analysis. However, the user must realize that increasing the detection probability often leads to false alarms that regularity interrupt the process. So, most current commercial monitoring systems utilize simple and robust algorithms, in which process features are averaged within user-defined time segments, filtered, and compared with a predefined threshold corresponding to normal welding conditions.

Welding process deviations detected via monitoring are to be compensated by control actions [59.12]. However, because of process complexity and indirect relevance of the observable data, simple feedback loops cannot be implemented. So, in addition to seam tracking, model-based strategies must be applied to enable adjustment of the welding equipment settings. However, in spite of its tremendous practical significance, this is still an active research area that employs various sophisticated decision-making techniques based on artificial intelligence and knowledge-based modeling.

59.5 Robotic Welding

Most industrial automated welding systems employ robotic manipulators, which are integrated with standard welding equipment that provides energy supply and basic control of welding parameters. The manipulators replace the human operator by handling the welding tool and positioning the workpiece. Usually this leads to an increase in quality and productivity, but poses a number of additional problems related to robot control, programming, calibration, and maintenance [59.13, 14].

59.5.1 Composition of Welding Robotic System

Currently, robots are mainly used for arc and spot welding processes. However, some recent applications deal with laser and plasma welding and also with friction stir welding. Typically, a robotic welding station includes a robot, a robot controller, welding equipment with relevant sensors, and clamping devices (fixture), allowing the workpiece to be held in the desired position in spite

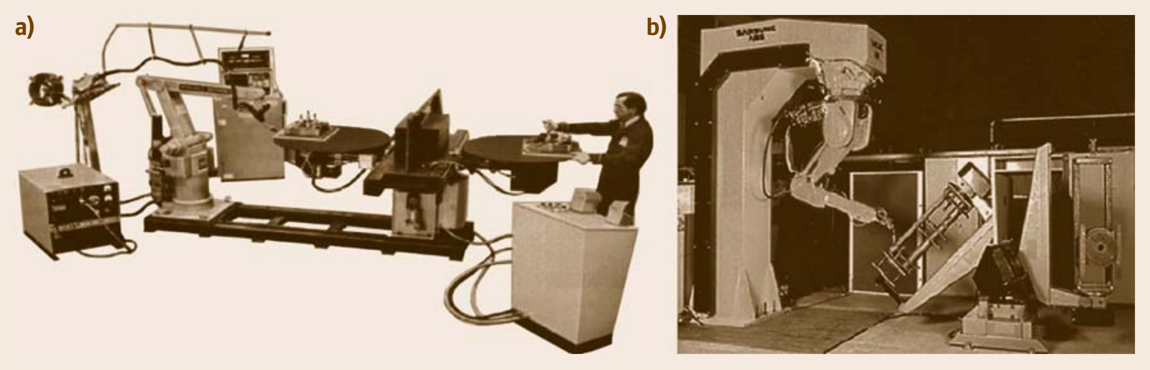

Fig. 59.8a,b Composition of arc welding robotic stations with floor-mounted **(a)** and column-mounted **(b)** robots (after [59.15, pp. 595, 602])

of thermal deformations. In addition, there are a variety of auxiliary mechanisms that provide an increasing in the robot workspace, better weld positioning, safety protection, and workpiece transportation between workstations.

The most common design of an *arc welding robotic station* is shown in Fig. 59.8. Usually, the robot has six actuated axes, so it can access any point within the working range at any orientation of the welding torch. In most cases robots are implemented with a serial architecture with revolute joints, which ensures larger workspaces (Fig. 59.9). Typical arc welding robots have a working envelope of 2000 mm and payload capacity of about 5 kg, which is sufficient for handling welding tools. To extend the working range, robots may be installed in an overhead position. A further extension of the working range can be achieved by installing the robot onto a linear carriage with auxiliary actuated axes (track, gantry or column). The wire feed unit and the spool carriers for the wire electrodes are often fixed to the robot, but can also be placed separately. In many cases the torch is equipped with shock absorption devices (such as springs) to protect it against collisions.

The workpiece positioners allow the location of seams in the best position relative to gravity (i. e., *downhand*) and to provide better weld accessibility. They usually have one or two actuated axes and may handle payload from a few kilograms to several hundred tons. The most common positioners are *turnover*, *turn–tilt*, and *orbital tables*, but *turning rolls* are also used to rotate the workpiece while making circular seams (in tank manufacturing, for instance). Positioners with orbital design have an advantage for heavy parts, allowing rotation of the workpiece around its center of gravity. In some cases, positioners are implemented with a multitable architecture, in which the operator feeds and removes the welded workpiece on one side, while the robot is welding on the other side. The positioner axes may either turn to certain defined positions (*index-based control*) or be guided by the robot controller and moved synchronically with the internal axes.

For spot welding, the robot payload capacity is essentially higher (about 150 kg), being defined by rather

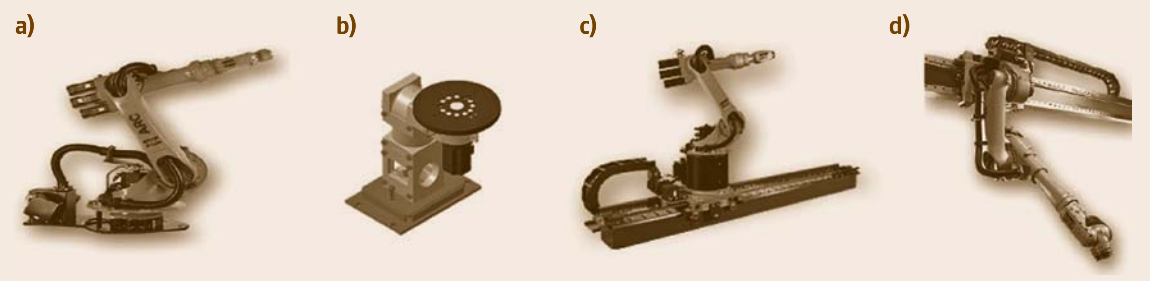

Fig. 59.9a–d Mechanical components of an arc welding robotic station: **(a)** robotic manipulator, **(b)** positioner; **(c)**,**(d)** robots with translational motion units (http://www.kuka.com)

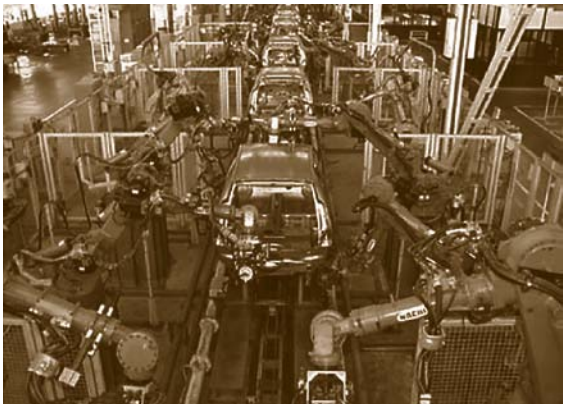

Fig. 59.10 Robotic spot welding line for the automotive industry (http://tal.co.in/solutions/equipments/robotics-automation.html)

heavy equipment mounted on the robotic manipulator arm. Usually, each spot welding station includes several robots working simultaneously to provide the same cycle time along the manufacturing line. An example of a spot welding line for car manufacturing is presented in Fig. 59.10. For such applications, robots usually perform several thousands welds on over a hundred parts with a cycle time of about 1 min. Besides the joining and handling operations, the robots also ensure online measurement and inspection by means of dedicated laser sensors.

To ensure coordination of all components of the automated welding system, a relevant multimicroprocessor control architecture usually comprises two hierarchical levels. At the lower level, the local controllers implement mainly position-based algorithms that can receive a desired trajectory and run it continuously (for each actuated axis separately, but simultaneously and coordinated). High-level controllers ensure trajectory correction in real time, as a function of the observed results of the welding process. Some robot controllers can be connected via the Internet with telediagnostic systems to support service personnel during troubleshooting.

59.5.2 Programming of Welding Robots

To take advantage of robotic welding, especially in small-batch manufacturing, it is necessary to reduce the prewelding phase (or setup time), which includes selection of welding parameters and generation of control program defining motions of the robot, positioner, and other related mechanisms. This process is time consuming and may be longer than the actual welding phase [59.16].

For selection of welding parameters, there are at present a number of generally accepted databases. They allow the definition of optimal values of the welding current, voltage, welding speed, wire diameter, and number of weld beads/layers depending on type of weld, welding position, properties of materials, plate thickness, etc. Also, these databases usually provide interface to computer-aided design (CAD) models of the joining components to simplify extraction of geometrical information.

For robot programming, two basic methods exist: *online* (programming at the robot) and *offline* (programming out of the robot cell). The former method, which is also referred to as manual teaching, requires extraction of the robot from the manufacturing process and involves operator-guided implementation of all required motions. The operator uses a dedicated teach-pendant to move the welding torch to notable points of the weld, to store the torch position and orientation, and to create corresponding motion commands with necessary attributes (defining velocity, type of interpolation along the path, weave pattern, welding parameters, etc.). The simplest implementation of the offline programming uses an external computer to create a text file describing the sequence of motions, but the command arguments (i. e., torch position and orientation) are obtained via manual teaching. Nevertheless, this offer essential shortening of programming time because of extensive use of standard macros.

Advanced offline programming systems provide fully autonomous program generation, completely outside of the manufacturing cell. They rely on so-

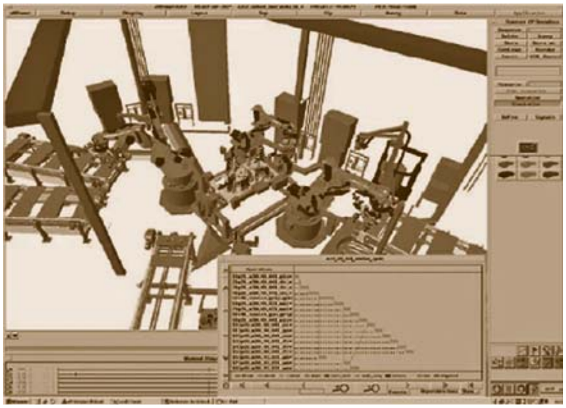

Fig. 59.11 Simulation and programming environment of eM-Workplace (Robcad) (http://www.ugs.com)

phisticated photorealistic 3-D graphical simulation of the robotic system and parts to be welded, allowing the required torch coordinates/orientations to be obtained directly from the models. Moreover, modern CAD-based robotic programming systems [such as em-Workplace (Robcad), IGRIP, CimStation, etc.] provide an interface to all standard 3-D modeling systems and incorporate a number of additional tools for robotic cell design, layout optimization, graphical simulation of the movements, program debugging and verification with respect to collisions and cycle time, program downloading to the robot controller, unloading of existing programs for optimization, etc. An example view of a CAD-based simulation and programming environment is presented in Fig. 59.11. However, while using the offline programming, it is necessary to ensure good correspondence between the nominal CAD model of the robot and its actual geometrical parameters. In practice, this is not a trivial problem, which is solved via calibration of all geometrical parameters describing the workcell components and their spatial location.

Automation of robot programming is still an active research area, which is targeted to replace movement-oriented program development to task-oriented programming. The final goal is automatic generation of robot programs from CAD drawings and welding databases, similar to programming methods for computer numerical control (CNC) machines.

59.6 Future Trends in Automated Welding

At present, welding automation is on the rise because of stricter customer demands and a shortage of skilled welders. So, equipment manufactures and system integrators are enhancing their production and implementing more advanced technologies. The most important technology-oriented directions defining future trends in welding automation are the following [59.17–20]:

- *Improvement of traditional welding processes* with respect to productivity and environmental issues (including development of better controllable power sources, new electrodes, shielding gases and flaxes; using twin-arc and tandem-arc torches)
- *Industrial implementation of new efficient and environment-friendly processes*, such as laser beam and electron beam welding, friction stir welding, and magnetic pulse welding (including development of new energy sources, relevant control algorithms, manipulating equipment)
- *Creating new knowledge-based welding process models* with ability for online learning and capability for online feedback control of essential process features (such as molten pool geometry, heat distribution, surface temperature profile, thermal deformations)
- *Development of advanced sensors and intelligent seam-tracking control algorithms* (to compensate for parts' mechanical tolerances in 3-D or 6-D space, and making welds in nonflat positions)
- *Development of new process monitoring and non-destructive evaluation methods* (using model-based condition monitoring and failure analysis techniques, and online ultrasonic and laser-based testing)

Concerning mechanical components (robotic manipulators, positioners, etc.), it is recognized that their current performance satisfies the requirements of most welding processes with respect to ability to reproduce the desired trajectory with given speed and accuracy. Future developments will focus on automation of robot programming and integration with other equipment:

- *Task-oriented offline programming and integration with product design* (using simulation-based methods; simultaneous product and fixture design; implementing 3-D virtual-reality tools and concurrent engineering concepts; developments of human–machine interfaces)
- *Standardization* of mechanical components, control platforms, sensing devices and control architectures (to reduce the system development time/cost and simplify its modification)
- *Monitoring of the welding equipment and robotic manipulators* (to predict or detect machine failures and reduce downtime using predefined exception-handling strategies)

In addition, there are a number of essential issues that are not directly linked with welding technology and equipment. These include marketing aspects, and also networking and collaboration using modern e-Manufacturing concepts.

60. Automation in Food Processing

Darwin G. Caldwell, Steve Davis, René J. Moreno Masey, John O. Gray

Factory-based food production and processing globally forms one of the largest economic and employment sectors. Within it, current automation and engineering practice is highly variable, ranging from completely manual operations to the use of the most advanced manufacturing systems. Yet overall there is a general lag in the use of automation technology compared with other industries. There are many reasons for this lack of uptake and this chapter will initially discuss the factors that make automation of food production so essential and at the same time consider counterinfluences that have prevented this automation uptake.

In particular the chapter will focus on the diversity of an industry covering areas such as bakery, dairy, confectionary, snacks, meat, poultry, seafood, produce, sauce/condiments, frozen, and refrigerated products, which means that generic solutions are often (considered by the industry) difficult or impossible to obtain. However, it will be shown that there are many features in the production process that are almost completely generic, such as labeling, quality/safety automation, and palletization, and others that do in fact require an almost unique approach due to the natural and highly variable features of food products. In considering these needs, this chapter has therefore approached the specific automation requirements of food production from two perspectives. Firstly, it will be shown that in many cases there are generic automation solutions that could be valuably used across the industry ranging from small cottage facilities to large multinational manufacturers. Examples of generic types of automation well suited across the industry will be provided. In addition, for some very specific difficult handling operations, customized solutions will be shown to give opportunities to study the problems/risks/demands associated with food handling and to provide an insight into the solution, thereby demonstrating that in most instances the difficult/impossible can indeed be achieved.

60.1 The Food Industry

Food and drink manufacturing forms one of the largest global industry sectors. In the European Union (EU), it is in fact the largest manufacturing sector with an annual turnover (in 2006) in excess of € 830 billion and a workforce of 3.8 million people [60.1]. However, unlike in other manufacturing sectors, there is still a very high level of low-skilled, low-paid labor.

Before considering the detailed use of automation in food processing, it is important to understand the nature of the industry. The food industry is not one single sector making a range of broadly similar products. It is in fact wide and diverse both in terms of the products and in structures and is characterized by:

- A very large number of small and medium enterprises (SMEs) operating in a highly competitive environment
- Rapid changes in product lines (often several changes per day)
- Generally low profit margins
- Extensive use of manual labor in often unattractive operating environments
- Low uptake of automation procedures.

It is also very important to note that, except for a few multinationals:

- Engineering research and development activity is low
- Ability to exploit and maintain advanced automation equipment is fairly poor
- Information technology (IT) and e-Commerce infrastructure is generally weak.

Within the industry there is a strong feeling that in the medium term (3–10 years) the number of people willing to work for the current low wages will decline and the industry will have to change to survive. Faced with this problem the industry has identified the application of automation and robotic systems as a major growth area with the aims of:

- Improving production efficiency and impacting on yield margins and profitability
- Reducing waste on all levels: product, energy, pollution, water, etc.
- Enhancing hygiene standards, and conforming to existing and future legislation pertaining to food production, including enhancing hygienic operation and product traceability
- Improving working conditions to improve retention of high-quality, motivated staff
- Improving the consistency of product quality.

However, despite these very significant and compelling driving influences, only a small number of companies are yet making significant use of automation for raw and in-progress product handling. The question therefore arises as to why the food sector should not be making extensive use of automation. There is no single simple answer to this question, but the answers seem to be embedded in a number of technical, financial, and cultural issues [60.2, 3].

Although the limited use of automation is certainly a reflection of a conservative investment policy in a low-margin industry, it is equally clear that in many instances the use of labor-intensive manual techniques is a deliberate policy because of:

i) The flexibility provided by the human worker. Humans handle manipulative complexities with ease, by combining dextrous handling capabilities (the human hand), advanced sensing, and behavioral models of the product accumulated with experience.
ii) A lack of understanding of the properties of the food product as an *engineering* material. The handling characteristics of many (most) food products cannot be adequately described with geometry-based information, as is usually the case with conventional engineering materials since the geometry of food product is:

- In many/most instances nonrigid, often delicate, and/or perishable
- Variable in texture, color, shape, and size
- Often variable as a function of time and the forces applied
- Affected by environmental conditions including temperature, humidity, and pressure
- Easily bruised and marked when it comes into contact with hard and/or rough surfaces
- Susceptible to bacterial contamination.

iii) The product deforming significantly during handling. Any system developed to handle such food items therefore needs to react accordingly to this deformation and there is a lack of handling strategies and end-effectors designed to cope with the variable characteristics of food products.

iv) The perceived inabilities of current automation systems to cope with the variation in product and production demands.

In addition, the food sector often feels that there are significant issues relating to automation including:

- Robotic systems and application technology have been developed for the engineering manufacturing industry and they cannot transfer across into food manufacture without significant changes.
- Robot manufacturers and system integrators often have a poor understanding of the economics, payback rationale, and operating pressures in the food industry, which are very different from those in other sectors that make more use of automation/robotics. This results in the wrong products being offered for sale at the wrong price and with the wrong sales model.
- Support for complex IT-based systems is largely absent in smaller food manufacturers and there is no cost-effective outsourced support available.
- The space and flexibility requirements of, in particular, the smaller food manufacturer require that any automation fits around, and works with, existing manual operations. This is in contrast to most engineering automation which is physically separated from people.

60.2 Generic Considerations in Automation for Food Processing

When considering automation within the sector it is clear that there are very large differences in the exact nature of the work and the level and form of automation. For instance, unlike in the car industry, which is generally homogenous, making one easily recognizable product, in the food industry this is not true. The sector can be broken down in many ways, e.g., bakery, dairy, confectionary, snacks, meat, poultry, seafood, produce, sauce/condiments, frozen, and refrigerated. Within these areas there are of course many more subdivisions and these subdivisions mean that it is almost impossible to consider the industry as a whole and certainly from the viewpoint of automation this is extremely difficult, although there are several key aspects that have commonality.

60.2.1 Automation and Safety

Issues relating to food safety through accidental or deliberate contamination are of paramount concern in all food manufacturing facilities. To address these concerns and ensure public confidence there are a number of national and international standards. Depending on the country where the food is being manufactured these standards may be compulsory or voluntary and may be more or less strictly enforced. Among the most readily recognized of these standards are

- Hazard analysis and critical control points (HACCP) has been developed as a systematic preventive approach to food safety that addresses physical, chemical, and/or biological hazards during the manufacturing process, rather than through end-of-line and finished product testing/inspection. This goal is achieved by identifying potential food safety risks in the manufacturing process and acting on these critical control points (CCPs), e.g., by cooking, to prevent the hazard being realized. HACCP forms part of the whole manufacturing process including packaging, and distribution [60.4].
- Current good manufacturing practice (cGMP) deals with the control, quality assurance/testing, and management of food, pharmaceutical, and medical products in a manufacturing environment [60.5].
- ISO 22000 aims to bring the structures and benefits of ISO 9000, from which it is derived, to the food and drink processing and manufacturing sectors [60.6].

The introduction of automation and robotic equipment must of course conform to these standards, ideally without introducing any new hazards, but at the same time it is clear that the introduction of automation can have a positive impact since it permits humans, who are the most significant and certainly the most unpredictable contamination source, to be removed from the hazard consideration.

60.2.2 Easy-to-Clean Hygienic Design

Machinery to be used for direct handling of food can be designed following a set of hygienic design guidelines that ensure good standards of hygiene in production [60.7, 8], yet there is often a certain degree of

Part F | 60.2

confusion regarding what constitutes hygienic design and how hygienic a particular piece of machinery needs to be. Fundamentally this is product/task specific but it is clear that products such as raw meat, fish, and poultry are highly susceptible to contamination from microorganisms and require very high levels of hygienic design, while for dry foods such as biscuits or cakes lower levels of hygienic design may be more than adequate.

Routine cleaning and disinfection procedures involve the use of acidic, alkaline, and chlorinated cleaning chemicals. The need for frequent wash-downs makes a sealed, waterproof structure essential to enclose and protect internal components. The preferred material for food processing machinery is 304 or 316 grade stainless steel (BS EN 10088:2005), polished to a unidirectional satin polish finish [60.9]. Aluminum is not sufficiently corrosion resistant to commonly used cleaning chemicals and its use should be avoided for food-contact applications. Surfaces should be nonporous and free from cracks, crevices, scratches or pits that could harbor microorganisms after cleaning. Painted or coated surfaces should be avoided on food-contact parts; however, if used, the finish must be resistant to flaking or cracking. All parts likely to come into contact with food should be readily visible for inspection and accessible for cleaning. Joints that are screwed or bolted together inherently have crevices that cannot be adequately cleaned. A rubber seal or gasket should be used between components joined in this way. Exposed threads and fasteners such as screws, bolts, and rivets should be avoided if possible in food contact areas. All corners should be radiused and sharp internal corners should be avoided.

The use of plastics can offer certain advantages over stainless steel in some applications. However, plastics are generally more susceptible to failure from a range of different causes [60.7]. A database of plastics approved for food use by the US Food and Drug Administration (FDA) is available online [60.10]. In Europe, the use of plastics for food-contact applications is regulated by EU Commission Directive 2002/72/EC. One significant disadvantage of plastics is that they are easily scratched through manual cleaning. Surface scratches can accumulate over time and harbor microorganisms. A study by *Midelet* and *Carpentier* [60.11] suggests that microorganisms also attach themselves more strongly to plastics than to stainless steel. Rubber compounds used for seals, gaskets, and suction cups should also be food approved. Nitrile butyl rubber (Buna-N), fluoroelastomers (Viton), and silicone rubber are among those commonly used in the food industry. Likewise lubricants, adhesives, and any other materials that may come into contact with food should be approved for food use [60.10, 12].

60.2.3 Fast Operational Speed (High-Speed Pick and Place)

High speed becomes important when an automation/robotic solution must compete on economic terms with hard automation or human workers. Low profit margins in food manufacturing mean that throughput must be maximized in order to increase profit. Increased production capacity also leads to reduced production costs. Arguably the most common task in food manufacturing is pick-and-place handling, where an object is picked from a conveyor belt and placed into its primary packaging. The pick-and-place speed of industrial robots is based on a standard $25\times300\times25\,\text{mm}^3$ cycle and has been steadily rising. Speeds of between 80 and 120 picks/min, which are comparable to that of a human operator, are now becoming commonplace. Conveyor belts used in the food industry are generally no more than 50 or 60 cm wide. This width corresponds to the maximum distance that an operator, standing on one side of the conveyor, can comfortably reach to pick an object on the opposite side.

This need for high-speed handling is most acutely observed in the bakery and confectionary subsectors, where there is a need for high-speed handling of products that do in general have relatively good structural formal and repeatability and can be moved at high speed without disintegrating.

Biscuits/cookies form a particularly good example of this type of product but other breaded products, e.g., croissants and even meat precuts such as pepperoni for a pizza can be considered. In these tasks human operators are required to identify the product (visually), grasp the product, and place it either into a container or on to a secondary product. The operating frequencies are typically high (over 100 picks/min) with motions in the range of 30–50 cm one way. The mass of the objects are typically very low (only a few grams) and when undertaken by humans the user will often pick up several objects at one instance to minimize the movements to and from the conveyor. Recently the ABB IRB 340 FlexPicker robot has been extensively and generally very successfully used in this type of application to pick up multiple products as a group, or one at a time.

With recent advances in vision technology, robotic packing lines can handle varying or irregular products (Fig. 60.1). Automation of this type often integrates with a variety of sensor systems, e.g., checkweighers, vision, and metal detectors to enhance the handling process and combine this with online inspection.

60.2.4 Joints and Seals

Careful attention should be paid to the design of joints in automation/robotic systems to ensure that they are both waterproof and hygienic, and avoid deep, narrow crevices at the joints which are impossible to clean. This is illustrated in Fig. 60.2a. An improved design using a spring-energized polytetrafluoroethylene (PTFE) face seal is shown in Fig. 60.2b. Commercial seals are available where the spring groove is filled with silicone for use in food processing applications. Cover plates, which provide access to the inside of food processing machinery, are sealed using rubber gaskets. The screws securing the cover plates should also be sealed. Small screws can be sealed using a food-grade sealant. The screws should have plain hexagon heads, which are easier to clean.

60.2.5 Actuators

Pneumatic cylinders are low cost and commonly used in the food industry to actuate fixed automation machinery. Accurate position control of pneumatic actuators without the use of mechanical stops is, however, difficult to achieve under either proportional or pulse width modulation control schemes [60.13, 14]. In addition, position control using pulse-width modulation requires rapid cycling of the solenoid valves used to drive the actuator and this wears out the valves extremely quickly. Hydraulic actuators are not used in the food industry, as there is a risk that hydraulic fluid may contaminate the product.

Electric motors are comparatively easy to control and reliable in service. Brushless direct-current (DC) motors, despite their higher initial cost, have a service life many times greater than that of brushed motors, leading to increased reliability, lower maintenance costs, and less down time. This makes brushless motors more economical to use over the lifetime of the automation. The most significant operational issue with motors is ensuring adequate sealing to prevent the ingress of water/solvents during cleaning etc.

60.2.6 Orientation and Positioning

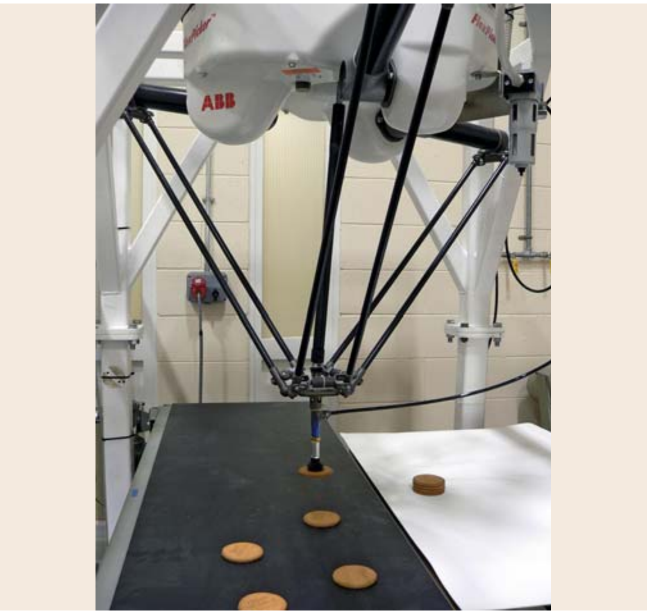

Fig. 60.1 An ABB IRB 340 used to pick and place biscuits

For all forms of automation knowledge of the exact position of a product is vital. This is no less true in the food sector than elsewhere but in this sector a number of factors conspire to place a low value on this information.

Figure 60.3 shows a very common example of an ordered layup of product that is taken from the production line and placed in *bins* that have complete disorder. To automate the process of recreating order from this chaos is at best difficult and expensive and at worst currently technically impossible, but humans easily cope with this disorder. In considering examples of this type it is clear that within a food plant many processes that are currently considered difficult or impossible could be automated if greater attention were paid to the retention of position and orientation data. In some instances this will involve changes to the handling process while

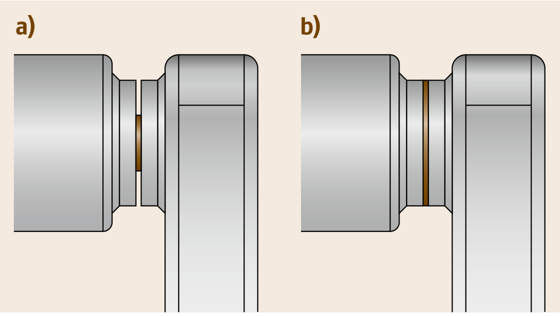

Fig. 60.2a,b Unhygienic and hygienic robot joint design. **(a)** Uncleanable gap, **(b)** PTFE face seal

Fig. 60.3 Food automation will often reverse traditional manufacturing aims that create disorder from the manufactured order

in others simple remedies such as properly adjusting guides, transfer conveyors or feed rates will be sufficient to create the order needed to satisfy the downstream automation. This is a process that has already been learned (often by hard experience) in other industries but has yet to be fully appreciated by the food processing sector.

At the same time it is possible to deal with aspects of orientation and positional inaccuracies and the vision systems that are becoming increasingly common in other industry sectors are finding useful outlets in food processing also. Indeed in the food sector the relatively low tolerances (due to the product variability) mean that vision-linked handling systems could potentially be even more successful in these applications than elsewhere.

60.2.7 Conveyors

Conveyors are typically belted transport machines to carry products, containers, packs or packaging along a production line or between production centers (Fig. 60.4). There are a very large number of types of conveyor designed to operate with different products, and selection of the correct conveyor system is essential to good automation in the food sector [60.15]. Conveyors can be formed as stand-alone linear or curved units or they can be integrated into complex transportation networks custom-designed for each factory application. In their simplest forms the conveyor merely moves product from point A to B but they can be integrated with control systems, advanced drives, programmable logic controllers (PLCs), sensors etc. and form an integral part of good automation.

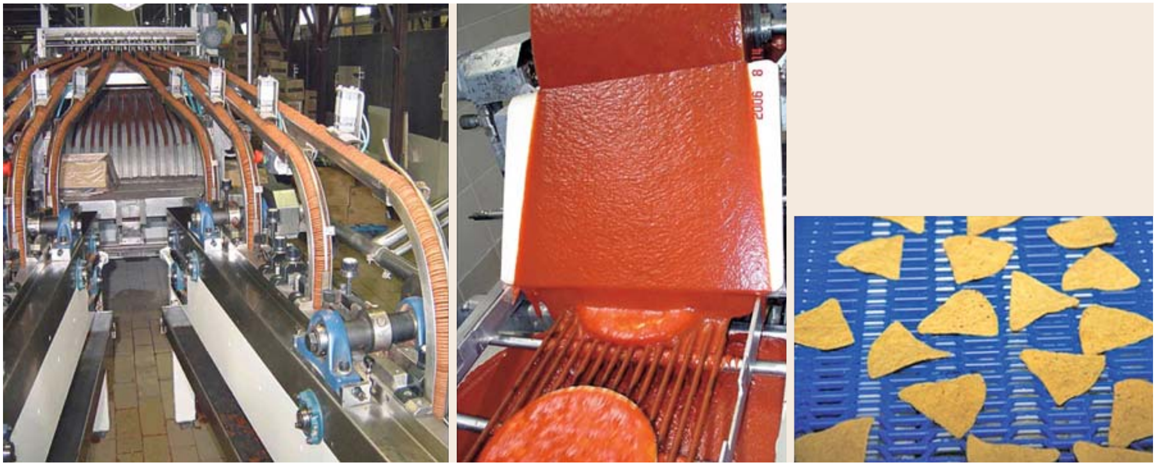

Fig. 60.4 Conveying solutions

60.3 Packaging, Palletizing, and Mixed Pallet Automation

One area of food production that has seen significant use of automation is end-of-line operations. For many years, food manufacturers have successfully used traditional hard automation, including wrappers, top loaders, and side loaders, to package easy-to-handle products, e.g., cartons, boxes, trays, bags, and bottles. In this area of the food production cycle the product has been changed from the highly variable food product into a *containerized* unit. Within the end-of-line packaging operations there are therefore a number of key areas that have wide application across the sector (Fig. 60.5).

These include aspects such as labeling, checkweighing, inspection (visual, metal detection etc.), and palletizing.

60.3.1 Check Weight

The checkweigher is an automatic machine for measuring the weight of packaged commodities and hence ensuring that the product is within specified limits (Fig. 60.6). Any packs that are outside the tolerance are ejected from the line automatically and may be reworked. Although there are many forms of checkweigher they generally follow a fairly common format. From the main production flow line the product is transferred to an accelerating belt that spaces products that are often closely located on the line. This means that individual products can be weighed without interference from neighbors. The weigh station is an instrumented conveyor belt incorporating a high-speed transducer (typically a load cell), with user interface and often data ports for Ethernet etc. At the outflow of the checkweigher there is a reject conveyor to remove out-of-tolerance packs without disrupting the normal flow. The reject mechanism is automatic and may involve a variety of approaches such as air jets and mechanical arms. Checkweighers can have a throughput of up to 750 products per minute. The communication ports ensure that the checkweigher can be integrated into the whole plant operation, communicating production data etc. and forming part of a full SCADA (supervisory control and data acquisition) system. By controlling and monitoring the throughput of the checkweigher it is possible to detect out-of-performance upstream operations and to dynamically change the performance of the upstream operations by adjusting their set-points. Unfortunately this is seldom achieved and machines often run with poor adjustments that increase reject rates or overfill and hence *gives away* product. In addition, by integrating production of several lines or monitoring data over time, it is possible to permit some underweight product, as the overall average is within tolerance and the data from the checkweigher can validate this. This can significantly reduce wastage and has potential enormous savings.

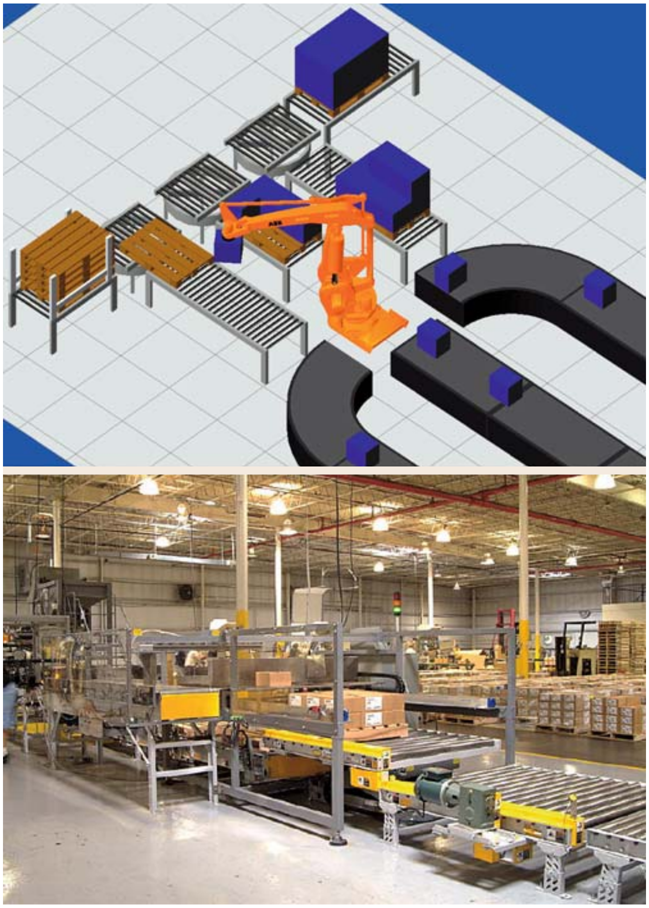

Fig. 60.5 End-of-line automation

60.3.2 Inspection Systems

Other inspection stations within the typical production line include metal detection and also on occasion x-ray machines (Fig. 60.6). These systems are primarily installed as safety systems to prevent physical contamination of food. In the instance of metal detectors which operate by enclosing the whole of the production conveyor belt, the product passes through the detector, which is tuned to detect small metal shards that may have become located in the food product. If the sensor is triggered the product is automatically rejected but in this instance there is no rework and indeed the product is usually inspected closely to discover the type of contamination and to ensure that this is eliminated. Metals detection is present on almost every production line. X-ray machines, although slightly less common, are used to check for nonmetallic contamination, e.g., glass, plastics, bone, and fibres, and also in some meat products as a quality control system to identify gristle.

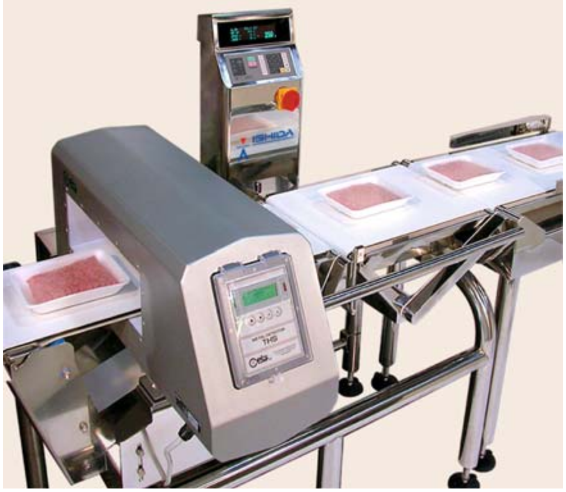

Fig. 60.6 Combined check weight and metal detection station

60.3.3 Labeling

Labels are used on every kind of product to brand, decorate or provide information, and in the food sector it is not uncommon that a label fulfils all three functions simultaneously (Fig. 60.7). Labeling is one of the final aspects of the production process and may be independent or integrated with other systems such as the checkweigher and inspection systems. There are two main types of labeling machine: wet glue and self-adhesive (pressure-sensitive) applicators. For the food processing industry self-adhesive labelers are by far the more common, using preglued labels that are supplied on a reel of release paper or film. This method of application enables labels to be applied at medium/high speed to soft packages as well as rigid containers. This is very suited to the food sector.

60.3.4 Palletizing

The pallet is the fundamental loading and transportation unit for most food operations. As such, automation of the warehousing and palletizing operations for food companies, as in most industry sectors, is potentially one of the most profitable areas. As with most industry sectors many features influence the selection of automation for palletizing, including line speeds, factory layout, space at the end of production lines, and of course cost, but in food operations there is also the advantage that, by the time the products reach the palletizing stage, the packaging has usually created a fairly repeatable form that is missing in many other upstream areas and this is therefore one of the easiest areas to automate.

While it can be recognized that there are many features in common with other industry sectors, one recent trend that is particularly strongly driven in the food sector is the assembly of mixed product pallets, which reflected demand from retailers for custom pallet loads that suit the store rather than the shipper. The mixed load pallet is therefore emerging as one of the most ef-

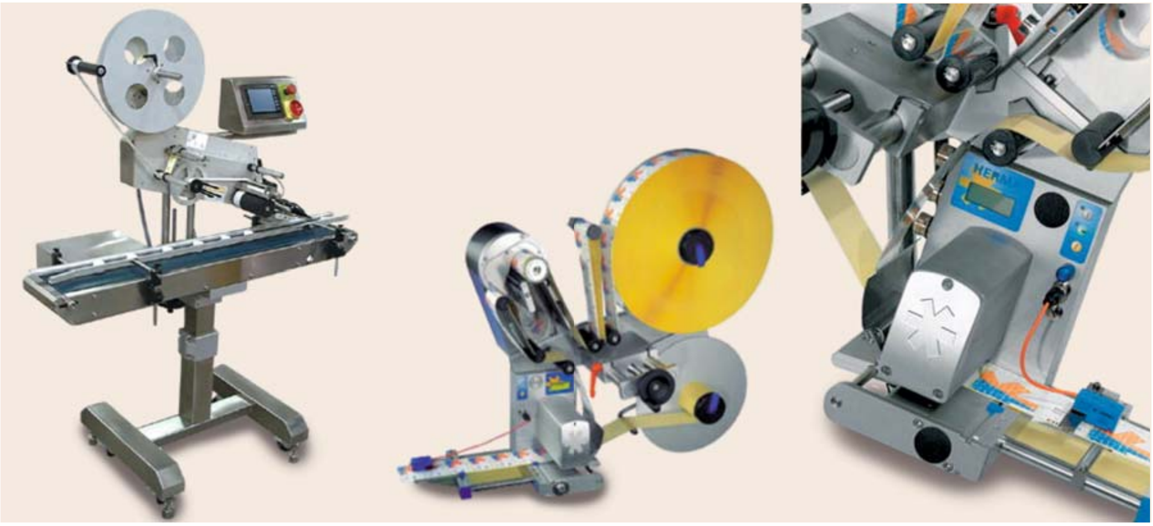

Fig. 60.7 Labeling stations

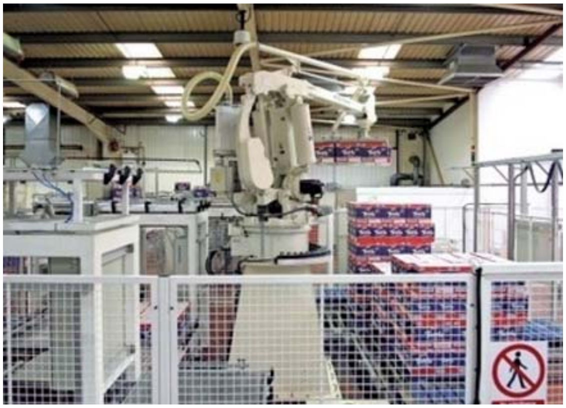

Fig. 60.8 Robotic palletizing

ficient technologies available in the food supply chain process.

To address these demands and opportunities and the use of multiple feeder lines and rapid pattern changes, the automation industry has focused on the development of software needed to pick the product and *design* the pallet, the hardware to recognize the product (sensors which are often visual based), hardware to manipulate the product (often robots), and the integration of the hardware–software solutions (Fig. 60.8).

Within the robotic community there have been important developments in the software to optimize picking, placement, and overall *construction* of diverse pallets, with many robot manufacturers, software houses, and systems developers introducing dedicated software that will allow online pallet preparation to meet the demands of the manufacturer and, more importantly, the retailer. These software systems can be fully integrated with external systems, e.g., machine-vision systems and image processing or other sensors to detect the presence of the product and its position and orientation, and this information can be directly communicated to a manipulation system, which is typically robotic, to allow flexibility in programming and motion control. This comprehensive integration of all components into one platform facilitates efficient communication and guarantees reliable robot operation. These software packages typically integrate only with one robot manufacturer's product line and it is therefore necessary to use combined hardware and software solutions. Integration suppliers can often integrate nonstandard units but this has a significant cost implication.

To address the increasing need for and use of robots in the food industry a number of robot manufacturers have or are developing products specifically for these applications. However, to date very few commercial robots have been developed specifically for the food industry. Often, existing models have simply been upgraded for use in food production and this has created a negative impression among sections of the food industry. Examples of industrial robots that are currently used for primary packaging and assembly of foods include the ABB IRB 340 FlexPicker (probably the most common robot in high-speed pick-and-place applications and well suited to handling wrapped and baked products) and Bosch Sigpack Delta robots, the FANUC LR Mate 200iB food robot, Gerhard Schubert's TLM-F4, and more recently the FANUC M-430iA/2F, which has a sleek profile with no food particle retention areas.

60.4 Raw Product Handling and Assembly

While the use of robots and advanced automation for end-of-line operations such as case packing and palletizing is already well established, robotics/automation of primary handling and assembly of foods has so far been limited. However, since financial justification for the installation of an automation/robotic system is typically based on the reduction of labor costs and the bulk of manual labor in a food production line is generally concentrated in primary packaging and assembly operations, this is the area that requires the greatest concentration of effort.

As already noted products handled by traditional automation are usually homogenous in terms of size, shape, and weight and also tend to be rigid; however, some or all of these conditions do not prevail in food processing. Food is very often fragile and, unless extreme care is taken during handling, products can be damaged and in the worst case this can mean they have to be discarded. This means that the handling techniques used in traditional automation are generally not suited to the handling of *raw* food products and the mechanism of *grasping* the food product (rather than basic motion) is often the key to successful automation.

Taylor [60.15] classified the gripping techniques for nonrigid materials into three separate classes defined by the mechanism of the grasp:

Mechanical techniques – the product is firmly clamped between two or more mechanical fingers and held due to the friction contact. To minimize the grip force the gripper jaws can be compliant or specifically shaped to the particular object. This can only be used where variation between products is relatively small.

Intrusive grippers – pins are fed into the surface or body of the material to be lifted. The pins are precisely located so that when inserted the object becomes locked to the gripper. This technique is generally unsuitable for food products, as it would often cause unacceptable levels of damage.

Surface attraction – adhesives or a vacuum are used to create a bonding force between the gripper and product. Vacuum grippers have been successfully used in the food industry and are well suited to objects with regular or flat surfaces, such as biscuits. However, not all food items can be handled with such grippers due to difficulties in achieving an airtight seal, bruising, and the inflow of particles that could lead to microbial growth unless equipment is sterilized regularly.

As can be seen above designing mechanisms to grasp food products is not straightforward and the techniques used in other industries cannot be directly applied. Different types of food product present different challenges and as a result there are numerous examples of grippers that have been developed for use in the food industry which address these challenges.

60.4.1 Handling Products That Bruise

There are many food products that are easy to bruise. These are typically fruits and vegetables, but other products can also develop unsightly marks if grasped too firmly. For this reason handling techniques that minimize forces and pressures must be developed. One example of a product that is particularly susceptible to bruising is the mushroom. Although not immediately obvious a bruise can appear on a mushroom as long as several days after being handled. This can mean that, while a product may appear acceptable when dispatched from a factory/farm, it can appear damaged by the time it reaches the retailer/customer.

Mushroom harvesting is typically performed manually and, despite the delicate capabilities of the human hand, mushrooms do become bruised during manual harvesting. An automated system for the harvesting of mushrooms was produced by *Reed* et al. [60.16] with the aim of reducing labor but also reducing product damage. The design of the system paid particular attention to the delicacy of the mushroom contact.

The mushroom harvesting process consists of four main stages: first the position of an individual viable mushroom is obtained, followed by picking and trimming of the mushroom before placing it in a container. The location of the mushroom is obtained from a vision system mounted vertically over the mushroom bed. Image-processing software identifies and numbers each mushroom and then determines how best to pick them. Mushrooms below a certain size threshold are disregarded and are left to be harvested another day. An isolated mushroom is easy to pick, but this is not typically the case and usually mushrooms touch or overlap. The control software must therefore determine the best way to extract each mushroom without disturbing those around it. This is achieved by bending the mushroom away from those that surround it before picking.

The mushrooms are grasped using a vacuum cup mounted through a compliant link to a rack and pinion allowing the cup to be positioned on the surface of the mushroom. The cup is then twisted about the vertical axis to break the mushrooms base and allow it to be removed. A turret mechanism was also included, which allowed the most appropriately sized cup to be used for the particular mushroom being grasped.

The contact between the vacuum cup and the mushroom is the source of potential produce bruising and so determining the optimum vacuum force is critical. Experiments revealed that the force of the vacuum on the mushroom produced a faint mark on the mushroom during grasping but this was not considered by the industry to be unacceptably severe. However, if slip occurred between the mushroom and vacuum cup during rotation this resulted in unacceptable shear damage on the mushroom's surface.

Once a mushroom has been removed from the ground it is placed in a fingered conveyor with the stalk pointing vertically downwards. A blade then removes the lower section of stalk which is discarded and the trimmed mushroom is placed in a plastic tray ready for dispatch. The mushrooms are not dropped as this would result in denting and bruising. The complete system was trialled at a commercial mushroom farm in The Netherlands and by the Horticultural Research International in the UK. The average picking speed of the system was nine mushrooms per minute and in both of these trials the amount of mushroom bruising and damage was found to be significantly lower than when manual picking was used.

60.4.2 Handling Fish and Meat

While less susceptible to bruising than fruits and vegetables, meat and fish present their own grasping challenges. Due to the ease with which such products deform a traditional parallel jaw gripper is typically unable to grasp them with sufficient firmness. Similarly vacuum grippers have had only limited success grasping meats since the fleshy nature of meat means that unsightly peaks can be produced when a vacuum force is applied. Also moisture on the surface of the meat can be drawn into the vacuum system, causing blockages and contamination as well as reducing the moisture content of the product.

For the above reasons a number of alternative approaches have been proposed to address the problem of handling meat. *Khodabandehloo* [60.17] proposed a gripper with similar functionality to the human hand which could use its fingers to grasp a product. A full dexterous hand would be unnecessarily complex and as yet no such system has been demonstrated in an industrial environment, however the principle still appeared promising and a multifingered gripper was developed [60.17], formed from a solid piece of flexible rubber. An internal cavity was created at the finger's knuckle which could be pressurized by an external air supply. As the cavity was filled with air it expanded, causing the rear surface of the finger to elongate. Due to the location of the cavity the front surface of the finger remained unextended. As the finger was formed from one solid piece of rubber this difference in extension caused the knuckle to flex.

A hand consisting of four such fingers was developed and tested at the University of Bristol, UK. It was positioned so that two fingers were located on each side of the piece of meat to be lifted. When activated, the fingers curled around the meat, creating a grasp. Due to the compliant nature of the fingers they did not create damage to the surface of the meat as there was no hard contact. Due to the low number of mechanical parts and lack of moving linkages the gripper was very well suited to the hygiene requirements of the food industry as the gripper could be washed or hosed down without risk of damage.

Whilst proving effective at handling some cuts of meat the Bristol University gripper was unsuited to grasping steaks or thin slices of meat as they deform too much for the fingers to produce a secure grasp.

An alternative approach is the Intelligent Portion Loading Robot produced by AEW Delford Systems Ltd. [60.18]. This system is robot based and is able to handle and manipulate a broad range of meat types including both bone-in and boneless portions, fish, cheese, and sliced products. Meat is fed to the system on a conveyor where a vision system determines the position and orientation of the product to be handled. An ABB IRB 340 FlexPicker robot fitted with a novel end-effector developed by AEW Delford is then used to pick each product and transfer it to packaging or a further processing machine.

The end-effector's design is simple with a low number of parts, making it well suited to the needs of the food industry. The end-effector is essentially a high-speed parallel jawed gripper. Each jaw consists of a very thin plate which, when the gripper activates, is forced under the product as can be seen in Fig. 60.9a,b. The low profile of the jaws means they can be inserted under the product without damaging it. Although the lateral force applied to the product as the jaws are closed is relatively low it is still possible that this might dislodge the product slightly. In order to prevent this, a spring-loaded guide plate rests on the upper surface of the product being lifted whilst the jaws close.

Fish pieces can be particularly difficult to handle as, due to their structure, they can crumble when handled, breaking into many pieces. *Gjersted* [60.19] developed a needle gripper for the picking and packing of pieces of fresh, cooked and uncooked fish.

The gripper operates using a surface hooking principle [60.19] and uses numerous pins which enter the product simultaneously from opposite sides. The pins are angled slightly towards the center of the product

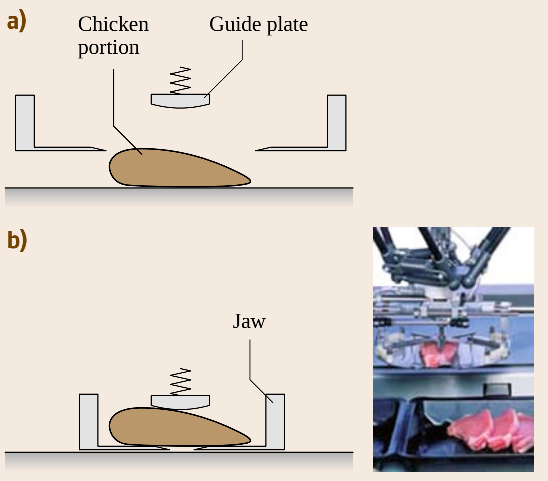

Fig. 60.9a,b AEW Delford gripper raised **(a)** and lowered with jaw closed **(b)**

and as a result when inserted they physically lock the fish firmly in place, which means it can be handled and accelerated rapidly without fear of being dropped. The only way that the product can be dropped whilst the pins are still inserted is if the product breaks apart, but this is unlikely to happen as, whilst the pins are in the product, they form an internal support structure which helps keep the product in one piece.

The gripper was developed according to European Hygienic Engineering and Design Group (EHEDG) principles for hygienic design, meaning it meets with the stringent requirements of the food industry. The gripper has been tested successfully with both salmon and cod and demonstrates excellent holding capability with minimal impact on the product surface and the overall product quality. In fact the impact on product appearance and quality was judged to be less than when conventional human handling was used.

60.4.3 Handling Moist Food Products

Within the food manufacturing industry it is extremely common that the materials to be handled are moist. This can be a result of washing, cooking or cutting or indeed just due to the nature of the product. This moisture can often make traditional grippers ineffective and so a number of novel techniques have been developed.

Sliced tomatoes and cucumbers used in a wide variety of products, e.g., salads and sandwiches, are typically washed and sliced in a secondary part of a factory using large-scale slicing machines capable of processing many kilos per minute. Once sliced the product is deposited into trays and delivered to production lines.

The high water content of most vegetables and the nature of the cutting process means that slices have a high residual moisture on their surfaces and cannot be placed directly into the product, which would become soggy reducing customer appeal, although it has no significant hygiene issues. To reduce this *sogginess* and improve shelf life the sliced vegetable trays are left to drain, for at least 2 h, before being used. The effectiveness of this method is highly variable, with the upper layers of ingredients draining more thoroughly than those towards the middle or bottom of the tray.

After draining, the trays are delivered to the assembly lines, where operators pick individual slices from the trays and place them in the assembled product, e.g., sandwiches. It is extremely difficult to do this without further damaging the slices and as a result it is not uncommon for the center of tomatoes to become detached. Furthermore the moisture causes the slices to stick together and the operators have to separate them, slowing the overall process. For this reason a production line working at 50 sandwiches per minute can typically have four operators just placing tomato slices and a similar number handling cucumber.

Davis et al. [60.20] proposed an automated system for the handling of sliced tomato and cucumber based on a novel end-effector. The solution involves cutting slices on the actual assembly line for immediate use. A slice would only be cut when required and thus the need to pick an individual slice from a tray is removed. Once cut, each slice is grasped using a noncontact Bernoulli gripper and a robot places it as required (Fig. 60.10).

A Bernoulli gripper operates using compressed air and a flat gripping face. Deflectors on the surface of the gripper direct the supplied air so that it radiates from the center of the gripper across the surface. When the grip-

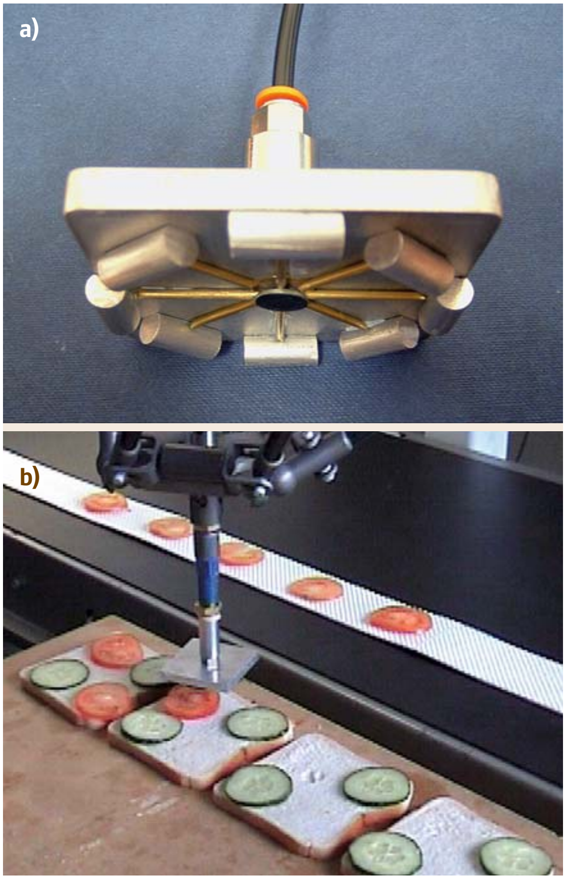

Fig. 60.10 (a) Noncontact Bernoulli gripper. (b) Gripper handling tomato

ping surface is brought close to an object to be grasped the gap through which the air travels becomes reduced. To maintain the volumetric air flow through the gripper this results in an increase in air velocity. The rapid flow of air between the object and gripper generates an attractive force in line with Bernoulli's principle. It is this force which allows the object to be grasped.

As well as lifting the products the gripper is also able to remove moisture from the object being handled using the air-knife principle where moisture is atomized by the air and blown off the surface.

Another technique developed for lifting moist products is the cryogenic gripper. *Stephan* and *Seliger* [60.21] developed a *freezing gripper* for use in the textile industry which created a bond between the gripper and products by freezing moisture on the surface of the product using a Peltier element. The reported grip forces were as high as $3.5\,\mathrm{N/cm^2}$ after 3 s of *freezing* with release after 1 s.

Although this gripper was developed for use in the textile industry the technique appeared to have potential in the food industry. To assess this, the Food Refrigeration and Process Engineering Research Center at the University of Bristol, UK [60.22] carried out tests on cryogenic grippers for the food industry. They were particularly interested to determine whether such techniques could be used to lift sheet-like food materials such as lasagne, sliced fish, cheese, and ham. Similar results to the work of *Stephan* et al. [60.21] regarding grasp times were obtained, however, unforced release times were found to be poor and mechanical release methods were found to produce unacceptable damage to the products' surface. Nonetheless it is suggested that with further development work a viable gripper can probably be developed that has the potential to be very useful in some sectors of the food industry, e.g., frozen foods.

60.4.4 Handling Sticky Products

Many food products are sticky and, whilst there is usually no problem developing automated systems for grasping such objects, releasing them can often present a challenge. The glacé cherry is an example of one such product. When handled with a traditional two-jaw gripper the cherry is found to stick to one of the jaws when released [60.23]. This meant that the cherry could not be positioned accurately. *Reed* et al. [60.23] developed a unique gripper for the production of Bakewell tarts. These small cakes require a decorative cherry to be place at the center of each cake and therefore a method of picking and reliably releasing a single cherry was developed.

The gripper developed is a two-fingered parallel jaw mechanism as shown in Fig. 60.11a. As with a standard gripper the jaws are closed and an object is held by a frictional grasp. However, the unique feature of this gripper is that the contact surface of each jaw is covered in a polyester film. This film takes the form of a narrow tape which is wound onto spools (Fig. 60.11). When the gripper releases an object a length of tape is wound off the inner spools and onto the outer spools as shown in Fig. 60.11.

To release an object the spools are rotated and the resultant motion of the polyester tape on each jaw causes the object being grasped to be transported downwards. At the tips of the jaws the tape doubles back on itself and this causes it to peel away from the object being held and therefore release it. The sharpness with which the tape doubles back on itself is vital. If insufficiently sharp it would be possible for the object to remain stuck to one of the tapes and be transported along the outside of the jaw. An appropriately tight turn ensures that the contact area between the tape and object is so small that the resulting adhesive force is not large enough to support the weight of the object.

In addition to its ability to handle sticky objects this gripper can be used to position objects in confined spaces as the jaws of the gripper do not need to be opened during product release. This makes the gripper particularly well suited to placing objects into boxes. *Reed* et al. demonstrated how the gripper could be used to place petits fours and fondants into presentation boxes [60.23].

Another sticky product that has a reputation of being particularly difficult to handle is fresh sheets of lasagne. Clamping-type end-effectors cannot be used as

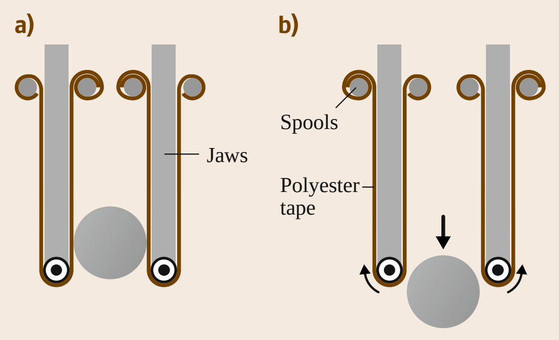

Fig. 60.11a,b Parallel jaw gripper grasping **(a)** and releasing **(b)** a sticky object

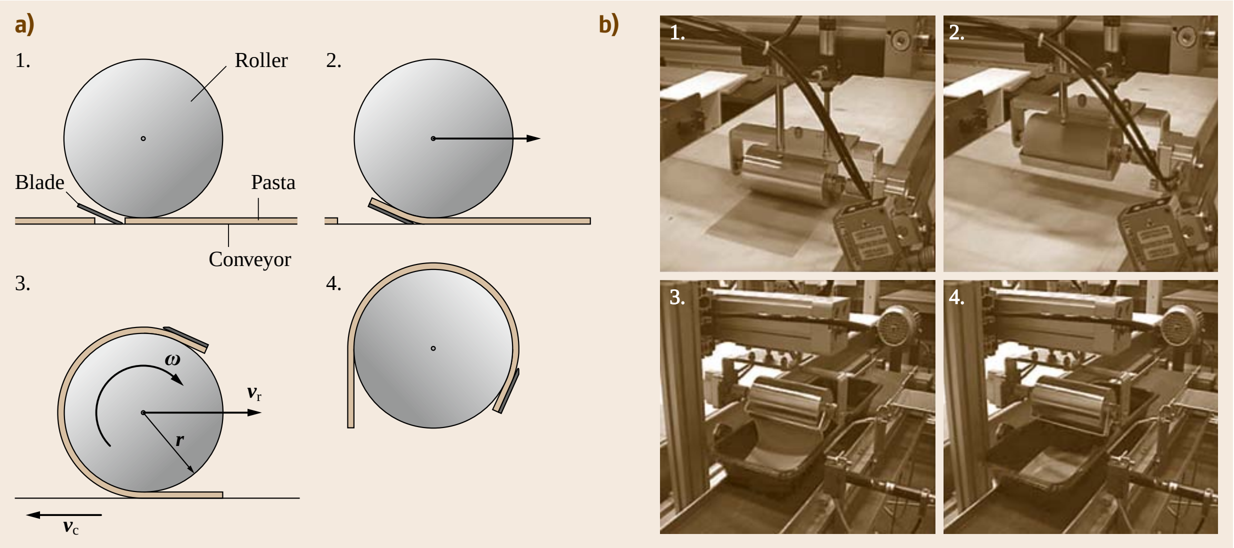

Fig. 60.12 **(a)** Lasagne lifting. **(b)** Motions in the automated handling of a lasagne pasta sheet

they would damage the surface of the pasta, and for similar reasons vacuum cups are also unsuitable.

Moreno-Masey et al. investigated the possibility of automating the manufacture of lasagne ready (microwave) meals and developed a method based on the rolling action common in making pastry [60.24]. By rolling a sheet of lasagne onto a roller and then gradually unrolling it above a product it was shown that the sheet could be positioned accurately and with little damage. The conceptual design with the envisaged sequence of operations is shown in Fig. 60.12a, with the automation system shown in Fig. 60.12b.

The gripper is initially positioned so that the spatula arm, needed to lift the front edge of the pasta, is located close to the pasta sheet. The gripper then moves horizontally a short distance towards the pasta, forcing the spatula under the leading edge of the sheet. The gripper continues moving in the horizontal direction and simultaneously rotates the roller. By coordinating the two motions the pasta is rolled onto the *gripper* in a controlled manner. To release the pasta and deposit it into a tray the roller is simply rotated in the opposite direction. The weight of the sheet causes the lasagne to peel free of the roller in an equally controlled manner. The machine constructed based on this design is shown in Fig. 60.12b. The motion of all actuators are pneumatically powered with PLC control over the joints using input sensing on the position of the lasagne sheets. The machine is sufficiently simple and low cost that nine identical machines could be used to produce ready meals at a typical production rate of 60 per minute.

60.5 Decorative Product Finishing

Many food products include components or features which add nothing to the taste or quality of the product but are purely decorative. Cake manufacture is an example of a production process where the product's appearance is as (perhaps even more) important as its flavor. There are many decorative features used, ranging from discrete components which are place on the surface of the cake to intricate patterns or text produced using icing.

Park Cakes in the UK is a large bakery producing cakes for special occasions which often include hand-written messages on their upper surface such as "Happy Birthday" or "Congratulations". These messages are produced by skilled staff using icing-filled pastry bags. The operators apply pressure to the bags in order to produce a constant flow of icing with which to *write* the messages. In order to be able to undertake this task to the required high standard requires both experience and training and this increases the overall staff costs.

At certain times of the year (Christmas, Valentines' day, and Easter) the demand for cakes increases dramatically and can mean production rates at the Park Cakes factory can increase by as much as 300%. This presents a significant problem as additional labor is needed but finding skilled staff is difficult and additional training is often required. This is costly and requires detailed planning to ensure labor levels are available at just the right time.

A robot-based solution was proposed and developed [60.25] in which the messages were initially produced in a computer-aided design (CAD) package which converted the written text into a series of coordinate positions used to programme the robot. A four-degree-of-freedom SCARA (selective compliance assembly robot arm) design was sufficient to achieve the icing task. In addition to the basic motions involved in writing, the appearance of the icing is also dependent on the relative distance between the depositor and the surface of the cake. To ensure knowledge and maintenance of correct separation a laser range finder was used to measure the distance to the cake's surface and allowed the robot's height to be adjusted to correspond to the individual profile of each cake. The robot carries the icing head, which was capable of producing a steady stream of chocolate icing. It was essential that the icing depositor could be switched off with a clean cutoff (i. e., when stopped the icing flow would instantly cease without any stringing). This was achieved using a stainless-steel 2200-245-Series KISS Tip Seal Valve. Whilst the robot system operated as intended there were some initial problems with the depositing system caused by the flow characteristics of the icing, and input from a chocolate technologist allowed the icing to be produced more consistently resolving the problems.

The quality of the final products exceeded Park Cakes' expectations and the system removed some of the pressures on the company to find large numbers of skilled laborers during periods of high demand.

60.6 Assembly of Food Products – Making a Sandwich

The instances already studied have shown uses of automation in applications involving containerized food products and individual or discrete food product handling. However, one of the major challenges in the automation of food production is the assembly of food products from a large number of discrete components. The assembly of a sandwich is one such problem.

Until recently sandwich production has been performed almost entirely manually with lines employing up to 80 people. The little automation that is used typically takes the form of slicers or depositors. The high level of labor means that there is a real incentive to look to automation. However, the only successful example of an automated sandwich line is that developed for Uniq Plc. by *Lieder* [60.26]. This system uses industrial robots and an indexing system to automate the entire process from buttering to packing but operates most successfully for products with paste fillings. Due to the use of robots there are significant safety issues and as such the line must be enclosed by guarding. This means it cannot operate alongside humans and also leads to a large machine footprint.

An alternative approach was described by *Davis* et al. based on simpler dedicated yet more flexible concepts [60.27, 28]. In this system the ingredients included: two slices of bread, butter, mayonnaise, chicken (diced), lettuce (shreaded), four slices of tomato, and four slices of cucumber. This is considered by the industry to represent the most difficult sandwich handling scenario and does not benefit from the binding effects found in the pastes used on the Lieder line. The automated system consisted of a continuously running corded conveyor which transports the bread slices and sandwich assemblies between workstations. This conveyor is separated into two lanes with each lane handling half of the sandwich (top and bottom slice). A piece of bread is placed in each lane and as they progress along the line additional ingredients are added to the bottom (supporting) slice. After all the ingredients are added the second slice must be lifted, inverted, and then placed on the top of the first slice. Studies of current production lines identified a number of individual processes needed to construct the sandwich:

1. Ingredient placement – individual ingredients are placed onto a single slice of bread.
2. Topping – a second slice of bread is placed on top of the first.
3. Cutting – the sandwich is positioned and cut once diagonally to form two triangular sandwiches.

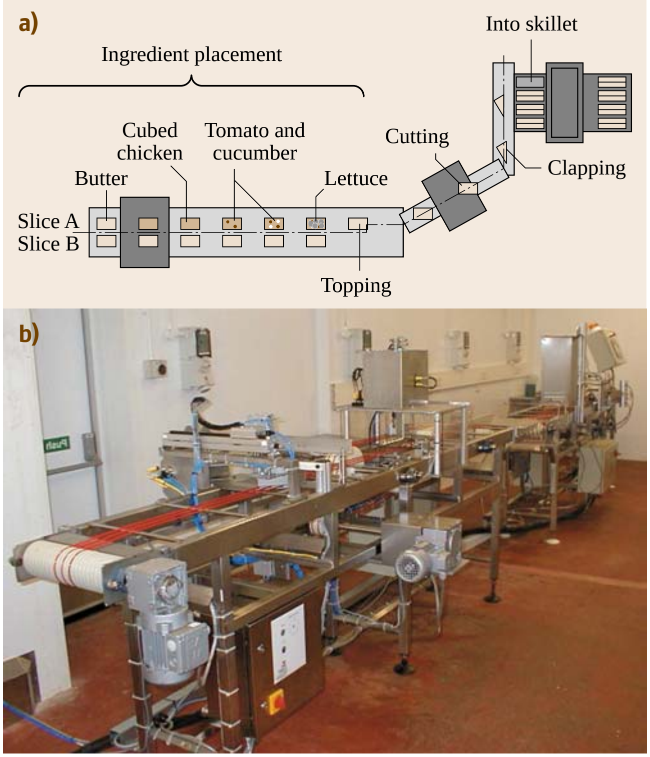

Fig. 60.13a,b Chicken salad sandwich production processes

4. Clapping – one triangular sandwich is placed on top of another prior to top packing.
5. Packing – the two sandwiches are placed into a skillet.

Figure 60.13a shows these five individual operations, while Fig. 60.13b shows the developed system.

An industry-standard programmable logic controller (PLC) is used to control the basic functions of the process. All sensors, variable-speed drives, stepper drives, the vision system and pneumatic control valves are connected to and controlled by this PLC. A touchscreen human–machine interface (HMI) is used to operate the machine and to give the operator feedback about the operating state. The HMI also has an engineer mode that allows qualified personnel to change conveyor speeds and perform basic sequencing checks.

Stepper drives are used where controlled movement of the sandwiches is required. A stepper drive is used at the optimum cut station to precisely align the sandwich before the sandwich is cut. The clapping station uses three stepper drives to place the two halves of the cut sandwich precisely on top of each other prior to being packed. The packing station uses a stepper drive to rotate the assembled sandwich through precisely 90° before being dropped into the awaiting skillet. All the stepper drives are controlled by the PLC and all the sensors are connected to the PLC.

To establish the validity of each principle a series of trials over a 10 week period on 250 000 sandwiches were conducted within a sandwich factory. The aim of the trails was to analyze each process critically and establish whether these principles worked with real products and in a true factory environment. For each of the individual results there were very satisfactory outcomes with high levels of acceptance and reliability.

60.7 Discrete Event Simulation Example

With automation projects being expensive, and the cost of lost production during the installation of equipment being high, it is vital that any potential problems with an automation project be identified as early as possible. Discrete event simulation is a software tool which allows machines, production lines or even entire factories to be produced, tested, and assessed on a computer before any real equipment is purchased or installed.

The simulations provide accurate representations of production processes and product flow. This means an appropriately constructed simulation can be used to identify bottlenecks in existing or planned layouts (Fig. 60.14). This is particularly useful when installing a discrete piece of automation onto a line as it allows the effect of the machine on the remainder of the line to be assessed.

Simulation can also be used to determine if labor is being used efficiently. The example described below is of a sandwich production line. From video footage of the line it was determined how long each operator took to perform their particular task. The simulation was then created and sandwiches were input onto the line at the appropriate rate. Analysis was then performed to determine what percentage of each operator's time was spent idle. It was shown that each of the three operators tasked

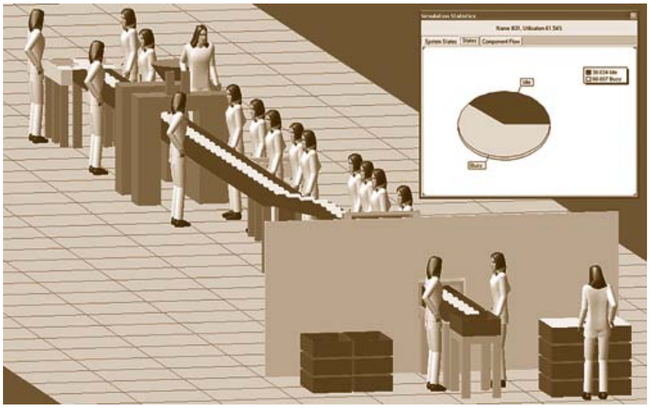

Fig. 60.14 Simulation of sandwich production line

with placing lettuce on the sandwiches was only busy for 60% of their time. This meant that either one of the operators could be removed or the line speed could be increased. The simulation then showed that increasing the line speed produced problems elsewhere as other operators no longer had enough time to perform their tasks.

This is just one example of how simulation can be useful. More complex simulations allow the introduction of variation of task time, variability of product flow, and changes in shift patterns, to mention just three factors.

60.8 Totally Integrated Automation

While production hardware forms the most obvious feature on the food factory landscape, it is only part of a larger automation scheme which can ultimately deliver a totally integrated form of automation encompassing management and strategic functions (logistics, sales, orders, dispatch, traceability, energy, maintenance etc.), production functions including SCADA, networking, HMI, distributed process control (DPC), and (at the machine level) PLC, sensors, actuators etc. A typical format for this type of layout is shown in Fig. 60.15, and the techniques used in the food sector vary little from those in other sectors.

Although the levels of uptake do vary across the industry, in general, at the managerial and administrative level most food processing companies do make extensive use of at least some aspect of control systems. This is particularly important with regard to production scheduling, logistics, and distribution as in the food sector the concept of *just in time* is taken to perhaps its greatest extreme. In food product manufacture it is not

unusual that orders are placed at midnight for dispatch in under 12 h. These orders can amount to tens or even hundreds of thousands of units. While the manufacturers do try to predict demand it is not unknown for the customer (supermarkets) to vary the orders by 50% or more. Indeed it is not unknown for expected orders to be canceled with only hours of warning. In these instances efficient and effective process control and management is essential.

In terms of process automation there is use of SCADA, DCS, PLC integrated networks, etc. In areas such as batch production, for the beverage sector etc., the use of this technology is common, but in the broader food sector dealing with discrete components the use of process automation is more patchy. Certainly most of the hardware which is developed for the food sector now comes with PLC, DCS, and networking capability and can be integrated into a full SCADA system, however, a fully integrated and networked operation is certainly not the normal practice, although it does represent best practice. There are several reasons for reduced uptake even when automation machinery has been installed that has advanced control functionality.

60.9 Conclusions

The food processing sector is the largest manufacturing industry in many countries, but to date it has been one of the least effective at using automation, and particularly following the newer automation trends. This has been driven by many factors that are both commercial and technical and it is certainly true that in many instances food products pose questions that are not present when handling traditional materials. Yet those within the industry are acutely aware of the pressure to reduce food costs while maintaining quality and it is also true that when there is a genuine desire from the food processing organization there are many ways in which automation can be used to enhance the performance of the business. It is particularly hoped that SMEs that have least experience (and confidence) with advanced automation will find the necessary guidance to reap the benefits.

Part G

Infrastru

Part G Infrastructure and Service Automation

Infrastructure and Service Automation. Part G Without automation, certain infrastructure and services could not even be imagined, as in space exploration and secure electric power distribution. In others, automation is essential in improving them so fundamentally, that their benefit influences tremendous social and economic transformation and even revolution, as with transportation, agriculture and entertainment. Chapters in this part explain how automation is designed, selected, integrated, justified and applied, its challenges and emerging trends in those areas and in the construction of structures, roads and bridges; of smart buildings, smart roads and intelligent vehicles; cleaning of surfaces, tunnels and sewers; land, air, and space transportation; information, knowledge, learning, training, and library services; and in sports and entertainment. With the enormous increase in the importance of the service sector in the global economy, this infrastructure and service automation part clarifies not only how it has evolved and is being enabled, but also how automation will influence future growth and further innovations in these domains.

61. Construction Automation

Daniel Castro-Lacouture

The construction industry is labor intensive, project based, and slow to adopt emerging technologies. Combined, these factors make the construction industry not only one of the most dangerous industries worldwide, but also prone to low productivity and cost overruns due to shortages of skilled labor, unexpected site conditions, design changes, communication problems, constructability challenges, and unsuitability of construction means and techniques. Construction automation emerged to overcome these issues, since it has the potential to capitalize on increasing quality expectations from customers, tighter safety regulations, greater attention to computerized project control, and technological breakthroughs led by equipment manufacturers. Today, many construction operations have incorporated automated equipment, means, and methods into their regular practices.

The Introduction to this chapter provides an overview of construction automation, highlighting the contribution from robotics. Several motivations for automating construction operations are discussed in Sect. 61.1, and a historical background is included in Sect. 61.2. A description of automation in horizontal construction is included in Sect. 61.3, followed by an overview of building construction automation in Sect. 61.4. Some techniques and guidelines for construction management automation are discussed in Sect. 61.5, which also presents several emerging trends. Section 61.6 shows some typical application examples in today's construction environment. Finally, Sect. 61.7 briefly draws conclusions and points out challenges for the adoption of construction automation.

Construction automation has been continuously redefined throughout the past two decades. In 1988, construction automation was defined as "the work to increase the contribution of machines or tools while decreasing the human input" [61.1]. Another definition states that it is "the technology concerned with the application of electronic, mechanical and computer-based systems to operate and control construction production" [61.2]. Construction automation was further characterized as [61.3]:

the work using construction techniques including equipment to operate and control construction production in order to reduce labor, reduce duration, increase productivity, improve the working environment of labor and decrease the injury of labor during construction process.

From a systemic perspective, construction automation is the technology-driven method of streamlining construction processes with the intention of improving safety, productivity, constructability, scheduling or control, while providing project stakeholders with a tool for prompt and accurate decision making. This method must not be limited to replicating skilled labor or conventional equipment performance. The latter is the purpose of single-task robots, which have been an important component of construction automation. In the year 2000, robotics applications in the construction industry completed 20 years of research, exploration, and prototyping, as documented in the first book on robotics in civil engineering [61.4]. These applications made important contributions to replicating single tasks, which could be completed faster and safer, since no laborers were operating equipment. However, initial and operating costs have been a problem for the massive deployment of construction robots [61.5, 6]. Later, the distinction between single-task robots and construction automation became more evident. Single-task robots perform a specific job, whereas construction automation uses principles of industrial automation to streamline repetitive tasks, such as just-in-time delivery systems, coded components or computerized information management systems [61.7]. Automation has been associated with repetitive processes, while robotics has targeted single tasks or jobs, imitating skilled labor. Nevertheless, construction processes may not be repetitive as a whole, due to the planning, design, and assembly requirements that must be addressed prior to initiating construction. In addition, site layout and logistics constraints may pose another obstacle so that a theoretical repetitive process must be decomposed into simpler tasks. These simpler tasks may be treated as repetitive in nature. Some examples of repetitive tasks are digging a trench, placing a pipe, backfilling, placing masonry tiles, hauling topsoil, etc.

61.1 Motivations for Automating Construction Operations

Based on a market research questionnaire conducted in 1998 to construction industry respondents from 24 countries, the strongest reasons for robotic construction automation were: productivity improvement, quality and reliability, safety, enhancement of working conditions, savings in labor costs, standardization of components, life cycle cost savings, and simplification of the workforce [61.8].

The project-based nature of the construction industry implies the periodic mobilization of construction equipment, materials, supplies, personnel, and temporary facilities at the start of every construction project. Recent hires, especially field laborers, may not be familiar with the construction practices adopted by the firm on a particular project, making it difficult to engage them in technologically advanced processes from the beginning of the project. Shortages of skilled labor, due to economic fluctuations, immigration policies, or geographic considerations, make the adaptation to project-based means and techniques even more challenging. Therefore, the possibility of automating construction processes would constitute a great opportunity for overcoming the transition to project-based demands. Difficulties in the delivery of supplies and the assembly of materials on site have been alleviated by the adoption of off-site assemblies, manufacturing automation principles, and procurement of premanufactured components.

Another motivation for automating construction tasks is safety in the workplace. Research has found that the causes of accidents can be attributed to factors such as human error, unsafe behavior, and the interaction of humans with materials, tools, and environmental factors [61.9]. Some of the incidents leading to construction injuries and fatalities can be attributed to collisions between workers and equipment, or from workers falling from roofs, scaffolds or trench edges [61.10]. In the USA in 2006, there were 1226 fatalities associated with the construction industry. This accounts for almost 24% of all fatalities in the private sector [61.11]. However, the construction industry accounts for only 5% of the US workforce [61.12]. This high proportion of construction injuries and fatalities may indicate that the industry needs new approaches in order to improve safety environments for workers on construction sites. Some efforts have focused on using machines to complete repetitive tasks that were once performed by workers. This practice has removed workers from hazardous construction environments, but those workers that need to remain in place are still vulnerable to accidents. Automation efforts may further reduce the possibility of accidents or near misses by creating a sensor-based network that tracks the position of workers and equipment, thereby alerting the worker and supervisor when a hazardous condition arises.

Productivity improvement constitutes another reason for automating construction operations. This improvement is critical since traditionally the construction industry has been one of the worst industries with regard to annual increase in productivity [61.13]. This concern, combined with ever-increasing costs, high accident rates, late completions, and poor quality, has been the subject of dedicated studies on construction productivity improvement [61.14]. Construction is one of the largest product-based industries, and contributes a major portion to the gross domestic product of both developed and developing countries [61.15, 16]. However, when compared with manufacturing, construction is rather slow in terms of technological progress [61.17]. There are also differences associated with purchasing conditions, risk, market environment, sales network, product uniqueness, and project format [61.18]. Construction is often considered an antiquated industry. There have not been dramatic changes in basic construction methods in the last 40 years. The modest attention to research and development by both the public and private construction sectors has undermined possible breakthroughs in construction automation that may impact the overall productivity of the industry. Furthermore, the assumed endless availability of workers and the focus on cost reduction and short-term efficiency have continued to limit the rationale for automation efforts in construction [61.19].

61.2 Background

The historical development of construction automation has been marked by equipment inventions aimed at performing specific tasks originally done by workers, and by ground-breaking methodologies intended for improving the systematic behavior of resources in a construction project setting. Table 61.1 shows the historical development of construction automation, from the early stages of equipment inventions to the latest trends in automated project control and decision support systems. Since construction has been mostly an adopter of innovation from other fields rather than a source of innovation, every development indicated in the table is shown in the period where it had a dramatic impact on construction means, management, and methods, and not necessarily when it was invented.

Table 61.1 includes chronological developments related to technologies, means, and methods that have had a dramatic impact on the way construction operations are performed, managed, and conceived, allowing them to be partially or fully automated. The discipline of construction management studies the practice of the managerial, technological, and business-oriented characteristics of the construction industry, whereas construction engineering analyzes design, operational, and constructability aspects. This differentiation has been reflected in the way several automation efforts have been focused throughout the last few decades. These efforts and periods have been catalogued in different manners: based on the taxonomy of field operations [61.3, 20, 21]; based on geographical development [61.6, 7]; based on maturity [61.22]; and whether technologies are considered hard or soft [61.23]. This chapter describes automation efforts from the perspective of their purpose in the construction domain, that is, whether the automation effort has been focused primarily on the construction of highway or heavy structures, on buildings, or on computer-supported integrated technologies that facilitate construction management decision making, which can be applied to the design, procurement, assembly, construction, maintenance, and management of any type of facility.

Table 61.1 Historical development of construction automation

Period	Development
1100s	Pulleys, levers
1400s	Cranes
1500s	Pile driver
1800s	Elevators, steam shovels, internal combustion engine, power tools, reinforced concrete
1900s	Slip-form construction
1910s	Gantt charts, work breakdown structures (WBS)
1920s	Dozers, engineering vehicles
1930s	Prefabrication, hydraulic power, concrete pumps
1950s	Project evaluation and review technique (PERT), computers
1960s	Time-lapse studies, critical path method (CPM)
1970s	Robotics, computer-aided design (CAD), discrete-event simulation
1980s	3-D CAD, 4-D CAD, massification of personal computers, spreadsheets, relational databases, geographic information systems (GIS), large-scale manipulators
1990s	Internet, intranets, extranets, personal digital assistants (PDAs), global positioning systems (GPS), barcodes, radiofrequency identification systems (RFID), wireless communications, remote sensing, precision laser radars (LADARS), enterprise resource planning (ERP), object-oriented programming (OOP), concurrent engineering, industry foundation classes (IFC), building information models (BIM), lean construction (LC)
2000s	Web-based project management, e-Work, parametric modeling, Wi-Fi, ultra wide band (UWB) for tracking and positioning, machine vision, mixed augmented reality, nanotechnology

61.3 Horizontal Construction Automation

Horizontal construction has been prone to automation due to the repetitive tasks, intensive labor, and equipment involved in the operation. This type of construction comprises linear projects, such as road construction, paving, drilling, trench excavation, and pipe laying.

One of the first attempts to fully automate the paving process was the Road Robot [61.24]. The aim of this project was to develop a self-navigating, self-steering asphalt paver that would allow road engineers to improve the quality of pavements, while also being more environmentally friendly. The operation of the Road Robot was divided among four subsystems: asphalt materials logistics, traveling mechanism, road surface geometry, and screeding. Although the Road Robot successfully demonstrated the capabilities and advantages of a fully automated asphalt paver, further development appears to have been halted.

The computer-integrated road paving (CIRPAV) prototype was another attempt to automate paving operations [61.25]. The primary functions of the CIRPAV system were to assist the operator in maintaining the paver on its correct trajectory at the correct speed, to automatically adjust the position and cross-slope of the screed, and to record actual work performed by the paver and transmit performance data to a remote ground station, in order to maintain global quality control at the site level. The CIRPAV system consists of three main subsystems: the ground subsystem, the onboard subsystem, and the positioning subsystem. After several trials, the following improvements were achieved, in contrast with the conventional asphalt paving process: the costs of establishing and maintaining references for profile control and equipment operations were reduced from 10% of the total cost of the work to below 5%; the fluctuation of the

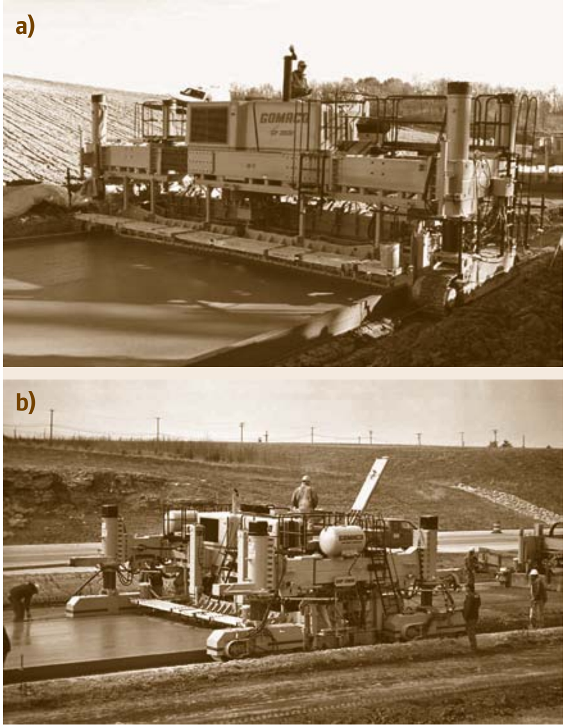

Fig. 61.1a,b Slip-form pavers: **(a)** screeding process, **(b)** idle workers during operation [61.26]

layer thickness was decreased, with estimated savings of materials of about 5% of the total cost of the work; and the quality of the final pavement was improved. The CIRPAV prototype was able to place asphalt within ±5 cm in both transversal and longitudinal directions, and within ±0.5 mm for the height component.

The appearance of slip-form pavers semi-automated concrete paving operations. Figure 61.1a shows an automated concrete screeding process.

However, these operations still require several laborers who remain idle most of the process time, as seen in Fig. 61.1b. Furthermore, slip-form machines still depend on visual inspection and manual samples to perform quality control of the concrete mix. In recent years, a prototype design of a fully autonomous robot for concrete paving was developed [61.30]. The Robopaver prototype is a battery-operated robot consisting of several different operations: placing prefabricated steel reinforcement bar cages, placing and distributing concrete, vibrating, screeding, final finishing, and curing. Results from the simulation of prototypical tests yielded productivity improvements for Robopaver of 20% over the traditional slip-form paver, while foreman utilization achieved 99% with no operators involved, as opposed to the traditional operation with 46% foreman utilization and six laborers [61.31]. The construction work zone for Robopaver was less prone to accidents involving construction workers, while being more productive.

Trench excavation and laying buried pipes are among the most dangerous tasks in the construction industry. While heavy construction equipment such as cranes, loaders or backhoe excavators are used to dig, hoist, and lower pieces of pipe into the trench, workers guide the operation from inside the trench to perform final alignment and jointing. Excavating operations, such as trenching, require precise control.

Fig. 61.2a–c Construction excavation automation: **(a)** robotic excavator [61.27], **(b)** Lancaster University Computerized Intelligent Excavator (LUCIE) [61.28], **(c)** PipeMan [61.29]

Previous experiments with robotic excavation have implemented a conventional industrial robot fitted with a bucket as the end-effector [61.32, 33]. More recently, a prototype Komatsu PC05-7 hydraulic mini-excavator was extensively modified to operate as an autonomous robotic excavator [61.27]. Figure 61.2a,b shows modified robotic excavators during trench-forming tasks.

Research in the telerobotic operation of hoisting and placing pipes on trenches has shown promising results for improving safety. Telerobotic systems are mechanical devices that combine human and machine intelligence to perform tasks remotely with the assistance of various sensors, computers, man–machine interface devices, and electronic controls. Building upon a previous-generation pipe manipulator dubbed PipeMan, further improvements were made by adding a laser and video system in order for the operator to control the entire device remotely, becoming a rugged but simple man–machine interface for motion control and control feedback, as shown in Fig. 61.2c. Pipe installation tasks could be initiated and observed by the operator with the help of wireless fidelity (Wi-Fi) interfaces to the electrohydraulic valves mounted on the manipulator, as well as the video images transmitted wireless to the flat screen mounted to the side of the cabin window [61.29].

61.4 Building Construction Automation

In the 1990s, despite numerous attempts to develop highly automated machines and robotics for construction field operations in the previous decade, few practical applications could be found on construction sites [61.21]. In Japan, however, pushed by building corporations and manufacturers, the largest construction firms of the time developed robots for building construction. Among these firms (e.g., Takenaka, Shimizu, Taisei, Kajima, Obayashi, and Kumagai-Gumi), a variety of single-task robots were manufactured for practical construction applications. These applications mainly consisted of concrete floor finishing, exterior wall spray painting, ceiling board installation, and fire proofing. The goals of the deployment of these single-task robots were mostly the improvement of productivity, safety, and quality.

Japanese contractors also developed automated building systems, which consisted of on-site construction factories that used ideas already tested in the manufacturing and automobile industries, such as just-in-time, material tracking or streamlining repetitive operations [61.7].

The WASeda construction robot (WASCOR) project entailed a building system carried out by assembling factory-made interior units installed with frames, boards, papers, and fixtures, and using construction robots [61.37]. The push-up method consisted of assembling the roof floor first, lifting it up with its supporting columns using hydraulic jacks, thereby serving as the working platform for the construction of the lower floors. Every time a lower floor was completed, the roof floor was jacked up [61.7]. Shimizu manufactur-

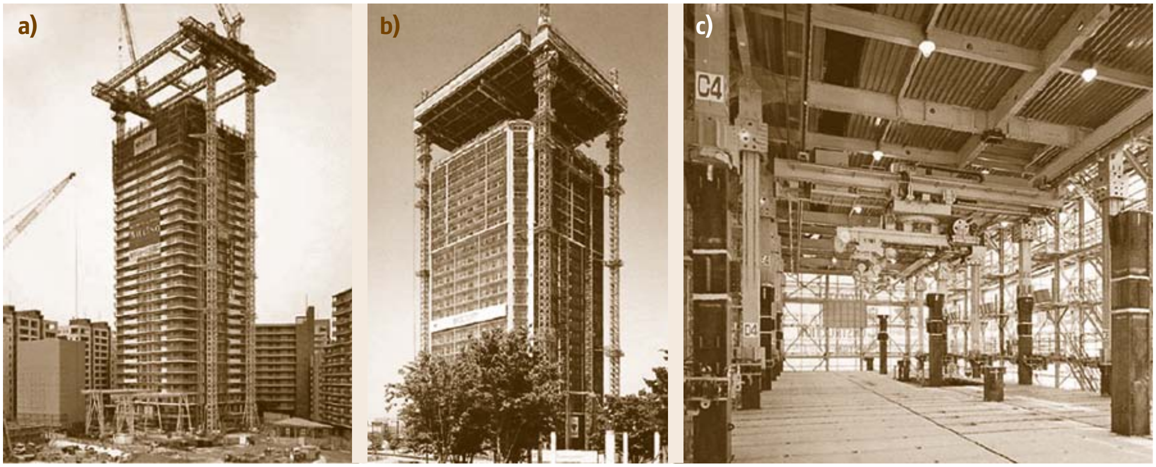

Fig. 61.3a–c Automated building systems in Japan: **(a)** SMART [61.34], **(b)** Big Canopy [61.35], and **(c)** ABCS [61.36]

ing system by advanced robotics technology (SMART) was an integrated system that automated the erection and welding of steel frames, laid concrete floor boards, and installed exterior and interior wall panels and other components. The automated building construction system (ABCS) system consisted of a *construction factory* placed on top of the building, lifting structural members to the lower floors and welding the components with robots. It had the capacity to build two floors at once. Productivity shortcomings and cost considerations associated with the operation of the ABCS prompted the development of the Big Canopy system. This system featured four tower masts and a massive canopy at the top, which lifted prefabricated material to the target floor, where workers controlled the maneuvering of the components with the use of joysticks. The T-up system comprised a support, a base, and a manipulator. The construction process began with the erection of the building core and the base was constructed at the ground level. Guide columns and hydraulic jacks elevate the base to the target floor. Figure 61.3 shows several examples of automated building systems developed in Japan.

Besides in Japan, there has been significant advancement in robotics research and development for building construction in the past two decades. Some of these research projects have been led by academic institutions and government agencies, as shown in Table 61.2.

Almost 30 years after robotics applications in construction started being researched, explored, and prototyped in the early 1980s, these applications are still considered atypical for the construction industry. However, robotic application efforts are still underway, mainly for performing single tasks that are part of tedious dangerous jobs that demand high quality and productivity. This trend goes along with the faster pace of robotics development in other industries, whose success has not been paralleled by the con-

struction industry. The decision-making and situational analysis complexities, coupled with the project-based nature and short-term focus of the construction industry has hindered success. Nevertheless, for the past decade, construction researchers and practitioners have shifted their efforts toward the development of integrated automated construction systems aimed at providing decision-makers with robust tools for project management. These systems consist of a variety of computer-supported applications that take advantage of the increasing computing power available, as well as accessibility to tracking and positioning technologies, such as global positioning system (GPS), radiofrequency identification (RFID), and Wi-Fi, which have demonstrated dramatic improvements in materials and resources management, progress tracking, cost monitoring, quality control, and equipment operator training.

Automation efforts have been implemented throughout the architecture, engineering, construction, and facility management life cycle. During the design phase, four-dimensional (4-D) computer models, i. e., three-dimensional (3-D) objects plus time dimension, allow project information to be shared among project participants, showing realistic views of objects and activities and their sequence of assembly. Complex designs take advantage of 4-D models by using animations to link computer-aided design (CAD) elements with schedule activities, thereby improving the clarity of design and construction information, allowing early clash detection, and helping track the construction progress. Building information models (BIM) emerged to formally address these design automation needs, modeling representations of the actual elements and components of a building. BIM is based on industry foundation classes (IFCs) and architecture, engineering and construction extensive markup language (aecXML), which are data structures for representing project information [61.38]. Further implications of BIM to design automation include the possibility of estimating building costs, schedule progress, green building rating, energy performance, safety plans, material availability, and creating a credible baseline for project control, among others.

At the other end of the project life time, facility managers continuously make decisions on whether or not to conduct refurbishments, and prioritize between cost and quality. As the built environment ages, these assessments are applicable to demolition decisions. Automated condition assessment and refurbishment decision support systems are leveraging the complexity of the building systems, such as technical, technological, ecological, social, comfort, aesthetical, etc., where every subsystem influences the total efficiency performance and where the interdependence between subsystems plays a critical role [61.39]. Furthermore, design changes for refurbishment projects appear frequently due to a number of factors such as the lack of suitable design data, insufficient condition data, inadequate information on building condition, and ineffective communication between the client and contractors [61.40].

61.5 Techniques and Guidelines for Construction Management Automation

The management of construction projects deals with planning and scheduling, material procurement, cost control, safety, performance tracking, and design–construction coordination, among other issues.

61.5.1 Planning and Scheduling Automation

Planning and scheduling consists of sequencing processes, activities, and tasks according to time, space, and resources constraints, specifying the duration of such tasks and the relationships between them. Traditionally, scheduling and planning were done through simple bar charts. In the 1960s, the critical path method (CPM) emerged, followed by discrete systems models [61.23]. Today, several software applications have been developed to automate the CPM, such as Microsoft Project, Primavera SureTrak, and Primavera P3. These applications allow users to link different activities, allocate resources, and optimize the schedule. In addition, they provide a user-friendly representation that can be used in different aggregation levels. A further step in the automation is taken by specialized software applications that include sophisticated methods of resource leveling and scheduling optimization considering uncertainty. Four-dimensional CAD emerged in the 1980s to associate time to spatial elements, thereby allowing visual representation of sequences and communication. To generate a 4-D simulation, a 3-D model is created and a manual or semi-automated process of linking

3-D objects to tasks in time takes place. Visualization of construction sequences is at the task level, which means that the active task is visualized when the associated construction object is highlighted. One drawback of this approach is that activities that are not associated to objects, such as milestones, cannot be visualized on the simulation. In addition, since the links have to be updated every time the 3-D model changes, it is a very time-consuming process. The new trend of scheduling automation is to incorporate BIM into the schedule, including spatial, resource utilization, and productivity information [61.38]. BIM consists of a set of parametric building elements that have associated several properties and relationships between elements, which store information on geometry, material, etc. Using BIM for scheduling, the model is linked to the schedule, not an object is linked to a task. This approach not only saves time and is more accurate, but also allows the evaluation of resources and material consumption over time [61.41].

61.5.2 Construction Cost Management Automation

Construction cost management deals with the relation between the owner's budget, the project estimates, and the actual cost of the project. Several attempts to automate cost estimating started in the 1980s, when software applications emerged to link construction quantities to cost databases or to standard industry databases. Later, this applications evolved to automate quantity take-offs from CAD drawings and to transfer such estimates to job cost management applications that allow automated tracking of contract amounts, subcontracts, purchase orders, quantity totals, billings, and payments. The new trend in cost construction automation is to incorporate a cost estimate application to BIM, becoming helpful in conceptual estimates because those estimates are calculated based on project characteristics and project type (i. e., office building, school, number of floors, parking spaces, number of offices, etc.). Those quantities are not available in CAD models because they do not define object types. On the other hand, BIM allows early quantity extraction and cost estimates. Later in design, BIM allows users to extract the quantities of components, area and volume spaces, and material quantities. In terms of a detailed estimate, the accuracy depends on the detail of the model. An important advantage of using BIM for estimating is that the estimate is automatically updated when the model changes; in addition, it helps reduce bid costs because it lowers uncertainty related to material quantities. There are three different ways how BIM can be used to aid the cost management process:

1. To export quantities to estimating software
2. To link BIM objects to estimating software, which allows manual inclusion of costs that are not associated to a specific object
3. As a quantity take-off tool [61.38].

61.5.3 Construction Performance Management Automation

Current research efforts to find appropriate methods for performance monitoring and control mainly fall into three categories: (1) a series of automated techniques for detection of building entities: radiofrequency identification (RFID), global positioning systems (GPS), laser scanners, Wi-Fi, and ultra wideband (UWB) positioning technologies, and visual sensing; (2) a series of visualization techniques used to represent discrepancies between as-planned and as-built; such methods could help in comparing real-world data with the five-dimensional (5-D) as-planned data (i. e., 3-D model plus sequencing and estimated cost described in BIM); for example, it could help automatically detect discrepancies and identify those elements that are ahead of or behind schedule, identify those elements that are on budget or present overruns, and assist in taking corrective control actions; and (3) enterprise resource planning (ERP) and computer-supported frameworks that allow the integration of workflow information for automated project performance control.

Radiofrequency Identification (RFID)

In RFID technology, radiofrequency is used to capture and transmit data from a tag embedded or attached to construction entities. RFID is helpful for material tracking due to its larger data storage capabilities, being more rugged, not requiring line of sight, and being faster in collecting data about batch of components [61.42, 43]. The technology also has the advantage that it can be combined with other tracking technologies (i. e., 3-D laser systems or barcoding) that can complement and enhance the tracking system. This method might be troublesome for tracking numerous and dissimilar types of construction objects and personnel, especially if the RFID chips are not given the appropriate amount of time to be recognized by RFID readers. Other disadvantages include the need for previously identifying and tagging the entity to be tracked. This greatly limits its tracking capabilities and makes it unreasonable for tracking ever-changing entities, such as personnel and cast-in-place materials on a construction site.

Global Positioning System (GPS)

GPS is a system that can provide 3-D position and orientation coordinates. The GPS system can be applied in two ways: differential GPS based on range measurements, and kinematic GPS based on phase measurements. Differential GPS can be used to measure locations at a metric or submetric accuracy. In kinematic GPS, positions are then computed with centimeter accuracy [61.42]. As for differential GPS, the kinematic computation can be performed either in postprocessing or in real-time, which is called real-time kinematic GPS. As a satellite-based technology, standard GPS needs a line of sight between the receiver and the satellite; therefore, it cannot normally operate indoors. Recent developments enable GPS to operate indoors by adding cellular, laser or other technology [61.44]. Research on the use of GPS in the construction industry has been characterized by the positioning of equipment and by construction metrology in field operations [61.25,45,46]. The latter has been complemented with deployment of laser radar imaging of construction sites. The GPS system is limited by several factors. It can only be applied for outdoor use and needs a GPS receiver to be attached to the entity that is being tracked. Since the number of materials involved in a project is usually significantly greater than the number of pieces of equipment involved in installing them, it is, in most cases, unfeasible to attach a GPS receiver to each piece of material.

Laser Scanning

Laser scanning is a terrestrial laser imaging system that creates a highly accurate 3-D image of a surface for use mainly in computer-aided design (CAD) [61.47]. Typical 3-D laser scanners can create highly accurate three-dimensional images of objects from quickly captured 3-D and 2-D data of the objects. Laser scanning is especially applicable in construction sites, where the high amount of objects and materials make it difficult to gather accurate spatial data. Although data acquisition is fast, postprocessing tasks, such as georeferencing and 3-D model generation, can take several times longer, accounting for 80% of the time needed to complete the task, depending on the level of detail of the 3-D model [61.48]. It also has issues with noise, which needs to be removed during the segmentation process. This segmentation process is still not realized automatically and takes considerable processing time. Other disadvantages include the high cost and current lack of automation.

Wi-Fi and UWB

Wireless local area networks (WLAN) featuring Wi-Fi, also technically known as 802.11 for a 2.4 GHz radio band, have been considered as a key opportunity for the construction industry sector [61.49]. The main function of the Wi-Fi system is to integrate hardware components, such as application server, positioning engine server, and finder client, with the CAD drawings of the facility. Integrated through a web interface, the user is allowed to obtain material information from the site and trace it on the finder client's graphical interface in real time. Presently, positioning accuracy is up to a meter with current Wi-Fi technology, although it may become 3 cm with the use of ultra-wide-band [61.50, 51]. Wi-Fi and UWB applications in construction suffer from several disadvantages. The necessity for tagging is one of the deficiencies of this system. Another limitation is the necessity for measurement of infrastructure, which means that , ideally, the use of a total station is required in order to obtain accurate results. This increases the time needed for the setup of the system, as well as the cost of the tracking method.

Vision Tracking

Vision tracking is a method that blends video cameras and computer algorithms to perform a variety of measurement tasks. Traditional vision-based tracking can provide real-time visual information of construction job sites. This technology is unobtrusive, which means that there is no need for tagging or installing sensors to the tracked entities. Additional advantages include the simplicity, commercial availability, and low cost associated with video equipment and the ability to significantly automate the tracking process [61.52]. Disadvantages of this technology are associated with its limitations due to field of view, visibility, and occlusion, and the inability to track indoor elements using peripheral cameras. There are also further complications of differentiating between interesting and irrelevant entities at the site.

e-Work

Research on the automation of preconstruction workflows has been documented with the application of e-Work methods in steel reinforcement [61.53], and in construction materials in general [61.54]. This work is built upon previous research in the manufacturing domain, where e-Work is composed of collaborative, computer-supported activities and communications-supported operations in highly distributed organizations, thereby investigating fundamental design principles for the effectiveness of these activities [61.55, 56]. See Chap. 88 on *Collaborative e-Work, e-Business, and e-Service*.

61.5.4 Design–Construction Coordination Automation

Design–construction coordination consists of synchronizing all designs, field conditions, special conditions, trades, and systems, in order to deliver the project according to the design intent. One of the most important tasks is clash detection. Currently, most clash detection is done manually by overlying drawings in order to try to detect clashes within the different systems, and some contractors use CAD applications to overlay layers to detect conflicts visually; both approaches are very slow and prone to errors. The new trends in clash detection are based on BIM tools, which allow automatic clash detection from two perspectives: 3-D geometry conflict detection and object relationship and interaction conflict detection [61.38, 57]. As all objects are in the model, clash detection can be performed at different levels of detail as needed. Finally, detected conflicts can be corrected very quickly before the next round of clash detection takes place, making the updating of drawings simpler.

61.6 Application Examples

Four particular application examples have been selected because of their current impact on construction automation. The first three examples are state of the art, whereas the last one is still in the research stage. The first example is related to earthmoving automation; the second example involves planning and scheduling automation; the third example describes the automation of a construction cost estimation process; the last example, still in the research stage, features the automation of construction progress monitoring.

61.6.1 Grade Control System for Dozers

One of the latest inventions toward the accomplishment of automation in construction is the technology incorporated into the new line of Caterpillar crawler tractors or bulldozers. Even though these machines are not factory-equipped with all the technical automated options, these units are preinstalled with all the accessories to make them compatible with these new technologies. The Caterpillar factory standard technology AccuGrade [61.58] is an integrated system that provides accessibility for the implementation of more advanced technologies into these machines; for example, the integration of GPS, laser grading, cross slope, etc. This system has benefits in terms of the productivity, accuracy, and overall effectiveness of the equipment use by the operator. It includes the automatic blade control function which ultimately eliminates the operator from the accuracy-demanding task of blade positioning, especially in cases where accuracy is very important. AccuGrade GPS control system is one of the most effective tools to have been integrated into these machineries, essentially because it creates 3-D model replicas of the ground contours designed by engineers and then automatically matches these contours with the actual work done by the machine. This machine eliminates the use of an operator's ability to match, as accurately as possible, the ground's elevation to the design, making it an automatic procedure calculated accurately by a machine and guided by an educated operator. Job site safety is improved, since it reduces the need for personnel to guide the machine, such as flaggers, stakers, checkers, surveyors, etc. Another feature that the AccuGrade system has integrated is the safety interlock, which locks the blade in a position when the system is not active.

In order to accomplish the overall goal of automating the earthwork activities of a construction project, this system provides a tool to create complex 3-D designs and incorporate them into the machine's GPS system. This tool is most commonly used for more complex earthwork projects, such as golf courses or specific projects requiring constant slope degrees differences. Also, the ability to create flat, single, and dual-planar designs for less demanding projects, such as parking lots or building pads, is a great advantage that the GPS control system provides in order to achieve greater automation, accuracy, and cost reductions.

Figure 61.4 shows the sloping designs that the GPS grade control system will integrate into the computer of the machine in order to automate the earthmoving necessary to achieve desired specs.

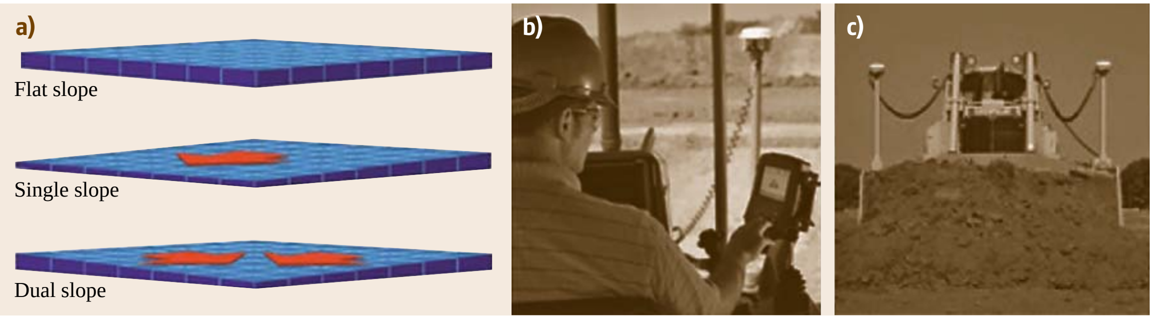

Fig. 61.4a–c Grade control system for CAT Dozer: **(a)** 3-D sloping designs, **(b)** in-cab computer, **(c)** earthmoving operation [61.58]

Using AccuGrade, the dozer achieves quicker completion times and minimizes the need for staking, string lines, and grade checkers, apart from automatically performing the job without having to worry about accuracy, material waste, and several other time-consuming factors that would regularly be involved in an earthmoving project. According to studies done by Caterpillar, productivity is increased by 50% and surveying costs are reduced by 90% [61.58].

There are some off-board components and some office components involved in the operation of the GPS system. The off-board component includes GPS satellites which send positioning information to the machine, a GPS base station located within radio range of the machine that is used to transfer information from the satellite, and a GPS receiver installed in the machine for information receipt by the machine. In addition, there are office components involved, including 3-D design software and office software used to design and convert any kind of design into a format that the machine can use to create its design models.

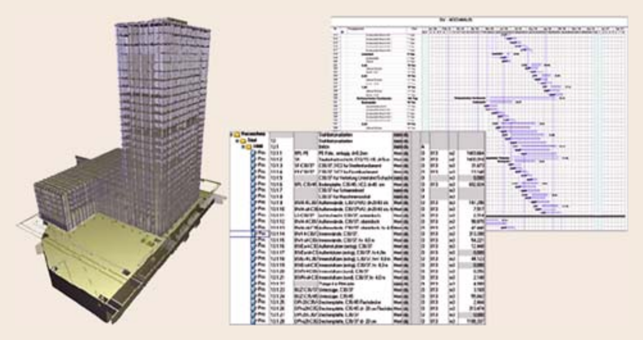

Fig. 61.5 CAD model, bill of quantities, and construction schedule [61.41]

61.6.2 Planning and Scheduling Automation

This example shows the use of BIM as an aid in the scheduling process [61.41]. The project was the construction of the Süddeutscher Verlag Corporate Headquarters in Munich, Germany, a 28-storey, high-rise office building with an area of 78 500 m^2. The construction period was 36 months. In order to manage the schedule of the project, 4-D CAD and BIM were used. The CAD model consisted of 40 000 objects and a schedule that included 800 tasks, 600 of which could be visualized in the 4-D simulation, as shown in Fig. 61.5.

Linking CAD objects and tasks took 4 days. When there was a change in the CAD model, the task linking update took another 4 days. Linking BIM and the time schedule took 0.5 days, while changes on the model just needed to reload the data and apply the relationships, a process that took just a few minutes. After comparing the quantities generated by the BIM tool and the quantities generated manually, the BIM quantities proved to be more accurate.

61.6.3 Construction Cost Estimating Automation

This example demonstrates BIM capabilities as a conceptual cost estimating automation tool [61.38]. The project, Hillwood Commercial in Dallas, USA, is a six-storey, mixed-use building with an area of 12 500 m^2. The building was constructed under a design–build delivery method. The design team started modeling during the conceptual stage to evaluate different alternatives to be presented to the client, using DProfiler, a parametric BIM tool that assigns cost information to the objects. DProfiler is integrated into a commercial cost database, giving the design team and the owner real-time cost data. The use of DProfiler instead of manual-based estimating resulted in a 92% reduction of time used to develop the estimate.

The team developed an initial concept design and created a model in DProfiler with links to cost information. The model took into consideration regional cost factors, building type, and other components using templates that have been developed with experience from similar projects. As the team constructed the building mass, the cost data was updated in real time. Then, as all components and assemblies were associated to cost in a database, when the team included more details the cost was automatically updated. In addition to linking components or assemblies to the cost database, DProfiler also allowed the creation of relationships and rules; for instance, it included one specific component that was not part of the model. In this way, as the model was developed, real-time information linked to the database was presented. The team also used DProfiler to run different scenarios and make informed decisions on floor-to-floor height, square footage, location of components, etc.

The team realized several benefits after using BIM to aid the conceptual estimate process. They found a reduction of labor hours to produce an estimate. DProfiler avoided the take-off process and also had an automatic link to commercial cost databases. The design team was able to produce an accurate estimate in real time, reducing the time spent in verifying the accuracy of the estimate, thereby spending more time in the financial analysis of the different options. Also, a visual representation of the estimate was created, reducing the potential for errors.

61.6.4 Construction Progress Monitoring Automation

This example illustrates a method of automated progress monitoring; the inputs are the as-planned 4-D model and a sequence of on-site time-lapse photographs that represent the as-built model. The objective of this method is to automatically overlay the as-built images with the as-planned model to determine and update the progress status. It consists of putting the real-world camera into the 4-D model; then, the image taken of the 4-D model is overlaid with the site photograph taken at the same time. The 4-D photograph displays the expected progress; therefore, superimposition of images allows comparison of discrepancies between what was intended and what was performed [61.59]. The method uses earned value analysis to present progress indicators and uses a color code to provide a visual representation, where a dark red color represents objects that are behind schedule/cost and dark green represents objects that are ahead of schedule, as shown in Fig. 61.6.

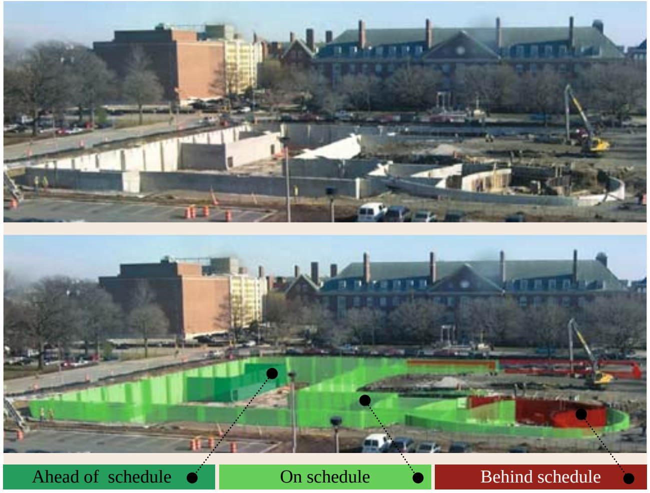

Fig. 61.6 Site photograph, superimposed photograph, and color coding [61.59]

Future trends in this domain include implementing combined progress tracking method that consists of generating a BIM model of the project that contains 3-D geometry, schedule, and cost information with the as-planned data. An as-built model is then generated using the combination of two automated data collection technologies: machine vision and Wi-Fi. To gather real-time object information, that information can be translated using an IFC language to generate a 4-D model with cost information on demand. Both models can be superimposed, detecting graphically in real-time the objects that are on time, the objects that are behind schedule, and the objects that are ahead of schedule. In addition, this application will allow the calculation of earned value indicators with the information stored in both models.

61.7 Conclusions and Challenges

The cyclical nature of the construction industry, featuring longer periods of reduced activity combined with imminent shortages of skilled labor, increasing quality expectations from costumers, tighter safety regulations, greater attention to computerized scheduling and project control, and technological breakthroughs led by equipment manufacturers, has once again put construction automation on the map of researchers and practitioners alike. In spite of challenges, such as cost, lack of governmental incentives, regulatory barriers, disbelief by the majority of the construction sector, or the lack of research and development, much advancement has been possible in construction automation in the past three decades. Presently, the demand for accurate, up-to-date, and timely information to manage construction projects is growing, so automating the construction management process presents enormous benefits. It has been proven that the use of technologies, such as automated data collection: reduces the time required to gather information at the job site; allows the use of real-time information; decreases the response time when corrective actions have to take place, reducing the costs associated with late response; and enhances the visualization and communication interactions within the project team. In addition, the use of BIM to support different project management processes also presents several benefits. It enhances communication with and understanding of stakeholders, and enables constructability decisions to be made during the design phase and not only during construction. It reduces the time spent in redesign and in answering requests for information, and allows a better sense of the time and the cost of the project, since estimates and the schedule are more accurate and do not have delays or overruns because of unexpected change orders.

However, there are still several technological gaps that need further research and development. A significant drawback is the lack of major research in the construction industry. The major challenges faced by the industry in regard to construction management automation are: reduction of the technological gaps and interoperability issues, the cost and availability of such technologies, and the systematic education of construction practitioners on these subjects.

62. The Smart Building

Timothy I. Salsbury

Buildings account for a large fraction of global energy use and have a correspondingly significant impact on the environment. Buildings are also ubiquitous in virtually every aspect of our lives from where we work, live, learn, govern, heal, and worship, to where we play. The application of control and automation to buildings can lead to significant energy savings, improved health and safety of occupants, and enhance life quality. The aim of this chapter is to describe what makes buildings smart, provide examples of common control strategies, and highlight emerging trends and open challenges. Today, the most prevalent use of automation in buildings is in heating, ventilating, and air-conditioning (HVAC) systems. This chapter reviews common control and automation methods for HVAC, but also describes how automation is being extended to other building processes. The number of controllable and interconnected systems is increasing in modern buildings and this is creating new opportunities for the application of automation to coordinate and manage operation. However, the chapter draws attention to the fact that the buildings industry is very large, fragmented, and cost-oriented, with significant economic and technical barriers that can, in some cases, impede the adoption and wide-scale deployment of new automation technologies.

62.1 Background

The worldwide energy used to heat, cool, ventilate, light, and deliver basic services to buildings was, on average, approximately 2.4 TW ($= 2.4 \times 10^{12}$ W) in 2004. A further 5.6 TW was attributed to industrial plants, with a large fraction of these housed in buildings such as factories, power plants, and other manufacturing facilities [62.1]. In developed countries, buildings can be responsible for as much as 50% of total energy use. These dramatic statistics coupled with the fact that human beings spend most of their lives inside buildings make this application of critical importance to the well-being of our planet and its global population.

There are many different types of buildings, ranging from simple places of shelter to highly complex ecosystems that provide a range of specialized services to support specific functions. One common purpose of buildings is to create a modified environment that is comfortable for occupants even when outside conditions are unfavorable. Comfortable conditions are maintained through the operation and coordination of mechanical and electrical systems and through the conversion of energy from one type to another. The control of indoor environmental conditions is the most common and widely exploited application of automation technologies in buildings and will be the main focus of this chapter. Factors that affect the indoor environment are air quality, temperature, and humidity, as well as lighting, and safety from fire and security threats.

For a building to be smart it must have some form of automatic control system. Building control systems vary widely in complexity from simple mechanical feedback mechanisms to a network of microprocessor-based digital controllers [62.2]. At the latter end of the spectrum, the network of controllers is often known as the building automation system (BAS). A BAS needs to interface with physical systems in order to effect desired changes on the building, and the interfacing is usually made through means of sensors and actuators. Buildings can contain many types of physical systems, the most common of which are described in more detail below.

HVAC and Plumbing. In terms of energy, the most important systems in buildings are those used to heat, cool, and ventilate the indoor environment. These systems are collectively known as the heating, ventilating, and air-conditioning (HVAC) plant. The HVAC plant is used to condition the psychrometric properties (temperature and humidity) of the indoor environment as well as air quality. HVAC systems range in complexity from simple residential units that may have only heating units to advanced systems for high-performance buildings such as clean rooms and chemical laboratories [62.3]. Plumbing systems are closely associated with the HVAC plant but are often handled by a different group of companies and contractors on a building project. Plumbing serves the HVAC systems with water supplies used for heating and cooling and also handles distribution of potable and waste water. Plumbing and waste disposal systems are critical elements in ensuring occupant health [62.4]. Automatic control is widely used in HVAC systems and ranges from simple feedback loops to complex sequences of operation that manage scheduling and interactions between systems.

Lighting Systems. Lighting systems are responsible for a large fraction of building energy use, close to that used by HVAC for the commercial sector. Most buildings have both artificial and natural lighting and the interaction between these sources is important in creating the right level of illumination. In most buildings, both artificial and natural lighting are operated manually using electric switches and window shades. However, automated lighting systems are available and are starting to be used in modern buildings. For these systems, sensors measure illumination levels in a space and also whether a space is occupied and this information is used to regulate artificial light levels and control shades on windows.

Fire and Security. Fire systems are found in large buildings and include fire detection and alarming as well as sprinkler systems for abatement. Security systems are used to control access to buildings and internal areas and trigger alarms when unauthorized access is detected. Both of these systems are evolving rapidly largely due to the availability of more advanced sensor technology and imaging devices. The additional and richer sensor information available from these systems is creating new opportunities for intelligent responses to particular situations. For example, having knowledge of where people are located in the case of a fire can be used to manage evacuation routes, improve emergency response team planning, and also provide input to the HVAC system to mitigate the spread of smoke.

Specialized Systems. Many buildings require specialist services to support specific tasks and functions. For example, a hospital might require oxygen supply and distribution and fume hoods for extracting dangerous and toxic chemicals. In common with other building services, these systems require piping or ducting for containment and distribution, and pumps/fans, valves, and dampers for fluid movement and control. Localized power generation and combined heat and power plants that use waste heat from electricity generation to power heating and cooling systems are also found in some buildings or campuses. These systems may include renewable sources of energy such as solar, wind, and geothermal, and other power generation technologies such as fuel cells and microturbines. Specialized systems, and in particular those that are packaged, often have dedicated embedded controls, but in some cases the BAS might be deployed to provide some higher-level control and supervision.

Supporting Infrastructures. Modern buildings contain systems powered by electricity and an increasing number powered by natural gas. Buildings therefore need to have a distribution network for these energy supplies. Key components include wiring, switch panels, circuit breakers, transformers for electricity, and valves, piping, and various safety devices for gas. Another key infrastructure in modern buildings is that associated with information technology (IT). The IT infrastructure in a building is usually considered to be separate from the other systems mentioned so far because it is handled by a different group of companies outside of the construction business. Similar to electricity distribution, IT systems require wires, switch panels, and access points in order to facilitate the transmission of both digital and analog data for devices such as computers and telephones. Specialized cooling systems may also be needed for high-powered computing devices and data centers. Electricity, gas, and IT distribution systems in a building will usually have some control elements, particularly for safety reasons.

The range of systems and processes in buildings is clearly very broad and cannot be covered comprehensively in the space available here. For this reason, this chapter will focus more on the control and automation aspects of a building rather on the systems that are under control. The chapter will also concentrate on the software and algorithmic aspects of control systems, which are the source of the smartness in buildings, rather than the hardware and supporting infrastructures. The outline of the chapter is as follows. The rest of this section provides a discussion on what makes buildings smart and concludes with a historical perspective of building technologies. An overview of common control strategies and their applications is presented in Sect. 62.2, followed by a discussion in Sect. 62.3 on emerging trends that are affecting the buildings industry. Section 62.4 describes open challenges and, in particular, business and technical barriers to the adoption of new technologies. Finally, Sect. 62.5 draws conclusions and reiterates some of the key points identified throughout the chapter.

62.1.1 What is a Smart Building?

A building is made *smart* through the application of intelligence or knowledge to automate the operation of building systems. In modern buildings, the intelligence or *smartness* of building operation is encapsulated in algorithms, which are implemented in software on microprocessor-based computing devices. Many of these computing devices are part of the building automation system, which can be decomposed into the following four main components:

- User interface – allows exchange of information between a human operator and the computer system
- Algorithms – methods or procedures for performing certain tasks such as control and automation
- Network – includes information transmission media (e.g., wiring), routers, and appropriate encoders and decoders for sharing information among devices
- Sensors and actuators – these represent the interfaces between the computing systems and the plant.

The user interface, network, sensors, and actuators are critical components of a BAS, but these are all enabling technologies that only provide the means by which the intelligence inherent in the algorithms can be applied. The algorithms fundamentally determine the operational behavior of the controlled systems and are the source of the smartness. In a typical building, numerous objectives can be defined suitable for the application of control methods. Examples are regulating a room temperature to a set level, turning off systems at a certain time, and controlling access to a room based on information read by a card reader. Controlling a variable, such as temperature, to a set level is probably the most common control objective and is most often carried out using feedback. Feedback is a fundamental building block of control and automation and its application in buildings will be discussed in more detail in Sect. 62.2.

Recent technological advances in information technology, including networking, computing power, and sensor technology, have meant that the number of controllable devices in buildings has proliferated. Not only are there more devices to control, but information can now be shared more easily between disparate systems. Information is more easily accessible both within system groups as well as across different groups. The HVAC group of systems is particularly notable in making information available to the BAS from multiple types of subsystems including boilers, chillers, fans, pumps, cooling towers, and measured by numerous types of sensors. Opportunities abound within just the HVAC group of systems for applying control strategies that take advantage of the available data to improve overall system performance.

The idea of combining information from different systems to implement new and smart control and automation strategies extends easily to system groups that traverse traditional boundaries. The example of combining data from the fire and access control systems to provide improved emergency response information and also more effectively manage evacuation was cited earlier. Another example is in utilizing access control data to estimate the number of people in a building and then using this estimate to operate the HVAC systems more energy-efficiently. Although huge potential exists for coordinated system operation, the reality today is that the handling of interactions is limited and in most cases ad hoc. However, despite the primitive nature of current automation strategies, the sharing of scheduling databases and responses to alarms represents significant progress toward smarter building operation.

Building operation is not the only way in which buildings have been made smarter. The lifecycle of a building includes its planning, design, construction, installation and commissioning, operation, maintenance, retrofit and remodeling, and destruction. Each of these tasks not only consumes energy and resources, but affects subsequent tasks. For example, a building will only operate energy-efficiently if it has been correctly designed and constructed. New and smart technologies are being utilized at each stage in the lifecycle to improve the overall process. A prime example is in being able to simulate the performance of a design before it is built [62.5]. This is a powerful technology that can lead to cost and energy savings for a project. The ability to simulate building systems is also enabling the development of innovative algorithmic smart technologies such as automated design and optimization [62.6].

It is also important to mention the significant energy and resources used during the construction phase of a building. Energy is used at every step; from the production of the building materials, to their transport to site, through to the operation of machines for excavation and assembly of the materials. The businesses devoted to this one phase of the building lifecycle are numerous, diverse, and employ various forms of automation to enhance efficiency. The term *smart* is frequently encountered in various construction technologies including prefabricated components, advanced supply chain and project management, and on-site machinery, to name only a few examples. However, the term *smart buildings* has come to mean smart operation more than anything else, and for this reason the operation phase will be the focus of this chapter. The smart operations, enabled by technological advances, guarantees cost savings in construction and operations, and improved functionality [62.7].

62.1.2 Historical Perspectives

Modification of the environmental conditions inside buildings is not new, with records showing that the ancient Egyptians used aqueducts for cooling as long ago as the second millennium BC [62.8]. Heating systems were also used by the Romans in 100 AD in their northern territories based on underfloor distribution of air heated by furnaces [62.9]. From the perspective of the building plant, evolution had been slow until the advent of commercially viable electrical air-conditioning systems in the first decade of the 1900s. The origin of these systems can be traced to discoveries by Michael Faraday in 1820 on how to create a cooling effect by compressing and liquefying ammonia, but it was the commercial success of the early electrical air-conditioners that triggered a new interest in the indoor environment and its control. Activity in this area was probably at its height in the first half of the 20th century. During this period, the field of heating, ventilating, and air-conditioning (HVAC) would have been considered a high-technology field that posed some of the most interesting engineering challenges of the time [62.10].

The application of automation technology to buildings has paralleled its application to other industries, with the idea of feedback playing a central role. The feedback concept is a fundamental element of automation and has a history of its own dating back to the water clocks of the ancient Greeks and Arabs [62.11]. The Dutch inventor Cornelis Drebbel is credited as creating one of the first feedback temperature controllers for a furnace in the early 1600s [62.12]. The first thermostats for space temperature control using heating plant appeared in the late 1800s. The thermostat feedback system is an implementation of an intelligent human concept, or procedure, to solve the problem of temperature regulation. These early applications of automation thus led to the creation of the first smart buildings. Implementation of feedback and other control methods originally used mechanical transmission of information, such as pneumatics. These systems were replaced by electrical devices with controllers first being implemented using analog circuits. Today, most analog controllers have given way to digital devices where earlier feedback strategies are now implemented as algorithms in software.

The feedback concept has remained central in building automation. It is the most common type of control strategy and is used to control everything from air-conditioning to lighting to fire and security to toilet flushing. Although the common room thermostat principle is still widely used, building automation systems now encompass an evermore sophisticated array of control algorithms that not only provide regulation of individual variables to setpoints, but also provide high-level coordination and management of building assets.

62.2 Application Examples

Possibly excepting certain types of chain stores, every building is different, having a unique mix of structure, geometry, orientation, location, number of people, and types of building plant. The control and automation systems mirror this bespoke nature and are usually specific to each particular building. Finding common elements of control logic that run across all building types is therefore a challenge. This problem is particularly exacerbated at the higher levels of control logic hierarchy that are used to coordinate the operation of different systems. The aim of this section is to identify and review a sample of control strategies that are generic and found in buildings of different types. Although these strategies are outnumbered in practice by ad hoc and rule-based logic, they usually have a better scientific basis and are more easily adapted and scaled across different buildings.

62.2.1 Control without Feedback

A very simple and yet effective form of building automation is to operate systems based on a time clock; for example, a heater in a building could be turned on at a certain time every day and turned off at another time. These times can be determined from some expected behavior that is known to be linked to time, such as people coming in to work, or even the sun rising and setting. This kind of control logic can be used to control everything from building access, lights, and HVAC. Time-based control is also a type of event-triggered logic where the event being monitored is time of day. The strategy does not contain feedback because time is unaffected by the action of the systems being operated. Time-based operational scheduling is commonplace in modern buildings as an overriding or supervisory logic even when more advanced control and building management strategies are employed. The logic is usually implemented as rules such as: IF TIME = 9.00AM TURN ON CHILLER; IF TIME = 5.00PM TURN OFF CHILLER.

Closed-loop control is synonymous with feedback control. *Open loop* refers to the case where no information associated with the controlled variable is used in deciding how to adjust the manipulated variable; the loop is thus open. In the HVAC industry, reference is sometimes made to *open-loop operation*. In most cases this involves having an operator make adjustments to a manipulated variable manually. However, if the operator is making adjustments in response to observations of the controlled variable, this is not truly open loop because the operator is providing the feedback mechanism. An example of this is when a room in a building has a heating device that can be either on or off but only activated by a human operator. When the room is too cold the person will turn on the heater and when it is too hot they will turn it off. Manual operation of this sort is common in buildings and may be carried out by a dedicated building operator who oversees plant operation. In many situations, preexisting automated feedback systems may be overridden by the operator because of lack of confidence or trust. The operator then manually adjusts things such as control valves and dampers to maintain comfort conditions.

62.2.2 Feedback Control

Single Loop

Feedback control is the most widely used automation concept in buildings, with the temperature thermostat being the vanguard of this strategy. Early examples of these devices were based on pneumatics and mechanical transmission of information [62.13]. Modern buildings use thermostats that contain a temperature sensor and a small integrated circuit that determines when the temperature is outside an acceptable range. The thermostat triggers a switch to operate a device which is then expected to bring the temperature back into its acceptable range. Thermostatic temperature devices usually require specification of a setpoint and a control band. A device would be switched either on or off whenever the measured temperature was outside of the control band, which surrounds the setpoint. Figure 62.1 shows an example thermostatic control strategy for a heater in a room with a setpoint of 20 °C and a control band of 1 °C. There is a trade-off between the closeness of control, determined by the control band, and the wear and tear on the equipment resulting from cycling between on and off states. Some equipment types may also have constraints on how long they can remain in an on or off state and these are called minimum on and off times. The maximum cycle frequency is the reciprocal of the sum of the minimum on and off times.

Thermostatic control is an example of single-loop feedback control where the controller is a switch or relay-type device that has infinite gain. The switching of the controlled device causes oscillations to occur in the controlled variable around its setpoint. These oscilla-

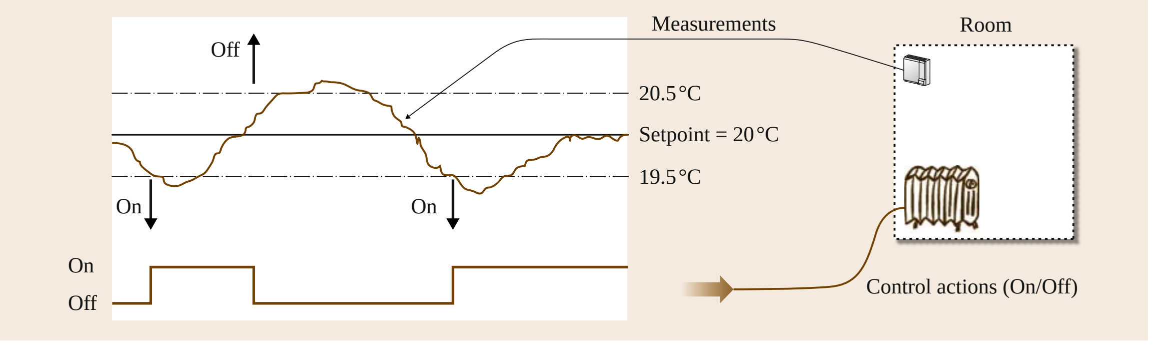

Fig. 62.1 Thermostatic temperature control of a heater

tions are usually undesirable, especially if the amplitude is large due to minimum on and off times being large relative to the dominant time constant of the controlled device. One way to avoid oscillations is to use a physical device whose output can be modulated. Instead of being only on or off, the device output can be modulated by manipulating an input between 0 and 100% of its range. Having a manipulated variable that can be varied opens the way for finite-gain controllers to be used in feedback loops. Modulated systems make up about two-thirds of controlled devices in buildings, with switched systems representing the other third.

Proportional, integral, and derivative (PID) action controllers are the most common type of finite-gain controllers used in building feedback loops. These controllers modulate the input to the controlled device based on the difference between the setpoint and the controlled variable, and the theory behind the algorithm is well established [62.14]. Proportional-only (P) controllers are still common in buildings where control exactly to setpoint is not critical. As is well known, these controllers yield a steady-state offset from setpoint and, when this is not desirable, proportional–integral (PI) controllers are used. This complexity of feedback control works well for most building control loops that are dominated by one time constant. The integral action of the controller ensures that the error signal can be maintained at zero and proper tuning allows good control without oscillations for most loops. Adding the derivate action can yield better results for common applications such as room temperature control, but the drawback is that tuning is more difficult.

PI(D) controllers can also be used in buildings to control switched devices. This is achieved by using an element in the control loop that converts the output signal from the controller (usually between 0 and 100%) to a pulse train (either 0 or 1). Pulse-width-modulation (PWM) logic can be used to provide this conversion, as illustrated in Fig. 62.2. PWM and other variants have been applied to HVAC system applications with promising results [62.15].

Although the PI algorithm is well established and almost ubiquitously deployed for building control, it has been recognized for some time that control performance is often poor in practice. One reason for this is that many plant items in buildings are nonlinear. When a PI controller is used to control a nonlinear system, its performance will vary with operating point. In severe cases, the control might be too aggressive, causing oscillations at one point and yet be too slow at another. These kinds of performance problems can jeopardize comfort and energy use and also wear out equipment. There are several methods for counteracting nonlinearity that are used in nonbuilding applications, such as gain scheduling and model-based control [62.16]. The research community has investigated using some of these methods in buildings including generalized minimum-variance control [62.17] and model-based control [62.18]. However, the industry has been reluctant to adopt these methods because of the extra time (and money) required for setup and tuning. More successful approaches in the building industry have been those that are self-tuning or automatically adaptive to changes; examples include neural networks [62.19] and pattern-recognition adaptive control [62.20]. The latter method of Seem has been commercialized and is

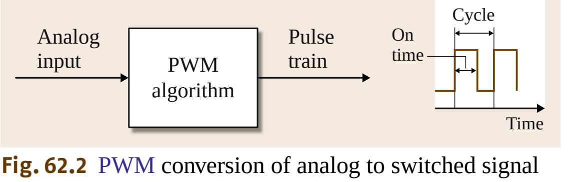

Fig. 62.2 PWM conversion of analog to switched signal

a standard offering from one large controls vendor in the USA.

Multiloop

Multiloop feedback control strategies are used in buildings, with the most common being cascaded control. In these configurations, there is an inner loop that controls a fast variable and an outer loop that controls the setpoint of the inner loop based on the feedback of a slower variable. An example is the control of variable-air-volume (VAV) boxes for regulating room temperature, as illustrated in Fig. 62.3. These boxes are supplied with conditioned air from a central air-handling unit and they can control the flow of conditioned air to a room by means of a damper. In the inner loop, the controlled variable is the airflow rate entering the room. In the outer loop, the controlled variable is the room temperature. The outer loop tries to control the room temperature to its setpoint by modulating the setpoint for the airflow in the inner loop. In turn, the inner loop tries to meet the airflow setpoint by modulating the VAV box damper. Cascaded control allows a control problem to be separated into two parts, one with slow dynamics and the other with fast dynamics. Each type of fast and slow disturbance is then handled by a separate controller, with improved performance compared with having just one controller. A general guideline for cascade control is that the inner loop should be at least three times faster than the outer loop. Further guidelines for implementation can be found in [62.14].

Multivariable control in the sense of having centralized controllers that are multiple-input multiple-output (MIMO) is not typical in building applications. The most common situation is to have multiple feedback controllers that do not share information with each other. For example, a large open-plan office space might have several controlled temperature zones that have separate feedback controllers. An obvious problem with this approach is when there are interactions between zones due to effects such as interzonal airflow. Poor performance in one zone can then propagate to other zones if interactions are strong. Current practice involves trying to minimize interactions by positioning sensors away from each other and making sure that control zones are separated.

There is generally significant interaction amongst building systems and in many cases operation could be improved through application of multivariable control methods. Model-based approaches are one way of handling multivariable systems and these methods have been investigated and applied to buildings, e.g., [62.21].

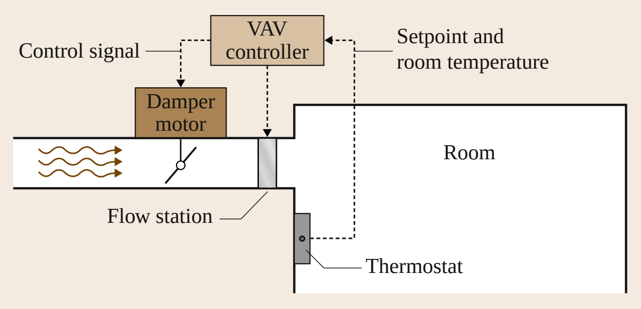

Fig. 62.3 Example cascaded control strategy

However, adoption of these methods by the building industry is impeded by the costs associated with setup and commissioning and of handling the additional complexity. Nevertheless, multivariable control is underexploited in building applications and it appears to be a promising direction for future research.

62.2.3 Energy Management Control Strategies

Strategies for energy management are usually employed at a higher level in the control hierarchy of a building. Many controls vendors offer proprietary algorithms for energy management and these are normally programmed into so-called *supervisory controllers*. In contrast to local controllers, which handle simple tasks such as feedback loops, supervisory controllers have more processing power and memory and consolidate data from multiple nodes on a network. Supervisory controllers perform functions that may affect the operation of several feedback controllers by adjusting things such as setpoint and operation schedules. This section reviews some of the most common energy management control strategies that are found in buildings. The overall idea behind the strategies is explained, but algorithmic details are not provided because no standard implementation exists and many different types of proprietary implementations can be found in practice.

A variable that is commonly used in energy management control strategies is the outside air temperature. This variable is known to affect the thermal loads on a building and its ultimate heating and cooling requirements. One example where the outside air temperature is used as part of feedforward control strategy is the optimum start algorithm. This algorithm uses the outside air temperature to determine when to turn on the heating and cooling systems in a building so that the internal temperatures will be at their respective setpoints by the time people occupy the building [62.22]. The algorithm needs to predict the time required to heat or cool the building from a known start temperature and outside conditions and thus requires some kind of model of the building's thermal response. The complement of optimum start is optimum stop, which determines a time when systems can be turned off, allowing the capacity of the building to hold conditions near their setpoints until people leave.

Optimum start and stop strategies are often combined with *night-setback*. Instead of just turning all systems off during unoccupied periods, night setback control maintains closed-loop control on space temperatures but at different setpoints. During the heating season, for example, temperatures inside the building would be kept lower during the unoccupied period, but only low enough that recovery time would be rapid enough and losses of energy stored in building materials minimized so that this stored energy can be carried over to the next day to reduce overall energy use. Various algorithms have been proposed for predicting the night-setback setpoints and startup and shutdown times based on models and optimization and the use of thermal storage systems, e.g., [62.23, 24]. Integrated optimum start and stop with night-setback algorithms are available from some control vendors, and tuning and setup requirements depend on the particular algorithm that is offered and the systems that are targeted for control.

Another higher-level control strategy that uses feedforward is setpoint reset, where the setpoint of a feedback loop is adjusted based on a feedforward variable; for example, the setpoint of the main supply of conditioned air to a building can be made a function of the outside air temperature. The setpoint would be adjusted to be higher when the outside air temperature is low and made to be lower if the outside temperature is high. The setpoint of cold and hot water supplies generated by building chiller and boiler plant are other variables that are sometimes linked to reset strategies based on outside air temperature. Most of these algorithms adjust setpoints between two specified limits as the outside air temperature varies between upper and lower bounds. Setup and tuning of these reset strategies usually requires specification of the upper and lower values for the setpoints and the outside air temperature.

Feedforward control can also be used to supplement feedback control in situations where disturbances such as changes in airflow and outside temperatures can be measured in systems such as air-handling units [62.25]. The advantage of supplementing feedback with feedforward is that the effect of disturbances can be mitigated when they occur instead of having to wait for their effect to be revealed in the feedback variable. It is unfortunate that many disturbance signals in buildings are in fact measured but not used in the control strategy. The number of potentially useful signals is also increasing as more types of systems become integrated in the BAS; for example, signals from lighting occupancy sensors could be used to improve the control of the HVAC systems by adjusting capacity based on anticipated changes in loads.

Economizer control is a very common energy-saving strategy, particularly in the USA, that is used to reduce cooling loads by switching the air source to the main air-handling systems between recirculated (with a mix of minimum outside air) and 100% outside air. An economizer strategy evaluates the temperature or enthalpy of the two potential air sources and issues control signals to dampers to provide an air supply to cooling heat exchangers with the aim of reducing required cooling capacity. This control method is usually part of sequencing logic that is used to coordinate the operation of heating, cooling, and recirculation systems. The energy saving potential of economizer control has been shown to be as high as 52% [62.26], but results depend on climatic conditions. Both temperature and enthalpy measurements are meant as proxies for the eventual cooling load. Improved results could thus be obtained by using more accurate methods for predicting loads, e.g., by using thermodynamic models of the cooling plant. Today, control vendors normally only offer a choice between temperature or enthalpy economizer strategies. In most cases, enthalpy-based strategies will yield more energy savings, but results can be inconsistent because most humidity sensors, which are used to calculate enthalpy, are notoriously inaccurate.

Peak load management is an aspect of energy management that has received increased attention in recent years. This is mostly due to the fact that utility companies often tie energy tariffs to peak demand statistics, thereby creating incentives to minimize peaks and flatten the load profile. The strategy is commonly termed *demand limiting* and involves shutting down the operation of certain plant items to keep demand below target levels. The concept is illustrated in Fig. 62.4, which shows how building demand is kept below a target level by shedding loads. The objective of this strategy is to control peak demands while at the same time minimizing the disruption to control objectives such as comfort conditions within the building [62.27]. Unresolved research issues are how to set the targets and how to determine the order and time over which equipment

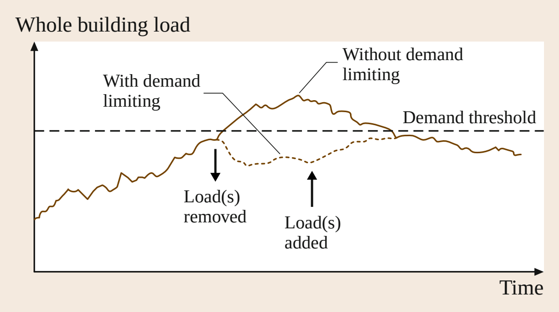

Fig. 62.4 Demand limiting scenario

loads should be added and removed. Currently, the algorithms available from control vendors for demand limiting require the user to set targets based on expert knowledge, which leads to very variable results from these strategies.

The discussion so far has focused on energy management and control of HVAC systems. The reason for this focus is that this group of systems usually represents the only example of where algorithms with more sophistication than simple scheduling and feedback can be found in contemporary buildings. Although more system types are being integrated into the BAS network, the control strategies for these systems are normally primitive and frequently just provide a means for centralized manual operation. However, the potential for more sophisticated control and coordination of systems such as lighting, fire, and security has been recognized for some time and examples of specialized buildings with more sophisticated control strategies can be found. Some of the ideas implemented in these showcase buildings are beginning to trickle down to the rest of the building stock but the rate of adoption is slow, mostly because of cost constraints. Lighting systems are one example of where the use of more sophisticated control can overcome cost constraints by reducing energy use. Traditionally, lights have been controlled manually as a form of open-loop control. However, studies have shown that the implementation of automated feedback signals such as occupancy measurements and outside light sensors can be very effective for control and energy reduction [62.28]. More advanced control is also starting to appear, making use of additional controllable elements such as shading devices that can be used to regulate the inflow of natural light into a space [62.29].

This section has only provided a brief overview of a sample of energy management strategies in buildings. Further examples related to HVAC can be found in [62.30]. The demand for these kinds of strategies is growing in response to higher energy prices and increased environmental concerns, and the computing and networking infrastructure needed to perform this kind of plant-wide control is becoming more widely availably. Most energy management strategies are implemented as supervisory logic on top of lower feedback control loops. In controls terminology the combination of this kind of supervisory logic with low-level feedback control is known as hybrid control. Design of hybrid control strategies in buildings is becoming more formalized due to the availability of new software design tools; for example, the lower-level control strategies might be designed using block diagrams and transfer functions and the supervisory logic designed using state-machine logic diagrams. Modern software programs also allow control logic to be simulated before being implemented, which greatly improves reliability and lowers development costs.

62.2.4 Performance Monitoring and Alarms

Control and operational automation is the most common application of intelligence in buildings. However, recent years have seen a growing interest in intelligent monitoring and analysis of operational performance [62.31]. This has paralleled similar research and application in other industries such as aerospace, chemical processing, and power generation. The most pressing need for monitoring and analysis technologies is to detect faults that could jeopardize performance and, more importantly, safety. The concept of generating an alarm when a critical variable is outside of acceptable bounds is the simplest implementation and is employed quite widely in modern buildings. Although the idea is simple, setting the alarm limits requires intelligence and in some cases may need to be periodically adjusted to cater for changing conditions. A detailed discussion on safety warnings in automation is provided in Chap. 39.

Recent years have seen a demand for more sophisticated performance monitoring and analysis, beyond simple alarming [62.32, 33]. The motivation for this derives from a recognition that control and automation of system operation frequently fall short of expectations. Poor performance can be caused by many things, ranging from faults and deteriorations in the plant, badly tuned controllers, wrongly implemented control logic, to sensor or actuator malfunction. There is also a drive to increase the automation of analysis and operational oversight tasks that were previously carried out manually, not only to reduce costs, but also to help operators deal with the overwhelming amount of data now

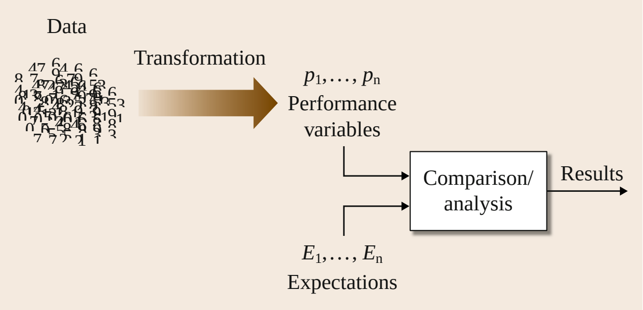

Fig. 62.5 Example performance assessment methodology

available to them through modern building automation systems.

The associated problems of performance analysis and fault detection and diagnosis primarily involve transforming data available from sensor measurements and control actions into variables related to performance that can be compared with expectations, as illustrated in Fig. 62.5. An example of a performance variable is the coefficient of performance (COP) of a chiller, which is calculated from several temperature and power measurements. Fault detection involves comparing performance variables with expectations and making a binary decision as to whether a fault exists or not. Fault detection is therefore very similar to simple alarming except that the variables being monitored are not raw measurements, but derived from them using models, statistics, expert rules or some other transformation method. Fault diagnosis is more complicated and can be broken down into locating the source of the problem, matching symptoms to a cause, and estimating the magnitude of the fault. In a building, a hierarchical approach might start with the detection of higher than normal energy use, get narrowed down to one air-handling system, and subsequently to a valve on a heat exchanger. Finally the fault might be diagnosed as a valve leakage and estimated to be 50% of maximum flow.

The problem of performance monitoring in buildings is also suitable for the application of single-input single-output (SISO) loop monitoring techniques developed for other industries. Measuring the variance of controlled variables and comparing with theoretical benchmarks for example is one method that has been successfully deployed in many industries [62.34]. However, variance of control variables is normally less important in buildings than in other manufacturing-type industries where product quality and profit is directly correlated with control variable variance. One of the biggest problems in buildings lies in detecting problems with the plant such as leaking valves, stuck dampers, sensor failures, and other more prevalent malfunctions [62.31].

62.3 Emerging Trends

As mentioned at the start of this chapter, buildings can be viewed as large processes with many interacting and diverse systems operating together to achieve various objectives. In this way buildings are broadly similar to other applications such as chemical processing, power generation or oil refineries. A building has numerous manipulated variables and measured signals like these other systems. The challenge lies in how to connect the variables together and what algorithms and logic to deploy between these linkages. Figure 62.6 illustrates the concept of how algorithms and logic routines link manipulated and measured variables.

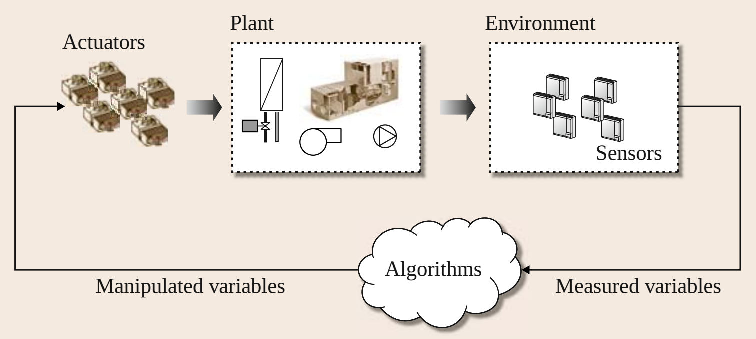

Fig. 62.6 Linking the measurements to the manipulated variables

One trend that is still emerging in some sectors of the buildings industry but is already mature in other sectors is the deployment of IT infrastructure to provide a backbone that allows all sensors actuators and other devices to be visible on a single network. This is part of a more general trend toward the convergence of the building automation and information technology systems in a building. Having an IT infrastructure in place that links disparate building devices facilitates the development of advanced control and operational management algorithms that take advantage of the plant-wide data. Energy management strategies that were mentioned in Sect. 62.2.3 are one example of algorithms that combine information from different subsystems to attain an overall objective. Application of these types of building-wide optimization is likely to increase in the future with the demand driven by rising energy costs and increasing environmental concerns.

IT infrastructure and networking is constantly evolving, making it easier to connect and redistribute devices; for example, wireless networking is becoming more popular in buildings because it reduces wiring costs and makes it easier to reconfigure spaces and move sensors from one location to another. The general trend is also for a greater diversity of devices to be connected to the network and for each device to contain some level of embedded intelligence. These so-called smart devices are part of a trend toward distributed computing. Distribution of computing functions across devices makes a system less prone to catastrophic failure and allows problems to be broken up into smaller pieces and solved using many low-cost devices rather than one high-cost computing engine.

The development of automation algorithms and control techniques has lagged that of hardware and IT infrastructure. Many opportunities therefore now exist for making better use of the information available from a building automation network to improve operation and control and address higher-level objectives such as minimizing energy use. One particularly underdeveloped topic is that of coordinating the operation of different building systems; for example, taking into account the interactions between lighting and HVAC could potentially yield large energy savings for many types of buildings [62.35]. Another example is food retail buildings that use refrigeration systems to keep products cool. Refrigeration systems generate heat and affect the indoor environment in these buildings but their operation is not usually coordinated with the HVAC plant. Combining information from security and access control systems to predict the number of people in a space for improved climate control is yet another example, mentioned earlier, of how information from one subsystem could be used to enhance the operation of another.

Continuing with the theme of IT infrastructure providing new opportunities for higher level-plant coordination, recent years have also seen the deployment of multibuilding control and operation management [62.27]. The concept here is to tie together several buildings and have operational oversight and alarm management handled in one location rather than in each individual building. This allows for centralized data processing and the possibility for a smaller group of highly qualified operators to spread their expertise over multiple buildings. The approach also opens the way for peer-based benchmarking and performance monitoring that can be particularly advantageous when many buildings are of the same type [62.36].

The discussion so far in this section has identified some potential opportunities for control and operational management that are the result of having more information from multiple diverse systems available on a network. Capitalizing on these opportunities often requires combining ideas and methods from different mathematical disciplines. This has been an emerging trend in recent years with a common example being the combination of statistics and control theory such as when employed in statistical process control [62.37]. Other examples are the use of economic ideas as a way to instigate distributed optimization. The availability of real-time energy prices in certain geographical areas is an example of using economics to encourage distributed optimization of load profiles with the aim of evening out the loads at the power plant [62.38].

The idea of using market-based theories is also beginning to be seen as a viable strategy for optimizing the operation of systems within a building. The way in which building systems are designed and implemented is inherently distributed, with small amounts of processing power usually available locally at each device rather than concentrated in a central location. Furthermore, the number of variables in a building and the complexity of interactions and nonlinear behaviors can make a centralized approach to optimization unviable. The metaphor of each device being an *agent* working to optimize its own objective function according to constraints and general guidelines is an emerging field of research with the aim being that overall building performance would reach some optimum behavior without the need for centralized optimization. This idea is beginning to be explored for building applications [62.39]

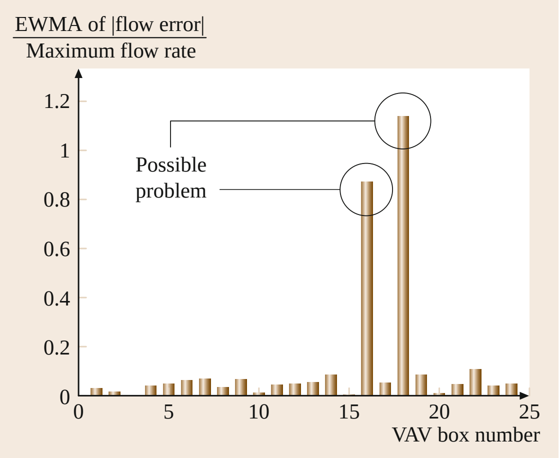

Fig. 62.7 Normalized EWMA statistics for VAV box control performance

and has already been applied to problems in other applications [62.40].

The expansion of control methods and plant operational management ideas that has occurred in other applications is highly relevant to buildings and many of the most promising ideas are beginning to be explored and adopted. The general subject of plant performance assessment and auditing is one example where advances from other applications are being adopted. Some control vendors now offer automatic trending and benchmarking of performance indices that are not just raw measurements, but quantities derived from physics and/or statistics. The methods of analyzing these performance indices and ways in which they can be presented to a user are emerging areas of research and application. The goal of this work is to be able to quickly detect problems and narrow down the cause so that downtimes are reduced, performance is more consistent, and maintenance can be more proactive and targeted. One popular approach is to group together operational statistics from multiple plant items that are of similar type and look for outliers amongst the set as a way to identify faults. Figure 62.7 illustrates this approach based on actual exponentially weighted moving averages (EWMA) of the setpoint error signal for VAV boxes in a large building [62.41].

An extension of the concepts of detecting and diagnosing problems is to make the control system able to adjust automatically so that the building can become fault-tolerant. Buildings usually have many different types of systems that can be used to compensate for each other; for example, a problem identified with cooling capacity that is affecting the temperature of conditioned air could be compensated for by operating the fans at higher loads to increase airflow. This redundancy is already (inadvertently) used to create fault tolerance in buildings by having multiple closed-loop control strategies that sometimes compete with each other. This creates problems for more conventional methods of fault detection that only check whether setpoints are being maintained because the effects of a fault are masked by the competing closed-loop controllers. Hence, there is increasing awareness that fault detection and diagnosis methods need to share information with the control strategy and be combined for the most effective solution [62.42].

The buildings industry is notoriously fragmented with multiple parties involved in the various lifecycle tasks of, among others: design, construction, occupation, maintenance, and renovation. An emerging area is the application of information management to a building lifecycle. Recent years have seen concerted efforts to standardize various aspects of a building process, ranging from standard data models for building geometry and plant description [62.43] to communication protocols for automation system networks [62.44]. The general goal of these standardization efforts is to improve the efficiency of passing information and also reduce the costs and risk of developing and marketing new products such as software. The proliferation of web-based commerce is testament to how standard (and stable) infrastructure can be an effective stimulant to innovation and technological progress.

62.4 Open Challenges

Although buildings can be considered similar to any other large-scale process, there are some unique issues that can hamper efforts to make buildings smart. Primary systemic issues in the building industry are that it is low cost, fragmented, and risk averse. The way in which buildings are financed is geared toward minimization of capital costs. Most contracts are awarded on a lowest-cost basis and this means that the operational costs of a building and other lifecycle costs are deemphasized. The result is that operational performance of the building is frequently compromised through poor design and poor-quality installation and maintenance. Several studies have shown that proper commissioning of buildings can lead to large energy savings and improvements in system performance [62.45]. Cost pressures also lead to the installation of low-quality sensors and actuators that detrimentally affect control performance. A related problem is when too few sensors are installed, causing measurements to be inaccurate and control performance and energy use to be affected.

At the control hardware level, cost constraints lead to minimal memory and processing power in local controllers and also low-resolution analog-to-digital and digital-to-analog converters. Eight-bit converters are still commonplace and the level of signal quantization can be severe enough to cause oscillations in feedback loops. Quantization can also corrupt signals, which makes later analysis and diagnosis of problems more difficult. Another source of quantization is logic that is included on a network so that data are only sent when there is a change of value beyond a certain threshold. This strategy provides data compression and network traffic minimization but it severely affects the signals being filtered and poses problems when trying to analyze data for control performance assessment and diagnostics [62.46].

The level of education and training tends to be low for building operators, also because of cost constraints. This means that there is often difficulty in understanding the processes in a building, their interactions, and the role of the control system. It is common therefore for operators to quickly shut-off control logic that they do not properly understand. The situation then arises of having many loops in a building left in override mode, leading to suboptimal and effectively open-loop, or no, control of the building systems. The primary objective of most operators is also to keep the occupants comfortable and respond to hot and cold complaints. The energy efficiency of the building is usually secondary and draws little attention. The lack of consideration for energy use is due to the still relatively cheap cost of energy and also the lack of performance indicators that could help identify energy problems.
